# Clinical Anesthesia

**EIGHTH EDITION**

**EDITED BY**

**Paul G. Barash, MD**

Emeritus Professor and Past Chair  
Department of Anesthesiology  
Yale University School of Medicine  
Honorary Attending Anesthesiologist  
Yale-New Haven Hospital  
New Haven, Connecticut

**Bruce F. Cullen, MD**

Emeritus Professor  
Department of Anesthesiology and Pain Medicine  
University of Washington School of Medicine  
Seattle, Washington

**Robert K. Stoelting, MD**

Emeritus Professor and Past Chair  
Department of Anesthesia  
School of Medicine  
Indiana University  
Indianapolis, Indiana

**Michael K. Cahalan, MD**

Professor and Chair  
Department of Anesthesiology  
School of Medicine  
The University of Utah  
Salt Lake City, Utah

**M. Christine Stock, MD**

Professor  
Department of Anesthesiology  
Feinberg School of Medicine  
Northwestern University  
Chicago, Illinois

**Rafael Ortega, MD**

Professor  
Vice-Chairman of Academic Affairs  
Department of Anesthesiology  
Boston University School of Medicine  
Boston, Massachusetts

**Sam R. Sharar, MD**

Professor  
Vice-Chair for Faculty Affairs and Development  
Department of Anesthesiology and Pain Medicine  
University of Washington School of Medicine  
Seattle, Washington

**Natalie F. Holt, MD, MPH**

Assistant Professor  
Department of Anesthesiology  
Yale University School of Medicine  
Medical Director  
Ambulatory Procedures Unit  
VA Connecticut Healthcare System  
West Haven, Connecticut

### **Library of Congress Cataloging-in-Publication Data**

Names: Barash, Paul G., editor.

Title: Clinical anesthesia / edited by Paul G. Barash, Bruce F. Cullen, Robert K. Stoelting, Michael K. Cahalan, M. Christine Stock, Rafael Ortega, Sam R. Sharar, Natalie F. Holt.

Other titles: Clinical anesthesia (Barash)

Description: Eighth edition. | Philadelphia : Wolters Kluwer, [2017] | Includes bibliographical references and index.

Identifiers: LCCN 2016058322 | ISBN 9781496337016 (hardback)

Subjects: | MESH: Anesthesia | Anesthesiology | Anesthetics

This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

# Contributing Authors

## **Ramon Abola, MD**

Assistant Professor  
Department of Anesthesiology  
Stony Brook Medicine  
Stony Brook, New York

## **Ron O. Abrons, MD**

Associate Professor  
Department of Anesthesiology  
The University of Iowa Hospitals and Clinics  
Iowa City, Iowa

## **Shamsuddin Akhtar, MD**

Associate Professor  
Department of Anesthesiology and Pharmacology  
Yale University School of Medicine  
New Haven, Connecticut

## **Michael L. Ault, MD, FCCP, FCCM**

Associate Professor of Anesthesiology, Medical Education, Neurological  
Surgery and Surgery  
Chief and Fellowship Program Director, Section of Critical Care Medicine  
Department of Anesthesiology  
Northwestern University Feinberg School of Medicine  
Chicago, Illinois

## **Douglas R. Bacon, MD, MA**

Professor and Chair  
Department of Anesthesiology  
University of Mississippi Medical Center  
Jackson, Mississippi

## **Gina C. Badescu, MD**

Division of Cardiothoracic Anesthesiology  
Maui Memorial Medical Center  
Wailuku, Hawaii

**Dalia Banks, MD, FASE**

Clinical Professor  
Division Chief of Cardiothoracic Anesthesiology  
Director of Cardiothoracic Anesthesiology Fellowship  
Clinical Director of Sulpizio CVC and PTU  
University of California San Diego  
San Diego, California

**Paul G. Barash, MD**

Professor Emeritus and Past Chair  
Department of Anesthesiology  
Yale University School of Medicine  
Honorary Attending Anesthesiologist  
Yale-New Haven Hospital  
New Haven, Connecticut

**John F. Bebawy, MD**

Associate Professor of Anesthesiology & Neurological Surgery  
Northwestern University  
Feinberg School of Medicine  
Chicago, Illinois

**Itay Bentov, MD, PhD**

Associate Professor  
Anesthesiology and Pain Medicine  
Adjunct Associate Professor  
Department of Medicine  
University of Washington School of Medicine  
Harborview Medical Center  
Seattle, Washington

**Honorio T. Benzon, MD**

Professor of Anesthesiology  
Northwestern University Feinberg School of Medicine  
Chicago, Illinois

**Marcelle E. Blessing, MD**

Assistant Professor of Anesthesiology  
Yale University School of Medicine  
New Haven, Connecticut

**Michelle Y. Braunfeld, MD**

Professor and Vice Chair

Department of Anesthesiology  
David Geffen School of Medicine at UCLA  
Chair, Department of Anesthesiology  
Greater Los Angeles VA Hospital  
Los Angeles, CA

**Ferne R. Braveman, MD**

Vice-Chair for Clinical Affairs  
Director of Division of Obstetrical Anesthesiology  
Professor of Anesthesiology and Obstetrics, Gynecology and Reproductive  
Medicine  
Department of Anesthesiology  
Yale School of Medicine  
New Haven, Connecticut

**Sorin J. Brull, MD, FCARCSI (Hon)**

Professor of Anesthesiology  
Department of Anesthesiology  
Mayo Clinic College of Medicine  
Mayo Clinic Florida  
Jacksonville, Florida

**Brenda A. Bucklin, MD**

Professor of Anesthesiology  
University of Colorado School of Medicine  
Aurora, Colorado

**Michael K. Cahalan, MD**

Professor and Chair  
Department of Anesthesiology  
The University of Utah School of Medicine  
Salt Lake City, Utah

**Levon M. Capan, MD**

Professor of Clinical Anesthesiology  
New York University School of Medicine  
Associate Director of Anesthesia Service  
Bellevue Hospital Center  
New York, New York

**Louanne M. Carabini, MD**

Assistant Professor  
Department of Anesthesiology

Northwestern University Feinberg School of Medicine  
Chicago, Illinois

**Christopher G. Choukalas, MD, MS**

Associate Clinical Professor  
Department of Anesthesia and Perioperative Care  
University of California, San Francisco  
San Francisco VA Medical Center  
San Francisco, California

**Amalia Cochran, MD, MA**

Associate Professor of Surgery  
Vice-Chair of Education and Professionalism  
University of Utah School of Medicine  
Salt Lake City, Utah

**Edmond Cohen, MD**

Professor of Anesthesiology and Thoracic Surgery  
Director of Thoracic Anesthesia  
Icahn School of Medicine at Mount Sinai  
New York, New York

**Christopher M. Conley, MD**

Clinical Assistant Professor of Anesthesiology  
Boston University School of Medicine  
Boston, Massachusetts

**Christopher W. Connor, MD, PhD**

Associate Professor of Anesthesiology and Biomedical Engineering  
Department of Anesthesiology  
Boston Medical Center  
Boston, Massachusetts

**C. Michael Crowder, MD, PhD**

Allan J. Treuer Endowed Professor and Chair  
Department of Anesthesiology and Pain Medicine  
Adjunct Professor of Genome Sciences  
University of Washington School of Medicine  
Seattle, Washington

**Marie Csete, MD, PhD**

President and Chief Scientist  
Huntington Medical Research Institutes

Pasadena, California  
Professor of Anesthesiology  
Keck USC School of Medicine  
Los Angeles, California  
Visiting Associate  
Medical Engineering  
California Institute of Technology  
Pasadena, California

**Bruce F. Cullen, MD**

Emeritus Professor  
Department of Anesthesiology and Pain Medicine  
University of Washington School of Medicine  
Seattle, Washington

**Albert Dahan, MD, PhD**

Department of Anesthesiology  
Leiden University Medical Center  
Leiden, The Netherlands

**Rossemmary De La Cruz, MD**

Academic, Media, and Risk Management Associate  
Department of Anesthesiology  
Boston Medical Center  
Boston, Massachusetts

**Steven Deem, MD**

Director, Neurocritical Care  
Swedish Medical Center  
Physicians Anesthesia Service  
Clinical Professor of Anesthesiology  
University of Washington  
Seattle, Washington

**Stephen F. Dierdorf, MD**

Professor of Clinical Anesthesia  
Department of Anesthesia and Perioperative Medicine  
Medical University of South Carolina  
Charleston, South Carolina

**Karen B. Domino, MD, MPH**

Professor and Vice-Chair for Clinical Research  
Department of Anesthesiology and Pain Medicine

University of Washington School of Medicine  
Seattle, Washington

**Thomas J. Ebert, MD, PhD**

Vice-Chair for Education  
Professor of Anesthesiology  
Medical College of Wisconsin and Zablocki VA Medical Center  
Milwaukee, Wisconsin

**Jan Ehrenwerth, MD**

Professor Emeritus  
Department of Anesthesiology  
Yale University School of Medicine  
New Haven, Connecticut

**John H. Eichhorn, MD**

Professor of Anesthesiology  
College of Medicine  
Provost's Distinguished Service Professor  
Department of Anesthesiology  
University of Kentucky Medical Center  
Lexington, Kentucky

**James B. Eisenkraft, MD**

Professor  
Department of Anesthesiology  
Icahn School of Medicine at Mount Sinai  
New York, New York

**Alex S. Evers, MD**

Henry S. Mallinckrodt Professor and Head  
Department of Anesthesiology  
Professor of Developmental Biology and Internal Medicine  
Washington University School of Medicine  
St. Louis, Missouri

**Ana Fernandez-Bustamante, MD, PhD**

Associate Professor  
Department of Anesthesiology  
University of Colorado School of Medicine  
Aurora, Colorado

**Lynne R. Ferrari, MD**

Chief, Perioperative Anesthesia  
Medical Director, Operating Rooms and Perioperative Programs  
Department of Anesthesiology, Perioperative and Pain Medicine  
Boston Children's Hospital  
Boston, Massachusetts

**Scott M. Fishman, MD**

Professor, Department of Anesthesiology and Pain Medicine  
Chief, Division of Pain Medicine  
Vice-Chair, Department of Anesthesiology and Pain Medicine  
Director, Center for Advancing Pain Relief  
University of California Davis School of Medicine  
Sacramento, California

**Michael A. Fowler, MD, MBA**

Assistant Professor  
Residency Program Director  
VCU Department of Anesthesiology  
Richmond, Virginia

**J. Sean Funston, MD**

Professor  
Department of Anesthesiology  
The University of Texas Medical Branch  
Galveston, Texas

**Tong J. Gan, MD, MHS, FRCA**

Professor and Chairman  
Department of Anesthesiology  
Stony Brook University  
Stony Brook, New York

**Steven I. Gayer, MD**

Professor of Anesthesiology  
University of Miami Health System  
Miami, Florida

**Sofia Geralemou, MD**

Department of Anesthesiology  
Stony Brook University Hospital  
Stony Brook, New York

**Loreta Grecu, MD**

Clinical Associate Professor of Anesthesiology  
Stony Brook University School of Medicine  
Stony Brook, New York

**Dhanesh K. Gupta, MD**

Professor of Anesthesiology  
Chief of Neuroanesthesiology  
Department of Anesthesiology  
Duke University Medical Center  
Durham, North Carolina

**Carin A. Hagberg, MD**

Joseph C. Gabel Professor and Chair  
Department of Anesthesiology  
UTHealth Medical School  
Houston, Texas

**Matthew R. Hallman, MD**

Assistant Professor  
Department of Anesthesiology and Pain Medicine  
University of Washington School of Medicine  
Seattle, Washington

**Kylene E. Halloran, MD**

Assistant Professor of Anesthesiology  
Dartmouth-Hitchcock Medical Center  
Lebanon, New Hampshire

**Stephen C. Haskins, MD**

Assistant Anesthesiologist  
Hospital for Special Surgery  
Clinical Assistant Professor of Anesthesiology  
Weill Cornell Medical College  
New York, New York

**J. Steven Hata, MD, MSc**

Vice Chairman, Education Continuum  
Center for Critical Care  
Anesthesiology Institute  
Cleveland Clinic  
Cleveland, Ohio

**Tara M. Hata, MD**

Clinical Assistant Professor  
Department of Pediatric Anesthesia  
Cleveland Clinic  
Cleveland, Ohio

**Laurence M. Hausman, MD**

Professor of Anesthesiology  
Vice-Chair, Academic Affiliations  
Director, Ambulatory Anesthesia  
Department of Anesthesiology  
Perioperative and Pain Medicine  
Icahn School of Medicine at Mount Sinai  
New York, New York

**Salim M. Hayek, MD, PhD**

Professor  
Department of Anesthesiology  
Case Western Reserve University  
Chief, Division of Pain Medicine  
University Hospitals Cleveland Medical Center  
Cleveland, Ohio

**Christopher L. Heine, MD**

Assistant Professor  
Department of Anesthesia and Perioperative Medicine  
Medical University of South Carolina  
Charleston, South Carolina

**Thomas K. Henthorn, MD**

Professor, Anesthesiology  
Department of Anesthesiology  
University of Colorado  
Aurora, Colorado

**Simon C. Hillier, MB, ChB**

Professor  
Departments of Anesthesiology and Pediatrics  
Geisel School of Medicine  
Dartmouth-Hitchcock Medical Center  
Lebanon, New Hampshire

**Natalie F. Holt, MD, MPH**

Assistant Professor

Department of Anesthesiology  
Yale University School of Medicine  
Medical Director  
Ambulatory Procedures Unit  
VA Connecticut Healthcare System  
West Haven, Connecticut

**Robert S. Holzman, MD, MS (Hon), FAAP**

Senior Associate in Perioperative Anesthesiology  
Department of Anesthesiology, Perioperative and Pain Medicine  
Boston Children's Hospital  
Professor of Anesthesia  
Harvard Medical School  
Boston, Massachusetts

**Harriet W. Hopf, MD**

Professor and Vice-Chair  
Department of Anesthesiology  
University of Utah School of Medicine  
Salt Lake City, Utah

**Robert W. Hurley, MD, PhD**

Professor and Vice-Chair  
Department of Anesthesiology  
Medical College of Wisconsin  
Milwaukee, Wisconsin

**Adam K. Jacob, MD**

Associate Professor of Anesthesiology  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**Farid Jadbabaie, MD**

Associate Professor of Medicine (Cardiology)  
Director of Echocardiography Laboratory  
VA Connecticut Healthcare System  
Yale School of Medicine  
New Haven, Connecticut

**Rebecca L. Johnson, MD**

Assistant Professor of Anesthesiology  
Department of Anesthesiology  
Mayo Clinic College of Medicine

Rochester, Minnesota

**Sharma E. Joseph, MD**

Instructor of Anesthesia  
Boston University School of Medicine  
Boston Medical Center  
Boston, Massachusetts

**Jonathan D. Katz, MD**

Clinical Professor of Anesthesiology  
Yale University School of Medicine  
Professor of Anesthesiology  
Frank H. Netter MD School of Medicine at Quinnipiac University  
Attending Anesthesiologist  
St. Vincent's Medical Center  
Bridgeport, Connecticut

**Christopher D. Kent, MD**

Associate Professor  
Department of Anesthesiology and Pain Medicine  
University of Washington  
Seattle, Washington

**Meghan A. Kirksey, MD, PhD**

Assistant Attending Anesthesiologist  
Hospital for Special Surgery  
Clinical Assistant Professor of Anesthesiology  
Weill Cornell Medical College  
New York, New York

**Sandra L. Kopp, MD**

Associate Professor of Anesthesiology  
Department of Anesthesiology  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**Catherine Kuhn, MD**

Director & Associate Dean, Graduate Medical Education  
Designated Institutional Official  
Professor of Anesthesiology  
Department of Anesthesiology  
Duke University  
Durham, North Carolina

**Jerrold Lerman, MD, FRCPC, FANZCA**

Clinical Professor of Anesthesiology  
Women and Children's Hospital of Buffalo  
State University of New York  
Buffalo, New York

**Jerrold H. Levy, MD, FAHA, FCCM**

Professor of Anesthesiology  
Associate Professor of Surgery  
Division of Cardiothoracic Anesthesiology and Critical Care  
Duke University School of Medicine  
Co-Director, Cardiothoracic ICU  
Duke University Hospital  
Durham, North Carolina

**Adam D. Lichtman, MD, FASE**

Associate Professor of Anesthesiology  
Director of Vascular Anesthesia  
Weill Cornell Medical College  
New York Presbyterian Hospital  
New York, New York

**J. Lance Lichtor, MD**

Department of Anesthesiology  
Yale University School of Medicine  
New Haven, Connecticut

**Yi Lin, MD, PhD**

Assistant Attending Anesthesiologist  
Hospital for Special Surgery  
New York, New York

**Spencer S. Liu, MD**

Clinical Professor of Anesthesiology  
Weill College of Medicine at Cornell University  
Department of Anesthesiology  
Hospital for Special Surgery  
New York, New York

**Justin B. Long, MD, FAAP**

Assistant Professor  
Emory University School of Medicine  
Department of Pediatric Anesthesiology

Children's Healthcare of Atlanta at Henrietta Eggleston Hospital for Children  
Atlanta, Georgia

**Stephen M. Macres, MD, PharmD**

Professor

Department of Anesthesiology and Pain Medicine  
University of California Davis Medical Center  
Sacramento, California

**Peter Mancini, MD**

Assistant Clinical Professor

Department of Anesthesiology  
Yale University School of Medicine  
New Haven, CT

**Aaron J. Mancuso, MD**

Assistant Professor of Anesthesiology  
Geisel School of Medicine  
Dartmouth-Hitchcock Medical Center  
Lebanon, New Hampshire

**Gerard Manecke, MD**

Chair, Department of Anesthesiology  
UCSD Medical Center  
San Diego, California

**Melissa M. Masaracchia, MD**

Assistant Professor of Anesthesiology  
Dartmouth-Hitchcock Medical Center  
Geisel School of Medicine  
Lebanon, New Hampshire

**Joseph P. Mathew, MD, MHSC, MBA**

Jerry Reves, MD, Professor and Chairman  
Department of Anesthesiology  
Duke University Medical Center  
Durham, North Carolina

**Kathryn E. McGoldrick, MD, FCAI (Hon)**

Professor and Chair of Anesthesiology, Emeritus  
Advisory Dean, Emeritus  
New York Medical College  
Valhalla, New York

Accreditation Council for Graduate Medical Education  
Department of Institutional Accreditation  
Chicago, Illinois

**Joseph H. McIsaac III, MD, MS**

Associate Clinical Professor of Anesthesiology  
Associate Adjunct Professor of Biomedical Engineering  
University of Connecticut  
Avon, CT

**Sanford M. Miller, MD**

Clinical Professor (Emeritus) of Anesthesiology  
NYU School of Medicine  
Former Assistant Director of Anesthesiology  
Bellevue Hospital Center  
New York, New York

**Shawn L. Mincer, MSW**

Research Coordinator  
Department of Anesthesiology and Pain Medicine  
University of Washington  
Seattle, Washington

**Peter G. Moore, MBBS, PhD, FANZCA, FICM**

Professor of Anesthesiology and Pain Medicine and Internal Medicine  
University of California, Davis Health System  
Sacramento, California

**Candice Morrissey, MD, MSPH**

Assistant Professor  
Department of Anesthesiology  
University of Utah  
Salt Lake City, Utah

**Michael J. Murray, MD, PhD**

Department of Critical Care Medicine  
Geisinger Medical Center  
Danville, Pennsylvania

**Sawyer A. Naze, MD**

Resident  
Department of Anesthesiology  
Feinberg School of Medicine

Northwestern University  
Chicago, Illinois

**Steven M. Neustein, MD**

Professor of Anesthesiology  
Icahn School of Medicine at Mount Sinai  
New York, New York

**Marieke Niesters, MD, PhD**

Department of Anesthesiology  
Leiden University Medical Center  
Leiden, The Netherlands

**Mark C. Norris, MD**

Director of Obstetric Anesthesia  
Boston Medical Center  
Clinical Professor of Anesthesiology  
Boston University School of Medicine  
Boston, Massachusetts

**E. Andrew Ochroch, MD, MSCE**

Professor of Anesthesiology, Critical Care, and Surgery  
University of Pennsylvania  
Philadelphia, Pennsylvania

**Rafael Ortega, MD**

Professor  
Vice-Chairman of Academic Affairs  
Department of Anesthesiology  
Boston University School of Medicine  
Boston, Massachusetts

**Charles W. Otto, MD, FCCM**

Professor of Anesthesiology  
Associate Professor of Medicine  
Department of Anesthesiology  
University of Arizona College of Medicine  
Tucson, Arizona

**Frank Overdyk, MSEE, MD**

Department of Anesthesiology  
Roper St. Francis Health System  
Charleston, South Carolina

**Nathan Leon Pace, MD, MStat**

Professor  
Department of Anesthesiology  
University of Utah  
Salt Lake City, Utah

**Paul S. Pagel, MD, PhD**

Staff Physician  
Anesthesiology Service  
Clement J. Zablocki VA Medical Center  
Milwaukee, Wisconsin

**Ben Julian Palanca, MD, PhD, MSc**

Assistant Professor  
Department of Anesthesiology  
Washington University School of Medicine  
St. Louis, Missouri

**Raymond S. Park, MD**

Assistant in Perioperative Anesthesia  
Department of Anesthesiology, Perioperative and Pain Medicine  
Boston Children's Hospital  
Instructor in Anaesthesia  
Harvard Medical School  
Boston, Massachusetts

**Jeffrey J. Pasternak, MS, MD**

Associate Professor of Anesthesiology  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**Albert C. Perrino Jr**

Division of Cardiothoracic Anesthesia  
Department of Anesthesiology and Pain Medicine  
University of Washington  
Seattle, Washington

**Andrew J. Pittaway, BM, BS FRCA**

Associate Residency Program Director  
Associate Professor  
University of Washington  
Attending Anesthesiologist  
Department of Anesthesiology & Pain Medicine  
Seattle Children's Hospital  
Seattle, Washington

**Mihai V. Podgoreanu, MD**

Perioperative Genomics Program  
Division of Cardiothoracic Anesthesia and Critical Care  
Department of Anesthesiology  
Duke University Medical Center  
Durham, North Carolina

**Wanda M. Popescu, MD**

Associate Professor of Anesthesiology  
Director, Thoracic and Vascular Anesthesia Division  
Co-Director, Grand Rounds  
Yale School of Medicine  
New Haven, Connecticut

**Karen L. Posner, PhD**

Research Professor  
Laura Cheney Professor in Anesthesia Patient Safety  
Department of Anesthesia and Pain Medicine  
University of Washington  
Seattle, Washington

**Jamie R. Privratsky, MD**

Department of Anesthesiology  
Duke University Medical Center  
Durham, North Carolina

**Donald S. Prough, MD**

Rebecca Terry White Distinguished Professor  
Chair of Anesthesiology  
The University of Texas Medical Branch at Galveston  
Galveston, Texas

**Glenn Ramsey, MD**

Professor

Department of Pathology  
Feinberg School of Medicine  
Northwestern University  
Medical Director  
Blood Bank  
Northwestern Memorial Hospital  
Chicago, Illinois

**Kevin T. Riutort, MD, MS**

USAP Colorado  
Greenwood Village, Colorado

**Gerardo Rodriguez, MD**

Assistant Professor  
Department of Anesthesiology  
Boston University School of Medicine  
Director, East Newton Surgical Intensive Care Unit  
Boston Medical Center  
Boston, Massachusetts

**G. Alec Rooke, MD, PhD**

Professor of Anesthesiology and Pain Medicine  
University of Washington  
Seattle, Washington

**Stanley H. Rosenbaum, MA, MD**

Professor of Anesthesiology, Internal Medicine and Surgery  
Yale University School of Medicine  
New Haven, Connecticut

**Meg A. Rosenblatt, MD**

Site Chair, Department of Anesthesiology, Mount Sinai West  
Professor of Anesthesiology  
Professor of Orthopaedics  
Mount Sinai St. Luke's  
New York, New York

**William H. Rosenblatt, MD**

Professor of Anesthesiology  
Yale University School of Medicine  
New Haven, Connecticut

**Richard W. Rosenquist, MD**

Chairman  
Pain Management Department  
Anesthesiology Institute  
Cleveland Clinic  
Cleveland, Ohio

**Antonio F. Saad, MD, MFM/CCM**

Fellow, Anesthesia and Obstetrics and Gynecology  
University of Texas Medical Branch  
Galveston, Texas

**Aaron Sandler, MD**

Assistant Professor of Anesthesiology  
Department of Anesthesiology  
Duke University  
Durham, North Carolina

**Barbara M. Scavone, MD**

Professor of Anesthesia and Critical Care, and Obstetrics and Gynecology  
University of Chicago  
Chicago, Illinois

**Corey Scher, MD**

Clinical Professor of Anesthesiology  
New York University School of Medicine-Bellevue Hospital Center  
New York, New York

**Jeffrey J. Schwartz, MD**

Associate Professor  
Department of Anesthesiology  
Yale University School of Medicine  
New Haven, Connecticut

**Sam R. Sharar, MD**

Professor  
Vice-Chair for Faculty Affairs and Development  
Department of Anesthesiology and Pain Medicine  
University of Washington School of Medicine  
Seattle, Washington

**Aarti Sharma, MD**

Associate Professor of Clinical Anesthesiology  
Department of Anesthesiology

Weill Cornell Medical College  
New York Presbyterian Hospital  
New York, New York

**Benjamin M. Sherman, MD**

Cardiothoracic Anesthesiology  
TeamHealth Anesthesia  
Legacy Good Samaritan Hospital  
Portland, Oregon

**Nikolaos J. Skubas, MD, DSc, FASE, FACC**

Professor of Anesthesiology and Cardiothoracic Surgery  
Weill Cornell Medicine  
Director, Cardiac Anesthesia  
NewYork-Presbyterian Hospital  
New York, New York

**Hugh M. Smith, MD**

Assistant Professor of Anesthesiology  
Department of Anesthesiology and Perioperative Medicine  
Mayo Clinic  
Rochester, Minnesota

**Terry Smith, PhD**

Associate Professor  
Department of Anesthesiology  
Leiden University Medical Center  
Leiden, The Netherlands

**Ellen M. Soffin, MD, PhD**

Assistant Attending Anesthesiologist  
Hospital for Special Surgery  
New York, New York

**Karen J. Souter, MB, BS, FRCA, MACM**

Professor  
Department of Anesthesiology and Pain Medicine  
University of Washington  
Seattle, Washington

**Bruce D. Spiess, MD, FAHA**

Professor and Associate Chair (Research)  
Department of Anesthesiology

University of Florida  
Gainesville, Florida

**Mark Stafford-Smith, MD, CM, FRCP**

Professor of Anesthesiology  
Vice-Chair of Education  
Fellowship Education Director  
Adult Cardiothoracic Anesthesiology Fellowship  
Department of Anesthesiology  
Duke University Medical Center  
Durham, North Carolina

**Andrew F. Stasic, MD**

Associate Professor of Clinical Anesthesia  
Department of Anesthesia  
Indiana University School of Medicine  
Riley Hospital for Children  
Indianapolis, Indiana

**Randolph H. Steadman, MD, MS**

Professor and Vice-Chair  
Department of Anesthesiology and Perioperative Medicine  
UCLA Health System  
Los Angeles, California

**Robert K. Stoelting, MD**

Emeritus Professor and Past Chair

**Joshua Zimmerman, MD**

Associate Professor  
Director of Perioperative Echocardiography  
Department of Anesthesiology  
University of Utah School of Medicine  
Salt Lake City, Utah

# Preface

Innovative use of audiovisual resources is the hallmark of the *Clinical Anesthesia* series. Integration of diverse educational materials into the fabric of each chapter serves to enrich the reader's experience and has been a part of the series since the second edition of *Clinical Anesthesia* in 1995, in which the editors introduced the Lippincott Raven Interactive Library on CD-ROM. Using the textbook as the keystone publication, other relevant books were added to the library, which facilitated cross-referencing topics from *Clinical Anesthesia*. This CD was awarded the prestigious International Folio Infobase Industry Award for the Best Science, Technology, Medicine CD-ROM.

With the fourth edition of *Clinical Anesthesia* in 2002, we introduced the first anesthesia software designed specifically for personal digital assistants (Palm Pilot PDA), and in conjunction with the sixth edition in 2009, we introduced another first in anesthesia textbooks: the podcast.

In 2013, we published the seventh edition of *Clinical Anesthesia* with the most robust electronic platform to date. Previously, the digital versions of textbooks were merely reproductions of the printed page, not formatted to be read on a mobile device, which resulted in a suboptimal reader experience. Now, powered by the VitalSource platform, the textbook is available in eBook format optimized for all major handheld and desktop devices (tablet, smartphone, and Mac/PC) and includes nearly 2,000 pages of high-fidelity text, images, animated videos, and hyperlinked references. The platform allows the reader to search text by keyword as well as to make notes in the same fashion as one would with a traditional printed textbook.

This rich history of cutting-edge advances in presenting educational material in a variety of formats to enrich different learning styles continues in the eighth edition of *Clinical Anesthesia*. The new Narrated Interactive Clinical Vignettes are an innovative, narrated audiovisual product that immerses viewers in a virtual classroom setting in which a master teacher guides them through a focused discussion on common and uncommon clinical topics. A clinical question is posed and viewers are given time to develop an appropriate answer. Then, in a stepwise and menu-driven fashion, viewers see and hear the answer unfold. The objective of these Interactive Clinical Vignettes, which are designed following research-based theories of learning and evidence-based techniques of instruction, is not to provide an exhaustive and complete review of each topic. Rather, the user is provided a springboard to explore features of a clinical scenario and weigh the relative merits and

drawbacks of a course of action, all with the objective of improving clinical reasoning and exercising the articulation of appropriate answers. Our initial testing of this concept has resulted in very positive feedback, and we currently have over 175 vignettes in our library.

In the eighth edition of *Clinical Anesthesia*, we use a series of icons in the margins of the text to alert the reader to key points as well as the available audiovisual material:

**Video** 

**Narrated Interactive Clinical Vignette** 

**Key Point** 

Although the textbook represents the work and input of all editors, it is essential to recognize Dr. Rafael Ortega and his staff, Drs. Faina Kotova and Rosemary De La Cruz (Department of Anesthesiology, Boston University), for their immense contribution to the creation of the Narrated Interactive Clinical Vignettes in this edition.

Important updates in the printed textbook include new chapters on cardiovascular pharmacology and a focused discussion of autonomic drugs in the autonomic pharmacology chapter. We have expanded the appendices with video sections on transthoracic echocardiography including the FAST and FOCUS examinations, as well as over 90 additional video examples of transesophageal echocardiograms, demonstrating core clinical applications of this powerful imaging technique. The Clinical Updates section is popular with our readers as a way to keep up with contemporary medical literature, and has a larger profile in the eighth edition. Importantly, the chapter on occupational hazards has been expanded to place significant emphasis on the topic of physician wellness (emotional considerations, nutrition, lifestyle interventions, and mindfulness).

It is with a note of sadness that after 25 years we say goodbye to *Clinical Anesthesia's* companion title, *Handbook of Clinical Anesthesia*. Because of advances in digital platforms and the publication of the entire eighth edition as a robust eBook, the editors felt it was time to move on.

In this edition we welcome two new editors: Dr. Sam Sharar and Dr. Natalie Holt. Both Sam and Natalie are experienced with the logistics of the *Clinical Anesthesia* series. Sam was instrumental in our new book aimed at early students and trainees in anesthesiology, *Clinical Anesthesia Fundamentals*, while Natalie has been in charge of the aforementioned Clinical Updates.

We wish to express our appreciation to all our contributors whose knowledge, hard work, dedication, and timely chapter submissions allowed us to maintain high quality while working on a tight production schedule. Our readers provided comments instrumental to the editorial process of continual improvement of *Clinical Anesthesia*. We also thank our administrative assistants, including Gail Norup. We would like to thank our editor at Wolters Kluwer, Keith Donnellan, for his commitment to excellence. Finally, we owe a debt of gratitude to developmental editors Grace Caputo and Brendan Huffman, marketing manager Dan Dressler, and Chris Miller, production manager at Aptara. Their day-to-day management of this endeavor resulted in a publication that exceeded the editors' expectations.

As we noted in previous editions, the discovery and application of anesthesia is the single most important contribution of American medicine to mankind. The major achievements of modern surgery could not have taken place without the accompanying vision of the pioneers in anesthesiology. This statement is echoed by surgeon-author Atul Gawande, who in the article "Two Hundred Years of Surgery" (*New England Journal of Medicine*), stated:

The crucial spark of transformation—the moment that changed not just the future of surgery but of medicine as a whole—was the publication on November 18, 1846, of Henry Jacob Bigelow's groundbreaking report, "Insensibility during Surgical Operations Produced by Inhalation."

The editors hope that every page of *Clinical Anesthesia* evokes the pride of being a part of the specialty of anesthesiology and its achievements for the betterment of mankind.

# Contents

## *Section 1*

### **INTRODUCTION AND OVERVIEW**

#### **1 The History of Anesthesia**

ADAM K. JACOB • SANDRA L. KOPP • DOUGLAS R. BACON • HUGH M. SMITH

#### **2 Scope of Practice**

JOHN H. EICHHORN

#### **3 Occupational Health**

JONATHAN D. KATZ • ROBERT S. HOLZMAN • AMY E. VINSON

#### **4 Anesthetic Risk, Quality Improvement, and Liability**

KAREN L. POSNER • CHRISTOPHER D. KENT • SHAWN L. MINCER • KAREN B. DOMINO

#### **5 Electrical and Fire Safety**

JAN EHRENWERTH

## *Section 2*

### **BASIC SCIENCE AND FUNDAMENTALS**

#### **6 Genomic Basis of Perioperative Medicine**

MIHAI V. PODGOREANU • JOSEPH P. MATHEW

#### **7 Experimental Design and Statistics**

NATHAN LEON PACE

#### **8 Inflammation, Wound Healing, and Infection**

HARRIET W. HOPF • AMALIA COCHRAN • CRISTIANE M. UENO • CANDICE MORRISSEY

#### **9 The Allergic Response**

JERROLD H. LEVY

#### **10 Mechanisms of Anesthesia and Consciousness**

C. MICHAEL CROWDER • BEN JULIAN PALANCA • ALEX S. EVERS

#### **11 Basic Principles of Clinical Pharmacology**

### *Section 3*

## **CORE CARE PRINCIPLES**

### **12 Cardiac Anatomy and Physiology**

PAUL S. PAGEL • DAVID F. STOWE

### **13 Cardiovascular Pharmacology**

PAUL S. PAGEL • LORETA GRECU

### **14 Autonomic Nervous System Anatomy and Physiology**

LORETA GRECU

### **15 Respiratory Function in Anesthesia**

PAUL C. TAMUL • MICHAEL L. AULT

### **16 Fluids, Electrolytes, and Acid–Base Physiology**

DONALD S. PROUGH • J. SEAN FUNSTON • ANTONIO F. SAAD • CHRISTER H. SVENSÉN

### **17 Hemostasis and Transfusion Medicine**

LOUANNE M. CARABINI • GLENN RAMSEY

### *Section 4*

## **ANESTHETIC DRUGS AND ADJUVANTS**

### **18 Inhaled Anesthetics**

THOMAS J. EBERT • SAWYER A. NAZE

### **19 Intravenous Anesthetics**

RAMON ABOLA • SOFIA GERALEMOU • MARTIN SZAFRAN • TONG J. GAN

### **20 Opioids**

ALBERT DAHAN • MARIEKE NIESTERS • TERRY SMITH • FRANK OVERDYK

### **21 Neuromuscular Blocking Agents**

SORIN J. BRULL

### **22 Local Anesthetics**

YI LIN • SPENCER S. LIU

### *Section 5*

## **PREOPERATIVE ASSESSMENT AND PERIOPERATIVE MONITORING**

## **23 Preoperative Patient Assessment and Management**

TARA M. HATA • J. STEVEN HATA

## **24 Rare Coexisting Diseases**

STEPHEN F. DIERDORF • J. SCOTT WALTON • ANDREW F. STASIC • CHRISTOPHER L. HEINE

## **25 The Anesthesia Workstation and Delivery Systems for Inhaled Anesthetics**

KEVIN T. RIUTORT • JAMES B. EISENKRAFT

## **26 Commonly Used Monitoring Techniques**

CHRISTOPHER W. CONNOR • CHRISTOPHER M. CONLEY

## **Conclusions**

## **KEY POINTS**

- 1 Anesthesiology is a young specialty historically, especially when compared with surgery or internal medicine.
- 2 Discoveries in anesthesiology have taken decades to build upon the observations and experiments of many people, and in some instances we are still searching. For example, the ideal volatile anesthetic has yet to be discovered.
- 3 Much of our current anesthesia equipment is the direct result of anesthesiologists being unhappy with existing tools and needing better ones to properly anesthetize patients.
- 4 Many safety standards have been established through the work of anesthesiologists who were frustrated by the status quo.
- 5 Regional anesthesia is the direct outgrowth of a chance observation by an intern who would go on to become a successful ophthalmologist.
- 6 Pain medicine began as an outgrowth of regional anesthesia.
- 7 Organizations of anesthesia professionals have been critical in establishing high standards in education and proficiency, which in turn has defined the specialty.
- 8 Respiratory critical care medicine started as the need by anesthesiologists to use positive-pressure ventilation to help polio victims.
- 9 Surgical anesthesia and physician specialization in its administration have allowed for increasingly complex operations to be performed on increasingly ill patients.

Surgery without adequate pain control may seem cruel to the modern reader, and in contemporary practice we are prone to forget the realities of preanesthesia surgery. Fanny Burney, a well-known literary artist from the early 19th century, described a mastectomy she endured after receiving a “wine cordial” as her sole anesthetic. As seven male assistants held her down, the surgery commenced: “When the dreadful steel was plunged into the

breast-cutting through veins—arteries—flesh—nerves, I needed no injunction not to restrain my cries. I began a scream that lasted unintermittently during the whole time of the incision—and I almost marvel that it rings not in my Ears still! So excruciating was the agony. Oh Heaven!—I then felt the knife racking against the breast bone—scraping it! This performed while I yet remained in utterly speechless torture.”<sup>1</sup> Burney’s description illustrates the difficulty of overstating the impact of anesthesia on the human condition. An epitaph on a monument to William Thomas Green Morton, one of the founders of anesthesia, summarizes the contribution of anesthesia: “BEFORE WHOM in all time Surgery was Agony.”<sup>2</sup> Although most human civilizations evolved some method for diminishing patient discomfort, *anesthesia*, in **1** its modern and effective meaning, is a comparatively recent discovery with traceable origins in the mid-19th century. How we have changed perspectives, from one in which surgical pain was terrible and expected to one in which patients reasonably assume they will be safe, pain free, and unaware during extensive operations, is a fascinating story and the subject of this chapter.

Anesthesiologists are like no other physicians: We are experts at controlling the airway and at emergency resuscitation; we are real-time cardiopulmonologists achieving hemodynamic and respiratory stability for the anesthetized patient; we are pharmacologists and physiologists, calculating appropriate doses and desired responses; we are gurus of postoperative care and patient safety; we are internists performing perianesthetic medical evaluations; we are the pain experts across all medical disciplines and apply specialized techniques in pain clinics and labor wards; we manage the severely sick and injured in critical care units; we are neurologists, selectively blocking sympathetic, sensory, or motor functions with our regional techniques; and we are trained researchers exploring scientific mystery and clinical phenomenon.

Anesthesiology is an amalgam of specialized techniques, equipment, drugs, and knowledge that like the growth rings of a tree have built up over time. Current anesthesia practice is the summation of the individual efforts and fortuitous discoveries of centuries. Every component of modern anesthesia was at some point a new discovery and reflects the experience, knowledge, and inventiveness of our predecessors. Historical examination enables understanding of how these individual components of anesthesia evolved. Knowledge of the history of anesthesia enhances our appreciation of current practice and foretells where our specialty might be headed.

## Anesthesia Before Ether

### *Physical and Psychological Anesthesia*

The Edwin Smith Surgical Papyrus, the oldest known written surgical document, describes 48 cases performed by an Egyptian surgeon from 3000 to 2500 BC. Although this remarkable surgical treatise contains no direct mention of measures to lessen patient pain or suffering, Egyptian pictographs from the same era show a surgeon compressing a nerve in a patient's antecubital fossa while operating on the patient's hand. Another image displays a patient compressing his own brachial plexus while a procedure is performed on his palm.<sup>3</sup> In the 16th century, military surgeon Ambroise Paré became adept at nerve compression as a means of creating anesthesia.

Medical science has benefited from the natural refrigerating properties of ice and snow as well. For centuries anatomic dissections were performed only in winter because colder temperatures delayed deterioration of the cadaver. In the 17th century, Marco Aurelio Severino described the technique of "refrigeration anesthesia" in which snow was placed in parallel lines across the incisional plane such that the surgical site became insensate within minutes. The technique never became widely used, likely because of the challenge of maintaining stores of snow year-round.<sup>4</sup> Severino is also known to have saved numerous lives during an epidemic of diphtheria by performing tracheostomies and inserting trocars to maintain patency of the airway.<sup>5</sup>

Formal manipulation of the psyche to relieve surgical pain was undertaken by French physicians Charles Dupotet and Jules Cloquet in the late 1820s with hypnosis, then called *mesmerism*. Although the work of Anton Mesmer was discredited by the French Academy of Science after formal inquiry several decades earlier, proponents like Dupotet and Cloquet continued with mesmeric experiments and pleaded to the Academie de Medicine to reconsider its utility.<sup>6</sup> In a well-attended demonstration in 1828, Cloquet removed the breast of a 64-year-old patient while she reportedly remained in a calm, mesmeric sleep. This demonstration made a lasting impression on British physician John Elliotson, who became a leading figure of the mesmeric movement in England in the 1830s and 1840s. Innovative and quick to adopt new advances, Elliotson performed mesmeric demonstrations and in 1843 published *Numerous Cases of Surgical Operations Without Pain in the Mesmeric State*. Support for mesmerism faded when in 1846 renowned surgeon Robert Liston performed the first operation using ether anesthesia in England and remarked, "This Yankee dodge beats mesmerism all hollow."<sup>7</sup>

### **Early Analgesics and Soporifics**

Dioscorides, a Greek physician from the first century AD, commented on the analgesia of mandragora, a drug prepared from the bark and leaves of the mandrake plant. He observed that the plant substance could be boiled in wine, strained, and used "in the case of persons . . . about to be cut or

cauterized, when they wish to produce anesthesia.”<sup>8</sup> Mandragora was still being used to benefit patients as late as the 17th century. From the ninth to the 13th centuries, the *soporific sponge* was a dominant mode of providing pain relief during surgery. Mandrake leaves, along with black nightshade, poppies, and other herbs, were boiled together and cooked onto a sponge. The sponge was then reconstituted in hot water and placed under the patient’s nose before surgery. Prior to the hypodermic syringe and routine venous access, ingestion and inhalation were the only known routes for administering medicines to gain systemic effects. Prepared as indicated by published reports of the time, the sponge generally contained morphine and scopolamine—drugs used in modern anesthesia—in varying amounts.<sup>9</sup>

Alcohol was another element of the pre-ether armamentarium because it was thought to induce stupor and blunt the impact of pain. Although alcohol is a central nervous system depressant, in the amounts administered it produced little analgesia in the setting of true surgical pain. Fanny Burney’s account underscores the ineffectiveness of alcohol as an anesthetic. Not only did alcohol provide minimal pain control, but it also did nothing to dull her recollection of events. Laudanum was an alcohol-based solution of opium first compounded by Paracelsus in the 16th century. It was wildly popular in the Victorian and Romantic periods and prescribed for a wide variety of ailments from the common cold to tuberculosis. Although appropriately used as an analgesic in some instances, it was frequently misused and abused. Laudanum was given by nursemaids to quiet wailing infants and abused by many upper-class women, poets, and artists who fell victim to its addictive potential.

In the first three decades of the 19th century, in Japan, Seisyu Hanaoka performed operations under what has been described as general anesthesia.<sup>10</sup> In the late 1900s, the manuscript “On the Use of Mafutsuto,” the name given to the anesthetic method by Hanaoka, was translated into English. Written by Hajime Matsuoka, the manuscript details preanesthetic evaluation, the timing of anesthesia, and the proposed duration of surgery. The manuscript stated that care should be taken to ensure that lighting is appropriate; therefore it recommended that operations be performed at noon. Similarly, it stated that operations should not last more than 2 hours, because there was no way to replace intraoperative fluid or blood losses. The manuscript also contains a section on postoperative care.<sup>11</sup>

## Inhaled Anesthetics

For many years nitrous oxide has been known for its ability to induce lightheadedness, and it was often inhaled by those seeking a thrill. It was made by heating ammonium nitrate in the presence of iron filings. The evolved gas was passed through water to eliminate toxic oxides of nitrogen

before being stored. Nitrous oxide was first prepared in 1773 by Joseph Priestley, an English clergyman and scientist, who ranks among the great pioneers of chemistry. Without formal scientific training, Priestley prepared and examined several gases, including nitrous oxide, ammonia, sulfur dioxide, oxygen, carbon monoxide, and carbon dioxide.

At the end of the 18th century in England, there was a strong interest in the supposed wholesome effects of mineral water and gases, particularly with regard to treatment of scurvy, tuberculosis, and other diseases. Thomas Beddoes opened his Pneumatic Institute close to the small spa of Hotwells, in the city of Bristol, to study the beneficial effects of inhaled gases. He hired Humphry Davy in 1798 to conduct research projects for the institute. Davy performed brilliant investigations of several gases but focused much of his attention on nitrous oxide. His human experimental results, combined with research on the physical properties of the gas, were published in *Nitrous Oxide*, a 580-page book published in 1800. This impressive treatise is now best remembered for a few incidental observations. Davy commented that nitrous oxide transiently relieved a severe headache, obliterated a minor headache, and briefly quenched an aggravating toothache. The most frequently quoted passage was a casual entry: “As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place.”<sup>12</sup> This is perhaps the most famous of the “missed opportunities” to discover surgical anesthesia. Davy’s lasting nitrous oxide legacy was coining the phrase “laughing gas” to describe its unique property.

### *Almost Discovery: Hickman, Clarke, Long, and Wells*

**2** As the 19th century progressed, societal attitudes toward pain changed, perhaps best exemplified in the writings of the Romantic poets.<sup>13</sup> Thus, efforts to relieve pain were undertaken, and several more near-breakthroughs that occurred deserve mention. An English surgeon named Henry Hill Hickman searched intentionally for an inhaled anesthetic to relieve pain in his patients.<sup>14</sup> Hickman used high concentrations of carbon dioxide in his studies on mice and dogs. Carbon dioxide has some anesthetic properties, as shown by the absence of response to an incision in the animals of Hickman’s study, but it was never determined whether the animals were insensate because of hypoxia rather than anesthesia. Hickman’s concept was magnificent; his choice of agent was regrettable.

The discovery of surgical anesthetics in the modern era remains linked to inhaled anesthetics. The compound now known as *diethyl ether* had been known for centuries; it may have been synthesized first by eighth-century

Arabian philosopher Jabir ibn Hayyan or possibly by Raymond Lully, a 13th-century European alchemist. But diethyl ether was certainly known in the 16th century, to both Valerius Cordus and Paracelsus, who prepared it by distilling sulfuric acid (oil of vitriol) with fortified wine to produce an *oleum vitrioli dulce* (sweet oil of vitriol). In one of the first “missed” observations on the effects of inhaled agents, Paracelsus observed that ether caused chickens to fall asleep and awaken unharmed. He must have been aware of its analgesic qualities because he reported that it could be recommended for use in painful illnesses.

For three centuries thereafter, this simple compound remained a therapeutic agent with only occasional use. Some of its properties were examined but without sustained interest by distinguished British scientists Robert Boyle, Isaac Newton, and Michael Faraday, none of whom made the conceptual link to surgical anesthesia. Its only routine application came as an inexpensive recreational drug among the poor of Britain and Ireland, who sometimes drank an ounce or two of ether when taxes made gin prohibitively expensive.<sup>15</sup> An American variation of this practice was conducted by groups of students who held ether-soaked towels to their faces at nocturnal “ether frolics.”

William E. Clarke, a medical student from Rochester, New York, may have given the first ether anesthetic in January 1842. From techniques learned as a chemistry student in 1839, Clarke entertained his companions with nitrous oxide and ether. Emboldened by these experiences, he administered ether, from a towel, to a young woman named Hobbie. One of her teeth was then extracted without pain by a dentist named Elijah Pope.<sup>16</sup> However, it was suggested that the woman’s unconsciousness was due to hysteria, and Clarke was advised to conduct no further anesthetic experiments.<sup>17</sup>

Two months later, on March 30, 1842, Crawford Williamson Long administered ether with a towel for surgical anesthesia in Jefferson, Georgia. His patient, James M. Venable, was a young man who was already familiar with ether’s exhilarating effects, for he reported in a certificate that he had previously inhaled it and was fond of its use. Venable had two small tumors on his neck but refused to have them excised because he feared the pain that accompanied surgery. Knowing that Venable was familiar with ether’s action, Dr. Long proposed that ether might alleviate pain and gained his patient’s consent to proceed. After inhaling ether from the towel and having the procedure successfully completed, Venable reported that he was unaware of the removal of the tumors.<sup>18</sup> In determining the first fee for anesthesia and surgery, Long settled on a charge of \$2.00.<sup>19</sup>

A common mid-19th century problem facing dentists was that patients refused beneficial treatment of their teeth for fear of the pain of the procedure. From a dentist’s perspective, pain was not so much life-threatening

as it was livelihood-threatening. One of the first dentists to engender a solution was Horace Wells of Hartford, Connecticut, whose great moment of discovery came on December 10, 1844. He observed a lecture-exhibition on nitrous oxide by an itinerant “scientist,” Gardner Quincy Colton, who encouraged members of the audience to inhale a sample of the gas. Wells observed a young man injure his leg without pain while under the influence of nitrous oxide. Sensing that it might provide pain relief during dental procedures, Wells contacted Colton and boldly proposed an experiment in which Wells was to be the subject. The following day, Colton gave Wells nitrous oxide before a fellow dentist, William Riggs, extracted a tooth.<sup>20</sup> Afterward Wells declared that he had not felt any pain and deemed the experiment a success. Colton taught Wells to prepare nitrous oxide, which the dentist administered with success to patients in his practice. His apparatus probably resembled that used by Colton: a wooden tube placed in the mouth through which nitrous oxide was breathed from a small bag filled with the gas.

### *Public Demonstration of Ether Anesthesia*

Another New Englander, William Thomas Green Morton, briefly shared a dental practice with Wells in Hartford. Wells’ daybook shows that he gave Morton a course of instruction in anesthesia, but Morton apparently moved to Boston without paying for the lessons.<sup>21</sup> In Boston, Morton continued his interest in anesthesia and sought instruction from chemist and physician Charles T. Jackson. After learning that ether dropped on the skin provided analgesia, he began experiments with inhaled ether, an agent that proved to be much more versatile than nitrous oxide. Bottles of liquid ether were easily transported, and the volatility of the drug permitted effective inhalation. The concentrations required for surgical anesthesia were so low that patients did not become hypoxic when breathing ether vaporized in air. It also possessed what would later be recognized as a unique property among all inhaled anesthetics: the quality of providing surgical anesthesia without causing respiratory depression. These properties, combined with a slow rate of induction, gave the patient a significant safety margin even in the hands of relatively unskilled anesthetists.<sup>22</sup>

After anesthetizing a pet dog, Morton became confident of his skills and anesthetized patients with ether in his dental office. Encouraged by his success, Morton sought an invitation to give a public demonstration in the Bullfinch amphitheater of the Massachusetts General Hospital (the site where Wells’ failed demonstration of the efficacy of nitrous oxide as a complete surgical anesthetic was incorrectly also thought to have occurred).<sup>146</sup> Many details of the October 16, 1846, demonstration are well

known. Morton secured permission to provide an anesthetic to Edward Gilbert Abbott, a patient of surgeon John Collins Warren. Warren planned to excise a vascular lesion from the left side of Abbott's neck and was about to proceed when Morton arrived late. He had been delayed because he was obliged to wait for an instrument maker to complete a new inhaler (Fig. 1-1). It consisted of a large glass bulb containing a sponge soaked with oil of orange mixed with ether and a spout that was placed in the patient's mouth. An opening on the opposite side of the bulb allowed air to enter and be drawn over the ether-soaked sponge with each breath.<sup>23</sup>

The conversations of that morning were not accurately recorded; however, popular accounts state that the surgeon responded testily to Morton's apology for his tardy arrival by remarking, "Sir, your patient is ready." Morton directed his attention to his patient and first conducted a much abbreviated preoperative evaluation. He inquired, "Are you afraid?" Abbott responded that he was not and took the inhaler in his mouth. After a few minutes, Morton turned to the surgeon and said, "Sir, your patient is ready." Gilbert Abbott later reported that he was aware of the surgery but experienced no pain. It has been alleged that when the procedure ended, Warren immediately turned to his audience and uttered the statement, "Gentlemen, this is no humbug," but this has since been disputed.<sup>24</sup>

**Figure 1-1** Morton's ether inhaler (1846).

What would be recognized as America's greatest contribution to 19th century medicine had occurred. However, Morton, wishing to capitalize on his "discovery," refused to divulge what agent was in his inhaler. Some weeks passed before Morton admitted that the active component of the colored fluid, which he had called "Letheon," was simple diethyl ether. Morton, Wells, Jackson, and their supporters soon became drawn into a contentious, protracted, and fruitless debate over priority for the discovery. This debate has subsequently been termed *the ether controversy*. In short, Morton had applied for a patent for Letheon and, when it was granted, tried to receive royalties for the use of ether as an anesthetic.

When the details of Morton's anesthetic technique became public knowledge, the information was transmitted by train, stagecoach, and coastal vessels to other North American cities and by ship to the world. As ether was easy to prepare and administer, anesthetics were performed in Britain, France, Russia, South Africa, Australia, and other countries almost as soon as surgeons heard the welcome news of the extraordinary discovery. Even though surgery could now be performed with "pain put to sleep," the frequency of operations did not rise rapidly, and several years would pass before anesthesia was universally recommended.

### **Chloroform and Obstetrics**

James Young Simpson was a successful obstetrician in Edinburgh, Scotland, and among the first to use ether for the relief of labor pain. Dissatisfied with ether, Simpson soon sought a more pleasant, rapid-acting anesthetic. He and his junior associates conducted a bold search by inhaling samples of several volatile chemicals collected for Simpson by British apothecaries. David Waldie suggested chloroform, which had first been prepared in 1831. Simpson and his friends inhaled it after dinner at a party in Simpson's home on the evening of November 4, 1847. They promptly fell unconscious and, when they awoke, were delighted with their success. Simpson quickly set about encouraging the use of chloroform. Within 2 weeks, he submitted his first account of its use for publication in *The Lancet*.

In the 19th century, the relief of obstetric pain had significant social ramifications and made anesthesia during childbirth a controversial subject. Simpson argued against the prevailing view, which held that relieving labor pain opposed God's will. The pain of the parturient was viewed as both a component of punishment and a means of atonement for Original Sin. Less than a year after administering the first anesthesia during childbirth, Simpson addressed these concerns in a pamphlet entitled *Answers to the Religious Objections Advanced Against the Employment of Anaesthetic Agents in Midwifery and Surgery and Obstetrics*. In it, Simpson recognized the Book of Genesis as being the root of this sentiment and noted that God promised to relieve the descendants of Adam and Eve of the curse. In addition, Simpson asserted that labor pain was a result of scientific and anatomic causes and not the result of religious condemnation. He stated that the upright position of humans necessitated strong pelvic muscles to support the abdominal contents. As a result, he argued that the uterus necessarily developed strong musculature to overcome the resistance of the pelvic floor and that great contractile power caused great pain. Simpson's pamphlet probably did not have a significant impact on the prevailing attitudes, but he did articulate many concepts that his contemporaries were debating at the time.<sup>25</sup>

Chloroform gained considerable notoriety after John Snow used it to deliver the last two children of Queen Victoria. The Queen's consort, Prince Albert, interviewed John Snow before he was called to Buckingham Palace to administer chloroform at the request of the Queen's obstetrician. During the monarch's labor, Snow gave analgesic doses of chloroform on a folded handkerchief. This technique was soon termed *chloroform à la reine*. Victoria abhorred the pain of childbirth and enjoyed the relief that chloroform provided. She wrote in her journal, "Dr. Snow gave that blessed chloroform and the effect was soothing, quieting, and delightful beyond measure."<sup>26</sup> When the Queen, as head of the Church of England, endorsed obstetric anesthesia, religious debate over the management of labor pain terminated abruptly.

John Snow, already a respected physician, took an interest in anesthetic practice and was soon invited to work with many leading surgeons of the day. In 1848, Snow introduced a chloroform inhaler. He had recognized the versatility of the new agent and came to prefer it in his practice. At the same time, he initiated what was to become an extraordinary series of experiments that were remarkable in their scope and for anticipating sophisticated research performed a century later. Snow realized that successful anesthetics should abolish pain and unwanted movements. He anesthetized several species of animals with varying strengths of ether and chloroform to determine the concentration required to prevent reflex movement from sharp stimuli. This work approximated the modern concept of minimum alveolar concentration.<sup>27</sup> Snow assessed the anesthetic action of a large number of potential anesthetics but did not find any to rival chloroform or ether. His studies led him to recognize the relationship between solubility, vapor pressure, and anesthetic potency, which was not fully appreciated until after World War II. Snow published two remarkable books, *On the Inhalation of the Vapour of Ether* (1847) and *On Chloroform and Other Anaesthetics* (1858). The latter was almost completed when he died of a stroke at the age of 45, and it was published posthumously.

## Anesthesia Principles, Equipment, and Standards

### Control of the Airway

Definitive control of the airway, a skill anesthesiologists now consider paramount, developed only after many harrowing and apneic episodes spurred the development of safer airway management techniques. Preceding tracheal intubation, however, several important techniques were proposed toward the end of the 19th century that remain integral to anesthesiology education and practice. Joseph Clover was the first Englishman to urge the

now-universal practice of thrusting the patient's jaw forward to overcome obstruction of the upper airway by the tongue. Clover also published a landmark case report in 1877 in which he created a surgical airway. Once his patient was asleep, Clover discovered that his patient had a tumor of the mouth that obstructed the airway completely, despite his trusted jaw-thrust maneuver. He averted disaster by inserting a small curved cannula of his design through the cricothyroid membrane. He continued anesthesia via the cannula until the tumor was excised. Clover, the model of the prepared anesthesiologist, remarked, "I have never used the cannula before although it has been my companion at some thousands of anaesthetic cases."<sup>28</sup>

### *Tracheal Intubation*

The development of techniques and instruments for tracheal intubation ranks among the major advances in the history of anesthesiology. The first tracheal tubes were developed for the resuscitation of drowning victims but were not used in anesthesia until 1878. The first use of elective oral intubation for an anesthetic was undertaken by Scottish surgeon William Macewan. He had practiced passing flexible metal tubes through the larynx of a cadaver before attempting the maneuver on an awake patient with an oral tumor at the Glasgow Royal Infirmary on July 5, 1878.<sup>29</sup> Because topical anesthesia was not yet known, the experience must have demanded fortitude on the part of Macewan's patient. Once the tube was correctly positioned, an assistant began a chloroform-air anesthetic via the tube. Once anesthetized, the patient soon stopped coughing. Unfortunately, Macewan abandoned the practice following a fatality in which a patient had been successfully intubated while awake but the tube became dislodged once the patient was asleep. After the tube was removed, an attempt to provide chloroform by mask anesthesia was unsuccessful and the patient died.

An American surgeon named Joseph O'Dwyer is remembered for his extraordinary dedication to the advancement of tracheal intubation. In 1885, O'Dwyer designed a series of metal laryngeal tubes, which he inserted blindly between the vocal cords of children suffering a diphtheritic crisis. Three years later, O'Dwyer designed a second rigid tube with a conical tip that occluded the larynx so effectively that it could be used for artificial ventilation when applied with the bellows and T-piece tube designed by George Fell. The Fell-O'Dwyer apparatus, as it came to be known, was used during thoracic surgery by Rudolph Matas of New Orleans. Matas was so pleased with it that he predicted, "The procedure that promises the most benefit in preventing pulmonary collapse in operations on the chest is ... the rhythmical maintenance of artificial respiration by a tube in the glottis directly connected with a bellows."<sup>147</sup>

After O'Dwyer's death, the outstanding pioneer of tracheal intubation was Franz Kuhn, a surgeon of Kassel, Germany. From 1900 until 1912, Kuhn<sup>148</sup> published several articles and a classic monograph, "*Die perorale Intubation*," which were not well known in his lifetime but have since become widely appreciated. His work might have had a more profound impact if it had been translated into English. Kuhn described techniques of oral and nasal intubation that he performed with flexible metal tubes composed of coiled tubing similar to those now used for the spout of metal gasoline cans. After applying cocaine to the airway, Kuhn introduced his tube over a curved metal stylet that he directed toward the larynx with his left index finger. Although he was aware of the subglottic cuffs that had been used briefly by Victor Eisenmenger, Kuhn preferred to seal the larynx by positioning a supralaryngeal flange near the tube's tip before packing the pharynx with gauze. Kuhn even monitored the patient's breath sounds continuously through a monaural earpiece connected to an extension of the tracheal tube by a narrow tube.

Intubation of the trachea by palpation was an uncertain and sometimes traumatic act; surgeons even believed that it would be anatomically impossible to visualize the vocal cords directly. This misapprehension was overcome in 1895 by Alfred Kirstein in Berlin, who devised the first direct-vision laryngoscope.<sup>30</sup> Kirstein was motivated by a friend's report that a patient's trachea had been accidentally intubated during esophagoscopy. Kirstein promptly fabricated a handheld instrument that at first resembled a shortened cylindrical esophagoscope. He soon substituted a semicircular blade that opened inferiorly. Kirstein could now examine the larynx while standing behind his seated patient, whose head had been placed in an attitude approximating the currently termed "sniffing position." Although Alfred Kirstein's "autoscope" was not used by anesthesiologists, it was the forerunner of all modern laryngoscopes. Endoscopy was refined by Chevalier Jackson in Philadelphia, who designed a U-shaped laryngoscope by adding a handgrip that was parallel to the blade. The Jackson blade has remained a standard instrument for endoscopists but was not favored by anesthesiologists. Two laryngoscopes that closely resembled modern L-shaped instruments were designed in 1910 and 1913 by two American surgeons, Henry Janeway and George Dorrance, but neither instrument achieved lasting use despite their excellent designs.<sup>31</sup>

Before the introduction of muscle relaxants in the 1940s, intubation of the trachea could be challenging. This challenge was made somewhat easier, however, with the advent of laryngoscope blades specifically designed to increase visualization of the vocal cords. Robert Miller of San Antonio, Texas, and Robert Macintosh of Oxford University created their respectively named blades within an interval of 2 years. In 1941, Miller brought forward the

slender, straight blade with a slight curve near the tip to ease the passage of the tube through the larynx. Although Miller's blade was a refinement, the technique of its use was identical to that of earlier models as the epiglottis was lifted to expose the larynx.<sup>32</sup>

The Macintosh blade, which is placed in the vallecula rather than under the epiglottis, was invented as an incidental result of a tonsillectomy. Sir Robert Macintosh later described the circumstances of its discovery in an appreciation writing regarding the career of his technician, Mr. Richard Salt, who constructed the blade. As Sir Robert recalled, "A Boyle-Davis gag, a size larger than intended, was inserted for tonsillectomy, and when the mouth was fully opened the cords came into view. This was a surprise since conventional laryngoscopy, at that depth of anaesthesia, would have been impossible in those pre-relaxant days. Within a matter of hours, Salt had modified the blade of the Davis gag and attached a laryngoscope handle to it; and streamlined (after testing several models), the end result came into widespread use."<sup>33</sup> Macintosh underestimated the popularity of the blade, as more than 800,000 have been produced and many special-purpose versions have been marketed.

The most distinguished innovator in tracheal intubation was the self-trained British anesthetist Ivan (later, Sir Ivan) Magill.<sup>34</sup> In 1919, while serving in the Royal Army as a general medical officer, Magill was assigned to a military hospital near London. Although he had only rudimentary training in anesthesia, Magill was obliged to accept an assignment to the anesthesia service, where he worked with another neophyte, Stanley Rowbotham.<sup>35</sup> Together, Magill and Rowbotham attended casualties disfigured by severe facial injuries who underwent repeated restorative operations. These procedures required that the surgeon, Harold Gillies, have unrestricted access to the face and airway. These patients presented formidable challenges, but both Magill and Rowbotham became adept at tracheal intubation and quickly understood its current limitations. Because they learned from fortuitous observations, they soon extended the scope of tracheal anesthesia.

They gained expertise with blind nasal intubation after they learned to soften semirigid insufflation tubes for passage through the nostril. Even though their original intent was to position the tips of the nasal tubes in the posterior pharynx, the slender tubes frequently ended up in the trachea. Stimulated by this chance experience, they developed techniques of deliberate nasotracheal intubation. In 1920, Magill devised an aid to manipulating the catheter tip, the "Magill angulated forceps," which continues to be manufactured according to his original design over 90 years ago.

With the war over, Magill entered civilian practice and set out to develop a wide-bore tube that would resist kinking but be conformable to the contours of the upper airway. While in a hardware store, he found mineralized red

rubber tubing that he cut, beveled, and smoothed to produce tubes that clinicians around the world would come to call “Magill tubes.” His tubes remained the universal standard for more than 40 years until rubber products were supplanted by inert plastics. Magill also rediscovered the advantage of applying cocaine to the nasal mucosa, a technique that greatly facilitated awake blind nasal intubation.

In 1926, Arthur Guedel began a series of experiments that led to the introduction of the cuffed tube. Guedel transformed the basement of his Indianapolis home into a laboratory, where he subjected each step of the preparation and application of his cuffs to a vigorous review.<sup>36</sup> He fashioned cuffs from the rubber of dental dams, condoms, and surgical gloves that were glued onto the outer wall of tubes. Using animal tracheas donated by the family butcher as his model, he considered whether the cuff should be positioned above, below, or at the level of the vocal cords. He recommended that the cuff be positioned just below the vocal cords to seal the airway. Ralph Waters later recommended that cuffs be constructed of two layers of soft rubber cemented together. These detachable cuffs were first manufactured by Waters’ children, who sold them to the Foregger Company.

Guedel sought ways to show the safety and utility of the cuffed tube. He first filled the mouth of an anesthetized and intubated patient with water and showed that the cuff sealed the airway. Even though this exhibition was successful, he searched for a more dramatic technique to capture the attention of those unfamiliar with the advantages of intubation. He reasoned that if the cuff prevented water from entering the trachea of an intubated patient, it should also prevent an animal from drowning, even if it were submerged under water. To encourage physicians attending a medical convention to use his tracheal techniques, Guedel prepared the first of several “dunked dog” demonstrations (Fig. 1-2). An anesthetized and intubated dog, Guedel’s own pet, “Airway,” was immersed in an aquarium. After the demonstration was completed, the anesthetic was discontinued before the animal was removed from the water. According to legend, Airway awoke promptly, shook water over the onlookers, saluted a post, then trotted from the hall to the applause of the audience.

After a patient experienced an accidental endobronchial intubation, Ralph Waters reasoned that a very long cuffed tube could be used to isolate the lungs. The dependent lung could be ventilated while the upper lung was being resected.<sup>37</sup> On learning of his friend’s success with intentional one-lung anesthesia, Arthur Guedel proposed an important modification for chest surgery, the double-cuffed single-lumen tube, which was introduced by Emery Rovenstine. These tubes were easily positioned, an advantage over bronchial blockers that had to be inserted by a skilled bronchoscopist. In 1953, single-lumen tubes were supplanted by double-lumen endobronchial tubes. The

double-lumen tube currently most popular was designed by Frank Robertshaw of Manchester, England, and is prepared in both right- and left-sided versions. Robertshaw tubes were first manufactured from mineralized red rubber but are now made of extruded plastic, a technique refined by David Sheridan. Sheridan was also the first person to embed centimeter markings along the side of tracheal tubes, a safety feature that reduced the risk of the tube's being incorrectly positioned.

**Figure 1-2** The “dunked dog.”

### **Advanced Airway Devices**

Conventional laryngoscopes proved inadequate for patients with “difficult airways.” A few clinicians credit harrowing intubating experiences as the incentive for invention. In 1928, a rigid bronchoscope was specifically designed for examination of the large airways. Rigid bronchoscopes were refined and used by pulmonologists. Although it was known in 1870 that a thread of glass could transmit light along its length, technologic limitations were not overcome until 1964, when Shigeto Ikeda developed the first flexible fiberoptic bronchoscope. Fiberoptic-assisted tracheal intubation has become a common approach in the management of patients with difficult airways having surgery.

Roger Bullard desired a device to simultaneously examine the larynx and intubate the vocal cords. He had been frustrated by failed attempts to visualize the larynx of a patient with Pierre-Robin syndrome. In response, he developed the Bullard laryngoscope, whose fiberoptic bundles lie beside a curved blade. Similarly, the Wu-scope was designed by Tzu-Lang Wu in 1994 to combine and facilitate visualization and intubation of the trachea in patients with difficult airways.<sup>38</sup>

Dr. A. I. J. “Archie” Brain first recognized the principle of the laryngeal mask airway (LMA) in 1981 when, like many British clinicians, he provided dental anesthesia via a Goldman nasal mask. However, unlike any before him,

he realized that just as the dental mask could be fitted closely about the nose, a comparable mask attached to a wide-bore tube might be positioned around the larynx. He not only conceived of this radical departure in airway management, which he first described in 1983,<sup>39</sup> but also spent years in single-handedly fabricating and testing several incremental modifications. Scores of Brain's prototypes are displayed in the Royal Berkshire Hospital, Reading, England, where they provide a detailed record of the evolution of the LMA. He fabricated his first models from Magill tubes and Goldman masks, then refined their shape by performing postmortem studies of the hypopharynx to determine the form of cuff that would be most functional. Before silicone rubber was selected, Brain had even mastered the technique of forming masks from liquid latex. Every detail of the LMA, the number and position of the aperture bars and the shape and the size of the masks, required repeated modification.<sup>40</sup>

### *Early Anesthesia Delivery Systems*

The transition from ether inhalers and chloroform-soaked handkerchiefs **3** to more sophisticated anesthesia delivery equipment occurred gradually, with incremental advances supplanting older methods. One of the earliest anesthesia apparatus designs was that of John Snow, who had realized the inadequacies of ether inhalers through which patients rebreathed via a mouthpiece. After practicing anesthesia for only 2 weeks, Snow created the first of his series of ingenious ether inhalers.<sup>41</sup> His best-known apparatus featured unidirectional valves within a malleable, well-fitting mask of his own design, which closely resembles the form of a modern face mask. The face piece was connected to the vaporizer by a breathing tube, which Snow deliberately designed to be wider than the human trachea so that even rapid respirations would not be impeded. A metal coil within the vaporizer ensured that the patient's inspired breath was drawn over a large surface area to promote the uptake of ether. The device also incorporated a warm water bath to maintain the volatility of the agent (Fig. 1-3). Snow did not attempt to capitalize on his creativity, in contrast to William Morton; he closed his account of its preparation with the generous observation, "There is no restriction respecting the making of it."<sup>42</sup>

Joseph Clover, another British physician, was the first anesthetist to administer chloroform in known concentrations through the "Clover bag." He obtained a 4.5% concentration of chloroform in air by pumping a measured volume of air with a bellows through a warmed evaporating vessel containing a known volume of liquid chloroform.<sup>43</sup> Although it was realized that nitrous oxide diluted in air often gave a hypoxic mixture and that the oxygen-nitrous oxide mixture was safer, Chicago surgeon Edmund Andrews complained about

the physical limitations of delivering anesthesia to patients in their homes. The large bag was conspicuous and awkward to carry along busy streets. He observed that “In city practice, among the higher classes, however, this is no obstacle as the bag can always be taken in a carriage, without attracting attention.”<sup>44</sup> In 1872, Andrews was delighted to report the availability of liquefied nitrous oxide compressed under 750 pounds of pressure, which allowed a supply sufficient for three patients to be carried in a single cylinder.

**Figure 1-3** John Snow's inhaler (1847). The ether chamber (B) contained a spiral coil so that the air entering through the brass tube (D) was saturated by ether before ascending the flexible tube (F) to the face mask (G). The ether chamber rested in a bath of warm water (A).

Critical to increasing patient safety was the development of a machine capable of delivering a calibrated amount of gas and volatile anesthetic. In the late 19th century, demands in dentistry instigated development of the first freestanding anesthesia machines. Three American dentist-entrepreneurs, Samuel S. White, Charles Teter, and Jay Heidbrink, developed the original series of US instruments that used compressed cylinders of nitrous oxide and oxygen. Before 1900, the S. S. White Company modified Frederick Hewitt's apparatus and marketed its continuous-flow machine, which was refined by Teter in 1903. Heidbrink added reducing valves in 1912. In the same year, physicians initiated other important developments. Water-bubble flowmeters, introduced by Frederick Cotton and Walter Boothby of Harvard University, allowed the proportion of gases and their flow rate to be approximated. The Cotton and Boothby apparatus was transformed into a practical portable machine by James Tayloe Gwathmey of New York. The Gwathmey machine caught the attention of London anesthetist Henry E. G. “Cockie” Boyle, who acknowledged his debt to the American when he incorporated Gwathmey's concepts in the first of the series of “Boyle” machines that were marketed by

Coxeter and British Oxygen Corporation. During the same period in Lubeck, Germany, Heinrich Draeger and his son, Bernhaard, adapted compressed gas technology, which they had originally developed for mine rescue equipment, to manufacture ether and chloroform–oxygen machines.

In the years after World War I, several US manufacturers continued to bring forward widely admired anesthesia machines. Richard von Foregger was an engineer who was exceptionally receptive to clinicians' suggestions for additional features for his machines. Elmer McKesson became one of the country's first specialists in anesthesiology in 1910 and developed a series of gas machines. In an era of flammable anesthetics, McKesson carried nitrous oxide anesthesia to its therapeutic limit by performing inductions with 100% nitrous oxide and thereafter adding small volumes of oxygen. If the resultant cyanosis became too profound, McKesson depressed a valve on his machine that flushed a small volume of oxygen into the circuit. Even though his techniques of primary and secondary saturation with nitrous oxide are no longer used, the oxygen flush valve is part of McKesson's legacy.

### **Alternative Circuits**

A valveless device, the Ayre's T-piece, has found wide application in the management of intubated patients. Phillip Ayre practiced anesthesia in England when the limitations of equipment for pediatric patients produced what he described as "a protracted and sanguine battle between surgeon and anaesthetist, with the poor unfortunate baby as the battlefield."<sup>45</sup> In 1937, Ayre introduced his valveless T-piece to reduce the effort of breathing in neurosurgical patients. The T-piece soon became particularly popular for cleft palate repairs, as the surgeon had free access to the mouth. Positive-pressure ventilation could be achieved when the anesthetist obstructed the expiratory limb. In time, this ingenious, lightweight, nonrebreathing device evolved through more than 100 modifications for a variety of special situations. A significant alteration was Gordon Jackson Rees' circuit, which permitted improved control of ventilation by substituting a breathing bag on the outflow limb.<sup>46</sup> An alternative method to reduce the amount of equipment near the patient is provided by the coaxial circuit of the Bain–Spoerel apparatus.<sup>47</sup> This lightweight tube-within-a-tube has served very well in many circumstances since its Canadian innovators described it in 1972.

### **Ventilators**

Mechanical ventilators are now an integral part of the anesthesia machine. Patients are ventilated during general anesthesia by electrical or gas-powered devices that are simple to control yet sophisticated in their function. The

history of mechanical positive-pressure ventilation began with attempts to resuscitate victims of drowning by a bellows attached to a mask or tracheal tube. These experiments found little role in anesthetic care for many years. At the beginning of the 20th century, however, several modalities were explored before intermittent positive-pressure machines evolved.

A series of artificial environments were created in response to the frustration experienced by thoracic surgeons who found that the lung collapsed when they incised the pleura. Between 1900 and 1910, continuous positive- or negative-pressure devices were created to maintain inflation of the lungs of a spontaneously breathing patient once the chest was opened. Brauer (1904) and Murphy (1905) placed the patient's head and neck in a box in which positive pressure was continually maintained. Sauerbruch (1904) created a negative-pressure operating chamber encompassing both the surgical team and the patient's body and from which only the patient's head projected.<sup>48</sup>

In 1907, the first intermittent positive-pressure device, the Draeger "Pulmotor," was developed to rhythmically inflate the lungs. This instrument and later American models such as the E & J Resuscitator were used almost exclusively by firefighters and mine rescue workers. In 1934, a Swedish team developed the "Spiropulsator," which C. Crafoord later modified for use during cyclopropane anesthesia.<sup>49</sup> Its action was controlled by a magnetic control valve called *the flasher*, a type first used to provide intermittent gas flow for the lights of navigational buoys. When Trier Morch, a Danish anesthesiologist, could not obtain a Spiropulsator during World War II, he fabricated the Morch "Respirator," which used a piston pump to rhythmically deliver a fixed volume of gas to the patient.<sup>48</sup>

A major stimulus to the development of ventilators came as a consequence of a devastating epidemic of poliomyelitis that struck Copenhagen, Denmark, in 1952. As scores of patients were admitted, the only effective ventilatory support that could be provided to patients with bulbar paralysis was continuous manual ventilation via tracheostomy employing devices such as Waters' "to-and-fro" circuit. This succeeded only through the dedicated efforts of hundreds of volunteers. Medical students served in relays to ventilate paralyzed patients. The Copenhagen crisis stimulated a broad European interest in the development of portable ventilators in anticipation of another epidemic of poliomyelitis. At this time, the common practice in North American hospitals was to place polio patients with respiratory involvement in "iron lungs," metal cylinders that encased the body below the neck. Inspiration was caused by intermittent negative pressure created by an electric motor acting on a piston-like device occupying the foot of the chamber.

Some early American ventilators were adaptations of respiratory-assist

machines originally designed for the delivery of aerosolized drugs for respiratory therapy. Two types employed the Bennett or Bird “flow-sensitive” valves. The Bennett valve was designed during World War II when a team of physiologists at the University of Southern California encountered difficulties in separating inspiration from expiration in an experimental apparatus designed to provide positive-pressure breathing for aviators at high altitude. An engineer, Ray Bennett, visited their laboratory, observed their problem, and resolved it with a mechanical flow-sensitive automatic valve. A second valving mechanism was later designed by an aeronautical engineer, Forrest Bird.

The use of the Bird and Bennett valves gained anesthetic application when the gas flow from the valve was directed into a rigid plastic jar containing a breathing bag or bellows as part of an anesthesia circuit. These “bag-in-bottle” devices mimicked the action of the clinician’s hand as the gas flow compressed the bag, thereby providing positive-pressure inspiration. Passive exhalation was promoted by the descent of a weight on the bag or bellows.

### **Carbon Dioxide Absorption**

Carbon dioxide (CO<sub>2</sub>) absorption is a basic element of modern anesthetic machines. It was initially developed to allow rebreathing of gas and minimize loss of flammable gases into the room, thereby reducing the risk of explosion. In current practice, it permits decreased utilization of oxygen and anesthetic, thus reducing cost. The first CO<sub>2</sub> absorber in anesthesia came in 1906 from the work of Franz Kuhn, a German surgeon. His use of canisters developed for mine rescues by Draeger was innovative, but his circuit had unfortunate limitations. The exceptionally narrow breathing tubes and a large dead space explain its very limited use, and Kuhn’s device was ignored.

A few years later, the first American machine with a CO<sub>2</sub> absorber was independently fabricated by a pharmacologist named Dennis Jackson. In 1915, Jackson developed an early technique of CO<sub>2</sub> absorption that permitted the use of a closed anesthesia circuit. He used solutions of sodium and calcium hydroxide to absorb CO<sub>2</sub>. As his laboratory was located in an area of St. Louis, Missouri, heavily laden with coal smoke, Jackson reported that the apparatus allowed him the first breaths of absolutely fresh air he had ever enjoyed in that city. The complexity of Jackson’s apparatus limited its use in hospital practice, but his pioneering work in this field encouraged Ralph Waters to introduce a simpler device using soda lime granules nine years later. Waters positioned a soda lime canister (Fig. 1-4) between a face mask and an adjacent breathing bag to which was attached the fresh gas flow. As long as the mask was held against the face, only small volumes of fresh gas flow were required and no valves were needed.<sup>50</sup>

Waters' device featured awkward positioning of the canister close to the patient's face. Brian Sword<sup>51</sup> overcame this limitation in 1930 with a freestanding machine with unidirectional valves to create a circle system and an inline CO<sub>2</sub> absorber. James Elam and his coworkers at the Roswell Park Cancer Institute in Buffalo, New York, further refined the CO<sub>2</sub> absorber, increasing the efficiency of CO<sub>2</sub> removal with a minimum of resistance for breathing.<sup>52</sup> Consequently, the circle system introduced by Sword in the 1930s, with a few refinements, became the standard anesthesia circuit in North America.

## *Flowmeters*

As closed and semiclosed circuits became practical, gas flow could be measured with greater accuracy. Bubble flowmeters were replaced with dry bobbins or ball-bearing flowmeters, which, although they did not leak fluids, could cause inaccurate measurements if they adhered to the glass column. In 1910, M. Neu had been the first to apply rotameters in anesthesia for the administration of nitrous oxide and oxygen, but his machine was not a commercial success, perhaps because of the great cost of nitrous oxide in Germany at that time. Rotameters designed for use in German industry were first employed in Britain in 1937 by Richard Salt; but as World War II approached, the English were denied access to these sophisticated flowmeters. After World War II rotameters became regularly employed in British anesthesia machines, although most American equipment still featured nonrotating floats. The now-universal practice of displaying gas flow in liters per minute was not a customary part of all American machines until more than a decade after World War II.

**Figure 1-4** Waters' carbon dioxide absorbance canister.

## *Vaporizers*

The art of a smooth induction with a potent anesthetic was a great challenge, particularly if the inspired concentration could not be determined with accuracy. Even the clinical introduction of halothane after 1956 might have been thwarted except for a fortunate coincidence: the prior development of calibrated vaporizers. Two types of calibrated vaporizers designed for other anesthetics had become available in the half decade before halothane was marketed. The prompt acceptance of halothane was in part because of an ability to provide it in carefully titrated concentrations.

The Copper Kettle was the first temperature-compensated, accurate vaporizer. It had been developed by Lucien Morris at the University of Wisconsin in response to Ralph Waters' plan to test chloroform by giving it in controlled concentrations.<sup>53</sup> Morris achieved this goal by passing a metered flow of oxygen through a vaporizer chamber that contained a sintered bronze disk to separate the oxygen into minute bubbles. The gas became fully saturated with anesthetic vapor as it percolated through the liquid. The concentration of the anesthetic inspired by the patient could be calculated by knowing the vapor pressure of the liquid anesthetic, the volume of oxygen flowing through the liquid, and the total volume of gases from all sources entering the anesthesia circuit. Although experimental models of Morris' vaporizer used a water bath to maintain vaporizer temperature stability, the excellent thermal conductivity of copper, especially when the device was attached to a metal anesthetic machine, was substituted in later models. When

first marketed, the Copper Kettle did not feature a mechanism to indicate changes in the temperature (and vapor pressure) of the liquid. Shuh-Hsun Ngai proposed the incorporation of a thermometer, a suggestion that was later added to all vaporizers of that class.<sup>54</sup> The Copper Kettle (Foregger Company) and the Vernitrol (Ohio Medical Products) were universal vaporizers that could be charged with any anesthetic liquid, and, provided that its vapor pressure and temperature were known, the inspired concentration could be calculated quickly.

When halothane was first marketed in Britain, an effective temperature-compensated, agent-specific vaporizer had recently been placed in clinical use. The TECOTA (TEmpérature COmpensated Trichloroethylene Air) vaporizer featured a bimetallic strip composed of brass and a nickel–steel alloy, two metals with different coefficients of expansion. As the anesthetic vapor cooled, the strip bent to move away from the orifice, thereby permitting more fresh gas to enter the vaporizing chamber. This maintained a constant inspired concentration despite changes in temperature and vapor pressure. After their TECOTA vaporizer was accepted into anesthetic practice, the technology was used to create the “Fluotec,” the first of a series of agent-specific “tec” vaporizers for use in the operating room.

## *Patient Monitors*

In many ways, the history of late-19th and early-20th century anesthesiology is the quest for the safest anesthetic. The discovery and widespread use of electrocardiography, pulse oximetry, blood gas analysis, capnography, and neuromuscular blockade monitoring have reduced patient morbidity and mortality and revolutionized anesthesia practice. Although safer machines assured clinicians that appropriate gas mixtures were delivered to the patient, monitors provided an early warning of acute physiologic deterioration before patients suffered irrevocable damage.

Joseph Clover was one of the first clinicians to routinely perform basic hemodynamic monitoring. Clover developed the habit of monitoring his patients’ pulse, but, surprisingly, this was a contentious issue at the time. Prominent Scottish surgeons scorned Clover’s emphasis on the action of chloroform on the heart. Baron Lister and others preferred that senior medical students give anesthetics and urged them to “strictly carry out certain simple instructions, among which is that of never touching the pulse, in order that their attention may not be distracted from the respiration.”<sup>55</sup> Lister also counseled, “it appears that preliminary examination of the chest, often considered indispensable, is quite unnecessary, and more likely to induce the dreaded syncope, by alarming the patients, than to avert it.”<sup>56</sup> Little progress in anesthesia could come from such reactionary statements. In contrast,

Clover had observed the effect of chloroform on animals and urged other anesthetists to monitor the pulse at all times and to discontinue the anesthetic temporarily if any irregularity or weakness was observed in the strength of the pulse.

Two American surgeons, George W. Crile and Harvey Cushing, developed a strong interest in measuring blood pressure during anesthesia. Both men wrote thorough and detailed examinations of blood pressure monitoring; however, Cushing's contribution is better remembered because he was the first American to apply the Riva Rocci cuff, which he saw while visiting Italy. Cushing introduced the concept in 1902 and had blood pressure measurements recorded on anesthesia records.<sup>57</sup> In 1894, Cushing and a fellow student at Harvard Medical School, Charles Codman, initiated a system of recording patients' pulses to assess the course of the anesthetics they administered. In 1902, Cushing continued the practice of monitoring and recording patient blood pressures and pulses. The transition from manual to automated blood pressure devices, which first appeared in 1936 and operate on an oscillometric principle, has been gradual.

The first precordial stethoscope was believed to have been used by S. Griffith Davis at Johns Hopkins University.<sup>41</sup> He adapted a technique developed by Harvey Cushing in a laboratory in which dogs with surgically induced valvular lesions had stethoscopes attached to their chest wall so that medical students might listen to bruits characteristic of a specific malformation. Davis' technique was forgotten but was rehabilitated by Dr. Robert Smith, an energetic pioneer of pediatric anesthesiology in Boston in the 1940s. A Canadian contemporary, Albert Codesmith, of the Hospital for Sick Children, Toronto, became frustrated by the repeated dislodging of the chest piece under the surgical drapes and fabricated his first esophageal stethoscope from urethral catheters and Penrose drains. His brief report heralded its clinical role as a monitor of both normal and adventitious respiratory and cardiac sounds.<sup>58</sup>

### *Electrocardiography, Pulse Oximetry, and Capnography*

Clinical electrocardiography began with Willem Einthoven's application of the string galvanometer in 1903. Within two decades, Thomas Lewis had described its role in the diagnosis of disturbances of cardiac rhythm, whereas James Herrick and Harold Pardee first drew attention to the changes produced by myocardial ischemia. After 1928, cathode ray oscilloscopes were available, but the risk of explosion owing to the presence of flammable anesthetics forestalled the introduction of the electrocardiogram into routine anesthetic practice until after World War II. At that time, the small screen of the heavily shielded "bullet" oscilloscope displayed only 3 seconds of data,

but that information was highly prized.

Pulse oximetry, the optical measurement of oxygen saturation in tissues, is one of the more recent additions to the anesthesiologist's array of routine monitors. Although research in this area began in 1932, its first practical application came during World War II. An American physiologist, Glen Millikan, responded to a request from British colleagues in aviation research. Millikan set about preparing a series of devices to improve the supply of oxygen that was provided to pilots flying at high altitude in unpressurized aircraft. To monitor oxygen delivery and to prevent the pilot from succumbing to an unrecognized failure of his oxygen supply, Millikan created an oxygen-sensing monitor worn on the pilot's earlobe and coined the name *oximeter* to describe its action. Before his tragic death in a climbing accident in 1947, Millikan had begun to assess anesthetic applications of oximetry. Refinements of oximetry by a Japanese engineer, Takuo Aoyagi, led to the development of pulse oximetry. As John Severinghaus recounted the episode, Aoyagi had attempted to eliminate the changes in a signal caused by pulsatile variations when he realized that this fluctuation could be used to measure both the pulse and oxygen saturation.<sup>56</sup>

Anesthesiologists have recognized a need for breath-by-breath measurement of respiratory and anesthetic gases. After 1954, infrared absorption techniques gave immediate displays of the exhaled concentration of CO<sub>2</sub>. The ability to confirm endotracheal intubation and monitor ventilation, as reflected by concentrations of CO<sub>2</sub> in respired gas, began in 1943. At that time, Luft<sup>59</sup> described the principle of infrared absorption by CO<sub>2</sub> and developed an apparatus for measurement. Routine application of capnography in anesthesia practice was pioneered by Smalhout and Kalenda in the Netherlands. Breath-to-breath continuous monitoring and a waveform display of CO<sub>2</sub> levels help anesthesiologists recognize abnormalities in metabolism, ventilation, and circulation. More recently, infrared analysis has been perfected to enable breath-by-breath measurement of anesthetic gases as well. This technology has largely replaced mass spectrometry, which initially had only industrial applications before Albert Faulconer of the Mayo Clinic first used it to monitor the concentration of an exhaled anesthetic in 1954.

## Safety Standards

**4** The introduction of safety features was coordinated by the American National Standards Institute (ANSI) Committee Z79, which was sponsored from 1956 until 1983 by the American Society of Anesthesiologists. Since 1983, representatives from industry, government, and health-care professions have met on Committee Z79 of the American Society for Testing and Materials. They establish voluntary goals that may become accepted national

standards for the safety of anesthesia equipment.

Ralph Tovell voiced the first call for standards during World War II while he was the US Army Consultant in Anesthesiology for Europe. Tovell found that because there were four different dimensions for connectors, tubes, masks, and breathing bags, supplies dispatched to field hospitals might not match their anesthesia machines. As Tovell<sup>60</sup> observed, “When a sudden need for accessory equipment arose, nurses and corpsmen were likely to respond to it by bringing parts that would not fit.” Although Tovell’s reports did not gain an immediate response, after the war Vincent Collins and Hamilton Davis took up his concern and formed ANSI Committee Z79. One of the committee’s most active members, Leslie Rendell-Baker,<sup>61</sup> wrote an account of the committee’s domestic and international achievements. He reported that Tovell encouraged all manufacturers to select the now-uniform orifice of 22 mm for all adult and pediatric face masks and to make every tracheal tube connector 15 mm in diameter. For the first time, a Z79-designed mask-tube elbow adapter would fit every mask and tracheal tube connector.

The Z79 Committee introduced other advances. Tracheal tubes of nontoxic plastic bear a Z79 or IT (*implantation tested*) mark. The committee also mandated touch identification of the oxygen flow control knob on the anesthesia machine at the suggestion of Roderick Calverley,<sup>62</sup> which reduced the risk that the wrong gas would be selected before internal mechanical controls prevented the selection of a hypoxic mixture. Pin indexing reduced the hazard of attaching a wrong cylinder in the place of oxygen. Diameter indexing of connectors prevented similar errors in high-pressure tubing. For many years, however, errors committed in reassembling hospital oxygen supply lines led to a series of tragedies before polarographic oxygen analyzers were added to the inspiratory limb of the anesthesia circuit.

## The History of Anesthetic Agents and Adjuvants

### *Inhaled Anesthetics*

Throughout the second half of the 19th century, other compounds were examined for their anesthetic potential. The pattern of fortuitous discovery that brought nitrous oxide, diethyl ether, and chloroform forward between 1844 and 1847 continued. The next inhaled anesthetics to be used routinely, ethyl chloride and ethylene, were also discovered as a result of unexpected observations. Ethyl chloride and ethylene were first formulated in the 18th century. Ethyl chloride was used as a topical anesthetic and counterirritant; it was so volatile that the skin transiently “froze” after ethyl chloride was sprayed on it. Its rediscovery as an anesthetic came in 1894, when a Swedish dentist named Carlson sprayed ethyl chloride into a patient’s mouth to

“freeze” a dental abscess. Carlson was surprised to discover that his patient suddenly lost consciousness.

As the mechanisms to deliver drugs were refined, entirely new classes of medications were also developed, with the intention of providing safer, more pleasant pain control. Ethylene gas was the first alternative to ether and chloroform, but it had some major disadvantages. The rediscovery of ethylene in 1923 also came from a serendipitous observation. After it was learned that ethylene gas had been used to inhibit the opening of carnation buds in Chicago greenhouses, it was speculated that a gas that put flowers to sleep might also have an anesthetic action on humans. Arno Luckhardt was the first to publish a clinical study in February 1923. Within a month, Isabella Herb in Chicago and W. Easson Brown in Toronto presented two other independent studies. Ethylene was not a successful anesthetic because high concentrations were required and it was explosive. An additional significant shortcoming was a particularly unpleasant smell, which could only be partially disguised by the use of oil of orange or a cheap perfume. When cyclopropane was introduced, ethylene was abandoned.

The anesthetic action of cyclopropane was inadvertently discovered in 1929.<sup>63</sup> Brown and Henderson had previously shown that propylene had desirable properties as an anesthetic when freshly prepared, but after storage in a steel cylinder, it deteriorated to create a toxic material that produced nausea and cardiac irregularities in humans. Velyien Henderson, a professor of pharmacology at the University of Toronto, suggested that the toxic product be identified. After a chemist, George Lucas, identified cyclopropane among the chemicals in the tank, he prepared a sample in low concentration with oxygen and administered it to two kittens. The animals fell asleep quietly but quickly recovered unharmed. Rather than being a toxic contaminant, Lucas saw that cyclopropane was a potent anesthetic. After its effects in other animals were studied and cyclopropane proved to be stable after storage, human experimentation began.

Henderson was the first volunteer; Lucas followed. They then arranged a public demonstration in which Frederick Banting, a Nobel Laureate for the discovery of insulin, was anesthetized before a group of physicians. Despite this promising beginning, further research was abruptly halted. Several anesthetic deaths in Toronto had been attributed to ethyl chloride, and concern about Canadian clinical trials of cyclopropane prevented human studies from proceeding. Rather than abandon the study, Henderson encouraged an American friend, Ralph Waters, to use cyclopropane at the University of Wisconsin. The Wisconsin group investigated the drug thoroughly and reported their clinical success in 1934.<sup>64</sup>

In 1930, Chauncey Leake and MeiYu Chen performed successful laboratory trials of Vinethene (divinyl ether) but were thwarted in its further

development by a professor of surgery in San Francisco. Ironically, Canadians, who had lost cyclopropane to Wisconsin, learned of Vinethene from Leake and Chen in California and conducted the first human study in 1932 at the University of Alberta, Edmonton. International research collaboration enabled early anesthetic use of both cyclopropane and divinyl ether, advances that may not have occurred independently in either the United States or Canada.

All potent anesthetics of this period were explosive save for chloroform, whose hepatic and cardiac toxicity limited use in America. Anesthetic explosions remained a rare but devastating risk to both anesthesiologist and patient. To reduce the danger of explosion during the incendiary days of World War II, British anesthetists turned to trichloroethylene. This nonflammable anesthetic found limited application in America, as it decomposed to release phosgene when warmed in the presence of soda lime. By the end of World War II, however, another class of noninflammable anesthetics was prepared for laboratory trials. Ten years later, fluorinated hydrocarbons revolutionized inhalation anesthesia.

Fluorine, the lightest and most reactive halogen, forms exceptionally stable bonds. These bonds, although sometimes created with explosive force, resist separation by chemical or thermal means. For that reason, many early attempts to fluorinate hydrocarbons in a controlled manner were frustrated by the marked chemical activity of fluorine. In 1930, the first commercial application of fluorine chemistry came in the form of the refrigerant, Freon. This was followed by the first attempt to prepare a fluorinated anesthetic by Harold Booth and E. May Bixby in 1932. Although their drug, monochlorodifluoromethane, was devoid of anesthetic action, as were other drugs studied in that decade, their report predicted future developments. "A survey of the properties of 166 known gases suggested that the best possibility of finding a new noncombustible anesthetic gas lay in the field of organic fluoride compounds. Fluorine substitution for other halogens lowers the boiling point, increases stability, and generally decreases toxicity."<sup>65</sup>

After the war, a team at the University of Maryland under professor of pharmacology John C. Krantz, Jr., investigated the anesthetic properties of dozens of hydrocarbons over a period of several years, but only one, ethyl vinyl ether, entered clinical use in 1947. Because it was flammable, Krantz requested that it be fluorinated. In response, Julius Shukys prepared several fluorinated analogues. One of these, trifluoroethyl vinyl ether, or fluroxene, became the first fluorinated anesthetic. Fluroxene, which was nonflammable in concentrations needed for anesthesia, was marketed from 1954 until 1974. Despite its flammability at high concentrations, it was popular because, unlike halothane, it had favorable respiratory and circulatory depressant properties similar to its "cousin" diethyl ether.

In 1951, Charles Suckling, a British chemist at Imperial Chemical

Industries, was asked to create a new anesthetic. Suckling, who already had an expert understanding of fluorination, began by asking clinicians to describe the properties of an ideal anesthetic. He learned from this inquiry that his search must consider several limiting factors, including the volatility, inflammability, stability, and potency of the compounds. After 2 years of research and testing, Charles Suckling created halothane. He first determined that halothane possessed anesthetic action by anesthetizing mealworms and houseflies before he forwarded it to pharmacologist James Raventos. Suckling also made accurate predictions as to the concentrations required for anesthesia in higher animals. After Raventos completed a favorable review, halothane was offered to Michael Johnstone, a respected anesthetist of Manchester, England, who recognized its great advantages over other anesthetics available in 1956. After Johnstone's endorsement, halothane use spread quickly and widely within the practice of anesthesia.<sup>66</sup>

Halothane was followed in 1960 by methoxyflurane, an anesthetic that remained popular for a decade. By 1970, however, it was learned that dose-related nephrotoxicity following protracted methoxyflurane anesthesia was caused by inorganic fluoride. Similarly, because of persisting concern that rare cases of hepatitis following anesthesia might be a result of a metabolite of halothane, the search for newer inhaled anesthetics focused on the resistance to metabolic degradation.

Two fluorinated liquid anesthetics, enflurane and its isomer isoflurane, were results of the search for increased stability. They were synthesized by Ross Terrell in 1963 and 1965, respectively. Because enflurane was easier to create, it preceded isoflurane. Its application was restricted after it was shown to be a marked cardiovascular depressant and to have some convulsant properties. Isoflurane was nearly abandoned because of difficulties in its purification, but after Louise Speers overcame this problem, several successful trials were published in 1971. The release of isoflurane for clinical use was delayed again for more than half a decade by calls for repeated testing in lower animals, owing to an unfounded concern that the drug might be carcinogenic. As a consequence, isoflurane received more thorough testing than any other drug heretofore used in anesthesia. The era when an anesthetic could be introduced following a single fortuitous observation had given way to a cautious program of assessment and reassessment. Remarkably, no anesthetics were introduced into clinical use for another 20 years. Finally, desflurane was released in 1992 and sevoflurane was released in 1994. Xenon, a gas having many properties of the ideal anesthetic, was administered to a few patients in the early 1950s but it never gained popularity because of the extreme costs associated with its removal from air. However, interest in xenon has been renewed now that gas concentrations can be accurately measured when administered at low flows, and devices are available to

scavenge and reuse the gas.

## **Intravenous Anesthetics**

Prior to William Harvey's description of a complete and continuous intravascular circuit in *De Motu Cordis* (1628), it was widely held that blood emanated from the heart and was propelled to the periphery where it was consumed. The idea that substances could be injected intravascularly and travel systemically probably originated with Christopher Wren. In 1657, Wren injected aqueous opium into a dog through a goose quill attached to a pig's bladder, rendering the animal "stupefied."<sup>67</sup> Wren similarly injected intravenous *crocus metallorum*, an impure preparation of antimony, and observed the animals to vomit and then die. Knowledge of a circulatory system and intravascular access spurred investigations in other areas, and Wren's contemporary, Richard Lower, performed the first blood transfusions of lamb's blood into dogs and other animals.

In the mid-19th century, equipment necessary for effective intravascular injections was conceived. Vaccination lancets were used in the 1830s to puncture the skin and force morphine paste subcutaneously for analgesia.<sup>68</sup> The hollow needle and hypodermic syringe were developed in the following decades but were not initially designed for intravenous use. In 1845, Dublin surgeon Francis Rynd created the hollow needle for injection of morphine into nerves in the treatment of "neuralgias." Similarly, Charles Gabriel Pravaz designed the first functional syringe in 1853 for perineural injections. Alexander Wood, however, is generally credited with perfecting the hypodermic glass syringe. In 1855, Wood published an article on the injection of opiates into painful spots by the use of hollow needle and his glass syringe.<sup>69</sup>

In 1872, Pierre Oré of Lyons performed what is perhaps the first successful intravenous surgical anesthesia by injecting chloral hydrate immediately prior to incision. His 1875 publication describes its use in 36 patients, but several postoperative deaths lent little to recommend this method to other practitioners.<sup>70</sup> In 1909, Ludwig Burkhardt produced surgical anesthesia by intravenous injections of chloroform and ether in Germany. Seven years later, Elisabeth Bredenfeld of Switzerland reported the use of intravenous morphine and scopolamine. The trials failed to show an improvement over inhaled techniques. Intravenous anesthesia found little application or popularity, primarily because of a lack of suitable drugs. In the following decades, this would change.

The first barbiturate, barbital, was synthesized in 1903 by Fischer and von Mering. Phenobarbital and all other successors of barbital had very protracted action and found little use in anesthesia. After 1929, oral pentobarbital was

used as a sedative before surgery, but when it was given in anesthetic concentrations, long periods of unconsciousness followed. The first short-acting oxybarbiturate was hexobarbital (Evipal), available clinically in 1932. Hexobarbital was enthusiastically received by the anesthesia communities in Europe and North America because its abbreviated induction time was unrivaled by any other technique. A London anesthetist, Ronald Jarman, found that it had a dramatic advantage over inhalation inductions for minor procedures. Jarman instructed his patients to raise one arm while he injected hexobarbital into a vein of the opposite forearm. When the upraised arm fell, indicating the onset of hypnosis, the surgeon could begin. Patients were also amazed in that many awoke unable to believe they had been anesthetized.<sup>71</sup>

Even though the prompt action of hexobarbital had a dramatic effect on the conduct of anesthesia, it was soon replaced by two thiobarbiturates. In 1932, Donalee Tabern and Ernest H. Volwiler of the Abbott Company synthesized thiopental (Pentothal) and thiamylal (Surital). The sulfated barbiturates proved to be more satisfactory, potent, and rapid acting than were their oxybarbiturate analogues. Thiopental was first administered to a patient at the University of Wisconsin in March 1934, but the successful introduction of thiopental into clinical practice followed a thorough investigation conducted by John Lundy and his colleagues at the Mayo Clinic in June 1934.

When first introduced, thiopental was often given in repeated increments as the primary anesthetic for protracted procedures. Its hazards were soon appreciated. At first, depression of respiration was monitored by the simple method of observing the motion of a wisp of cotton placed over the nose. Only a few skilled practitioners were prepared to pass a tracheal tube if the patient stopped breathing. Such practitioners realized that thiopental without supplementation did not suppress airway reflexes, and they therefore encouraged the prophylactic provision of topical anesthesia of the airway beforehand. The vasodilatory effects of thiobarbiturates were widely appreciated only when thiopental caused cardiovascular collapse in hypovolemic burned civilian and military patients in World War II. In response, fluid replacement was used more aggressively and thiopental administered with greater caution.

In 1962, ketamine was synthesized by Dr. Calvin Stevens at the Parke Davis Laboratories in Ann Arbor, Michigan. One of the cyclohexylamine compounds that includes phencyclidine, ketamine was the only drug of this group that gained clinical utility. The other compounds produced undesirable postanesthetic delirium and psychotomimetic reactions. In 1966, the neologism “dissociative anesthesia” was created by Guenter Corrsen and Edward Domino to describe the trancelike state of profound analgesia produced by ketamine.<sup>72</sup> It was released for use in 1970, and although it

remains primarily an agent for anesthetic induction, its analgesic properties are increasingly studied and used by pain specialists.

Etomidate was first described by Paul Janssen and his colleagues in 1964 and originally given the name hypnomidate. Its key advantages, minimal hemodynamic depression and lack of histamine release, account for its ongoing utility in clinical practice. It was released for use in 1974 and despite its drawbacks (pain on injection, myoclonus, postoperative nausea and vomiting [PONV], and inhibition of adrenal steroidogenesis), etomidate is often the drug of choice for anesthetizing hemodynamically unstable patients.

Propofol, or 2,6-diisopropylphenol, was first synthesized by Imperial Chemical Industries and tested clinically in 1977. Investigators found that it produced hypnosis quickly with minimal excitation and that patients awoke promptly once the drug was discontinued. In addition to its excellent induction characteristics, the antiemetic action of propofol made it an agent of choice in patient populations prone to nausea and emesis. Regrettably, Cremophor EL, the solvent with which it was formulated, produced several severe anaphylactic reactions, and it was withdrawn from use. Once propofol was reformulated with egg lecithin, glycerol, and soybean oil, the drug reentered clinical practice and gained great success. Its popularity in Britain coincided with the introduction of the LMA, and it was soon noted that propofol suppressed pharyngeal reflexes to a degree that permitted the insertion of an LMA without a need for either muscle relaxants or potent inhaled anesthetics.

## Local Anesthetics

Centuries after the conquest of Peru, Europeans became aware of the stimulating properties of a local, indigenous plant that the Peruvians called *khoka*. *Khoka*, which meant *the plant*, quickly became known as *coca* in Europe. In 1860, shortly after the Austrian Carl von Scherzer imported enough coca leaves to allow for analysis, German chemists Albert Niemann and Wilhelm Lossen isolated the main alkaloid and named it *cocaine*. Twenty-five years later, at the recommendation of his friend Sigmund Freud, Carl Koller became interested in the effects of cocaine. After several animal experiments, Koller successfully demonstrated the analgesic properties of cocaine applied to the eye in a patient with glaucoma.<sup>73</sup> Unfortunately, nearly simultaneous with the first reports of cocaine use, there were reports of central nervous system and cardiovascular toxicity.<sup>74,75</sup> As the popularity of cocaine grew, so did the frequency of toxic reactions and cocaine addictions.<sup>76</sup> Skepticism about the use of cocaine quickly grew within the medical community, forcing the pharmacologic industry to develop alternative local anesthetics.

In 1898, Alfred Eihorn synthesized nivaquine the first amino amide local anesthetic.<sup>77</sup> Nirvaquine proved to be an irritant to tissues, and its use was immediately stopped. Returning his attention to the development of amino ester local anesthetics, Eihorn synthesized benzocaine in 1900 and procaine (Novocaine) shortly after in 1905. Amino esters were commonly used for local infiltration and spinal anesthesia despite their low potency and high likelihood to cause allergic reactions. Tetracaine, the last (and probably safest) amino ester local anesthetic developed, proved to be quite useful for many years.

In 1944, Nils Löfgren and Bengt Lundquist developed lidocaine, an amino amide local anesthetic.<sup>76</sup> Lidocaine gained immediate popularity because of its potency, rapid onset, decreased incidence of allergic reactions, and overall effectiveness for all types of regional anesthetic blocks. Since the introduction of lidocaine, all local anesthetics developed and marketed have been of the amino amide variety.

Because of the increase in lengthy and sophisticated surgical procedures, the development of a long-acting local anesthetic took precedence. From that demand, bupivacaine was introduced in 1965. Synthesized by B. Ekenstam<sup>78</sup> in 1957, bupivacaine was initially discarded after it was found to be highly toxic. By 1980, several years after being introduced to the United States, there were several reports of almost simultaneous seizures *and* cardiovascular collapse following unintended intravascular injection.<sup>79</sup> Shortly after this, as a result of the cardiovascular toxicity associated with bupivacaine and the profound motor block associated with etidocaine, the pharmaceutical industry began searching for a new long-acting alternative. Introduced in 1996, ropivacaine is structurally similar to mepivacaine and bupivacaine, although it is prepared as a single levorotatory isomer rather than a racemic mixture. The levorotatory isomer has less potential for toxicity than the dextrorotatory isomer.<sup>80</sup> The potential safety of ropivacaine is controversial because ropivacaine is approximately 25% less potent than bupivacaine. Therefore, at equal-potent doses the margin of safety between ropivacaine and bupivacaine becomes less apparent, although systemic toxicity with ropivacaine may respond more quickly to conventional resuscitation.<sup>81</sup>

Each local anesthetic developed has had its own positive and negative attributes, which is why some are still used today and others have fallen out of favor. The pharmaceutical industry is in the process of developing extended-release local anesthetics using liposomes and microspheres.<sup>81–83</sup>

## Opioids

Opioids (historically referred to as *narcotics*, although semantically incorrect—see [Chapter 19](#)) remain the analgesic workhorse in anesthesia practice.

They are used routinely in the perioperative period, in the management of acute pain, and in a variety of terminal and chronic pain states. The availability of short-, medium-, and long-acting opioids, as well as the many routes of administration, gives physicians considerable flexibility in the use of these agents. The analgesic and sedating properties of opium have been known for more than two millennia. Certainly the Greeks and Chinese civilizations harnessed these properties in medical and cultural practices. Opium is derived from the seeds of the poppy (*Papaver somniferum*) and is an amalgam of more than 25 pharmacologic alkaloids. The first alkaloid isolated, morphine, was extracted by Prussian chemist Freidrich A. W. Sertürner in 1803. He named this alkaloid after the Greek god of dreams, Morpheus. Morphine became commonly used as a supplement to inhaled anesthesia and for postoperative pain control during the latter half of the 19th century. Codeine, another alkaloid of opium, was isolated in 1832 by Robiquet, but its relatively weaker analgesic potency and nausea at higher doses limit its role in managing moderate-to-severe perioperative surgical pain.

Meperidine was the first synthetic opioid and was developed in 1939 by two German researchers at IG Farben, Otto Eisleb and O. Schaumann. Although many pharmacologists are remembered for the introduction of a single drug, one prolific researcher, Paul Janssen, has since 1953 brought forward more than 70 agents from among 70,000 chemicals created in his laboratory. His products have had profound effects on disciplines as disparate as parasitology and psychiatry. The pace of productive innovation in Janssen's research laboratory is astonishing. Chemical R4263 (fentanyl), synthesized in 1960, was followed only a year later by R4749 (droperidol), and then etomidate in 1964. Innovar, the fixed combination of fentanyl and droperidol, is less popular now but Janssen's phenylpiperidine derivatives, fentanyl, sufentanil, and alfentanil, are staples in the anesthesia pharmacopeia. Remifentanil, an ultra-short-acting opioid introduced by Glaxo-Wellcome in 1996, is a departure from other opioids in that it has very rapid onset and equally rapid offset owing to metabolism by nonspecific tissue esterases. Ketorolac, a nonsteroidal anti-inflammatory drug (NSAID) approved for use in 1990, was the first parenteral NSAID indicated for postoperative pain. With analgesic potency equivalent to 6 to 8 mg of morphine, Ketorolac provides significant postoperative pain control and has particular use when an opioid-sparing approach is essential. Ketorolac use is limited by side effects and may be inappropriate in patients with underlying renal dysfunction, bleeding problems, or compromised bone healing.

## **Muscle Relaxants**

Muscle relaxants entered anesthesia practice nearly a century after

inhalational anesthetics (Table 1-1). Curare, the first known neuromuscular blocking agent, was originally used in hunting and tribal warfare by native peoples of South America. The curares are alkaloids prepared from plants native to equatorial rain forests. The refinement of the harmless sap of several species of vines into toxins that were lethal (through creation of total muscular paralysis and apnea) only when injected was an extraordinary triumph introduced by paleopharmacologists in loincloths. Their discovery was more remarkable because it was independently repeated on three separate continents—South America, Africa, and Asia. These jungle tribes also developed nearly identical methods of delivering the toxin by darts, which, after being dipped in curare, maintained their potency indefinitely until they were propelled through blowpipes to strike the flesh of monkeys and other animals of the treetops. Moreover, the American Indians knew of the juice of a herb that would counteract the effects of the poison if administered in time.<sup>84</sup>

The earliest clinical use of curare in humans was to ameliorate the tortuous muscle spasms of infectious tetanus. In 1858, New York physician Louis Albert Sayres reported two cases in which he attempted to treat severe tetanus with curare at the Bellevue Hospital. Both his patients died. Similar efforts were undertaken to use muscle relaxants to treat epilepsy, rabies, and choreiform disorders. Treatment of Parkinson-like rigidity and the prevention of trauma from seizure therapy also preceded the use of curare in anesthesia.<sup>85</sup>

Interestingly, curare antagonists were developed well before muscle relaxants were ever used in surgery. In 1900, Jacob Pal, a Viennese physician, recognized that curare could be antagonized by physostigmine. This substance had been isolated from the Calabar bean some 36 years earlier by Scottish pharmacologist Sir T. R. Fraser. Neostigmine methylsulfate was synthesized in 1931 and was significantly more potent in antagonizing the effects of curare.<sup>86</sup>

In 1938, Richard and Ruth Gill returned to New York from South America, bringing with them 11.9 kg of crude curare collected near their Ecuadorian ranch. Their motivation was a mixture of personal and altruistic goals. Some months before, while on an earlier visit to the United States, Richard Gill learned that he had multiple sclerosis. His physician, Dr. Walter Freeman, mentioned the possibility that curare might have a therapeutic role in the management of spastic disorders. When the Gills returned to the United States with their supply of crude curare, they encouraged scientists at E. R. Squibb & Co. to take an interest in its unique properties. Squibb soon offered semirefined curare to two groups of American anesthesiologists, who assessed its action but quickly abandoned their studies when it caused total respiratory paralysis in two patients and the death of laboratory animals.

**Table 1-1** Events in the Development of Muscle Relaxants

Year	Event
1516	Peter Martyr d'Anghera, <i>De orbe novo</i> , published account of South American Indian arrow poisons
1596	Sir Walter Raleigh provides detailed account of arrow poison effects and antidote
1745	Charles-Marie de la Condamine returns from Ecuador and conducts curare experiments with chickens and attempted to use sugar as an antidote
1780	Abbe Felix Fontana inserts curare directly into exposed sciatic nerve of rabbit without effect and concludes that mechanism is the destruction of the irritability of voluntary muscles. Publishes <i>On the American Poison Ticunas</i> (name of South American tribe)
1811	Benjamin Collins Brodie demonstrates that animals mechanically ventilated may survive significant doses of curare
1812	William Sewell suggests use of curare in "hydrophobia" (rabies) and tetanus
1844	Claude Bernard determines that death occurs by respiratory failure, motor nerves are unable to transmit stimuli from higher centers, differential effect on muscles with peripheral and thoracic muscles being affected before respiratory muscles. Bernard concludes that the site of action is the junction between muscles and nerves, neuromuscular junction
1858	Louis Albert Sayres, New York physician, uses curare to treat tetanus in two patients
1864	Physostigmine isolated from Calabar beans by Sir T. R. Fraser, a Scottish pharmacologist
1886–1897	R. Boehm, a German chemist, demonstrated three separate classes of alkaloids in each of three types of indigenous containers: tube-curares, pot-curares, and calabash-curares
1900	Jacob Pal recognizes that physostigmine can antagonize the effects of curare
1906	Succinylcholine, prepared by Reid Hunt and R. Taveau, experimented on rabbits pretreated with curare to learn of cardiac effects and so paralysis went unrecognized
1912	Arthur Lawen uses curare in surgery but report published in German so it goes largely unrecognized
1938	Richard and Ruth Gill bring large quantity of curare to New York for further study by pharmaceutical company
1939	Abram E. Bennett uses curare in children with spastic disorders and to prevent trauma from metrazol therapy (precursor to electroconvulsive therapy)
1942	Harold Griffith and Enid Johnson use curare for abdominal relaxation in surgery
1942	H. A. Halody develops rabbit head-drop assay for standardization and large-scale production of curare and d-tubocurarine
1948	Decamethonium, a depolarizing relaxant, is synthesized
1949	Succinylcholine prepared by Daniel Bovet and the following year by J. C. Castillo and Edwin de Beer
1956	Distinction between depolarizing and nondepolarizing neuromuscular blockade is made by William D. M. Paton
1964	Pancuronium released for use in humans, synthesized by Savage and Hewett
1979	Vecuronium introduced, specifically designed to be more hepatically metabolized than pancuronium
1993	Mivacurium released for clinical use
1994	Rocuronium introduced to clinical practice

The earliest effective clinical application of curare in medicine occurred in psychiatry. After A. R. McIntyre refined a portion of the raw curare in 1939, Abram E. Bennett of Omaha, Nebraska, injected it into children with spastic disorders. Although no persistent benefit could be observed in these patients, he next administered it to patients about to receive metrazol, a precursor to electroconvulsive therapy. Because it eliminated seizure-induced fractures, they termed it a "shock absorber." By 1941, other psychiatrists followed this practice and, when they found that the action of curare was protracted, occasionally used neostigmine as an antidote.

Curare was used initially in surgery by Arthur Lawen in 1912, but the published report was written in German and was ignored for decades. Lawen, a physiologist and physician from Leipzig, used curare in his laboratory before boldly producing abdominal relaxation at a light level of anesthesia in a surgical patient. Lawen's efforts were not appreciated for decades, and although his pioneering work anticipated later clinical application, safe use

would have to await the introduction of regular intubation of the trachea and controlled ventilation of the lungs.<sup>87</sup>

Thirty years after Lawen, Harold Griffith, the chief anesthetist of the Montreal Homeopathic Hospital, learned of A. E. Bennett's successful use of curare and resolved to apply it in anesthesia. Because Griffith was already a master of tracheal intubation, he was much better prepared than were most of his contemporaries to attend to potential complications. On January 23, 1942, Griffith and his resident, Enid Johnson, anesthetized and intubated the trachea of a young man before injecting curare early in the course of his appendectomy. Satisfactory abdominal relaxation was obtained, and the surgery proceeded without incident. Griffith and Johnson's report of the successful use of curare in the 25 patients of their series launched a revolution in anesthetic care.<sup>88</sup>

Anesthesiologists who practiced before muscle relaxants recall the anxiety they felt when a premature attempt to intubate the trachea under cyclopropane caused persisting laryngospasm. Before 1942, abdominal relaxation was possible only if the patient tolerated high concentrations of an inhaled anesthetic, which might bring profound respiratory depression and protracted recovery. Curare and the drugs that followed transformed anesthesia profoundly. Because intubation of the trachea could now be taught in a deliberate manner, a neophyte could fail on a first attempt without compromising the safety of the patient. For the first time, abdominal relaxation could be attained when curare was supplemented by light planes of inhaled anesthetics or by a combination of intravenous agents providing "balanced anesthesia." New frontiers opened. Sedated and paralyzed patients could now successfully undergo the major physiologic trespasses of cardiopulmonary bypass, deliberate hypothermia, or long-term respiratory support after surgery.

Credit for successful and safe introduction of curare and d-tubocurarine into anesthesia must in part be given to a Squibb researcher named H. A. Holladay. Crude, unstandardized preparations of curare produced uncertain clinical effects and undesirable side effects related to various impurities. Isolation of d-tubocurarine in 1935 renewed clinical interest, but a method for standardizing "Intocostrin" and its purer derivative, d-tubocurarine, had yet to be devised. In the early 1940s, in part as a result of Griffith and Johnson's successful trials, Squibb embarked on wide-scale production. Holladay developed a reliable, easily reproducible method for standardizing curare doses that became known as the rabbit head-drop assay (Fig. 1-5). The assay consisted of aqueous curare solution injected intravenously in 0.1-mL doses every 15 seconds until the end point, when the rabbit became unable to raise its head, was reached.<sup>89</sup>

Successful clinical use of curare led to the introduction of other muscle

relaxants. By 1948, gallamine and decamethonium had been synthesized. Metubine, a curare “rediscovered” in the 1970s, was used clinically in the same year. Succinylcholine was prepared by the Nobel Laureate Daniel Bovet in 1949 and was in wide international use before historians noted that the drug had been synthesized and tested long beforehand. In 1906, Reid Hunt and R. Taveaux prepared succinylcholine among a series of choline esters, which they had injected into rabbits to observe their cardiac effects. If their rabbits had not been previously paralyzed with curare, the depolarizing action of succinylcholine might have been recognized decades earlier.

The ability to monitor intraoperative neuromuscular blockade with nerve stimulators began in 1958. Working at St. Thomas’ Hospital in London, T. H. Christie and H. Churchill-Davidson developed a method for monitoring peripheral neuromuscular blockade during anesthesia. It was not until 1970, however, that H. H. Ali et al.<sup>90</sup> devised the technique of delivering four supramaximal impulses delivered at 2 Hz (0.5 seconds apart), or a “train of four,” as a method of quantifying the degree of residual neuromuscular blockade.

Research in relaxants was rekindled in 1960 when researchers became aware of the action of maldetine, a relaxant from the Congo basin. It was remarkable in that it had a steroidal nucleus. Investigations of maldetine led to pancuronium in 1968. In the 1970s and 1980s, research shifted toward identification of specific receptor biochemistry and development of receptor-specific drugs. From these isoquinolines, four related products emerged: vecuronium, pipecuronium, rocuronium, and rapacuronium. Rapacuronium, released in the early 1990s, was withdrawn from clinical use after several cases of intractable bronchospasm led to brain damage or death. Four clinical products based on the steroid parent drug d-tubocurarine (atracurium, mivacurium, doxacurium, and *cis*-atracurium) also made it to clinical use. Recognition that atracurium and *cis*-atracurium undergo spontaneous degradation by Hoffmann elimination has defined a role for these muscle relaxants in patients with liver and renal insufficiency.

## **Antiemetics**

Effective treatment for PONV evolved relatively recently and has been driven by incentives to limit hospitalization expenses and improve patient satisfaction. But PONV is an old problem for which late-19th century practitioners recognized many causes including anxiety, severe pain, sudden changes in blood pressure, ileus, ingestion of blood, and the residual effects of opioids and inhalational anesthetics. Risk of pulmonary aspiration of gastric contents and subsequent death from asphyxia or aspiration pneumonia was a feared consequence of anesthesia, especially preceding use of cuffed

endotracheal tubes. Vomiting and aspiration during anesthesia led to the practice of maintaining an empty stomach preoperatively, a policy that continues today despite evidence that clear fluids up to 3 hours before surgery do not increase gastric volumes, change gastric pH, or increase the risk of aspiration.

**Figure 1-5** The rabbit head-drop assay. H. A. Halladay of Squibb pharmaceutical company developed a method of standardizing doses of curare and d-tubocurarine. A normal rabbit (**A**) had 0.1 mL of aqueous cecurane solution injected every 15 seconds until it could no longer raise its head (**B**).

A variety of treatments for nausea and vomiting were proposed by early anesthetists. James Gwathemy's 1914 publication, *Anesthesia*, commented that British surgeons customarily gave tincture of iodine in a teaspoonful of water every half hour for three or four doses. Inhalation of vinegar fumes and rectal injection of 30 to 40 drops of tincture of opium with 60 grains of sodium bromide were also thought to quiet the vomiting center.<sup>91</sup> Other practitioners attempted olfactory control by placing a piece of gauze moistened with essence of orange or an aromatic oil on the upper lip of the patient.<sup>92</sup> A 1937 anesthesia textbook encouraged treatment of PONV with lateral positioning, "iced soda water, strong black coffee, and chloretone.\*" Counterirritation, such as mustard leaf on the epigastrium, was also believed useful in limiting emesis.<sup>93</sup> As late as 1951, anesthesia texts recommended oxygen administration, whiffs of ammonia spirits, and control of blood pressure and positioning.<sup>94</sup> The complex central mechanisms of nausea and vomiting were largely unaffected by most of these treatments. Newer drugs capable of intervening at specific pathways were needed to have an impact on PONV. As more short-acting anesthetics were developed, the problem received sharper focus in awake postoperative patients in the recovery room. The nausea accompanying use of newer chemotherapy agents provided additional impetus to the development of antiemetic medications.

In 1955, a nonrandomized study of patients demonstrated that the antihistamine cyclizine significantly reduced PONV. The following year, a more rigorous study by Knapp and Beecher reported a significant benefit from prophylaxis with the neuroleptic chlorpromazine. In 1957, promethazine (Phenergan) and chlorpromazine were both found to reduce PONV when used prophylactically. Thirteen years later, a double-blind study evaluating metoclopramide was published, and that drug became a first-line drug in the management of PONV. Droperidol, released in the early 1960s, became widely used until 2001, when concerns regarding prolongation of QT intervals prompted a warning from the Food and Drug Administration about its continued use.

The antiemetic effects of corticosteroids were first recognized by oncologists treating intracranial edema from tumors.<sup>95</sup> Subsequent studies have borne out the antiemetic properties of this class of drugs in treating PONV. Recognition of the serotonin 5-HT<sub>3</sub> pathway in PONV has led to a unique class of drugs devoted only to addressing this particular problem. Ondansetron, the first representative of this drug class, was approved by the Food and Drug Administration in 1991. Additional serotonin 5-HT<sub>3</sub> antagonists have been approved and are available today.

## Anesthesia Subspecialties

### Regional Anesthesia

Cocaine, an extract of the coca leaf, was the first effective local anesthetic. After Albert Niemann refined the active alkaloid and named it *cocaine*, it was used in experiments by a few investigators. It was noted that cocaine provided topical anesthesia and even produced local insensibility when injected, but Carl Koller, a Viennese surgical intern, first recognized the utility of cocaine in clinical practice.

In 1884, Carl Koller was completing his medical training at a time when many operations on the eye were performed without general anesthesia. Almost four decades after the discovery of ether, general anesthesia by mask still had limitations for ophthalmic surgery: lack of patient cooperation, interference of the anesthesia apparatus with surgical access, and a high incidence of PONV. At that time, because fine sutures were not available and surgical incisions of the eye were not closed, postoperative vomiting threatened the extrusion of the globe's contents, putting the patient at risk for irrevocable blindness.<sup>96</sup>

While a medical student, Koller had worked in a Viennese laboratory in a search of a topical ophthalmic anesthetic to overcome the limitations of general anesthesia. Unfortunately, the suspensions of morphine, chloral

hydrate, and other drugs that he had used had been ineffectual. In 1884, Koller's friend, Sigmund Freud, became interested in the cerebral-stimulating effects of cocaine and gave him a small sample in an envelope, which he placed in his pocket. When the envelope leaked, a few grains of cocaine stuck to Koller's finger and he absentmindedly licked it with his tongue. When 5 his tongue became numb, Koller instantly realized that he had found the object of his search. In his laboratory, he made a suspension of cocaine crystals that he and a laboratory associate tested in the eyes of a frog, a rabbit, and a dog. Satisfied with the anesthetic effects seen in the animal models, Koller dropped the solution onto his own cornea. To his amazement, his eyes were insensitive to the touch of a pin.<sup>97</sup> As an intern, Carl Koller could not afford to attend the Congress of German Ophthalmologists in Heidelberg on September 15, 1884. However, a friend presented his article at the meeting, and a revolution in ophthalmic surgery and other surgical disciplines began. Within the next year, more than 100 articles supporting the use of cocaine appeared in European and American medical journals. In 1888, Koller immigrated to New York, where he practiced ophthalmology for the remainder of his career.

American surgeons quickly developed new applications for cocaine. Its efficacy in anesthetizing the nose, mouth, larynx, trachea, rectum, and urethra was described in October 1884. The next month, the first reports of its subcutaneous injection were published. In December 1884, two young surgeons, William Halsted and Richard Hall, described blocks of the sensory nerves of the face and arm. Halsted<sup>98</sup> even performed a brachial plexus block but did so under direct vision while the patient received an inhaled anesthetic. Unfortunately, self-experimentation with cocaine was hazardous, as both surgeons became addicted.<sup>99</sup> Addiction was an ill-understood but frequent problem in the late 19th century, especially when cocaine and morphine were present in many patent medicines and folk remedies.

Other regional anesthetic techniques were attempted before the end of the 19th century. The term *spinal anesthesia* was coined in 1885 by Leonard Corning, a neurologist who had observed Hall and Halsted. Corning wanted to assess the action of cocaine as a specific therapy for neurologic problems. After first assessing its action in a dog, producing a blockade of rapid onset that was confined to the animal's rear legs, he performed a neuraxial block using cocaine on a man "addicted to masturbation." Corning administered one dose without effect, then after a second dose, the patient's legs "felt sleepy." The man had impaired sensibility in his lower extremity after about 20 minutes and left Corning's office "none the worse for the experience."<sup>100</sup> Although Corning did not describe escape of cerebrospinal fluid (CSF) in either case, it is likely that the dog had a spinal anesthetic and that the man had an epidural anesthetic. No therapeutic benefit was described, but Corning

closed his account and his attention to the subject by suggesting that cocainization might in time be “a substitute for etherization in genitourinary or other branches of surgery.”<sup>101</sup>

Two other authors, August Bier and Theodor Tuffier, described authentic spinal anesthesia, with mention of CSF, injection of cocaine, and an appropriately short onset of action. In a comparative review of the original articles by Bier, Tuffier, and Corning, it was concluded that Corning’s injection was extradural, and Bier merited the credit for introducing spinal anesthesia.<sup>102</sup>

Fourteen years passed before spinal anesthesia was performed for surgery. In the interval, Heinrich Quincke of Kiel, Germany, had described his technique of lumbar puncture. He offered the valuable observation that it was most safely performed at the level of the third or fourth lumbar interspace because entry at that level was below the termination of the spinal cord. Quincke’s technique was used in Kiel for the first deliberate cocainization of the spinal cord in 1899 by his surgical colleague, August Bier. Six patients received small doses of cocaine intrathecally, but because some cried out during surgery and others vomited and experienced headaches, Bier considered it necessary to conduct further experiments before continuing this technique for surgery.

Professor Bier permitted his assistant, Dr. Hildebrandt, to perform a lumbar puncture, but after the needle penetrated the dura, Hildebrandt could not fit the syringe to the needle, and a large volume of the professor’s spinal fluid escaped. They were at the point of abandoning the study when Hildebrandt volunteered to be the subject of a second attempt. Their persistence was rewarded with an astonishing success. Twenty-three minutes after the spinal injection, Bier noted: “A strong blow with an iron hammer against the tibia was not felt as pain. After 25 minutes: Strong pressure and pulling on a testicle were not painful.”<sup>92</sup> They celebrated their success with wine and cigars. That night, both developed violent headaches, which they attributed at first to their celebration. Bier’s headache was relieved after 9 days of bed rest. Hildebrandt, as a house officer, did not have the luxury of continued rest. Bier postulated that their headaches were a result of the loss of large volumes of CSF and urged that this be avoided if possible. The high incidence of complications following lumbar puncture with wide-bore needles and the toxic reactions attributed to cocaine explain his later loss of interest in spinal anesthesia.<sup>103</sup>

Surgeons in several other countries soon practiced spinal anesthesia, and progress occurred by many small contributions to the technique. Theodor Tuffier published the first series of 125 spinal anesthetics from France and later counseled that the solution should not be injected before CSF was seen. The first American report was by Rudolph Matas of New Orleans, whose first

patient developed postanesthetic meningismus, a frequent complication that was overcome in part by the use of hermetically sealed sterile solutions recommended by E. W. Lee of Philadelphia and sterile gloves as advocated by Halsted. During 1899, Dudley Tait and Guidlo Caglieri of San Francisco performed experimental studies in animals and therapeutic spinals for orthopedic patients. They encouraged the use of fine needles to lessen the escape of CSF and urged that the skin and deeper tissues be infiltrated beforehand with local anesthesia.<sup>104</sup> This had been suggested earlier by William Halsted and the foremost advocate of infiltration anesthesia, Carl Ludwig Schleich of Berlin. An early American specialist in anesthesia, Ormond Goldan, published an anesthesia record appropriate for recording the course of “intraspinal cocainization” in 1900. In the same year, Heinrich Braun learned of a newly described extract of the adrenal gland, epinephrine, which he used to prolong the action of local anesthetics with great success. Braun developed several new nerve blocks, coined the term *conduction anesthesia*, and is remembered by European writers as the “father of conduction anesthesia.” Braun was the first person to use procaine, which, along with stovaine, was one of the first synthetic local anesthetics produced to reduce the toxicity of cocaine.

Before 1907, anesthesiologists were sometimes disappointed to observe that their spinal anesthetics were incomplete. Most believed that the drug spread solely by local diffusion before the property of baricity was investigated by Arthur Barker, a London surgeon.<sup>105</sup> Barker constructed a glass tube shaped to follow the curves of the human spine and used it to demonstrate the limited spread of colored solutions that he had injected through a T-piece in the lumbar region. Barker applied this observation to use solutions of stovaine made hyperbaric by the addition of 5% glucose, which worked in a more predictable fashion. After the injection was complete, Barker placed his patient’s head on pillows to contain the anesthetic below the nipple line. Lincoln Sise acknowledged Barker’s work in 1935 when he introduced the use of hyperbaric solutions of tetracaine (Pontocaine). John Adriani advanced the concept further in 1946 when he used a hyperbaric solution to produce “saddle block,” or perineal anesthesia. Adriani’s patients remained seated after injection as the drug descended to the sacral nerves.

Tait, Jonnesco, and other early masters of spinal anesthesia used a cervical approach for thyroidectomy and thoracic procedures, but this radical approach was supplanted in 1928 by the lumbar injection of hypobaric solutions of “light” nupercaine by G. P. Pitkin. Although the use of hypobaric solutions is now limited primarily to patients positioned in the jackknife position, their former use for thoracic procedures demanded skill and precise timing. The enthusiasts of hypobaric anesthesia devised formulas to attempt to predict the time in seconds needed for a warmed solution of hypobaric

nupercaine to spread in patients of varying size from its site of injection in the lumbar area to the level of the fourth thoracic dermatome.

The recurring problem of inadequate duration of single-injection spinal anesthesia led a Philadelphia surgeon, William Lemmon, to devise an apparatus for continuous spinal anesthesia in 1940.<sup>106</sup> Lemmon began with the patient in the lateral position. The spinal tap was performed with a malleable silver needle, which was left in position. As the patient was turned supine, the needle was positioned through a hole in the mattress and table. Additional injections of local anesthetic could be performed as required. Malleable silver needles also found a less cumbersome and more common application in 1942 when Waldo Edwards and Robert Hingson encouraged the use of Lemmon's needles for continuous caudal anesthesia in obstetrics. In 1944, Edward Tuohy of the Mayo Clinic introduced two important modifications of the continuous spinal techniques. He developed the now familiar Tuohy needle<sup>107</sup> as a means of improving the ease of passage of lacquered silk ureteral catheters through which he injected incremental doses of local anesthetic.<sup>108</sup>

In 1949, Martinez Curbelo of Havana, Cuba, used Tuohy's needle and a ureteral catheter to perform the first continuous epidural anesthetic. Silk and gum elastic catheters were difficult to sterilize and sometimes caused dural infections before being superseded by disposable plastics. Yet deliberate single-injection peridural anesthesia had been practiced occasionally for decades before continuous techniques brought it greater popularity. At the beginning of the 20th century, two French clinicians experimented independently with caudal anesthesia. Neurologist Jean Athanase Sicard applied the technique for a nonsurgical purpose, the relief of back pain. Fernand Cathelin used caudal anesthesia as a less dangerous alternative to spinal anesthesia for hernia repairs. He also demonstrated that the epidural space terminated in the neck by injecting a solution of India ink into the caudal canal of a dog. The lumbar approach was first used solely for multiple paravertebral nerve blocks before the Pagés–Dogliotti single-injection technique became accepted. Because they worked separately, the technique carries the names of both men. Captain Fidel Pagés prepared an elegant demonstration of segmental single-injection peridural anesthesia in 1921, but died soon after his article appeared in a Spanish military journal.<sup>109</sup> Ten years later, Achille M. Dogliotti of Turin, Italy, wrote a classic study that made the epidural technique well known.<sup>72</sup> Whereas Pagés used a tactile approach to identify the epidural space, Dogliotti identified it by the loss-of-resistance technique.

Surgery on the extremities lent itself to other regional anesthesia techniques. In 1902, Harvey Cushing coined the phrase *regional anesthesia* for his technique of blocking either the brachial or sciatic plexus under direct

vision during general anesthesia to reduce anesthesia requirements and provide postoperative pain relief.<sup>57</sup> Fifteen years before his publication, George Crile advanced a similar approach to reduce the stress and shock of surgery. Crile, a dedicated advocate of regional and infiltration techniques during general anesthesia, coined the term *anoci-association*.<sup>110</sup>

An intravenous regional technique with procaine was reported in 1908 by August Bier, the surgeon who had pioneered spinal anesthesia. Bier injected procaine into a vein of the upper limb between two tourniquets. Even though the technique is termed the *Bier block*, it was not used for many decades until it was reintroduced 55 years later by Mackinnon Holmes, who modified the technique by introducing exsanguination before applying a single proximal cuff. Holmes used lidocaine, the very successful amide local anesthetic synthesized in 1943 by Lofgren and Lundquist of Sweden.

Several investigators achieved upper extremity anesthesia by percutaneous injections of the brachial plexus. In 1911, based on his intimate knowledge of the anatomy of the axillary area, Hirschel promoted a “blind” axillary injection. In the same year, Kulenkampff described a supraclavicular approach in which the operator sought out paresthesias of the plexus while keeping the needle at a point superficial to the first rib and the pleura. The risk of pneumothorax with Kulenkampff’s approach led Mulley to attempt blocks more proximally by a lateral paravertebral approach, the precursor of what is now popularly known as the *Winnie block* (after Alon Winnie from Chicago).

Heinrich Braun wrote the earliest textbook of local anesthesia, which appeared in its first English translation in 1914. After 1922, Gaston Labat’s *Regional Anesthesia* dominated the American market. Labat migrated from France to the Mayo Clinic in Minnesota, where he served briefly before taking a permanent position at the Bellevue Hospital in New York. He formed the first American Society for Regional Anesthesia.<sup>112</sup> After Labat’s death, Emery A. Rovenstine was recruited to Bellevue to continue Labat’s work, among other responsibilities. Rovenstein created the first American clinic for the treatment of chronic pain, where he and his associates refined techniques of lytic and therapeutic injections and used the American Society of Regional Anesthesia to further the knowledge of pain management across the United States.<sup>112</sup>

**6** The development of the multidisciplinary pain clinic was one of the many contributions to anesthesiology made by John J. Bonica, a renowned teacher of regional techniques. During his periods of military, civilian, and university service at the University of Washington, Bonica formulated a series of improvements in the management of patients with chronic pain. His classic text *The Management of Pain* is regarded as a standard of the literature of anesthesia.

## Cardiovascular Anesthesia

The earliest attempts to operate on the heart were limited to repairing cardiac wounds. These attempts generally failed until German surgeon Ludwig Rehn repaired a right ventricular stab wound in September 1896.<sup>113</sup> Despite this success, the field was not ready to advance. The taboo of cardiac surgery was summarized by Theodore Billroth when he supposedly said “any surgeon who would attempt an operation on the heart should lose the respect of his colleagues.”<sup>114</sup> The resistance to such operations was partly because of fledgling anesthetic medications, lack of adequate monitors, and even a clear understanding of cardiovascular physiology that pervades modern anesthesia practice.

Fortunately, the turn of the 20th century saw many advances in anesthesia practice, blood typing and transfusion, anticoagulation, and antibiotics as well as surgical instrumentation and technique. Some continued to attempt procedures like closed mitral valvotomy in the midst of these technologic advancements, but outcomes were still very poor with mortality rates exceeding 80%. Many believe that the successful ligation of a 7-year-old girl’s patent ductus arteriosus by Robert Gross in 1938 served as the landmark case for modern cardiac surgery. Soon after Gross’ achievement, a host of new procedures were developed for repairing congenital cardiac lesions, including the first Blalock–Taussig shunt performed on a 15-month-old “blue baby” in 1944.<sup>68</sup> Although the shunt had been successfully demonstrated in animal models, Austin Lamont, Chief of Anesthesia at Johns Hopkins, was not supportive of the procedure. He emphatically stated “I will not put that child to death” and left the open drop ether–oxygen anesthetic to resident anesthesiologist Merel Harmel.<sup>115</sup> Lamont attended on the second Blalock–Taussig shunt 2 months later. Together, Harmel and Lamont<sup>116</sup> would publish the first article on anesthesia for cardiac surgery in 1946 based on 100 cases with Alfred Blalock and repair of congenital pulmonic stenosis.

Closed cardiac surgery ensued, and anesthesia pioneers like William McQuiston and Kenneth Keown worked side by side with surgeons during procedures like the first aortic–pulmonary anastomosis and the first transmyocardial mitral commissurotomy. Never before had anesthesia providers worked as intimately with surgeons for the patient’s welfare. Anesthesiologist and World War II physician Max Samuel Sadove remarked, “the small-arms fire of the anesthesiologist joins the spy system of the lab to back up the surgeon’s big artillery in a coordinated attack to conquer disease.”<sup>117</sup>

Through the 1930s and 1940s, John Gibbon had been experimenting with several extracorporeal circuit designs and by 1947 was able to successfully place dogs on heart–lung bypass. The first successful use of Gibbon’s

cardiopulmonary bypass machine in humans in May 1953 was a monumental advance in the surgical treatment of complex cardiac pathology that stimulated international interest in open heart surgery and the specialty of cardiac anesthesia.

Over the next decade, rapid growth and expanded applications of cardiac surgery, including artificial valves and coronary artery bypass grafting, required many more anesthesiologists acquainted with these specialized techniques. In 1967, J. Earl Wynands published one of the first articles on anesthetic management of patients undergoing surgery for coronary artery disease.

As cardiac surgery evolved, so did the perioperative monitoring and care of patients undergoing cardiac surgery. Postoperative mechanical ventilation and surgical intensive care units appeared by the late 1960s. Devices like the left atrial pressure monitor and the intra-aortic balloon pump offered new methods of understanding cardiopulmonary physiology and treating postoperative ventricular failure. Cardiac anesthesiologists were quick to bring the pulmonary artery catheter (PAC) into the operating room, permitting more precise hemodynamic monitoring and intervention. Joel Kaplan, already known for using the V<sub>5</sub> lead to monitor for myocardial ischemia and nitroglycerin infusions to treat ischemia, popularized the use of the PAC to detect myocardial ischemia. At Texas Heart Institute, Stephen Slogoff and Arthur Keats demonstrated the negative impact of myocardial ischemia on clinical outcome. By the end of the 1980s, the same duo would reveal that the choice of anesthetic agent had little impact on outcome, challenging the earlier paradigm of “isoflurane steal” proposed by Sebastian Reiz.

Developments like cold potassium cardioplegia, monitoring and reversal of heparin, and reduction of blood loss with aprotinin would change the practice of cardiac anesthesia. Transesophageal echocardiography, introduced into cardiac surgery by Roizen, Cahalan, and Kremer in the 1980s, helped to further define the subspecialty of cardiac anesthesia.

## **Neuroanesthesia**

Brain surgery is considered by some to be the oldest of the practiced medical arts. Evidence of trephination, a form of neurosurgery in which a hole is drilled or scraped into the skull to access the dura, was discovered in skulls dating back to 6500 BC at a French burial site. Prehistoric brain surgery was also practiced by civilizations in South America, Africa, and Asia.<sup>118</sup>

With the introduction of inhalational anesthesia in the mid-1800s, Scottish surgeon and neurosurgery pioneer Sir William Macewen used this novel practice while performing the first successful craniotomy for tumor removal

in 1879. Macewen, well known for introducing the technique of orotracheal intubation, promoted the idea of teaching medical students at Glasgow Royal Infirmary the art of chloroform anesthesia.

Like Macewen, Sir Victor Horsely was a neurosurgeon with an interest in anesthesia. His experiments of how ether, chloroform, and morphine affected intracranial contents led him to conclude that “the agent of choice was chloroform and that morphine had some value because of its cerebral constriction effects.”<sup>119</sup> He first published his anesthetic technique for brain surgery in the *British Medical Journal* in 1886.<sup>120</sup> Later, he omitted morphine from his regimen after discovering its tendency to produce respiratory depression.

Meanwhile, Harvard medical student and aspiring neurosurgeon Harvey Cushing developed the first charts to record heart rate, temperature, and respiration during anesthesia. Soon after, he would add blood pressure readings to the record. Cushing was one of the first surgeons to recognize the importance of dedicated, specially trained anesthesia personnel versed in neurosurgery. Charles Frazier,<sup>121</sup> a neurosurgical contemporary of Cushing, also recognized this need, stating that “no [cranial] operation be undertaken unless the services of a skilled anesthetizer are available.”

Because ether and chloroform anesthesia had significant drawbacks, beginning in 1918 Cushing and his contemporaries explored the advantages of regional or local anesthesia for intracranial surgery. Part of the motivation driving this change was the increased duration in surgical time. Cushing and colleagues used a “slow” surgical technique for most surgical procedures, where the average duration for cranial operations was 5 hours.<sup>122</sup> In contrast, early neurosurgeons like Horsely and Sir Percy Sargeant could perform similar procedures in less than 90 minutes. Therefore, prolonged patient exposure to chloroform or ether anesthesia was likely to result in increased bleeding, postoperative headache, confusion, and/or vomiting. Cushing and his contemporaries thought the use of local or regional anesthesia lessened the risk of these complications.

After a decade, it was realized that the remote positioning of the anesthetist was troublesome when managing the airway of an awake or lightly sedated patient undergoing cranial surgery with regional anesthesia. Also, endotracheal tubes, although introduced at the beginning of the century, had become popular instruments for securing a patient’s airway and providing inhalation anesthesia. Combined, these circumstances led to the rapid resurgence of popularity in general anesthesia for cranial surgery, a trend that would continue to the present day.

Although the introduction of agents like thiopental, curare, and halothane advanced the practice of anesthesiology in general, the development of methods to measure brain electrical activity, cerebral blood flow, and

metabolic rate by Kety and Schmidt and intracranial pressure by Lundburg “put neuroanesthesia practice on a scientific foundation and opened doors to neuroanesthesia research.”<sup>123</sup> Clinician-scientists like John D. (Jack) Michenfelder, later known as the father of neuroanesthesia, conducted basic science and clinical research on cerebral blood flow and brain function and protection in response to various anesthetic agents and techniques. Many lessons learned during this period of groundbreaking research are still commonly used in modern neuroanesthesia practice.

## **Obstetric Anesthesia**

Social attitudes about pain associated with childbirth began to change in the 1860s, and women started demanding anesthesia for childbirth. Societal pressures were so great that physicians, although unconvinced of the benefits of analgesia, felt obligated to offer this service to their obstetric patients.<sup>124</sup> In 1907, an Austrian physician, Richard von Steinbüchel, used a combination of morphine and scopolamine to produce *Dämmerschlaflf* or “Twilight Sleep.”<sup>125</sup> Although these two drugs were well known, physicians remained skeptical that Twilight Sleep was essential to labor and delivery, which unfortunately contrasted with the opinion of most women. This method gained popularity after German obstetricians Carl Gauss and Bernhardt Krönig widely publicized the technique. Numerous advertisements touted the benefits of Twilight Sleep (analgesia, partial pain relief, and amnesia) as compared to ether and chloroform, which resulted in total unconsciousness.<sup>126</sup> Gauss recognized the narrow therapeutic margin of these medications and gave precise instructions on its use: The first injection (morphine 10 mg and scopolamine) was to be given shortly after active labor began—this was intended to blunt the pain of labor—and subsequent injections consisted of only scopolamine, which was dosed to obliterate the memory of labor. Because of the effects of scopolamine, many patients became disoriented and would scream and thrash about during labor and delivery. Gauss believed that he could minimize this reaction by decreasing the sensory input; therefore, he would put patients in a dark room, cover their eyes with gauze, and insert oil-soaked cotton into their ears. The patients were often confined to a padded bed and restrained with leather straps during the delivery.<sup>127</sup> Over time, the doses of morphine administered seemed to increase, although there were few, if any, reports of adverse neonatal effects. Virginia Apgar’s landmark 1953 publication of a system for evaluating newborns (the Apgar Score) helped to demonstrate that there actually was a difference in the neonates of mothers who had general versus regional anesthesia.<sup>128</sup>

The bulk of the interest in Twilight Sleep appears to have been popular rather than medical and, for a brief period, was intensely followed in the

United States.<sup>129</sup> Public enthusiasm for Twilight Sleep quickly subsided after a prominent advocate of the method died during childbirth. Her physicians claimed her death was not related to complications from the method of Twilight Sleep that was used.<sup>130</sup>

The first articles describing the obstetric application of spinal, epidural, caudal, paravertebral, parasacral, and pudendal nerve blocks appeared between 1900 and 1930. However, their benefits were underappreciated for many years because the obstetricians seldom used these techniques.<sup>130</sup> Continuous caudal anesthesia was introduced in 1944 by Hingson and Edwards,<sup>131</sup> and spinal anesthesia became popular shortly thereafter. Initially, spinal anesthesia could be administered by inexperienced personnel without monitoring. The combination of inexperienced providers and lack of patient monitoring led to higher rates of morbidity and mortality than those observed for general anesthesia.<sup>132</sup> Therefore, the use of spinal anesthesia was highly discouraged in the 1950s, leading to the “dark ages of obstetric anesthesia” when pain relief in obstetrics was essentially abandoned and women were forced to endure “natural childbirth” to avoid serious anesthesia-related complications.<sup>133</sup>

With an increased understanding of neuraxial anesthesia, involvement by well-trained anesthesiologists, and an appreciation for the physiologic changes during pregnancy, maternal and fetal safety greatly improved. At the onset of the 21st century, anesthesia-related deaths during cesarean sections under general anesthesia were reported as being more likely than neuraxial anesthesia-related deaths, making regional anesthesia the method of choice.<sup>134,135</sup> With the availability of safe and effective options for pain relief during labor and delivery, today’s focus is on improving the quality of the birth experience for expectant parents.

## *Transfusion Medicine*

Paleolithic cave drawings found in France depict a bear losing blood from multiple spear wounds, indicating that primitive man understood the simple relationship between blood and life.<sup>136</sup> More than 10,000 years later, modern anesthesiologists attempt to preserve this intimate relationship by replacing fluids and blood products when faced with intravascular volume depletion or diminished oxygen-carrying capacity from blood loss.

Blood transfusion was first attempted in 1667 by the physician to Louis XIV, Jean Baptiste Denis. Denis had learned of Richard Lower’s transfusion of lamb’s blood into a dog the previous year. Lamb’s blood was most frequently used because the donating animal’s essential qualities were thought to be transferred to the recipient. Despite this dangerous transspecies transfusion, Denis’ first patient got better. His next two patients were not as fortunate,

however, and Denis avoided further attempts. Given the poor outcomes of these early blood transfusions, and heated religious controversy regarding the implications of transferring animal-specific qualities across species, blood transfusion in humans was banned for more than a 100 years in both France and England beginning in 1670.<sup>68</sup>

In 1900, Karl Landsteiner and Samuel Shattock independently helped lay the scientific basis of all subsequent transfusions by recognizing that blood compatibility was based on different blood groups. Landsteiner, an Austrian physician, originally organized human blood into three groups based on substances present in the red blood cells. The fourth type, AB group, was identified in 1902 by two students, Decastrello and Sturli. On the basis of these findings, Reuben Ottenberg performed the first type-specific blood transfusion in 1907. Transfusion of physiologic solutions occurred in 1831, independently performed by O'Shaughnessy and Lewins in Great Britain. In his letter to *The Lancet*, Lewins described transfusing large volumes of saline solutions into patients with cholera. He reported that he would inject into adults 5 to 10 pounds of saline solution and repeat as needed.<sup>137</sup> Despite its publication in a prominent journal, Lewins' technique was apparently overlooked for decades, and balanced physiologic solution availability would have to await the coming of analytical chemistry.

## Professionalism and Anesthesia Practice

### Organized Anesthesiology

Physician anesthetists sought to obtain respect among their surgical colleagues by organizing professional societies and improving the quality of training. The first American organization was founded by nine members on October 6, 1905, and called the Long Island Society of Anesthetists with annual dues of \$1.00. In 1911, the annual assessment rose to \$3.00 when the Long Island Society became the New York Society of Anesthetists. Although the new organization still carried a local title, it drew members from several states and had a membership of 70 physicians in 1915.<sup>138</sup>

One of the most noteworthy figures in the struggle to professionalize anesthesiology was Francis Hoffer McMechan. McMechan had been a practicing anesthesiologist in Cincinnati until 1911, when he suffered a severe first attack of rheumatoid arthritis, which eventually left him confined to a wheelchair and forced his retirement from the operating room in 1915. McMechan had been in practice for only 15 years, but he had written 18 clinical articles in this short time. A prolific researcher and writer, McMechan did not permit his crippling disease to sideline his career. Instead of pursuing goals in clinical medicine, he applied his talents to establishing anesthesiology

societies.<sup>139</sup>

McMechan supported himself and his devoted wife through editing the *Quarterly Anesthesia Supplement* from 1914 until August 1926. He became editor of the first journal devoted to anesthesia, *Current Researches in Anesthesia and Analgesia*, the precursor of *Anesthesia and Analgesia*, the oldest journal of the specialty. As well as fostering the organization of the International Anesthesia Research Society (IARS) in 1925, McMechan and his wife, Laurette, became overseas ambassadors of American anesthesia. Because Laurette was French, it was understandable that McMechan combined his own ideas about anesthesiology with concepts from abroad.<sup>123</sup>

In 1926, McMechan held the Congress of Anesthetists in a joint conference with the Section on Anaesthetics of the British Medical Association. Subsequently, he traveled throughout Europe, giving lectures and networking with physicians in the field. On his final return to America, he was gravely ill and was confined to bed for 2 years. His hard work and constant travel paid dividends, however: In 1929, the IARS, which McMechan founded in 1922, had members not only from North America but also from several European countries, Japan, India, Argentina, and Brazil.<sup>119</sup> Most notable, McMechan influenced a young Australian anesthesiologist, Geoffry Kaye in a meeting in 1929 in Melbourne. Kaye became a devoted follower of McMechan, and in the following decades helped establish the Australian Society of Anesthesiologists, creating in the first floor of his home a meeting space, workshop, library, and museum.<sup>140</sup>

In the 1930s, McMechan expanded his mission from organizing anesthesiologists to promoting the academic aspects of the specialty. In 1931, work began on what would become the International College of Anesthetists. This body began to award fellowships in 1935. For the first time, physicians were recognized as specialists in anesthesiology. The certification qualifications were universal, and fellows were recognized as specialists in several countries. Although the criteria for certification were not strict, the college was a success in raising the standards of anesthesia practice in many nations.<sup>141</sup>

## **Academic Anesthesia**

Many Americans promoted the growth of organized anesthesiology. Ralph Waters and John Lundy, among others, participated in evolving organized anesthesia. Waters' greatest contribution to the specialty was raising its academic standards. After completing his internship in 1913, he entered medical practice in Sioux City, Iowa, where he gradually limited his practice to anesthesia. His personal experience and extensive reading were supplemented by the only postgraduate training available, a 1-month course

conducted in Ohio by E. I. McKesson. At that time, the custom of becoming a self-proclaimed specialist in medicine and surgery was not uncommon. Waters, who was frustrated by low standards and who would eventually have a great influence on establishing both anesthesia residency training and the formal examination process, recalled that before 1920, “The requirements for specialization in many Midwestern hospitals consisted of the possession of sufficient audacity to attempt a procedure and persuasive power adequate to gain the consent of the patient or his family.”<sup>142</sup>

In an effort to improve anesthetic care, Waters regularly corresponded with Dennis Jackson and other scientists. In 1925, he relocated to Kansas City with a goal of gaining an academic post at the University of Kansas, but the professor of surgery failed to support his proposal. The larger city did allow him to initiate his freestanding outpatient surgical facility, “The Downtown Surgical Clinic,” which featured one of the first postanesthetic recovery rooms.<sup>130</sup> In 1927, Erwin Schmidt, professor of surgery at the University of Wisconsin’s medical school, encouraged Dean Charles Bardeen to recruit Waters.

In accepting the first American academic position in anesthesia, Waters described four objectives that have been since adopted by many other academic departments. His goals were as follows: “(1) to provide the best possible service to patients of the institution, (2) to teach what is known of the principles of Anesthesiology to all candidates for their medical degree, (3) to help long-term graduate students not only to gain a fundamental knowledge of the subject and to master the art of administration, but also to learn as much as possible of the effective methods of teaching, (4) to accompany these efforts with the encouragement of as much cooperative investigation as is consistent with achieving the first objectives.”<sup>129</sup>

Waters’ personal and professional qualities impressed talented young men and women who sought residency posts in his department. He encouraged residents to initiate research interests in which they collaborated with two pharmacologists whom Waters had known before arriving in Wisconsin, Arthur Loevenhart and Chauncey Leake, as well as others with whom he became associated in Madison. Clinical concerns were also investigated. As an example, anesthesia records were coded onto punch cards to form a database that was used to analyze departmental activities. Morbidity and mortality meetings, now a requirement of all training programs, also originated in Madison. Members of the department and distinguished visitors from other centers attended these meetings. As a consequence of their critical reviews of the conduct of anesthesia, responsibility for an operative tragedy gradually passed from the patient to the physician. In more casual times, a practitioner could complain, “The patient died because he did not take a good anesthetic.” Alternatively, the death might be attributed to a mysterious force such as

“status lymphaticus,” of which Arthur Guedel, a master of sardonic humor, observed, “Certainly status lymphaticus is at times a great help to the anesthetist. When he has a fatality under anesthesia with no other cleansing explanation he is glad to recognize the condition as an entity.”<sup>129</sup>

In 1929, John Lundy at the Mayo Clinic organized the Anaesthetists’ Travel Club, whose members were leading American or Canadian teachers of anesthesia. Each year one member was the host for a group of 20 to 40 anesthesiologists who gathered for a program of informal discussions. There were demonstrations of promising innovations for the operating room and laboratory, which were all subjected to what is remembered as a “high-spirited, energetic, critical review.”<sup>127</sup> The Travel Club would be critical in the upcoming battle to form the American Board of Anesthesiology.

Even during the lean years of the Depression, international guests also visited Waters’ department. For Geoffrey Kaye of Australia, Torsten Gordh of Sweden, Robert Macintosh and Michael Nosworthy of England, and scores of others, Waters’ department was their “mecca of anesthesia.” Ralph Waters trained 60 residents during the 22 years he was the “Chief.” From 1937 onward, the alumni, who declared themselves the “Aqualumni” in his honor, returned annually for a professional and social reunion. Thirty-four Aqualumni took academic positions and, of these, 14 became chairpersons of departments of anesthesia. They maintained Waters’ professional principles and encouraged teaching careers for many of their own graduates.<sup>143</sup> His enduring legacy was once recognized by the dean who had recruited him in 1927, Charles Bardeen, who observed, “Ralph Waters was the first person the University hired to put people to sleep, but, instead, he awakened a world-wide interest in anesthesia.”<sup>144</sup>

## *Establishing a Society*

Waters and Lundy, along with Paul Wood of New York City, had an important role in establishing organized anesthesia and the definition of the specialty. In the heart of the Great Depression, these three physicians realized that anesthesiology needed to have a process to determine who was an anesthetic specialist with American Medical Association (AMA) backing. Using the New York Society of Anesthetists, of which Paul Wood was secretary-treasurer, a new class of members, “Fellows,” was created. The Fellows criteria followed established AMA guidelines for specialty certification. However, the AMA wanted a national organization to sponsor a specialty board. The New York Society of Anesthetists changed its name to the American Society of Anesthetists (ASA) in 1936. Combined with the American Society of Regional Anesthesia, whose president was Emery Rovenstein, the American Board of

Anesthesiology (ABA) was organized as a subordinate board to the American Board of Surgery in 1938. With McMechan's death in 1939, the AMA favored independence for the ABA, and in 1940, independence was granted.<sup>126,131</sup>

A few years later, the officers of the American Society of Anesthetists were challenged by Dr. M. J. Seifert, who wrote, "An Anesthetist is a technician and an Anesthesiologist is the specific authority on anesthesia and anesthetics. I cannot understand why you do not term yourselves the American Society of Anesthesiologists."<sup>133</sup> Ralph Waters was declared the first president of the newly named ASA in 1945. In that year, when World War II ended, 739 (37%) of 1977 ASA members were in the armed forces. In the same year, the ASA's first Distinguished Service Award was presented to Paul M. Wood for his tireless service to the specialty, one element of which can be examined today in the extensive archives preserved in the Society's Wood Library-Museum at ASA headquarters, Park Ridge, Illinois.<sup>144</sup>

## Conclusions

This overview of the development of anesthesiology is but a brief outline of the current roles in which anesthesiologists serve in hospitals, clinics, and laboratories. The operating room and obstetric delivery suite remain the central interest of most specialists. Aside from being the location where the techniques described in this chapter find regular application, service in these areas brings us into regular contact with new advances in pharmacology and bioengineering.

After surgery, patients are transported to the postanesthesia care unit or recovery room, an area that is now considered the anesthesiologist's "ward." Fifty years ago, patients were carried directly from the operating room to a surgical ward to be attended only by a junior nurse. That person lacked both the skills and the equipment to intervene when complications occurred. After the experiences of World War II taught the value of centralized care, physicians and nurses created recovery rooms, which were soon mandated for all major hospitals. By 1960, the evolution of critical care progressed through the use of mechanical ventilators. Patients who required many days of intensive medical and nursing management were cared for in a curtained corner of the recovery room. In time, curtains drawn about one or two beds **8** gave way to fixed partitions and the relocation of those areas to form intensive care units. The principles of resuscitative and supportive care established by anesthesiologists transformed critical care medicine.

The future of anesthesiology is a bright one. The safer drugs that once **9** revolutionized the care of patients undergoing surgery are constantly being improved. The role of the anesthesiologist continues to broaden as physicians with backgrounds in the specialty have developed clinics for

chronic pain control and centers for outpatient surgery and assumed a role as administrative heads of perioperative units in major medical centers. Anesthesia practice continues to increase in scope, both inside and outside the operating suite, such that anesthesiologists have increasingly become an integral part of the entire perioperative experience.

## Cost and Quality Issues

### Conclusion

#### KEY POINTS

- 1 Anesthesia trainees, and many postgraduates, tend to lack sufficient knowledge (with sometimes unfortunate results) about modes of practice or employment, financial matters of all types, and the forces that shape them, but contracting in particular. They must educate themselves and also seek expert advice and counsel to survive (and hopefully flourish) in today's exceedingly intricate medical practice milieu.
- 2 Concerns about the unsustainable increases in the cost of health care in the United States have led to a major new emphasis on value (get more and better results for less cost) and quality (avoid expensive complications, both improving care and reducing costs). New models of surgical care that significantly impact the practice of clinical anesthesia and payment for it have been proposed and are progressing toward implementation. Anesthesia professionals must understand and appreciate these models and their potential changes to the practice and scope of anesthesia.
- 3 There are several very helpful detailed information resources concerning practice and operating room (OR) management available from the American Society of Anesthesiologists and other sources. Factors influencing anesthesiology practice conditions are changing rapidly, and today's anesthesia professionals must be armed with detailed information about concepts (such as "accountable care organizations," "quality reporting," and "pay for performance") that did not exist just a few years ago.
- 4 Securing hospital privileges is far more than a bureaucratic annoyance and must be taken seriously by anesthesiologists.
- 5 Anesthesiology is the leading medical specialty in establishing and promulgating standards of practice that have significantly influenced practice in a positive manner.
- 6 The immediate response to a major adverse anesthesia event is critical to the eventual result. An extremely valuable protocol is available at [www.apsf.org](http://www.apsf.org), "Resource Center: Clinical Safety Tools."
- 7 Anesthesiologists must be involved, concerned, active participants and leaders in their institution and medical community in order to enhance their practice function and image.
- 8 Although the threatened impact of "managed care" largely failed to materialize regarding anesthesiology practice, other types of reorganization will matter. The impact of the "Great Recession" on the

- health-care system was substantial and will resonate into the future on budgets, availability of resources, and the economics of medical practice.
- 9 Anesthesiologists must participate in OR management in their facilities and should play a central leadership role. OR scheduling, staffing, utilization, and patient flow issues are complex, and anesthesiologists should work hard to both thoroughly understand and positively influence them.
  - 10 Anesthesiology personnel issues involve an elaborate balancing act that is subject to complex conflicting forces. Anesthesiology groups/departments should give these issues, as well as their constituent personnel, more attention and energy than has been done traditionally in the past.
  - 11 Attention to the many often-underemphasized details of infrastructure, organization, and administration can transform a merely endurable anesthesia practice into one that is safe, efficient, effective, productive, collegial, and even fun.

The structure and function of anesthesia practice are evolving rapidly in the United States in conjunction with the overhaul of the entire health-care system.

As the landscape shifts, many leaders of anesthesia professional organizations, along with some practitioners, have become engaged as activists attempting to influence the decisions that will ultimately affect the practice of anesthesiology.

This is in contrast to the past when anesthesia professionals as a group traditionally were little involved in the administration and management of many components of their practice beyond the strictly medical elements of applied physiology and pharmacology, pathophysiology, and therapeutics. This was perhaps somewhat understandable because anesthesia professionals traditionally spent most of their usually very long work hours in an OR. Business and regulatory matters were often left to the one or two members of the old-style traditional private practice group who were interested in or willing to deal with an outside-contractor billing agency, hospital administration, and so forth. In that era, very little formal teaching about **1** factors affecting anesthesiology or practice management occurred. Today, the Anesthesiology Residency Review Committee of the Accreditation Council on Graduate Medical Education requires that the didactic curricula of anesthesiology residencies include material on “practice management.” Training programs offer at least an introduction to such issues, but these may be insufficient to satisfactorily prepare professionals for the real infrastructure, administrative, business, and management challenges of the current practice of anesthesiology. All of the dramatic changes in

anesthesiology practice further emphasize the need for insight and understanding.

This chapter presents a wide variety of topics that, a generation ago, were not included in anesthesiology textbooks or residency program curricula. Outlined are several basic components of the background and administrative, organizational (including both practice arrangements and daily functioning of the OR), and, especially, financial aspects of anesthesiology practice in the complex modern environment. Although many issues are undergoing almost constant and sometimes unpredictable change, it is important to understand the basic vocabulary and principles in this dynamic universe. Lack of understanding of these issues may well leave anesthesia professionals at a disadvantage when attempting to maximize the efficiency and impact of their daily activities, to make critical decisions about practice arrangements, and to secure fair compensation in an increasingly complex health-care system featuring greater and greater competition for scarcer and scarcer resources.

## Changing Anesthesiology Practice

Pressure on the American health-care system to shift away from traditional models of organization and financing is significant. Concern about the fraction of the national gross domestic product devoted to health care has driven the dramatic emphasis on “value”<sup>1</sup> (get more and better results for less cost) in assessing and formulating the health-care “industry.” There is widespread perception that inefficient, poorly coordinated, redundant efforts that are divided into “silos” that do not communicate well lead to suboptimal health-care outcomes at both the individual and population levels. Many American leaders from a wide diversity of perspectives have called for stopping the growth of health-care costs as a start and then actually reducing them to a much more manageable level. Accordingly, there are multiple initiatives focused on improving both the process and outcomes of health care, usually involving the concepts of “quality” (improved outcome and decreasing expensive complications) and also “value.” This type of improvement is one of the main goals of the US Federal Government in promoting the creation of multidisciplinary integrated networked health-care delivery entities known as Accountable Care Organizations (ACOs), a central feature of the 2010 Patient Protection and Affordable Care Act (ACA).<sup>2-4</sup> The quality and value improvement initiatives in general often advocate standardization of care through adoption of evidence-based “best practices.” This incorporates the desire to very sharply reduce individual variability in practice among practitioners, which is sometimes viewed negatively by health-care practitioners, including anesthesia professionals, who traditionally have evolved their own practice habits and preferences based on their personal

education, training, and experience. It may yet be a long time before there are serious efforts to impose national protocols prescribing, for example, which muscle relaxant and which inhalation anesthetic will be used for all laparoscopic cholecystectomies. However, the current pervasive belief that the health-care system must be “smarter, better, safer, faster, and cheaper” with fixation on value cannot be ignored. Beyond going faster, reducing medication costs, placing fewer invasive monitors, and avoiding complications, value in clinical anesthesia practice can be difficult to define.<sup>5</sup> Overall, anesthesia professionals need to be aware of the involved forces 2 and proposals regarding patterns of practice so they can participate constructively to further the interests of their patients, and their practices, rather than allowing themselves to become passive casualties of the inevitable changes that are coming.

### *Bundled Payment Model*

One of the greatest changes affecting anesthesia practice is the concept that the organizations (and eventually individuals) who pay for health care are intending to alter radically the mechanism of rendering those payments. At its outset, this does not involve changing who pays (e.g., U.S. Federal Government, state government, private indemnity insurance companies, health plans, including health maintenance organizations, and cooperatives of many types), but rather how much is paid and to whom exactly. Whether this situation could be a harbinger of an attempt to totally revolutionize the U.S. health-care system by creating a universal-coverage single-payer (Federal Government administered) tax-supported system is unknown and impossible to predict.

A model program illustrates the concept of bundled payments for health care. The U.S. Federal Government agency, the Centers for Medicare and Medicaid Services (CMS), introduced in late 2015, with implementation in April 2016, their Comprehensive Care for Joint Replacement model. The stated aim is: “to support better and more efficient care for beneficiaries undergoing the most common inpatient surgeries for Medicare beneficiaries: hip and knee replacements.... This model tests bundled payment and quality measurement for an episode of care associated with hip and knee replacements to encourage hospitals, physicians, and postacute care providers to work together to improve the quality and coordination of care from the initial hospitalization through recovery.”<sup>6</sup> The initial roll-out is complex, with all involved professional providers continuing to bill and collect from Medicare as always—until the end of the plan year, when CMS will compare a grand total of payments for the episode of care (defined as including 90 days after hospital discharge) for all covered patients at a given hospital within the

test areas with calculated historic benchmarks. If the total cost is under the benchmark, CMS will pay the difference to the hospital to distribute as determined internally. If, on the other hand, the total paid by CMS exceeds the benchmark, the hospital will be required to refund (from what was already collected) the difference to CMS.<sup>7</sup> The source of the money refunded to CMS would be determined internally within the hospital, presumably involving collection (internal “clawback”) of money from the various providers, including private practice anesthesia professionals, who already collected their professional fee reimbursement from CMS. Overall, the idea of this system is a blueprint for the future. CMS is a critical revenue source for most hospitals and many anesthesiology practices. Further, many health plans/health systems structure their payments for services parallel to the CMS system payment amounts, and more and more indemnity insurance companies are doing so also.

The fundamental concept introduced by the CMS Comprehensive Care for Joint Replacement model is straightforward. The ultimate goal is to transition to a prospective “bundled payment model” from all purchasers of health care for all defined “episodes of care,” particularly including episodes involving surgical procedures. Thus, with implementation of such a system, when a patient has an operation, the involved physicians (primary care physician and/or internist, radiologist, surgeon, anesthesiologist, pathologist, consulting cardiologist, physical medicine/rehab physician, etc.) would not send any bills to the responsible payer for their professional services. Their traditional direct relationship with the payer will be ended. Rather, each of those physician specialists would be required to negotiate for a share of the bundled payment that comes directly to the hospital for the care episode for each patient the physician specialist cared for in any way. Obviously, this change would have a profound impact on what previously was the traditional fee-for-service private practice of anesthesiology, a model that still persists widely in the United States. Although the outcome of such a change is impossible to predict, popular speculation within organized anesthesiology in the United States is that income for involved anesthesia professionals would decrease, possibly significantly.

One important related consideration that is addressed in more detail below is the reference to traditional fee-for-service private practice of anesthesiology, usually involving organized groups of anesthesiologists (many employing Certified Registered Nurse Anesthetists [CRNAs]). These groups, in the past, included a large majority of the anesthesia professionals in the United States. The groups often had contracts to provide anesthesia care in private hospitals, but they were “independent practitioners,” who were not employed by the hospital. The groups billed to and collected from third-party payers (and sometimes the patients directly) for anesthesia services. In those

times, the small percentage of US anesthesia professionals who were employees of a health-care organization usually worked in university teaching hospitals or for integrated “clinics” or “systems” (e.g., Mayo, Cleveland, Kaiser, Inter-Mountain, Geisinger). Those employees received salaries, sometimes with additional variable (incentive) components. They authorized their employer to bill and collect for anesthesia professional services. Today, there has been a noteworthy trend of anesthesia professionals becoming full-time employees of private hospitals and health systems with prospectively negotiated salaries. They also authorize their employer to bill and collect for their services. These employees could reasonably expect that a transition to bundled payments directly to the hospital from third-party payers for episodes of surgical care would have less impact, if any, on their incomes—compared to anesthesia professionals still in independent traditional fee-for-service private practice situations.

Advancement of the concept of bundled payments for health care accelerated significantly in the United States after passage of the Patient Protection and Affordable Care Act in 2010, which stated “The Bundled Payments for Care Improvement (BPCI) initiative was developed by the Center for Medicare and Medicaid Innovation... [which]...was created by the Affordable Care Act to test innovative payment and service delivery models that have the potential to reduce...[CMS]...expenditures while preserving or enhancing the quality of care for beneficiaries.”<sup>8</sup> The BPCI initiative seeks voluntary participants, and, as of January 1, 2016, had contracted with hundreds each of hospitals, skilled nursing facilities, and physician group practices. There is an evolution through four stages or “models” of payment in the transition from traditional fee-for-service to the final model, in which “CMS makes a single, prospectively determined bundled payment to the hospital that encompasses all services furnished by the hospital, physicians, and other practitioners during the episode of care,” and the hospital divides and disburses the payment, as described above. This system can apply for any of 48 common “Medicare Service—Diagnosis Related Group” in-patient episodes, from “acute myocardial infarction” to “urinary tract infection,” including many surgical episodes. Although this program is an initiative, it is expanding. The Comprehensive Care for Joint Replacement model described above, which directly impacts anesthesia professionals, is functionally a subset of a much larger testing ground for the eventual across-the-board elimination of traditional fee-for-service reimbursement by all payers for health care and the adoption of a universal bundled payment model. Anesthesia professionals in the United States must be aware of this likely impending/eventual dramatic restructuring of how they receive compensation for their professional services to patients and how this could impact their financial future.

## Practice Model for Anesthesiologists: The Perioperative Surgical Home

Associated in some respects with the basic concept of bundling payments is a new practice model involving patient care provided by anesthesiologists and how it will be paid for. The Perioperative Surgical Home (PSH) model involves a controversial fundamental construct that is heavily promoted by the American Society of Anesthesiologists (ASA) and outlines a significantly expanded role for anesthesiologists in patient care.<sup>9</sup> In essence, the goal is a fully coordinated and integrated patient experience starting with the decision for a planned surgery and continuing through the preoperative, intraoperative, postoperative, and postdischarge phases of the surgical experience. The apparent intention as interpreted by many is that anesthesiologists will be the perioperative physicians who will essentially supervise the entire process and who will execute the coordination and integration of the care, for which they will be additionally compensated financially for this new role and responsibility by the applicable payer.

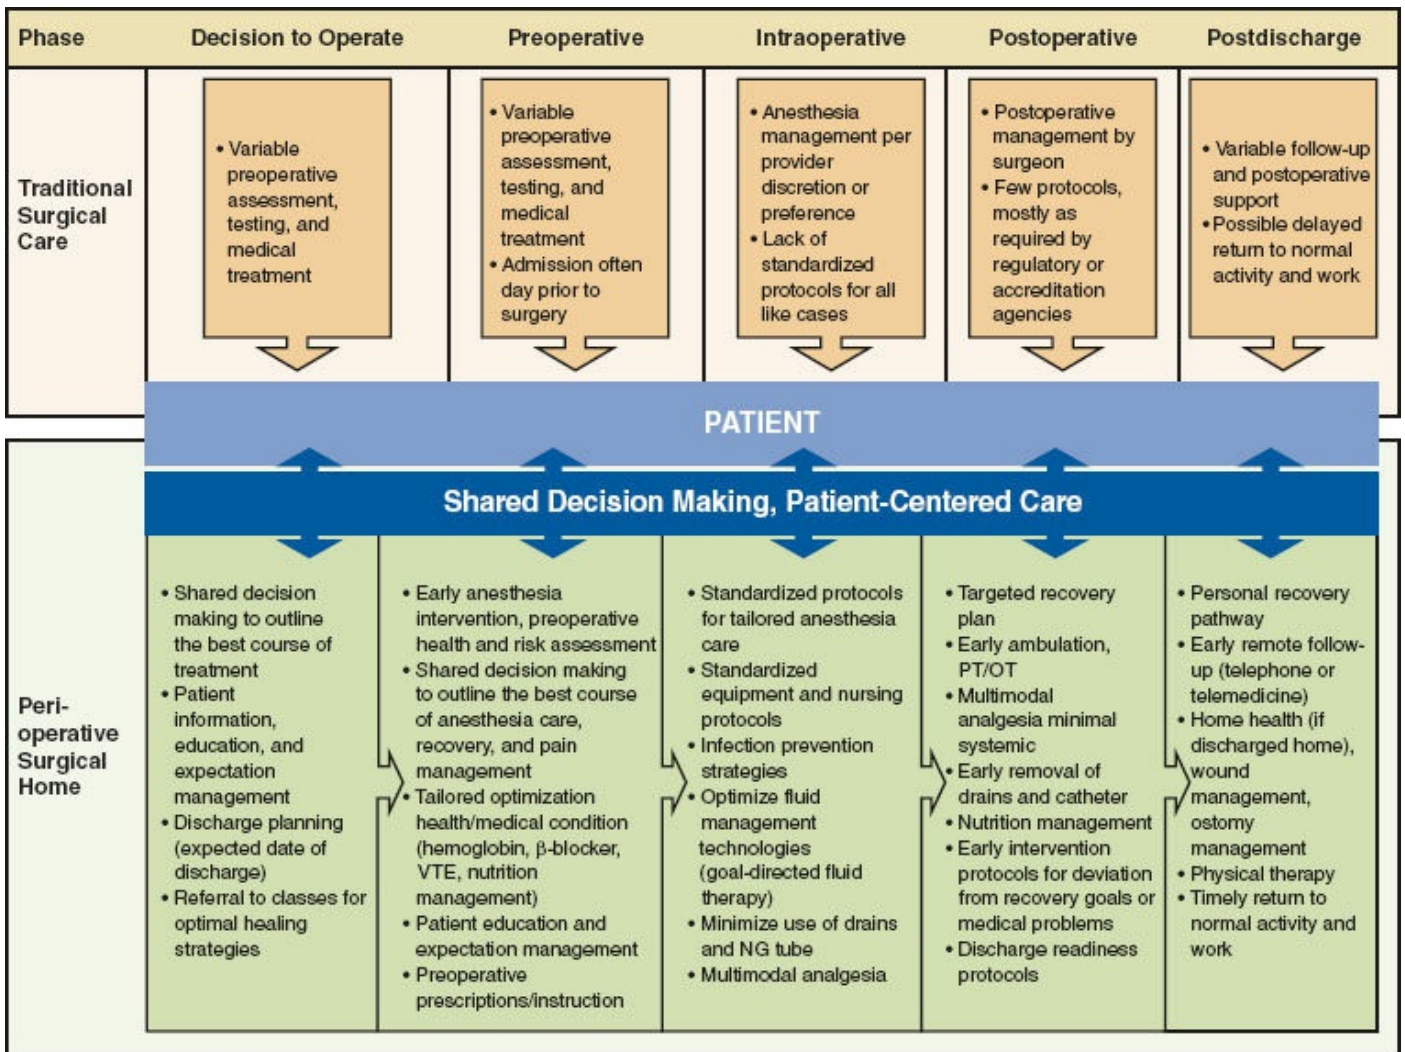

The ASA committee advancing this new approach states: “The PSH model is a patient-centered and physician-led multidisciplinary and team-based system of coordinated care that guides the patient throughout the entire surgical experience, from decision for the need for surgery to discharge from a medical facility and beyond. The goal is to create a better patient experience and make surgical care safer, efficient, and aligned in order to promote a better medical outcome at a lower cost.”<sup>10</sup> An analysis of the PSH proposed concept<sup>11</sup> focused on a smooth continuum of care that reduces variability (imposes standardization) as a way to reduce errors and complications, thus improving care and decreasing cost. This report stated, “This can be achieved by having one team headed by anesthesiologists, to manage all aspects of this continuum from the time that the patient and the surgeon make the decision for surgery until 30 days after discharge.... [Throughout the process,] patients will be informed, educated, and involved in the decision making and treatment planning . . . By applying these concepts, anesthesiologists have a unique opportunity to improve outcomes, decrease length of stay and other metrics, and improve patient satisfaction.” The potential for decreased costs for surgical care<sup>12</sup> has been promoted as a very positive feature that would increase the value of anesthesiologists and improve the stability and security of their position in the health-care arena into the future.

The elements of the PSH model involve new roles and responsibilities for anesthesiologists. Proponents maintain that anesthesiologists are in the best position to have an overview and maximum understanding of the entire perioperative interval and its process (Fig. 2-1). Coordination and direction

by team-leading anesthesiologists of the patient's involved primary care physician, internist, surgeon, and specialist (cardiologist, endocrinologist, etc.) would decrease the number steps in the sequence, preventing duplication and waste of resources. Verification of nutrition status and optimization of chronic medications (for hypertension, diabetes, COPD, etc.) would increase the likelihood of smooth transit through surgery to a good outcome. Then, indicated preoperative consults would be ordered by the team leader to facilitate "prehabilitation" (e.g., pulmonary consultation and treatment, including smoking cessation) to optimize further the patient's condition prior to surgery, facilitating planned faster recovery and earlier discharge and also decreasing the risk of (expensive) complications. Prescription of standardized "best-practice" protocols for intraoperative anesthetic management, including limiting benzodiazepines, transfusions, excessive fluid administration, and unnecessary invasive monitors would not only enhance speedy recovery but also decrease OR anesthesia costs. Multimodal pain therapy postoperatively with minimal narcotics has the same goals. Aggressive intervention to promote rapid recovery and discharge would be directed by the team-leading anesthesiologists who would coordinate input and plans with the surgeon, hospitalist, primary care physician, involved specialists, and medical consultants, as well as rehab planners, social services, and the patient's family, thus preventing confusing and sometimes conflicting orders from the various potential sources. Discharge planning would specifically focus on medication reconciliation and assuring medication compliance, arranging needed follow-up appointments and treatments, and generally doing everything possible to prevent unplanned readmissions.

Predictably, beyond consideration of the substantial administrative, interprofessional, and financial challenges of actually implementing such a dramatically expanded practice model, some anesthesiologists apparently do not embrace the PSH concept. Reservations expressed include the concern that currently practicing anesthesiologists have not been trained and do not have the experience to assume some of the responsibilities and roles of primary care physicians, internists, hospitalists, or specialist consultants. Countering that point is the suggestion that larger anesthesiology groups would hire new members who are able and willing to perform those functions. Further, there is concern about strain in relationships between anesthesiologists and surgeons (and hospitalists), particularly if payments to them would be reduced, with the subtracted amounts going to the anesthesia physician or group supervising the perioperative process. Likewise, a reciprocal concern is that shifting of payments would not ultimately occur as planned/promised and that the supervising/coordinating anesthesiologists would be doing much more work for little or no increase in financial compensation. Finally, some anesthesiologists simply do not want to expand their scope of practice in this

manner, stating that they are content to continue to practice as they envisioned when they became anesthesiologists: caring for patients at the time of their surgery or procedures. The proposals to implement PSH programs generated much scrutiny, analysis, and discussion that remain ongoing. There appears to be a consensus that essentially, although some evolution of the profession has occurred, the current practice model in anesthesiology is not sustainable and changes must be made. The concern is, exactly what changes and how?<sup>13-15</sup> Arguments included the contention that attractive as the overall idea may be, it will only succeed with the enthusiastic cooperation of surgeons and hospital administrators.<sup>16</sup> Intense, thoughtful consideration of a great many aspects of the PSH model is replete in the literature cited here as well as in many more publications. Successful movement in that direction appears dependent at least in part on wider and more education of future anesthesiologists (longer residency) who would practice in this model. A proposal to add “perioperative medicine” to the specialty name “anesthesiology” included an extensive list of new competencies—personal, clinical, administrative, and managerial—that will be required of anesthesiologists to practice fully in the PHS model.<sup>17</sup> All authors addressing the PSH concept emphasize how critically important the issues are to the future of anesthesia practice. The evolution will be complex and contentious. How it will have an impact and where it may lead the profession remain to be determined.

**Figure 2-1** Elements of the perioperative surgical home model. PT, physical therapy; OT, occupational therapy; VTE, venous thromboembolism; NG, nasogastric. (Reproduced with permission from Kain ZN, Vakharia S, Garson L, et al. The perioperative surgical home as a future perioperative practice model. *Anesth Analg*. 2014;118:1126–1130. ### **Practice Model Involving Anesthesiologists: The Service Line**

Another approach to organizing surgical care can be considered a hybrid of the bundled payment model and the PSH model. Implementation of a “service line” (or “all-inclusive package” or “clinical pathway”) model for selected elective major surgical procedures has been successful at several large health-care institutions across the United States. Anesthesiologists participate as integral caregivers within the model, but it is usually organized and administered by financial officers of a hospital or medical center. The American Hospital Association promotes this organizational approach.<sup>18</sup> The concept is straightforward. The health-care organization delivers complete comprehensive care for one patient having a specified procedure, such as a total hip replacement, a colectomy, or bariatric surgery, for one pre-established package price. This price is usually somewhat lower than the

average cumulative total of the fee-for-service charges (facility, materials, and professional) customarily collected from third-party payers for that particular procedure. The established limited cost (which likely includes covering any necessary extended inpatient stay or complications within, e.g., 30 days postoperatively) is very attractive to third-party payers, who have an incentive to encourage or direct their patients to ward that health-care facility. There is no separate fee-for-service billing and no itemized bookkeeping by departments or practices. The facility collects the global fee and distributes a component of it to the various professional members of the integrated team, who would have, in the traditional model, submitted fee-for-service bills to the third-party payer.

Mutual benefits accrue with this model. The third-party payers benefit by possibly saving some money on each patient, but mostly by being able to predict their payments and budget accordingly. This gives them an advantage in pricing and marketing their insurance plans, which they hope will translate into more business. The health-care organization expects to be attractive to the payers and, thus, have more patients referred from the involved payers. Then, classically, the medical facility invests great effort into streamlining the care of patients in a given service line. This includes increased efficiency through coordination of efforts and services along with elimination of duplication and waste—in many of the same ways outlined earlier in the other models. Particular emphasis is on minimizing the risk of complications (and the associated expense) and reducing inpatient length of stay, which can dramatically reduce cost of care to the facility. Standardization of care by interdisciplinary cross-department teams with consistent members, especially in the OR, via detailed protocols involves application of techniques that are proven in that facility to be most efficient. The concept of “standardization” of practice via “best practice” protocols remains controversial. Some anesthesia professionals resist the idea as an infringement on their personal habits and preferences developed through their education, training, and experience. However, research evidence has suggested on some points that standardization of care can improve patient outcome.<sup>19</sup> In the application of the model, successful protocols and patterns of care are replicated for each patient passing through a given service line. The team therefore gets more and more experienced and facile with moving the patients through the line. Patient satisfaction should increase because, functionally, they are moving through a coordinated “well-oiled machine” in which everyone is very capable and experienced in their roles. Costs within the facility per patient should decrease, but revenue remains at the package price, affording the facility increased margins.

Often a significant element of the clinical pathway approach in a surgical service line is enhanced recovery after surgery (ERAS), which specifically

organizes postoperative activities to limit interventions, strictly minimize potential complications, and accelerate discharge. First popularized in Europe and England,<sup>20</sup> ERAS included specific emphasis on nutrition and metabolic homeostasis.<sup>21</sup> ERAS has been widely promoted as improving both efficiency and clinical outcomes.<sup>22</sup> Application of ERAS principles in the United States has been shown to reduce length of stay after colorectal surgery, particularly by emphasizing early mobilization and feeding.<sup>23</sup> Creative and minimalistic pain management regimens, orchestrated by the team's anesthesiologists, are often a central feature of ERAS. Likewise, surgical site infections after colorectal surgery (and their costs) were significantly reduced with application of a service line model of practice.<sup>24</sup>

The service line model, specifically as practiced by one large regional health system, has received attention and praise in the lay media.<sup>25</sup> Independent of their particular practice settings, anesthesiologists can reasonably expect continued significant growth of the service line model in US surgical care now and in the near future. They should be prepared to contribute constructively, as should the involved surgeons. Resisting and holding out for exclusive preservation of the traditional itemized fee-for-service model may well lead to situations in which such uncooperative practitioners would be uncomfortable with attempting to continue practice in that facility.

### *Large Group Practices: Anesthesia and Multispecialty*

A noteworthy trend in US anesthesia practice that interlocks with all the evolving practice models described previously is the dramatic proliferation of large (and in some cases, very large) group practices. This started initially as a burgeoning business model much as has been the case with other industries, such as the consolidation by merger of large US commercial airlines or pharmacy chains. In health care, there has been and is a widespread well-known movement in which health systems or large hospitals, usually in urban areas, purchase, merge with, or absorb smaller previously free-standing community hospitals in the surrounding area. Note that for actual anesthesia practice, however, and particularly "scope of practice" in its traditional sense, there are many spill-over implications for the day-to-day administration of individual anesthetics as well as for organizational, quality improvement, and research aspects of anesthesia care.

The business case for large urban hospitals taking over outlying community hospitals and enfolding their medical staffs into a centralized network is clear. The "core," "base," or "home" institution expands its "book of business" both by adding volume to its primary care role and by guaranteeing referrals for some secondary and most tertiary care to the core

facility and its specialist medical staff. Economies of expanded scale (elimination of duplication, price bargaining advantage with suppliers, etc.) are similar to many other industries. Further, in the ACA, the significant financial incentives for implementation and use of electronic health records (EHRs) are perceived as functionally making these cross-platform integrated health information technology systems *mandatory*. Many smaller hospitals simply are unable to afford the cost of installing and maintaining their own EHR system, thus increasing the financial advantage of merging into a networked health system. Although details may vary from place to place, when a community hospital in which the hospital-based specialists (anesthesia, radiology, pathology, and emergency medicine) are private practitioners who are not hospital employees merges into a networked system, the practice arrangements for these specialists usually are re-evaluated. When such a community hospital has an exclusive contract with a private-practice anesthesia group, there are various potential eventualities. The group could attempt to maintain the same contract with the administration of the health system, or, alternatively, the group could dissolve and become direct employees of the health system. However, when the core facility has its contract with an anesthesia practice group, it is most likely that the community hospital anesthesia practice merges with the larger group based at the “home” hospital. This concept was one original impetus for the start of what evolved into some of the very large regional and national anesthesia practice groups.

As several of the consolidated anesthesia practice groups grew through merger after merger, administrative and financial support staffs evolved that accomplished significant economies of scale and organization. They became, in essence, successful startup businesses. It became clear to the physician and nonphysician leaders of these organizations that such a group could approach additional hospitals and ambulatory surgery centers that were not part of the original health system network and offer exclusive contracted anesthesia services to those facilities, wherever they might be located. The large group would seek to absorb or displace the anesthesia practice group that may have had an exclusive contract at a community hospital for many years. Because of the economies of scale (especially human resources and financial management), the large group frequently tries to offer a “better deal” to the community hospital than the local group, whether the terms involve more and more flexible staffing (more accommodation of surgeons’ desires), decreased salary subsidy from the hospital, or other relevant considerations. Although the potential for conflict is clear, the large group can often offer to employ most or all of the existing members of the local group, whose work location and condition are then little affected, but they are relieved of all the administrative and overhead burdens of running a practice. Individual

compensation arrangements change, and some anesthesiologists are willing to trade unpredictable income (albeit with upside potential for the partners) for a predictable guaranteed income that often comes with more predictable work hours. Likewise, the services (including educational), support, and benefits associated with being an employee along with hundreds or even thousands of other anesthesia professionals can be improvements over what existed with the small group. In the (relatively rare) cases in which the local small anesthesia group resists and refuses to cooperate, but the hospital awards an exclusive contract to the large regional or national group, that large organization moves in a new complement of employed anesthesia professionals, which may be mostly temporary personnel until permanent replacements from the large group's pool of employees relocate to the hospital's community.

Beyond the practice details described earlier, the large anesthesia groups can marshal special new resources. They can have dedicated directors devoted to quality improvement and patient safety efforts and projects. They can partner with an academic institution and then organize and offer their own internal continuing medical education (CME). Further, members can evolve or even be specifically hired to conduct clinical, epidemiologic, and organizational research using the sophisticated database that is a key component to the success of the large groups. Such research efforts can support the development of genuinely evidence-based best practice standardized protocols that are central to the PSH and service line practice models. Research results can be submitted for publication and presented at state, regional, or national anesthesia professional meetings, highlighting the thesis that the large anesthesia groups are not just business entities but also contributors to the development of the profession in general.

A variant on the concept of the large anesthesia group involves something of a similar construct, but as a component of a large multispecialty group that is part of a health system.<sup>26</sup> These may be regional networks (e.g., Kaiser Permanente or Inter-Mountain) or "clinics" (e.g., Mayo or Cleveland) with base locations and satellites. Anesthesia professionals, full-time employees like all other professional staff, are members of a department within those organizations. Some of the features and benefits of the large anesthesia groups exist, but the concept of growth by merger with or absorption of smaller entities applies to entire hospitals or health-care organizations. Integration of those anesthesiology departments into the whole of the multispecialty group and health system can have many of the features of the service-line approach to delivery of health care. Further, the resources accessible within these multispecialty-based health systems can be vast and can thus support major research, population health, and outreach initiatives, potentially affording anesthesia professionals new opportunities for

engagement and impact not otherwise available.

As is the case with all aspects of change in anesthesiology practice, evolution continues regarding groups. The ASA<sup>27</sup> is making a concerted effort to engage and involve the large groups, even creating a standing Committee on Large Group Practice that emphasizes educational opportunities, advocacy, networking, participation in the Anesthesia Quality Institute and the Qualified Clinical Data Registry, practitioner surveys, and enhancing practice management. Overall, it seems unlikely, given the realities of health-care financing, organization, and politics now in the United States, that events would ever support dissolution of the large group practices and return to more locally based exclusive contract small anesthesia groups. Large groups, in all likelihood, will continue to proliferate and grow.

## *Further Issues*

### **Payment Machinations**

For the past several decades, great attention has been focused on payments from the US federal Medicare program for physician services in the current fee-for-service structure. Although fee-for-service appears to be slated for eventual phase-out, as outlined above, concern persists now because elements of fee-for-service payment from Medicare quite likely will persist at least through 2019. Interest is high because in some practices a substantial fraction of income is derived from Medicare. Moreover, a greater issue is that many private insurance companies consider Medicare payment rates when determining relative value of various services performed by practitioners. Accordingly, the vast majority of the US health-care establishment was pleased in 2015 when the US Congress repealed the so-called sustainable growth rate (SGR) formula component of Medicare payments that led to annual concerns that Medicare payments for professional services would be drastically reduced and annual drama with last-minute passage by Congress of an act to prevent that. However, the law that fixed the SGR problem known as the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA) introduced new issues of concern. MACRA is cited by CMS as, “Making a new framework for rewarding health care providers for giving better care not just more care.”<sup>28</sup> It is intended to be a bridge connecting quality to fee-for-service payment and employing a “value trajectory” into population health that eventually totally changes how practitioners are paid by Medicare. MACRA specifies modest annual automatic reductions in Medicare payments to practitioners until 2019 when a new Medicare payment model is scheduled to be implemented. The new system is very complex. It involves practitioners making a choice between two models that will determine their payment. First

is the Merit Based Incentive Payment System, which retains some elements of fee-for-service but creates a functional zero-sum game. Practitioners who chose this method of determining their payment will be graded on four elements (Physician Quality Reporting System, Value Based Modifiers, Meaningful Use of EHRs, and Clinical Practice Improvement Activities). Practices whose scores exceed the median benchmark will receive payment bonuses, whereas, reciprocally, practices that underperform the benchmark will be penalized an equal amount. The other method of determining Medicare payments will be the “Alternative Payment Models,”<sup>29</sup> the details of which are being established, but that likely will significantly reward practice models configured along the lines of bundled payments, the PSH, and the service line model. The ASA leadership has expressed concern about how all these changes will impact the earnings of anesthesiologists, but at the same time is preparing its members for the transition to the new Medicare payment system mandated by CMS.<sup>30</sup>

### **APRN Consensus Model Implications**

Because CRNAs in the United States are included in the large classification “advanced practice registered nurses” (APRN), evolving policies and regulations regarding scope of practice for APRNs are relevant to anesthesia professional practice. In 2008, the APRN Consensus Work Group and the National Council of State Boards of Nursing APRN Advisory Committee published an extensive document titled “Consensus Model for APRN Regulation: Licensure, Accreditation, Certification, and Education,”<sup>31</sup> that had been endorsed by 48 nursing professional organizations. It outlines a regulatory model that, in essence, eventually expands the scope of practice of APRNs to fully independent practice with full prescribing authority. One of the main themes is consistency throughout the United States because, often, regulations governing APRNs vary widely from state to state. Implementation of this model has been championed by the American Nurses Credentialing Center,<sup>32,33</sup> which is a subsidiary of the American Nurses Association that conducts the certifying process, including examinations, for APRNs (analogous in a sense to the American Board of Anesthesiology [ABA]). The main activities, which are ongoing and accelerating, are to promote and secure legislation in each state that adopts the model for APRN certification, accreditation, and licensure. The National Council of State Boards of Nursing maintains an online national map and scoring system that shows the implementation status for the APRN Consensus Model for each state, thus indicating “progress toward uniformity.”<sup>34</sup> One of the stated main goals of this national effort is to increase access to primary care, particularly in less densely populated areas of the United States through allowing APRNs to

practice to the “full extent of their education and training.” Emphasis is in the areas of family practice, pediatrics, internal medicine, geriatrics, and women’s health. In addition, subsumed within the same proposed policies and regulations are Certified Nurse Midwives and CRNAs. The American Association of Nurse Anesthetists (AANA) was one of the participating organizations in the creation and endorsement of the APRN Consensus Model. The relationship of CRNAs and physician anesthesiologists in the United States is long and complex—and beyond the scope of this chapter. The AANA advocates for increased independent practice for CRNAs and notes that as of the end of 2012, 17 states in the United States had adopted the so-called opt-out rule that removes the federal regulatory requirement for physician supervision of CNRAs. This “opt-out” has traditionally been opposed by the leadership of organized anesthesiologists, as was also consideration of a similar change within the Veterans’ Administration health system. Although naturally concerned about the practice incomes and financial well-being of their members, both professional organizations, the AANA and the ASA, maintain that their positions regarding anesthesia practice characteristics in general and specifically of CRNAs are based on concerns about quality of care, patient safety, and patient outcomes. It seems virtually certain that extensive considerations of multiple aspects of these issues as they relate to anesthesia practice will continue into the foreseeable future.

## **Administrative Components of Anesthesiology Practice**

### ***Operational and Information Resources***

Outlined in this chapter is an overview summary intended as an **3** introduction to organization, administration, and practice management in anesthesiology. Further, the ASA, the professional association for physician anesthesiologists in the United States, for many years has made available to its members extensive resource material regarding practice in general and specific arrangements for its execution. Citation and availability of this material can be found on the ASA website, [www.asahq.org](http://www.asahq.org). Elements are updated periodically by the ASA through its physician officers, committees, task forces, administrative and support staff, and its various offices. Although many of the documents and even the advice given in response to members’ requests for help contain broad-brush generalities that must be interpreted in each individual practice situation, these nonetheless stand as a foundation on which many anesthesiology practices traditionally have been based. Prospective familiarity with the principles outlined in the ASA material likely could help avoid some of the problems leading to calls for help. Also, each spring, the ASA offers a Practice Management Conference at which both

reviews and current updates of a wide variety of relevant administrative and financial topics are covered.

## Background

The ASA<sup>35</sup> publishes the *Manual for Anesthesia Department Organization and Management*, an outline of a great many factors relevant to anesthesia practice and a large number of links to related ASA documents, such as information on physician responsibilities for medical care and on medical–administrative organization and responsibilities; the *ASA Guidelines for the Ethical Practice of Anesthesiology* (which incorporate sections on the principles of medical ethics); the definition of medical direction of nonphysician personnel (including the specific statement that an anesthesiologist engaged in medical direction should not personally be administering another anesthetic); the anesthesiologist’s relationship to patients and other physicians; the anesthesiologist’s duties, responsibilities, and relationship to the hospital; the anesthesiologist’s relationship to nurse anesthetists and other nonphysician personnel; and quality improvement and data reporting resources. Further, beyond summaries such as this textbook chapter, reference to the great body of material created and presented by the ASA is an excellent starting point to help young anesthesia professionals during training prepare for the increasing rigors of starting and managing a career in practice. On the ASA website, within the “For Members” area, the “Practice Management” section is functionally a gold mine. It includes extensive information on the organization, administration, and business of anesthesia practice with reference to an extensive catalog of documents, webinars, and podcasts. Sections include the ASA Qualified Clinical Data Registry (QCDR), the National Anesthesia Clinical Outcomes Registry (NACOR), and the Physician Quality Reporting System (PQRS) regarding quality and data reporting. Also included are practice management educational resources; timely topics in payment and practice management; employment agreements; coding and billing; templates that satisfy the CMS “interpretative guidelines;” practice parameters; Quality Management and Departmental Administrative (QMDA) toolkit; Recovery Audit Contractor (RAC); and a bibliography of payment and practice management articles. Likewise, there is a great deal of other information on the ASA website concerning the most recent governmental regulations, rulings, and billing codes. Further, the *ASA Monitor* newsletter (mailed to members and on the ASA website) contains many articles on related current administrative, quality and regulatory, organizational, and financial developments.

In addition to the ASA and the AANA, the anesthesiology subspecialty societies and interest groups have web locations, as do most journals.

Particularly, the website of the Anesthesia Patient Safety Foundation, [www.apsf.org](http://www.apsf.org), has been cited as especially useful in promoting safe clinical practice. Electronic bulletin boards allow anesthesiology practitioners from around the world to exchange ideas in real time on diverse topics, both medical and administrative. One of the original sites that remains available is “GASNet” (<http://anestit.unipa.it/homepage.html>) and a web search (“anesthesiology + bulletin board”) reveals a great number of sites that contain a variety of discussions about all manner of anesthesiology-related topics, including practice organization, administration, finance, and management. In addition, references to the entirety of the medical literature are readily accessible to any practitioner (such as by starting with [www.nlm.nih.gov](http://www.nlm.nih.gov) to access Medline). A modern anesthesiology practice cannot reasonably exist without readily available high-speed Internet connections.

### *The Credentialing Process and Clinical Privileges*

The system of credentialing a health-care professional and granting 4 clinical privileges in a health-care facility is motivated by a fundamental assumption that appropriate education, training, and experience, along with the absence of excessive numbers of bad patient outcomes, increase the chances that the individual will deliver acceptable-quality care. The process of credentialing health-care professionals has been the focus of considerable public attention (particularly in the mass media), in part the result of very rare incidents of untrained persons (impostors) infiltrating the health-care system and sometimes harming patients. The more common situation, however, involves health professionals who exaggerate past experience and credentials or fail to disclose adverse past experiences. In the past, there was justified publicity concerning physicians who lost their licenses sequentially in several states and simply moved on each time to start practice elsewhere (which should be much, much more difficult today).

Intense public and political pressure has been brought to bear on various lawmaking bodies, regulatory and licensing agencies, and health-care institution administrations to discover and purge both (1) fraudulent, criminal, and deviant health-care providers and (2) incompetent or simply poor-quality practitioners whose histories show sufficient poor patient outcomes to attract attention, usually through malpractice suits. Identifying and avoiding or correcting an incompetent practitioner is the goal. Verification of appropriate education, training, and experience on the part of a candidate for a clinical anesthesia position assumes special importance in light of the legal doctrine of *vicarious liability*, which can be described as follows: if an individual, group, or institution hires an anesthesia professional

or even simply approves of that person (e.g., by granting clinical privileges through a hospital medical staff), those involved in the decision may later be held liable in the courts, along with the individual, for the individual's actions. This would be especially true if it were later discovered that the offending practitioner's past adverse outcomes had not been adequately investigated during the credentialing process.

Out of these various longstanding concerns has arisen the sometimes cumbersome process of obtaining state licenses to practice and obtaining hospital privileges. The stringent credentialing process for health-care practice is intended both to protect patients and to safeguard the integrity of the profession. Central credentialing systems have been developed, including those affiliated with the American Medical Association, American Osteopathic Association, and, particularly, the Federation Credentials Verification Service of the Federation of State Medical Boards. These systems verify a physician's basic credentials (e.g., identity, citizenship or immigration status, medical education, postgraduate training, licensure examination history, prior licenses, and board actions) once, and then thereafter can certify the validity of these credentials to a state licensing board or medical facility. A few states do not yet accept this verification and most states seek specific supplemental information.

There are checklists of the requirements for the granting of medical staff privileges by hospitals (see the American Hospital Association Resource Center, [www.aha.org/research/rc/index.shtml](http://www.aha.org/research/rc/index.shtml)). In addition, the National Practitioner Data Bank and reporting system administered by the US government contains a great deal of information. This data bank is a central repository of licensing and credentials information about physicians. Virtually all adverse situations involving a physician—particularly, malpractice litigation and the revocation, suspension, or limitation of that physician's license to practice medicine or ability to hold hospital privileges—must be reported (via the particular state board of medical registration/licensure) to the National Practitioner Data Bank. It is a statutory requirement that all applications for hospital staff privileges be cross-checked against this national data bank. The potential medicolegal liability on the part of a facility's medical staff, and the anesthesiology group in particular, for failing to do so is significant. The data bank, however, is not a complete substitute for direct documentation and background checking. Often, practitioners reach private negotiated solutions following quality-driven medical staff problems, thereby avoiding the mandatory public reporting. In such cases, a practitioner in question may be given the option to resign medical staff privileges and avoid data bank reporting rather than undergo full involuntary privilege revocation (although most license and privilege applications contain a question specifically about this).

## Documentation

The documentation for the credentialing process for each anesthesia practitioner must be complete. Privileges to administer anesthesia must be officially granted and delineated in writing. This can be straightforward or it can be more complex to accommodate institutional needs to identify practitioners specially qualified to practice in designated anesthesia subspecialty areas such as cardiac, infant/pediatric, obstetric, intensive care, or invasive pain management. Specific documentation of the process of granting or renewing clinical privileges is required and, unlike some other administrative records, the documentation likely is protected as confidential peer review information. Any questions about complex sensitive issues such as this should be referred to an experienced attorney familiar with applicable federal and state law. Verification of an applicant's credentials and experience is mandatory. Because of another type of legal case involving references, some examples of which have been highly publicized, medical practitioners may be hesitant to give an honest evaluation (or any evaluation at all) of individuals known to them who are seeking a professional position elsewhere. Obviously, someone writing a reference for a current or former coworker should be honest. Sticking to clearly documentable facts is advisable. Stating a fact that is in the public record (such as a malpractice case lost at trial) should not justify an objection from the subject of the reference. Whether such potentially "negative" facts can be omitted by a reference writer is complex. Including positive opinions and enthusiastic recommendations, of course, is no problem. Some fear that including facts that may be perceived as negative (e.g., the lost malpractice case or personal problems such as a history of treatment for substance abuse) and/or negative opinions will provoke a retaliatory lawsuit (such as for libel, defamation of character, or loss of livelihood) from the subject of the reference. Further, however, there have been cases of the facility doing the hiring suing reference writers for failing to mention (perceived as concealing) negative information about an applicant who later was charged with substandard practice. Because of the complexities and even apparent contradictions, many reference writers in these questionable situations confine their written material to brief, simple facts such as dates employed and position held. As always, questions about complex sensitive issues such as this should be referred to an experienced attorney familiar with applicable federal and state law. Further, one relevant strategy for investigating an anesthesia professional applying to a new institution traditionally has been seeking informal but important opinions from nurses in the OR where the applicant works or has worked. A call to the OR head nurse can often identify nurses who have worked with the applicant. Then, when speaking to them, simply asking whether they would be comfortable having the applicant care for a beloved member of his or her family can itself elicit

valuable information and initiate a helpful conversation.

Because there should be no hesitation for a reference giver to include positive facts and opinions, receipt of a reference that includes nothing more than dates worked and position held can in some cases be a suggestion that there may be more to the story (although some entities have adopted such a policy in *all* cases simply to eliminate any value judgments as to what is positive or negative information). Receipt of such a “dates/position only” reference about a person applying for a position should usually provoke a telephone call to the writer. A telephone call to the writer is likely advisable in all cases, independent of whatever the written reference contains. Frequently, pertinent questions over the telephone can elicit more candid information. In rare instances, there may be dishonesty through omission by the reference giver even at this level. This may involve an applicant who an individual, a department or group, or an institution would like to see leave.

In all cases, new personnel in an anesthesia practice environment must be given a thorough and documented orientation and checkout. Policy, procedures, and equipment may be unfamiliar to even the most thoroughly trained, experienced, and safe practitioner. This may occasionally seem tedious, but it is a sound and critically important safety policy. Being in the midst of a crisis situation caused by unfamiliarity with a new setting is not the optimal orientation session.

After the initial granting of clinical privileges to practice anesthesia, anesthesia professionals must periodically renew their privileges within the institution or facility (e.g., annually or every other year). There are moral, ethical, and societal obligations on the part of the privilege-granting entity to take this process seriously. State licensing bodies often become aware of problems with health professionals very late in the evolution of any difficulties. An anesthesia professional’s peers in the hospital or facility are much more likely to notice troublesome developments as they first appear. However, privilege renewals are often essentially automatic and receive little of the necessary attention. Judicious checking of renewal applications and awareness of relevant peer review information are absolutely essential. The anesthesia professionals or administrators responsible for evaluating staff members and reviewing their practices and privileges may be justifiably concerned about retaliatory legal action by a staff member who is censured or denied privilege renewal. Accordingly, such evaluating groups must be thoroughly objective (totally eliminating any hint of political or financial motives) and must have documentation that the staff person in question is in fact practicing below the standard of care. Court decisions have found liability by a hospital, its medical staff, or both, when the incompetence of a staff member was known, or should have been known, and was not acted upon. Again, questions about complex sensitive issues such as this should be referred

to an experienced attorney familiar with applicable federal and state law.

A major issue in the granting of clinical privileges, especially in procedure-oriented specialties such as anesthesiology, is whether it is reasonable to continue the once common practice of “blanket” privileges. This process in effect authorizes the practitioner to attempt any treatment or procedure normally considered within the purview of the applicant’s medical specialty. These considerations may have profound political and economic implications within medicine, such as which type of surgeon should be doing carotid endarterectomies or lumbar discectomies. More important, however, is whether the practitioner being evaluated is qualified to do everything traditionally associated with the specialty. Specifically, should the granting of privileges to practice anesthesia automatically approve the practitioner to handle pediatric cardiac cases, critically ill newborns (such as a day-old premature infant with a large diaphragmatic hernia), ablative pain therapy (such as an alcohol celiac plexus block under fluoroscopy), high-risk obstetric cases, and so forth? This question raises the issue of procedure-specific or limited privileges. The quality assurance (QA) and risk management considerations in this question are weighty if inexperienced or insufficiently qualified practitioners are allowed or even expected, because of peer or scheduling pressures, to undertake major challenges for which they are not prepared. The likelihood of complications and adverse outcomes will be higher, and the difficulty of defending the practitioner against a malpractice claim in the event of catastrophe will be significantly increased.

There is no clear answer to the question of procedure-specific credentialing and granting of privileges. Ignoring issues regarding qualifications to undertake complex and challenging procedures has clear negative potential. On the other hand, stringent procedure-specific credentialing is impractical in smaller groups, and in larger groups encourages many small “fiefdoms,” with a consequent further atrophy of the clinical skills outside the practitioner’s specific area(s). Each anesthesia department or group needs to address these issues. At the very least, the common practice of every applicant for privileges (new or renewal) checking off every line on the printed list of anesthesia procedures should be reviewed. In addition, board certification for physicians is now essentially a standard of QA of the minimum skills required for the consultant practice of anesthesiology. Subspecialty boards, such as those in pain management, critical care, and transesophageal echocardiography, further objectify the credentialing process. This is significant because initial board certification after the year 2000 by the ABA is time-limited and subject to periodic testing and recertification (see Maintenance of Certification below). Many states, some institutions, and even some regulatory bodies have requirements for a minimum number of hours of CME. Documentation of fulfilling such a standard again acts as one type of

QA mechanism for the individual practitioner, while providing another objective credentialing measurement for those granting licenses or privileges.

### ***Maintenance of Certification in Anesthesiology***

American anesthesiologists certified as diplomates by the ABA after January 1, 2000, are issued a “time-limited” board certification valid for 10 years. A formal process culminating in the recertification of an anesthesiologist for an additional and then subsequent 10-year intervals has evolved and now appropriately is called “Maintenance of Certification in Anesthesiology” (MOCA). Because certification by a medical specialty board is now often expected or actually required by medical staff bylaws in order to obtain and maintain medical facility privileges, even anesthesiologists who were certified (without a time limit) prior to the year 2000 likely will be engaging in the MOCA process.

In 1999, the American Board of Medical Specialties (ABMS) initiated a process to better ensure continuing professional development of diplomates certified by the member boards. An enhancement of the traditional CME process, this initiative by the ABMS is designed to provide a transparent public system of accountability that the physician’s skill and knowledge base do not wane after completion of formal training. Centered on the American Council for Graduate Medical Education core competencies of (1) patient-centered care, (2) medical knowledge, (3) interpersonal and communication skills, (4) professionalism, (5) system-based practice, and (6) practice-based learning improvement, each member board designs a curricular process to enhance and evaluate continued development of the competencies throughout the professional career of the certified clinician.

The MOCA program of the ABA has had significant evolution since its introduction (<http://www.theaba.org/MOCA/MOCA-Timeline>), much of which was prompted by input from participants in the program. As of the 2016 “MOCA 2.0” update, the elements of the program include Professionalism and Professional Standing; Lifelong Learning and Self-Assessment, based on CME; Assessment of Knowledge, Judgment, and Skills (based on the MOCA Minute concept that involves the anesthesiologist answering 30 questions per calendar quarter online—each of which includes an explanatory learning module—thus replacing the written examination component of the process); and Improvement in Medical Practice, for which participants complete activities (each with a point value counting toward the required total) during the 10-year cycle, demonstrating participation in practice improvement activities and evaluations of their clinical practice.

Clinicians with subspecialty training in Critical Care and Pain Medicine also have an MOCA process available. The updated version, also “MOCA 2.0,”

launches in 2017 and will have many of the same type of features as regular MOCA, but oriented to the specific subspecialty.

It is reasonable to project that the MOCA process will continue to evolve and likely will become more comprehensive over time as the overall emphasis on assuring both quality and efficiency of medical care in the United States increases further due to the expectations of accrediting bodies, government regulators, third-party payers, malpractice insurers, and, above all, the public.

### *Professional Staff Participation and Relationships*

All medical care facilities and practice settings depend on their professional staffs, of course, for daily activities of the delivery of health care but, importantly, they also depend on those staffs to provide administrative structure and support. Medical staff activities are increasingly important in achieving favorable accreditation status from the “Joint Commission” (formerly known as the Joint Commission for the Accreditation of Healthcare Organizations or JCAHO) and in meeting a wide variety of governmental regulations and reviews. Principal medical staff activities involve sometimes time-consuming efforts, such as duties as a staff officer or committee member. Anesthesiologists should be participants in—in fact, should play a significant role in—credentialing, peer review, tissue review, transfusion review, OR management, and medical direction of same-day surgery units, postanesthesia care units (PACUs), intensive care units (ICUs), and pain management units. Also, it is very important that anesthesiology personnel be involved in fund-raising activities, benefits, community outreach projects sponsored by the facility, publicity, and social events of the facility staff.

Anesthesia professionals as a group have a reputation for lack of involvement in medical staff and facility issues, allegedly because of lack of time due to long hours in the OR or simply lack of interest. In fact, anesthesiology professionals are all-too-often perceived in a facility as the ones who slip in and out of the building essentially anonymously (often dressed very casually or even in the pajama-like comfort of scrub suits) and virtually unnoticed. This is an unfortunate state of affairs, and it has frequently come back in various painful ways to haunt those who have not been involved, or even noticed, within their own facility. Anesthesia professionals sometimes respond that the demands for anesthesiology service are so great that they simply never have the time or the opportunity to become involved in their facility and with their peers. If this is really true, it is clear that more anesthesia professionals must be added at that facility, even if doing so slightly reduces the income of those already there.

If anesthesia professionals are not involved and not perceived as interested, dedicated “team players,” they will be shut out of critical

negotiations and decisions relevant to their practice. Although one obvious instance in which others could make key decisions for uninvolved anesthesia professionals is the distribution of “bundled” professional payment income collected by a central “umbrella” medical practice organization or even the facility administration itself, there are many such situations, and the excluded uninvolved anesthesia professionals will be forced to comply with the resulting mandates.

Similarly, involvement with a facility, a professional staff, or a multispecialty group goes beyond formal organized governance and committee activity. Collegial relationships with professionals of other specialties and with administrators are central to maintenance of a recognized position and avoidance of the situation of exclusion just described. Being readily available for formal and informal consults, particularly regarding preoperative patient workup and the maximally efficient way to get surgeons’ patients to the OR in a timely, expedient manner, is extremely important. No one individual can be everywhere all the time, but an anesthesiology group or department should strive to be always responsive to any request for help from physicians or administrators. It often appears that anesthesia professionals fail to appreciate just how great a positive impact a relatively simple involvement (starting an intravenous line for a pediatrician, helping an internist manage an ICU ventilator, or helping a facility administrator unclog a jammed recovery room) may have. Something as simple as having a departmental telephone extension within the facility that is always answered by a person, whoever it may be, who can direct the caller to the needed help is an extremely effective positive presentation for the facility’s anesthesia professionals.

### ***Establishing Standards of Practice and Understanding the Standard of Care***

The increasing frequency and intensity of “production pressure,”<sup>36</sup> with the tacit (or even explicit) directive to anesthesia professionals to “go fast” no matter what, and to “do more with less,” creates situations in which anesthesia professionals may conclude that they must cut corners and compromise safe patient care just to stay in business. This type of pressure has become even greater with the implementation of more and more protocols or parameters for practice, some from professional societies such as the ASA and some mandated by or developed in conjunction with purchasers of health care (government, insurance companies, health plans, or managed care organizations [MCOs]). Many of these protocols are devised to fast-track patients through the medical care system, especially when an elective procedure is involved, in as absolutely little time as possible, thus minimizing costs. Do these fast-track protocols constitute or establish standards of care

that health-care providers must implement? What are the implications of doing so? Of not doing so?

To better understand answers to such questions, it is important to have a basic background in the concept of the standard of care.

The *standard of care* is the conduct and skill of a prudent (or “reasonable”) practitioner that can be expected by a reasonable patient. This is a very important medicolegal concept because a bad medical result due to failure to meet the standard of care is malpractice. Courts have traditionally relied on medical experts knowledgeable about the point in question to give opinions as to what is the standard of care and if it has been met in an individual case. This type of standard is somewhat different from the standards promulgated by various standard-setting bodies regarding, for example, the color of gas hoses connected to an anesthesia machine in the United States or the inability to open two vaporizers on that machine simultaneously. However, ignoring the equipment standards and tolerating an unsafe situation is a violation of the standard of care. Promulgated standards, such as the various safety codes and anesthesia machine specifications, rapidly become the standard of care because patients (through their attorneys, in the case of an untoward event) expect the published standards to be observed by the prudent practitioner.

Ultimately, the standard of care for an individual practitioner is what a jury says it is. However, it is possible to anticipate, at least in part, what knowledge and actions will be expected. There are two main sources of information as to exactly what is the expected standard of care. Traditionally, the beliefs offered by expert witnesses in medical liability lawsuits regarding what is actually being done in real life (*de facto* standards of care) were the main input juries had in deciding what was reasonable to expect from the defendant. The resulting problem is well known: except in the most egregious cases, it is usually possible for the lawyers to find experts who will support each of the two opposing sides, making the process more subjective than objective. (Because of this, there are even *ASA Guidelines for Expert Witness Qualifications and Testimony* and an equivalent document from the AANA). Of course, there can be legitimate differences of opinion among thoughtful, insightful experts, but even in these cases the jury still must decide who is more believable, looks better, or sounds better. The second, much more objective, source for defining certain component parts of the standard of care is the published standards of care, guidelines, practice parameters, and protocols that have become more and more common since the idea was originally introduced.<sup>37</sup> These serve as more objective evidence of what can be reasonably expected of practitioners and can make it easier for a jury evaluating whether a malpractice defendant failed to meet the applicable standard of care. Several types of documents exist and have differing implications.

## Leading the Way

Anesthesiology likely is the medical specialty most involved with published standards of care. It has been suggested that the nature of anesthesia practice (having certain central critical functions relatively clearly defined and common to all situations and also having an emphasis on technology) makes it the most amenable of all the fields of medicine to the application of published standards. The original intraoperative monitoring standards<sup>38</sup> are a classic example. The ASA first adopted its own set of basic intraoperative monitoring standards in 1986 and has modified them many times. The text of all ASA standards, guidelines, statements, practice parameters, practice advisories, and other documents is readily available on the ASA website home page: select “Resources” and then “Standards, Guidelines, Statements, Practice Parameters” headings.

The Standards for Basic Anesthetic Monitoring document includes clear specifications for the presence of personnel during an anesthetic episode and for continual evaluation of oxygenation, ventilation, circulation, and temperature. These ASA monitoring standards very quickly became part of the accepted standard of care in anesthesia practice. This means they are important to practice management because they have profound medicolegal implications: a catastrophic accident occurring while the standards are being actively ignored is very difficult to defend in the consequent malpractice suit, whereas an accident that occurs during well-documented full compliance with the standards will automatically have a strong defense because the standard of care was being met. Several states in the United States have made compliance with these ASA standards mandatory under state regulations or even statutes. Various malpractice insurance companies offer discounts on malpractice insurance policy premiums for compliance with these standards, something quite natural to insurers because they are familiar with the idea of managing known risks to help minimize financial loss to the company. Note also that some malpractice insurance companies offer discounts to their insured anesthesia professionals for participating in simulation training, particularly for Crisis Resource Management of clinical emergencies during anesthesia care.

With many of the same elements of thinking, the ASA adopted “Basic Standards for Preanesthesia Care.” This was supplemented significantly by another type of document, the *ASA Practice Advisory for Preanesthesia Evaluation*.<sup>39</sup> Also, the ASA adopted “Standards for Postanesthesia Care,” in which there was consideration of and collaboration with the very detailed standards of practice for PACU care published by the American Society of Post Anesthesia Nurses (another good example of the sources of standards of care). This also was later supplemented by an extensive practice guideline.<sup>40</sup>

A slightly different situation exists with regard to the standards for

conduct of anesthesia in obstetrics. These standards were originally passed by the ASA in 1988, in the same manner as the other ASA standards, but the ASA membership eventually questioned whether they reflected a realistic and desirable standard of care. Accordingly, the obstetric anesthesia standards were “downgraded” in 1990 to “guidelines,” specifically to remove the mandatory nature of the document. Because there was no agreement as to what should be prescribed as the standard of care, the medicolegal imperative of published standards in this instance has been temporarily set aside. From a management perspective, this makes the guidelines no less valuable because the intent of optimizing care through the avoidance of complications is no less operative. However, in the event of the need to defend against a malpractice claim in this area, it is clear from this sequence of events that the exact standard of care is debatable and not yet finally established (an extremely important medicolegal consideration). A different ASA document has since been generated, *Practice Guidelines for Obstetrical Anesthesia*, with more detail and specificity as well as an emphasis on the meta-analytic approach.<sup>41</sup>

## Practice Guidelines

Beyond formal standards that do prescribe the standard of care, an important type of related ASA document is the *Practice Guideline* (formerly “Practice Parameter”). This has some of the same elements as a standard of practice but is more intended to guide judgment, largely through algorithms with some element of guidelines, in addition to directing the details of specific procedures as would a formal standard. Beyond the details of the minimum standards for carrying out the procedure, these practice parameters set forth algorithms and guidelines for helping to determine under what circumstances and with what timing to perform it. Understandably, purchasers of health care (government, insurance companies, health plans, and MCOs) with a strong desire to limit the costs of medical care have great interest in practice parameters as potential vehicles for helping to eliminate “unnecessary” procedures and limit even the necessary ones.

The ASA has been very active in creating and publishing practice guidelines. The first published parameter (since revised) concerned the use of pulmonary artery (PA) catheters.<sup>42</sup> It considered the clinical effectiveness of PA catheters, public policy issues (costs and concerns of patients and providers), and recommendations (indications and practice settings). Also, the *ASA Difficult Airway Algorithm* has been updated periodically.<sup>43</sup> This thoughtful document synthesizes a strategy summarized in a decision tree diagram for dealing acutely with airway problems. The difficult airway algorithm has been discussed extensively in the literature, including suggestions regarding the role of supraglottic airways and, more recently, adding the various airway

video imaging technologies. This illustrates that all the ASA practice guidelines involve fluid concepts that are subject to reconsideration, reinterpretation, and revision as experience and technology evolve. Undoubtedly, the difficult airway algorithm has great clinical value and helps many patients. However, there is concern that as with many modern things, it starts to outdate as soon as it is published. Such considerations are important, both clinically and because all these documents are readily noted by plaintiffs' lawyers as relevant to establishing the applicable standard of care.

An important question is whether guidelines and practice parameters from recognized entities such as the ASA *define* the standard of care. There is no simple answer. This will be decided over time by practitioners' actions, debates in the literature, mandates from malpractice insurers, and, of course, court decisions. Some guidelines, such as the concepts in the U.S. Food and Drug Administration (FDA) preanesthetic apparatus checkout, are accepted as the standard of care. There will be debate among experts, but the practitioner must make the decision as to how to apply practice parameters and guidelines such as those from the ASA. Practitioners have incorrectly assumed that they *must* do everything specified. This is clearly not true, yet there is a valid concern that these will someday be held up as defining the standard of care. Accordingly, prudent attention within the bounds of reason to the principles outlined in guidelines and parameters will put the practitioner in at least a reasonably defensible position, whereas radical deviation from them should be based only on obvious exigencies of the situation at that moment or clear, defensible alternative beliefs (with documentation).

The most recent type of document has been the "practice advisory," which can seem functionally similar to a guideline, but appears to have the implication of more consensus compromise than previous documents driven more by meta-analysis of the relevant literature. Examples of ASA Practice Advisories include "Intraoperative Awareness and Brain Function Monitoring," "Perioperative Management of Patients with Cardiac Rhythm Management Devices: Pacemakers and Implantable Cardioverter-Defibrillators," "Perioperative Visual Loss Associated with Spine Surgery," and "Practice Advisory on Anesthetic Care for Magnetic Resonance Imaging." At any given time, there are several additional topics under consideration and new advisories being prepared.

The potential QA and medicolegal implications of these documents are so important to anesthesia professionals and their practices that the ASA has what is essentially a guideline for the guidelines in its 2013 update of the "Policy Statement on Practice Parameters" in which the distinction is made between evidence-based documents and consensus-based documents with explanations of the background and formulation processes for each.

On the other hand, practice protocols, such as those for the fast-track

management of coronary artery bypass graft patients, that are handed down by MCOs or health insurance companies are a different matter. Even though the desired implication is that practitioners must observe (or at least strongly consider) them, they do not have the same implications in defining the standard of care as the other documents. Practitioners must avoid getting trapped. It may well not be a valid legal defense to justify action or the lack of action because of a company or facility protocol. As difficult as it may be to reconcile with the payer, the practitioner still is subject to the classic definitions of standard of care.

The other types of standards associated with medical care are those of the Joint Commission, which is the best-known medical care quality regulatory agency. As noted, these standards were for many years concerned largely with structure (e.g., gas tanks chained down) and process (e.g., documentation complete), but in recent years they have been expanded to include reviews of the *outcome* of care and also review of the sequence of one individual inpatient's care through "tracer" sequences during an inspection. Joint Commission standards also focus on credentialing and privileges, verification that anesthesia services are of uniform quality throughout an institution, the qualifications of the director of the service, continuing education, and basic guidelines for anesthesia care (need for preoperative and postoperative evaluations, documentation, and so forth). Full Joint Commission accreditation of a health-care facility is usually for 3 years, although the process is considered "continuous." Even the best hospitals and facilities receive some citations of problems or deficiencies that are expected to be corrected, and an interim report of efforts to do so is required. If there are enough problems, accreditation can be conditional for 1 year, with a complete reinspection at that time. Being ready for a Joint Commission inspection (which is unannounced and can come at any time) starts with verification that an essential group/department structure is in place. The process of "constant preparation" ultimately involves a great deal of work, but because the standards usually do promote high-quality care, the majority of this work is highly constructive and of benefit to the institution and its medical staff.

## **Review Implications**

"Peer review organizations"<sup>44</sup> were established in the 1980s and 1990s in every state, usually affiliated with state medical associations and/or state licensing agencies both to monitor quality of medical care and perform utilization reviews (URs), which were oriented to reducing health-care costs. These functions have migrated in recent years largely to the government insurers Medicare and Medicaid and have become fixated essentially

exclusively on cost issues. Also, each private health insurance company has UR functions, whether internal or contracted out to a company that performs that function for the insurer.

The most likely interaction between a UR agency or office and anesthesia professionals will involve a request for perioperative admission of a patient whose care is mandated to be outpatient surgery (this could also occur in dealing with a health plan or MCO). If the anesthesiologist feels, for example, that either (1) preoperative admission for treatment to optimize cardiac, pulmonary, diabetic, or other medical status or (2) postoperative admission for monitoring of labile situations such as uncontrolled hypertension will reduce clear anesthetic risks for the patient, an application to UR for approval of admission must be made and vigorously supported. All too often, however, such issues surface a day or so before the scheduled procedure in a preanesthesia screening clinic or even in a preoperative holding area outside the OR on the day of surgery. This will continue to occur until anesthesia providers educate their constituent surgeon community as to what types of associated medical conditions may disqualify a proposed patient from the outpatient (ambulatory) surgical schedule. If adequate notice is given by the surgeon, the patient can be seen far enough in advance by an anesthesiologist to allow appropriate planning.

In the circumstance in which the first knowledge of a questionable patient comes 1 or 2 days before surgery, the anesthesiologist can try to have the procedure postponed, if possible, or can undertake the time-consuming task of multiple telephone calls to get the surgeon's agreement, get UR approval, and make the necessary arrangements. Because neither alternative is particularly attractive, especially from administrative and reimbursement perspectives, there may be a strong temptation to "let it slide" and try to deal with the patient as an outpatient even though this may be questionable. In almost all cases, it is likely that there would be no adverse result (the "get away with it" phenomenon). However, the patient might well be exposed to an avoidable risk. Both because of the workings of probability and because of the inevitable tendency to let sicker and sicker patients slip by as lax practitioners repeatedly "get away with it" and are lulled into a false sense of security, sooner or later there will be an unfortunate outcome or some preventable major morbidity or even mortality.

The situation is worsened when the first contact with a questionable ambulatory patient is preoperatively (or possibly even already in the OR) on the day of surgery. There may be intense pressure from the patient, the surgeon, or the OR administrator and staff to proceed with a case for which the anesthesia practitioner believes the patient is poorly prepared. The arguments made regarding patient inconvenience and anxiety are valid. However, they should not outweigh the best medical interests of the patient.

Although this is a point in favor of screening all outpatients before the day of surgery, the anesthesia professional facing this situation on the day of operation should state clearly to all concerned the reasons for postponing the surgery, stressing the issue of avoidable risk and standards of care, and then help with alternative arrangements (including, if necessary, dealing with UR or an MCO).

Potential liability in this regard is the other side of the standard of care issue. Particularly concerning is the question of postoperative admission of ambulatory patients who have been unstable. It is an extremely poor defense against a malpractice claim to state that the patient was discharged home, only later to suffer a complication, because the UR process or a health plan or MCO deemed that operative procedure outpatient and not inpatient surgery. As bureaucratically annoying as it may be, it is a prudent management strategy to admit the patient if there is any legitimate question, thus minimizing the chance for complications, and later haggle with the UR bureaucracy.

### ***Policy and Procedure***

One important organizational point that is sometimes overlooked in anesthesia practice is the need for a complete policy and procedure manual. Such a compilation of documents is necessary for all practices, from the largest departments covering multiple hospitals to a single-room outpatient facility with one anesthesia provider. Such a manual can be extraordinarily valuable as, for example, when it provides crucial information during an emergency. Organizational and procedural elements should be included. A sample of a table of contents is in the ASA manual.<sup>35</sup> The organizational elements that should be present include a chart of organization and responsibilities that is not just a call schedule but a clear explanation of who is responsible for what functions of the department and when, with attendant details such as expectations for the practitioner's presence within the institution at designated hours, telephone availability, pager availability, the maximum permissible distance from the institution when on call, and so forth. Experience suggests it is especially important for there to be an absolutely clear specification of the availability of qualified anesthesiology personnel for emergency cesarean section, particularly in practice arrangements in which there are several people on call covering multiple locations. Sadly, these issues often are only considered after a disaster has occurred that involved miscommunication and the mistaken belief by one or more people that someone else would take care of an acute problem.

The organizational component of the policy and procedure manual should also include a clear explanation of the orientation and checkout procedure for

new personnel, CME requirements and opportunities, the mechanisms for evaluating personnel and for communicating this evaluation to them, disaster plans (or reference to a separate disaster manual or protocol), QA activities of the department, and the format for statistical record keeping (number of procedures, types of anesthetics given, types of patients anesthetized, number and types of invasive monitoring procedures, number and type of responses to emergency calls, complications, or whatever the group/department decides).

The procedural component of the policy and procedure manual should give both handy practice tips and specific outlines of proposed courses of action for particular circumstances; it also should store little used but valuable information. Reference should be made to the statements, guidelines, practice parameters and advisories, and standards appearing on the ASA website. Also included should be references to or specific protocols for the areas mentioned in the Joint Commission standards: preanesthetic evaluation, immediate preinduction reevaluation, safety of the patient during the anesthetic period, release of the patient from any PACU, recording of all pertinent events during anesthesia, recording of postanesthesia visits, guidelines defining the role of anesthesia services in hospital infection control, and guidelines for safe use of general anesthetic agents. Other appropriate topics include the following:

1. Recommendations for preanesthesia apparatus checkout, such as from the ASA
2. Guidelines for admission to, minimal monitoring and duration of stay of an infant, child, or adult in, and then discharge from the PACU
3. Procedures for transporting patients to/from the OR, PACU, or ICU
4. Policy on ambulatory surgical patients—for example, screening, use of regional anesthesia, discharge home criteria
5. Policy on evaluation and processing of same-day admissions
6. Policy on ICU admission and discharge
7. Policy on physicians responsible for writing orders in recovery room and ICU
8. Policy on informed consent for anesthesia and its documentation
9. Policy on the use of patients in clinical research (if applicable)
10. Guidelines for the support of cadaveric organ donors and its termination (plus organ donation after cardiac death if applicable)
11. Guidelines on environmental safety, including pollution with trace gases and electrical equipment inspection, maintenance, and hazard prevention
12. Procedure for change of personnel during an anesthetic and documentation (particularly if a printed hand-off protocol is used)
13. Procedure for the introduction of new equipment, drugs, or clinical practices
14. Procedure for epidural and spinal narcotic administration and

subsequent patient monitoring (e.g., type, minimum time, nursing units)

15. Procedure for initial treatment of cardiac or respiratory arrest (updated Advanced Cardiac Life Support guidelines)
16. Policy for handling patient's refusal of blood or blood products, including the mechanism to obtain a court order to transfuse
17. Procedure for the management of malignant hyperthermia
18. Procedure for the induction and maintenance of barbiturate coma
19. Procedure for the evaluation of suspected pseudocholinesterase deficiency
20. Protocol for responding to an adverse anesthetic event (such as a copy of the update of the "Adverse Event Protocol" [Eichhorn JH. Organized response to major anesthesia accident will help limit damage: Update of "Adverse Event Protocol" provides valuable plan. *APSF Newsletter*. 2006;21:11.])
21. Policy on resuscitation of do-not-resuscitate patients in the OR

Individual departments will add to and modify these suggestions as dictated by their specific needs. A thorough, carefully conceived policy and procedure manual is a valuable tool. The manual should be reviewed and updated as needed but at least annually. Each member of a group or department should review the manual at least annually and sign off in a log indicating familiarity with current policies and procedures.

### **Meetings and Case Discussion**

There must be regularly scheduled departmental or group meetings. Although didactic lectures and continuing education meetings are valuable and necessary, there must also be regular opportunities for open clinical discussion about interesting cases and problem cases. Also, the Joint Commission requires that there be at least monthly meetings at which risk management and QA activities are documented and reported. Whether these meetings are called case conferences, morbidity and mortality conferences, or deaths and complications conferences, the entire department or group should gather for an interchange of ideas. More recently, these gatherings can be called *QA meetings*. An open review of departmental statistics should be done, including all complications, even those that may appear trivial. Unusual patterns of small events may point toward a larger or systematic problem, especially if they are more frequently associated with one individual practitioner.

A problem case presented at the departmental meeting might be an overt accident, a near accident (critical incident), or an untoward outcome of unknown origin. Honest but constructive discussion, even of an anesthesia

professional's technical deficiencies or lack of knowledge, should take place in the spirit of constructive peer review. The classic question, "What would you do differently next time?" is a good way to start the discussion. There may be situations in which inviting the surgeon or the internist involved in a specific case would be advantageous. The opportunity for each type of provider to hear the perspective of another discipline not only is inherently educational but also can promote communication and cooperation in future potential problem cases.

Records of these meetings must be kept for accreditation purposes, but the enshrining of overly detailed minutes (potentially subject to discovery by a plaintiff's attorney at a later date) may inhibit true educational and corrective interchanges about untoward events. In the circumstance of discussion of a case that seems likely to provoke litigation, it is appropriate to be certain that the meeting is classified as official "peer review" and possibly even invite the hospital attorney or legal counsel from the relevant malpractice insurance carrier (to guarantee the privacy of the discussion and minutes).

### **Support Staff**

There is a fundamental need for support staff in every anesthesia practice. Even independent practitioners rely in some measure on facilities, equipment, and services provided by the organization maintaining the anesthetizing location. In large, well-organized departments, reliance on support staff is often very great. What is often overlooked, however, is a process analogous to that of credentialing and privileges for anesthesia professionals, although at a somewhat different level. The people expected to provide clinical anesthesia practice support must be qualified and must at all times understand what they are expected to do and how to do it. It is singularly unfortunate to realize only after an anesthesia catastrophe has occurred that basic details of simple work assignments, such as the changing of carbon dioxide absorbent, were routinely ignored. This indicates the need for supervision and monitoring of the support staff by the involved practitioners. Further, such support personnel are favorite targets of cost-cutting administrators who do not understand the function of anesthesia technicians or their equivalent. In the modern era, many administrators seem driven almost exclusively by the "bottom line" and cannot appreciate the connection between valuable workers such as these and the "revenue stream." Even though it is obvious to all who work in an OR that the anesthesia support personnel make it possible for there to be patients flowing through the OR, it is their responsibility to convince the facility's fiscal administrator that elimination of such positions is genuinely false economy because of the attendant loss in efficiency, particularly in turning over the room between surgeries. Further, it is also

false economy to reduce the number of personnel below that genuinely needed to retrieve, clean, sort, disassemble, sterilize, reassemble, store, and distribute the tools of daily anesthesia practice. Vigorous defense (or initiation of new positions if the staff is inadequate) by the anesthesia professionals should be undertaken, even sometimes with the realization that it may be necessary in some circumstances for them to supplement the budget from the facility with some of their practice income to guarantee an adequate complement of competent workers.

Business and organizational issues in the management of an anesthesia practice are also critically dependent on the existence of a sufficient number of appropriately trained support staff. As noted, one frequently overlooked issue that contributes to the negative impression generated by some anesthesiology practices centers on being certain there is someone available to answer the telephone *at all times* during the hours surgeons, other physicians, and OR scheduling desks are likely to call. This seemingly trivial component of practice management is very important to the success of an anesthesiology practice as a business whose principal customers are the surgeons. Certainly there is a commercial server–client relationship both with the patient and the purchaser of health care; however, the uniquely symbiotic nature of the relationship between surgeons and anesthesiologists is such that availability even for simple “just wanted to let you know” telephone calls is genuinely important. The person who answers the telephone is the representative of the practice to the world and must take that responsibility seriously. From a management standpoint, significant impact on the success of the practice as a business often hinges on such details. Further, anesthesia professionals should always have reliable personal communication ability, whether electronic pagers (preferably with text, and even more preferably two-way) and/or mobile telephones (or the radio equivalent) to facilitate communications from other members of the department or group and from support or facility personnel. This may sound intrusive, but the unusual position of anesthesia professionals in the spectrum of health-care workers mandates this feature of managing an anesthesiology practice. Anesthesiology professionals should have no hesitation about spending their own practice income to do so. The symbolism alone is obvious.

### **Anesthesia Equipment and Equipment Maintenance**

Problems with anesthesia equipment have been discussed extensively for many years.<sup>45–47</sup> However, compared with human error, overt equipment failure rarely causes intraoperative critical incidents<sup>48</sup> or deaths resulting from anesthesia care. Aside from the obvious human errors involving misuse of or unfamiliarity with the equipment, when the rare equipment failure does

occur, it often appears that correct maintenance and servicing of the apparatus has not been done. These issues are part of anesthesia practice management efforts, which could have significant liability implications because there can often be confusion or even disputes about precisely who is responsible for arranging maintenance of the anesthesia equipment—the facility or the practitioners who use it and collect practice income from that activity. In many cases, the facility assumes the responsibility. In situations in which that is not true, however, it is necessary for the practitioners to recognize that responsibility and seek help securing a service arrangement, because this is likely an unfamiliar obligation for clinicians.

A distinction is made between failure resulting from progressive deterioration of equipment, which should be preventable because it is observable and should provoke appropriate remedial action, and catastrophic failure, which, realistically, often cannot be predicted. Preventive maintenance for mechanical parts is critical and involves periodic performance checks every 4 to 6 months. Also, an annual safety inspection of each anesthetizing location and the equipment itself is necessary. For equipment service, an excellent mechanism is a relatively elaborate cross-reference system (possibly kept handwritten in a notebook but ideal for maintenance on an electronic spreadsheet program) to identify both the device needing service and also the mechanism to secure the needed maintenance or repair. Most important, however, is the simple requirement that there is some type of reliable program for equipment maintenance and service for every anesthesia organization providing clinical care. Assuming that “someone must be taking care of it” without established certainty is an invitation to a potential medicolegal liability nightmare.

Equipment-handling principles are straightforward. Before purchase, it must be verified that a proposed piece of equipment meets all applicable standards, which will usually be true when dealing with new equipment from recognized major manufacturers. The renewed efforts of some facility administrators to save money by attempting to find “refurbished” anesthesia machines and monitoring systems (especially for “off-site,” “satellite,” or “office-based” locations) should provoke thorough review by the involved practitioners. On arrival, electrical equipment must be checked for absence of hazard (especially leakage of current) and compliance with applicable electrical standards. Complex equipment such as anesthesia machines, ventilators, and monitors should be assembled and checked out by a representative from the manufacturer or manufacturer’s agent. There are potential adverse medicolegal implications when relatively untrained personnel certify a particular piece of new equipment as functioning within specification, even if they do it perfectly. On arrival, a sheet or section in the departmental master equipment log must be created with the make, model,

serial number, and in-house identification for each piece of capital equipment (anything with a serial number). This not only allows immediate identification of any equipment involved in a future recall or product alert but also serves as the permanent repository of the record of every problem, problem resolution, maintenance, and servicing occurring until that particular equipment is scrapped. This log must be kept up-to-date at all times. There have been rare but frightening examples of potentially lethal problems with anesthesia machines leading to product alert notices requiring immediate identification of certain equipment and its service status. It is also very important to involve the manufacturer's representative in pre- and in-service training for those who will use the new equipment. Anesthesia systems with their ventilation and monitoring components have become significantly more integrated and more complex, particularly as they are increasingly electronic and less mechanical. Accordingly, it is critical that anesthesia professionals are properly trained to use their equipment safely. The perception that inadequate training is common and that this represents a threat to patient safety has led the Anesthesia Patient Safety Foundation to initiate a campaign urging anesthesia departments and groups to ensure organized verified complete training of all professionals who will use this new technology.<sup>49</sup>

## **Service**

Beyond the administrative liability implications, precisely what type of support personnel should maintain and service major anesthesia equipment has been widely debated. Some groups or departments rely on factory service representatives from the equipment manufacturers for all attention to equipment, others engage independent service contractors, and still other (often larger) departments have access to personnel (either engineers and/or technicians) permanently within their facility. The single underlying principle is clear: The person(s) doing preventive maintenance and service on anesthesia equipment must be qualified. Anesthesia practitioners may wonder how they can assess these qualifications. The best way is to unhesitatingly ask pertinent questions about the education, training, and experience of those involved, including asking for references and speaking to supervisors and managers responsible for those doing the work. Whether an engineering technician who spent a week at a course at a factory can perform the most complex repairs depends on a variety of factors, which can be investigated by the practitioners ultimately using the equipment in the care of patients. Failure to be involved in this oversight function exposes the practice to increased liability in the event of an untoward outcome associated with improperly maintained or serviced equipment.

Replacement of obsolete anesthesia machines and monitoring equipment is

a key element of a risk-modification program. Ten years is sometimes cited as an estimated useful life for an anesthesia machine, but although an ASA statement repeats that idea, it also notes that the ASA promulgated “Guidelines for Determining Anesthesia Machine Obsolescence” in 2004 does not subscribe to any specific time interval. Very old anesthesia machines likely do not meet certain safety standards now in force (such as vaporizer lockout, fresh gas ratio protection, and automatic enabling of the oxygen analyzer). Further, it appears likely that this technology will continue to advance, particularly because of the adoption of anesthesia workstation standards by the European Economic Union that are affecting anesthesia machine designs worldwide. Note that some anesthesia equipment manufacturers, anxious to minimize their own potential liability, have refused to support (with parts and service) some of the oldest of their pieces (particularly gas machines) still in use. This disowning of equipment by its own manufacturer is a very strong message to practitioners that such equipment must be replaced as soon as possible.

Should a piece of equipment fail, it must be removed from service and a replacement substituted. Groups, departments, and facilities are obligated to have sufficient backup equipment to cover any reasonable incidence of failure. The equipment removed from service must be clearly marked with a prominent label (so it is not returned into service by a well-meaning technician or practitioner) containing the date, time, person discovering, and the details of the problem. The responsible personnel must be notified so they can remove the equipment, make an entry in the log, and initiate the repair. As indicated in the protocol for response to an adverse event,<sup>50</sup> a piece of equipment involved or suspected in an injury-causing anesthesia accident must be immediately sequestered and not touched by anybody—particularly not by any equipment service personnel. If a severe accident occurred, it may be necessary for the equipment in question to be inspected at a later time by a group consisting of qualified representatives of the manufacturer, the service personnel, the plaintiff’s attorney, the insurance companies involved, and the practitioner’s defense attorney. The equipment should thus be impounded following a catastrophic adverse event and treated similarly to any object in a forensic “chain of evidence,” with careful documentation of parties in contact with and responsible for securing the equipment in question following such an event. Also, major equipment problems may, in some circumstances, reflect a pattern of failure due to a design or manufacturing fault. These problems should be reported to the FDA’s Medical Device Problem Reporting system via MedWatch on Form 3500 (found at [www.fda.gov/medwatch/index.html](http://www.fda.gov/medwatch/index.html), or telephone 800-FDA-1088). This system accepts voluntary reports from users and requires reports from manufacturers when there is knowledge of a medical device being involved in a serious incident. Whether or not filing

such a report will have a positive impact in subsequent litigation is impossible to know, but it is a worthwhile practice management point that needs to be considered in the unlikely but important instance of a relevant event involving equipment failure.

## **Malpractice Insurance**

All practitioners need liability insurance coverage specific for the specialty and role in which they are practicing. It is absolutely critical that applicants for medical liability insurance be completely honest in informing the insurer what duties and procedures they perform. Failure to do so, either from carelessness or from a foolishly misguided desire to reduce the resulting premium, may well result in retrospective denial of insurance coverage in the event of an untoward outcome from an activity the insurer did not know the insured engaged in.

Proof of adequate insurance coverage is usually required to secure or renew privileges to practice at a health-care facility. The facility may specify certain minimum policy limits in an attempt to limit its own liability exposure. It is difficult to suggest specific dollar amounts for policy limits because the details of practice vary so much among situations and locations. The malpractice crisis of the 1980s eased significantly in the early 1990s for anesthesia professionals, largely because of the decrease in number and severity of malpractice claims resulting from anesthesia catastrophes as anesthesia care in the United States became safer.<sup>51-53</sup> The exact analysis of this phenomenon can be debated,<sup>54,55</sup> but it is a simple fact that malpractice insurance risk ratings were decreased and premiums for anesthesia professionals have not been increased at the same rate as for other specialties over the same time and, in many cases, have actually decreased further. An ASA Committee on Professional Liability survey revealed: “In 2013, 72 percent of anesthesiologists had policy limits of \$1 million/\$3 million, 20 percent of anesthesiologists had higher limits, and greater than 8 percent had lower policy limits.”<sup>56</sup> This policy specification usually means that the insurer will cover up to \$1 million liability per claim and up to \$3 million total per year, but this terminology is not necessarily universal. Therefore, anesthesia professionals must be absolutely certain what they are buying when they apply for malpractice insurance. There are specific parts of the United States known for a pattern of exorbitant settlements and jury verdicts, and liability insurance coverage limits of \$2 to \$5 million or even greater may be considered prudent in some circumstances. Note also that malpractice insurance premiums for anesthesiologists practicing chronic pain management are moderately higher due to the potential liabilities associated with pain procedures.<sup>56</sup> An additional feature in regard to choosing malpractice

insurance policy limits is the potential to employ “umbrella” liability coverage above the limits of the base policy, as will be noted.

## **Background**

The fundamental mechanism of medical malpractice insurance changed significantly some years ago because of the need for insurance companies to have better ways to predict their “losses” (amounts paid in settlements and judgments). Traditionally, medical liability insurance was sold on an “occurrence” basis, meaning that if the insurance policy was in force at the time of the occurrence of an incident resulting in a claim, whenever within the statute of limitations that claim might be filed, the practitioner would be covered. Occurrence insurance was somewhat more expensive than the alternative “claims-made” policies, but was seen as worth it by some (many) practitioners. These policies created some open-ended exposure for the insurer that sometimes led to unexpected large losses, even some large enough to threaten the existence of the insurance company. As a result, medical malpractice insurers over the years have converted almost exclusively to “claims-made” insurance, which covers only claims that are filed while the insurance is in force. Premium rates for the first year a physician is in practice are relatively low because there is less likelihood of a claim coming in (a majority of malpractice suits are filed 1 to 3 years after the event in question). The premiums usually increase yearly for the first 5 years and then the policy is considered “mature.” The issue comes when the physician later, for whatever reason, must change insurance companies (e.g., because of relocation to another state). If the physician simply discontinues the policy and a claim is filed the next year, there will be no insurance coverage. Therefore, the physician must secure “tail coverage,” sometimes for a minimum number of years (e.g., 5) or, more often, indefinitely to guarantee liability insurance protection for claims filed after the physician is no longer primarily covered by that insurance policy. It may be possible in some circumstances to purchase tail coverage from a different insurer than was involved with the primary policy, but by far the most common thing done is to simply extend the existing insurance coverage for the period of the tail. This very often yields a bill for the entire tail coverage premium, which can be quite sizable, potentially staggering a physician who simply wants to move to another state where his or her existing insurance company is not licensed to or refuses to do business. Individual situations will vary widely, but it is reasonable for anesthesiologists organized into a fiscal entity to consider this issue at the time of the inception of the group and record their policy decisions regarding providing tail coverage as a benefit in writing, rather than facing the potentially difficult question of how to treat one individual later.

Other strategies have occasionally been employed when insuring the tail period, including converting the previous policy to part-time status for a period of years, or purchasing “nose” coverage from the new insurer—that is, paying an initial higher yearly premium with the new insurer, who then will cover claims that may occur during the tail period. Whatever strategy is adopted, it is critical that the individual practitioner is absolutely certain through personal verification that he or she is thoroughly covered at the time of any transition. The potential stakes are much too great to leave such important issues solely to an office clerk. Further, a practitioner arriving in a new location is often filling a need or void and is urged to begin clinical work as soon as possible by others who have been shouldering an increased load. It is essential that the new arrival verify with confirmation in writing (often called a “binder”) that malpractice liability insurance coverage is in force before there is any patient contact.

Another component to the liability insurance situation is consideration of the advisability of purchasing yet another type of insurance called *umbrella coverage*, which is activated at the time of the need to pay a claim that exceeds the limits of coverage on the standard malpractice liability insurance policy. Because such an enormous claim is extremely unlikely, many practitioners are tempted to forgo the comparatively modest cost of such insurance coverage in the name of economy. As before, it is easy to see that this is potentially a very false economy—if there is a huge claim. Practitioners should consult with their financial managers and advisors, but it is likely that it would be considered wise management to purchase “umbrella” liability insurance coverage.

Medical malpractice insurers are becoming increasingly active in trying to prevent incidents that will lead to insurance claims. They often sponsor risk management seminars to teach practices and techniques to lessen the chances of liability claims and, in some cases, suggest (or even mandate) specific practices, such as strict documented compliance with the ASA “Standards for Basic Anesthetic Monitoring.” In return for attendance at such events and/or the signing of contracts stating that the practitioner will follow certain guidelines or standards, the insurer often gives a discount on the liability insurance premium. Clearly, it is sound practice management strategy for practitioners to participate maximally in such programs. Likewise, some insurers make coverage conditional on the consistent implementation of certain strategies such as minimal monitoring, even stipulating that the practitioner will not be covered if it is found that the guidelines were being consciously ignored at the time of an untoward event. Again, it is obviously wise from a practice management standpoint to cooperate fully with such stipulations.

## Response to an Adverse Event

**6** Despite the decreased incidence of anesthesia catastrophes, even with the very best of practice, it is statistically likely that each anesthesiologist at least once in his or her professional life will be involved in a major anesthesia accident. Precisely because such an event is rare, very few are prepared for it. It is probable that the involved personnel will have no relevant past experience regarding what to do. Although an obvious resource is another anesthetist who has had some exposure or experience, one of these may not be available either. Suggestions have been published about what to do in that event.<sup>57-59</sup> Cooper et al.<sup>60</sup> thoughtfully presented the appropriate immediate response to an accident in a straightforward, logical, compact format (which has been updated<sup>50</sup>) that should periodically be reviewed by all anesthesiology practitioners and should be included in all anesthesia policy and procedure manuals. This “adverse events protocol” is also always immediately available at [www.apsf.org](http://www.apsf.org) (“Resource Center,” then “Clinical Safety Tools”). Unfortunately, however, the principal personnel involved in a significant untoward event may react with such surprise or shock as to temporarily lose sight of logic. At the moment of recognition that a major anesthetic complication has occurred or is occurring, help must be called. A sufficient number of people to deal with the situation must be assembled on site as quickly as possible. For example, in the unlikely but still possible event that an esophageal intubation goes unrecognized long enough to cause a cardiac arrest, the immediate need is for enough skilled personnel to conduct the resuscitative efforts, including making the correct diagnosis and replacing the tube into the trachea. Whether the anesthesiologist apparently responsible for the complication should direct the immediate remedial efforts will depend on the person and the situation. In such a circumstance, it would seem wise for a senior or supervising anesthesiologist quickly to evaluate the scenario and make a decision. This person becomes the “incident supervisor” and has responsibility for helping prevent continuation or recurrence of the incident, for investigating the incident, and for ensuring documentation while the original and helping anesthesiologists focus on caring for the patient. As noted, involved equipment must be sequestered and not touched until such time as it is certain that it was not involved in the incident.

With the hope of preventing or mitigating catastrophic anesthesia accidents, the utilization of emergency manuals, usually including checklists, as “cognitive aids” within the application of “crisis resource management”<sup>61</sup> when an adverse threatening situation develops during an anesthetic has gained significant attention.<sup>62,63</sup> Although such documents containing suggested protocols can be stored and accessed electronically on a computer or smart phone at the time of a crisis in the OR, many anesthesia

professionals who want these tools available prefer printed copies, often on thick laminated pages, actually attached to the anesthesia machine in each OR. Although the incident supervisor could seek guidance by reading a manual in real time during a crisis, having a “reader” who may or may not be another anesthesia professional whose sole activity during the crisis is to read out loud the relevant diagnostic and therapeutic suggestions in the protocol that applies to the crisis situation could be helpful. Overall, evidence from studies in simulated anesthesia crisis situations indicates on balance that the use of “emergency manual” type cognitive aids can improve patient outcome from an intraoperative anesthesia crisis.<sup>64,65</sup>

If the accident is not fatal, continuing care of the patient is critical. Measures may be instituted to help limit damage from brain hypoxia. Consultants may be helpful and should be called without hesitation. If not already involved, the chief of anesthesiology must be notified as well as the facility administrator, risk manager, and the anesthesiologist’s insurance company. The latter are critical to allow consideration of immediate efforts to limit later financial loss. (Likewise, there are often provisions in medical malpractice insurance policies that might limit or even deny insurance coverage if the company is not notified of any reportable event immediately.) If there is an involved surgeon of record, he or she probably will first notify the family, but the anesthesiologist and others (risk manager, insurance loss control officer, or even legal counsel) might appropriately be included at the outset. Full disclosure of facts as they are best known—with no confessions, opinions, speculation, or placing of blame—is still believed by many to be the best presentation. Any attempt to conceal or shade the truth will later only confound an already difficult situation. Obviously, comfort and support should be offered, including, if appropriate, the services of facility personnel such as clergy, social workers, and counselors. Note that there is a strong movement in medical risk management and liability insurance advocating immediate full disclosure to the victim or survivors, including “confessions” of medical judgment and performance errors with attendant sincere apologies. If indicated, early offers of reasonable compensation may be included. There have been instances when this overall strategy has prevented the filing of a malpractice lawsuit and has been applauded by all involved as an example of a shift from the “culture of blame” with punishment to a “just culture” with restitution. A widespread movement to implement immediate disclosure and apology has received support.<sup>66,67</sup>

Certain states have enacted or proposed the so-called “I’m sorry!” legislation intended to prevent any explanation or apology by the involved practitioners from being used as plaintiff’s evidence in a subsequent malpractice suit. The importance of the patient’s perspective on a serious adverse anesthesia event was highlighted in a riveting account of the stories

of both survivors of anesthesia catastrophes and the families of patients who died.<sup>68</sup> In each case, one main message was the enormous negative impact of the perceived failure of the involved anesthesia professionals and their institutions to share detailed information about what exactly happened. A general review summarized what patients want and expect following an adverse event.<sup>69</sup> Laudable as this policy of immediate full disclosure and apology may sound, it would be mandatory for an individual practitioner to check with the involved liability insurance carrier, the practice group, and the facility risk management officials and administration before attempting it.

The primary anesthesia provider and any others involved must document relevant information. Never, ever change any existing entries in the medical record. Write an amendment note if needed, with careful explanation of why amendment is necessary, particularly stressing explanations of professional judgments involved. State only facts as they are known. Make no judgments about causes or responsibility and do not “point fingers.” The same guidelines hold true for the filing of the incident (“event”) report in the facility, which should be done as soon as is practical. Further, all discussions with the patient or family should be carefully documented in the medical record. Because detailed memories of the events may fade in the 1 to 3 years that may pass before the practitioner faces deposition questions about exactly what happened, it is recommended that immediately after the incident, the involved clinical personnel sit down and write out their own personal notes, which will include opinions and impressions as well as maximally detailed accounts of the events as they unfolded. These personal notes are not part of the medical record or the facility files. These notes should be written in the physical presence of an involved attorney representing the practitioner, even if this is not yet the specific defense attorney secured by the malpractice insurance company, and then that attorney should take possession of and keep those notes as case material. This strategy is intended to make the personal notes “attorney–client work product,” and thus not subject to forced “discovery” (revelation) by other parties to the case.

Follow-up after the immediate handling of the incident will involve the primary anesthesiologist but should again be directed by a senior supervisor, who may or may not be the same person as the incident supervisor. The “follow-up supervisor” verifies the adequacy and coordination of ongoing care of the patient and facilitates communication among all involved, especially with the risk manager. Lastly, it is necessary to verify that adequate postevent documentation is taking place.

Of course, it is expected that such an adverse event will be discussed in the applicable morbidity and mortality meeting. It is necessary, however, to coordinate this activity with the involved risk manager and attorney so as to be completely certain that the contents and conclusions of the discussion are

clearly considered peer review activity, and thus are shielded (in most states) from discovery by the plaintiffs' attorney.

Unpleasant as this is to contemplate, it is better to have a clear plan and execute it in the event of an accident causing injury to a patient. Vigorous immediate intervention may improve the outcome for all concerned.

## Practice Essentials

### *The “Job Market” for Anesthesia Professionals*

Although there is and likely always will be debate about supply-and-demand considerations for anesthesia professionals in the United States, the aging of the Baby Boom population and the extension of health-care insurance coverage to a large number of underserved people by the ACA leads to the belief that there may be a shortage of all medical professionals in the United States, and this also includes anesthesia professionals. To this end, several new medical schools have opened in recent years in the United States. Also, the total number of anesthesia residents and fellows in training increased 13% from academic year 2007–2008 to 2014–2015.<sup>70</sup> Note also that the dramatic economic downturn (“Great Recession”) late in the first decade of the twenty-first century complicated the issues of supply and demand. Some finishing residents (who would otherwise not have) sought fellowship training in order to be “more competitive” when seeking a practice position. Older practicing anesthesiologists who would have normally been expected to retire and thus open up practice spots were thought to be postponing retirement due to financial uncertainties. With the United States economic “recovery,” in recent years, this may be less of a consideration. Also, state and federal budget support for medical schools and residency training positions were and continue to be threatened by economic uncertainties, and hospital budget pressures could influence subsidies for anesthesia practices. Another factor in the United States that may affect the decision of medical students to choose anesthesiology or of anesthesia residents projecting a career path is the complex issue noted above regarding independent practice by CRNAs and its potential impact. Although there will always be a need for anesthesia professionals, probably increasing now and in the immediate future, there likely will be more factors to consider in seeking a practice position than ever before. In an effort to assist anesthesiologists attempting to choose a practice mode, the ASA has created an online training course, Practice Management for Residents—Evaluating a Practice, the purpose of which is to “Provide the newly graduating anesthesiologist with basic knowledge and skills to make an informed choice regarding the type of anesthesiology practice that best fits their professional and personal goals and preferences.”

## **Types of Practice**

Anesthesiology professionals finishing their training still need to choose among three fundamental possibilities: academic practice in a teaching hospital environment, a practice of patient care in the private practice marketplace, or a practice of patient care as an employee of a health-care system, large group practice, organization, or facility.

Teaching hospitals with anesthesiology residency programs constitute only a very small fraction of the total number of facilities requiring anesthesia services. These academic departments tend to be among the larger groups of anesthesiologists, but the aggregate fraction of the entire anesthesiologist population is small. It is interesting, however, that by the nature of the system, most residents and fellows finishing their training have almost exclusively been exposed only to academic anesthesiology. Accordingly, finishing trainees in the past often were comparatively unprepared to evaluate and enter the anesthesiology job market.

Specialty certification by the ABA should be the goal of all anesthesia residency graduates. Some finishing trainees (residents or fellows) who know they are eventually headed for private practice have started their attending careers as full-time junior faculty in an academic department. This allows them to obtain some clinical practice and supervisory experience and offers them the opportunity to prepare for the ABA examinations in the nurturing, protected academic environment with which they are familiar. Most trainees, however, do not become junior faculty; they accept positions in practice immediately. But they should take into account the need to become ABA-certified and build into their new practice arrangements the stipulation that there will be time and consideration given toward this goal.

### **Academic Practice**

For those who choose to stay in academic practice, a number of specific characteristics of academic anesthesia departments can be used as screening questions.

*How big is the department?* Junior faculty sometimes can get lost in very big departments and be treated as little better than glorified senior residents. On the other hand, the availability of subspecialty service opportunities and significant research and educational resources can make large departments extremely attractive. In smaller academic departments, there may be fewer resources, but the likelihood of being quickly accepted as a valued and contributing member of the teaching faculty (and research team, if

appropriate) may be higher. In very small departments, the number of expectations, projects, and involvements could potentially be overwhelming. In addition, a small department may lack a dedicated research infrastructure, so it may be necessary for the faculty in this situation to collaborate with other, larger departments to accomplish meaningful academic work.

*What exactly is expected of junior faculty?* If teaching one resident class every other week is standard, the candidate must enthusiastically accept that assignment and the attendant preparation work and time up front. Likewise, if it is expected that junior faculty will, by definition, be actively involved in publishable research, specific plans for projects to which the candidate is amenable must be made. In such situations, clear stipulations about startup research funding and nonclinical time to carry out the projects should be obtained as much as possible (although clinical workload demands and revenue generation expectations may make this very difficult in some settings). Particularly important is determining what the expectation is concerning outside funding. For example, it can be a rude shock to realize that projects will suddenly halt after 2 years if extramural funding has not been secured.

*What are the prospects for advancement?* Many new junior faculty directly out of residency start with medical school appointments as instructors unless there is something else in their background that immediately qualifies them as assistant professors. It is wise to understand from the beginning what it takes in that department and medical school to facilitate academic advancement. There may be more than one academic “track”; the tenure track, for example, usually depends on published research whereas the clinical or teacher track relies more heavily on one’s value in patient care and as a clinical educator. The criteria for promotion may be clearly spelled out by the institution—number of papers needed, involvement and recognition at various levels, grants submitted and funded, and so on—or the system may be less rigid and depend more heavily on the department chairman’s and other faculty evaluations and recommendations. In either case, careful inquiry before accepting the position can avert later surprise and disappointment.

*How much does it pay?* Traditionally, academic anesthesiologists have not earned quite as much as those in private practice—in return for the advantage of more predictable schedules, continued intellectual stimulation, and the intangible rewards of academic success. There is now great activity and attention concerning reimbursement of anesthesiologists, and it is difficult to predict future income for any anesthesiology practice situation. However, all of the forces influencing payment for anesthesia care may significantly diminish the traditional income differential between academic and private practice. In many cases, a faculty member is exclusively an employee of the institution or a component financial entity, which bills and collects or

negotiates group contracts for the patient care rendered by the faculty member, and then pays a negotiated amount (either an absolute dollar figure or a floating amount based on volume—or, especially, a combination of the two) that constitutes the faculty person's entire income. Under other much less and less common arrangements, faculty members themselves may be able to bill and collect or negotiate contracts for their clinical work. Some institutions have an (comparatively small) academic salary from the medical school for being on the faculty, but many do not; some channel variable amounts of money (from the so-called Part A clinical revenue) into the academic practice in recognition of teaching and administration or simply as a subsidy for needed service. Usually, the faculty will be members of some type of group or practice plan (either for the anesthesia department alone or for the entire faculty as a whole) that bills and collects or negotiates contracts and then distributes the practice income to the faculty under an arrangement that must be examined by the candidate. In most academic institutions, practice expenses such as all overhead and malpractice insurance as well as reasonable benefits, including discretionary funds for meetings, subscriptions, books, dues, and so forth, are automatically part of the compensation package, which often may not be true in private practice and must be counted in making any comparison. An important corollary issue is that of the source of the salaries of the department's primary anesthesia providers—residents and, in some cases, nurse anesthetists. Although the hospital usually pays for at least some and, often, most or all of these, arrangements vary, and it is important to ascertain whether the faculty practice income is also expected to cover the cost of the primary providers. Overall, it is appropriate for the candidate to ask probing questions about the commitment of the institution to the maintenance of reasonable compensation for faculty.

### **Private Practice in the Marketplace**

Obviously, rotations to a private practice hospital in the final year of anesthesia residency could help greatly in regard to the realities of private practice, but not all residency programs offer such opportunities. In that case, the finishing trainee who is certain about going into traditional private practice must seek information on career development and mentors from the private sector.

In the past, independent individual practice was a viable option for some versus a position with a group (sole proprietorship, partnership, or corporation) that functions as a single financial entity. Independent practice became increasingly less viable in many locations because of the need to be able to bid for contracts with health systems, practice facilities, or managed care entities. However, where independent practice may still be possible, it

usually first involves attempting to secure clinical privileges at a number of hospitals or facilities in the area in which one chooses to live. This may not always be easy, and this issue has been the subject of many (frequently unsuccessful) antitrust suits over recent years (see Antitrust Considerations). Then the anesthesiologist makes it known to the respective surgeon communities that he or she is available to render anesthesia services and waits until there is a request for his or her services. The anesthesiologist obtains the requisite financial information from the patient and then either individually bills and collects for services rendered or employs a service to do billing and collection for a percentage fee (which will vary depending on the circumstances, especially the volume of business; for billing [without scheduling services] it would be unlikely to be more than 7% or, at the most, 8% of actual collections).

How much of the needed equipment and supplies will be provided by the hospital or facility and how much by the independent anesthesiologist has varied widely. If an anesthesiologist spends considerable time in one operating suite, he or she may purchase an anesthesia machine exclusively for his or her own use and move it from room to room as needed. It is likely to be impractical to move a fully equipped anesthesia machine from hospital to hospital on a day-to-day basis. Among the features of this style of practice are the collegiality and relationships of a genuine private practice based on referrals and also the ability to decide independently how much time one wants to work. The downside is the potential unpredictability of the demand for service and the time needed to establish referral patterns and obtain bookings sufficient to generate a livable income.

When seeking a position with a private group, the applicant should search for potential practice opportunities through word of mouth, recruiting letters received by the training program, journal and online announcements and advertisements, and placement services, either commercial or professional, such as that provided by the ASA Career Center (<http://careers.asahq.org/>). The growing availability and ease of access for online job searching has allowed prospective anesthesiologists and potential employers often to locate suitable candidates without the expense of commercial placement services. However, the most recent trend appears to be increasing reliance on placement services because these concerns vet an applicant for the practices, saving time and energy, and only present “qualified candidates” who look like a potential good fit for the practice. Traditional journal ads from private practices essentially disappeared by 2016. Some of the screening questions by the applicant are the same as for an academic position, but there must be even more emphasis on the exact details of clinical expectations and financial arrangements. Some trainees finish residency (or fellowship even more so) very highly skilled in complex, difficult anesthesia procedures. They can be

surprised to find that in some private practice group situations, the junior-most anesthesiologist must wait some time, perhaps even years, before being eligible to do, for example, open heart anesthesia, and in the meantime will mostly be assigned more routine or less challenging anesthetics.

Financial arrangements in private group practices vary widely. A few groups may still be loose organizational alliances of independent practitioners who bill and collect separately and rotate clinical assignments and call for mutual convenience. Many groups act also as an umbrella fiscal entity, and there are many possible variations on this theme. In many circumstances in the past, new junior members started out as functional employees of the group for a probationary interval before being considered for full membership or partnership. This is not a classic employment situation because it is intended to be temporary as a prelude to full financial participation in the group. However, there have been enough instances of established groups abusing this arrangement that the ASA includes in its fundamental “Statement of Policy” the proviso: “Exploitation of anesthesiologists by other anesthesiologists is improper.”<sup>35</sup> This goes on to say that after a reasonable trial period, income should reflect services rendered. These statements may have variable impact on groups in the marketplace. Some groups have a history of demanding excessively long trial periods during which the junior anesthesiologist’s income is artificially low and then denying partnership and terminating the relationship to go on to employ a new probationer and start the cycle over again. Accordingly, new junior staff attempting to join groups should try to have such a “path to partnership” spelled out carefully in the agreement drafted by an expert representing the anesthesiologist. One key issue is the partnership “buy-in” once partnership is offered. This usually represents a percentage of the receivables (bills sent but not yet collected). As the cash outlay can be substantial, it is frequently “borrowed” from the group and paid back over time through a decrease in income, further delaying true equity participation in the group’s profits. However, in times of great economic uncertainty and retrenchment, it could be theoretically possible that the equity partners in a group might take a cut in income while the employed junior associates continue to collect their full contracted compensation. At the very least, thorough investigation and understanding of the relationship is mandatory. Seeking assistance from an experienced medical practice contract attorney prior to any commitment is likely to be a very worthwhile investment.

### **Private Practice as an Employee**

As noted in the opening section, there has been a major increasing trend toward anesthesiologists becoming permanent employees of any one of

various fiscal entities. The key difference is that there is no intention or hope of achieving an equity position (share of ownership, usually of a partnership, thus becoming a full partner). Health systems, hospitals, outpatient surgery centers, multidisciplinary clinics, other facilities tied to a specific location where surgery is performed, physician groups that have umbrella fiscal entities specifically created to serve as the employer of physicians, and even surgeons may seek to hire anesthesiologists as permanent employees. The common thread in this idea is that these fiscal entities want guaranteed anesthesia services they can control. Also, they likely see the anesthesiologists as additional components for generating profits, or, worse yet, as a financial liability that must be mitigated. It has been argued occasionally that, in some cases, it may appear that employees are not paid compensation that is commensurate with their production of receivables, at least considering traditional collection for anesthesia services. That is, the fiscal entity will pay a salary plus appropriate overhead substantially below collections generated by the anesthesia professional's work. These arrangements seem particularly favored by some large MCOs in certain geographic areas that, uncharitably, view anesthesia professionals simply as expensive necessities that prevent facilities from realizing maximum profit (although sometimes there is a promise of a lighter or more manageable work schedule in these positions compared with marketplace private practice).

Negotiating for a position as a permanent full-time employee is somewhat simpler and more straightforward than it is in marketplace private practice. It parallels the usual understandings that apply to most regular employer-employee situations: job description, role expectations, working conditions, hours, pay, and benefits. Although some of the positions within large anesthesia groups may be quite similar to traditional marketplace private practice, the idea of anesthesiologists functionally becoming numbered shift workers disturbs many in the profession because it contradicts the traditional professional model. Again, the complex nature and multiple levels of such considerations make it a personal issue that must be carefully evaluated by each individual with full awareness and consideration of the issues outlined here and commensurate research of ASA resources and available data about common regional circumstances and details of any specific medical community (often involving efforts to seek out current and former employees of a given entity as sources of relevant information).

### *Practice as a Hospital Employee*

Although CRNAs in some locations have traditionally practiced as hospital employees, until recently, it was less common outside full vertically integrated MCOs for physician anesthesiologists to be hospital (or facility) employees. One of the potential responses of hospitals to requests for

subsidies from exclusive-contract private practice groups of anesthesiologists has been to offer the anesthesiologists full-time employment status rather than subsidize an independent practice group that has its own significant administrative and overhead costs. The hospital likely suggests that integrating the billing, collecting, and management functions as well as major overhead costs such as malpractice insurance into the existing larger hospital operation would be very cost-efficient, allowing more financial resources to go to physician salaries, and also with possibly a somewhat greater predictability in financially uncertain times. The hospital can also guarantee the availability of anesthesia care (a requirement to sustain the OR, one of the main hospital revenue sources) in an era when some anesthesiologist groups may simply walk away from a hospital in search of greater income elsewhere, leaving the hospital to seek a contract probably with one of the large and potentially expensive anesthesia management companies. Of course, in return for employee status, the anesthesiologists surrender some degree of independence and also, for the group's partners, their equity stake in sharing in any subsequent increased practice revenue. A hospital might counter that concern, particularly in the era of facilities subsidizing anesthesia practices, with the contention that traditional anesthesia fee-for-service private practice that has been so common for so long will *never again* yield enough revenue to maintain the compensation levels anesthesiologists have come to expect, so they will not be losing anything.

### *Practice for a Large Group Management Company*

As noted in the opening section, in recent years there has been a proliferation of large state, regional, and national management companies that provide comprehensive anesthesia services on a contract basis with hospitals, surgery centers, and clinics. These companies, some started and/or managed by anesthesia professionals, promise the facility availability of anesthesia care during the specified hours in return for a contract to do so. This is intended to relieve the facility from any concern about recruiting, hiring/contracting, and retaining anesthesia professionals, virtually eliminating concern about disruption of OR schedules due to limited availability of anesthesia care. The only requirement of the facility is approval of the already prepared credentialing information for each anesthesia professional. Unlike many locum tenens companies in which anesthesia professionals are considered independent contractors and paid fixed contract amounts per hour, per day, or per job for a limited interval with no benefits, many of the large group management companies may employ anesthesia professionals full time on a salary with benefits (paid vacation, health insurance, retirement contribution, and so forth). The employment agreement would stipulate whether travel for temporary assignments in locations away from the employee's permanent

home would be required as a condition of the full-time job or the position will always be in the practitioner's home community. When an existing company purchases an anesthesia practice and the former members of a group private practice agree to become employees of the company, usually the members remain in the community and practice at the same facility where they were previously located.

### *Practice in the Office-based Setting*

Increasingly, anesthesia professionals are being recruited into the office-based practice of sedation and general anesthesia for a growing number of procedures. While the governance and oversight of this practice is evolving, there are several issues which are clear. A medical director must be appointed to determine the adequacy of facilities and to ensure that the procedures undertaken may be safely and effectively performed given the space, available equipment, and training of personnel involved. The anesthesia professional is a key component in determining patient selection. Practice situations should be avoided where the anesthesia professional does not have real input into the decision making about the patient and procedure. One danger in the office-based setting is that the hired anesthesia professional may feel intense production pressure if the owner/proceduralist (e.g., plastic surgeon, gastroenterologist, oral surgeon) is adamant about proceeding with a given patient despite a discussion about clinical concerns. Basic monitoring standards must be adhered to at all times and supervision of the patient until discharge from the facility must be factored into the time commitment on the part of the anesthesia professional. In addition, ensuring that all anesthesia equipment is up to date and in working order and that the protocols for cardiopulmonary emergencies and transfer of the patient to an outside facility are appropriate is required before accepting an office-based position or assignment. Some office-based centers allow the anesthesia professional to bill the patient and/or their third-party payer directly for services rendered in an application of the older and more independent fee-for-service model. Those considering office-based practice should review the information and guidelines published by the ASA.<sup>71</sup>

### *Billing and Collecting*

In practices in which anesthesiologists are directly involved with the financial management, they need to understand as much as possible about the complex world of health-care reimbursement. This significant task is facilitated by the major section of the ASA website devoted to "Practice Management" (<http://www.asahq.org/quality-and-practice-management/practice->

management). One of its functions is helping ASA members understand and work with the sometimes confusing and convoluted issues of effective billing for anesthesiologists' services. There are several relevant sections of the ASA website regarding billing and coding, including a primer for residents (<https://www.asahq.org/shop-asa/detail?productid=133891>).

While dramatic plans and proposals for significant changes in payment for anesthesia care have been outlined (see above), the traditional basics have changed little in recent years. It is important to understand that many of the most contentious issues, such as the requirement for physician supervision of nurse anesthetists and the implications of that for reimbursement, apply in many circumstances mostly to Medicare and, in some states, Medicaid. Thus, the fraction of the patient population covered by these government payers is important in any consideration. Different practice situations have different arrangements regarding the financial relationships between anesthesiologists and nurse anesthetists, and this can affect the complex situation of who bills for what. The nurses may be employees of a hospital or surgery center, of the anesthesiologists who medically direct them, or of no one in that they are independent contractors billing separately (even in cases in which physician supervision—not medical direction—is required but where those physicians do not bill for that component). In 1998, Medicare mandated that an anesthesia care team of a nurse anesthetist medically directed by an anesthesiologist could bill as a team no more than 100% of the fee that would apply if the anesthesiologist did the case alone. The implications of this change were complex and variable among anesthesiology practices. However, the previously common practice of one anesthesiologist medically directing 2 to 4 CRNAs and billing a full professional fee for each case ended at that time. Also, complex related issues played out after that. In 2001, the federal government issued a new regulation allowing individual states to “opt out” of the requirement that nurse anesthetists be supervised by physicians and several states did so, as noted above. This was opposed by the ASA. Because perioperative patient care, one component of which is administering anesthesia, is traditionally considered the practice of medicine, the implications of this change as far as the role of surgeons (or no one) supervising nurse anesthetists and the malpractice liability status of nurse anesthetists practicing independently were believed to be unclear. Further, the implications of all this for billing insurers other than Medicare and Medicaid are exceedingly complex.

## **Classic Methodology**

Because there is still application of the traditional method of billing for anesthesiology services, understanding can be important for anesthesia

professionals entering or in practice. In this system, each anesthetic generates a value of so many “units,” which represent effort and time. A conversion factor (dollars per unit) that can vary widely multiplied by the number of units generates a dollar amount to be billed. Each anesthetic has a base value number of units (which includes payment for standard preoperative evaluation and immediate postoperative care), for example, 8 for a cholecystectomy, and then the time taken for the anesthetic is divided into units, usually 15 minutes per unit. Thus, a cholecystectomy with anesthesia time of 1 hour and 10 minutes would have 8 base units and 4.66 time units for a total of 12.66 units. In some practice settings, it may be allowed to add modifiers, such as extra units for complex patients with multiple problems as reflected by an ASA physical status classification of 3 to 5 and/or E (“emergency”) or for insertion of an arterial or PA catheter. The sum for all factors is the total billing unit value. Determining the base value for an anesthetic in units depends on full and correct understanding of what operation was done. Although this sounds easy, it is the most difficult component of traditional anesthesia billing. The process of determining the procedure done is known as *coding* because the procedure name listed on the anesthesia record is assigned an identifying code number from the universally used “current procedural terminology” (CPT)-4 coding book. This code is then translated through the ASA “Relative Value Guide,” which assigns a base unit value to the type of procedure identified by the CPT-4 code. In the past, some anesthesiologists failed to understand the importance of correct coding to the success of the billing process. Placing this task in the hands of someone unfamiliar with the system and with surgical terminology can easily lead to incorrect coding. This can fail to capture charges and the resulting income to which the anesthesiologist is entitled or, worse, can systematically overcharge the payers, which will bring sanctions, penalties and, in certain cases, criminal prosecution. The international collection of diseases (ICD) terminology is the method by which providers and payers communicate concerning the type and classification of a given *diagnosis*. Usually, the diagnosis codes are entered by the facility billing for the time in the OR using the ICD-10 codes that went into effect in October 2015.

There has been a prevailing official governmental attitude that there are no simple, innocent coding errors. All upcoding (charging for more expensive services than were actually delivered) is considered to be prima facie evidence of fraud and is subject to severe disciplinary and legal action. All practices should have detailed compliance programs in place to ensure correct coding for services rendered. The ASA website has several relevant sections with information. Further, outside expert help (such as from a health-care law firm that specializes in compliance programs) can be highly desirable for the process of formulating and implementing a compliance plan regarding correct

coding and billing.

Assembly and transfer of the information necessary to generate bills must be efficient and complete. Traditionally, this involved depositing in a secure central location an extra paper copy of the anesthesia record and often a “billing sheet” with it, on which was inscribed the names of all the involved personnel and any additional information about other potentially billable services, such as invasive monitors. Any practice involved with a comprehensive computerized electronic perioperative information management system in the facility should be using that to assemble this “front end” billing information. Short of that, some practices collect electronic information specifically generated by the anesthesia providers for that purpose. They have equipped each staff member with a handheld electronic device into which data are entered and then the device is synched with a departmental computer at the end of the day. If the OR suite has “Wi-Fi” (wireless electronic connection), the same function could be accomplished in real time with the providers entering the requisite information into a program on a computer or tablet affixed to each anesthesia machine (or carried by each staff member) or a smartphone with the appropriate application installed. Once the information has been secured, a mechanism must be employed to generate the actual bill and communicate it to the payer (on paper, on disk, or, usually, directly computer to computer: “Electronic claims submission”). The possible exact arrangements for doing this vary widely.

Whether an anesthesia practice that will be billing and collecting for anesthesia services should employ its own inhouse clerical and bookkeeping personnel to perform this function or should contract with an outside company whose sole function is medical billing and collecting (possibly, ideally, for anesthesiology only) can be debated endlessly. Whichever is chosen, knowledgeable oversight by the anesthesia professionals who ultimately will derive income from the revenue collected is required. Ultimately, the entity actually submitting the bill will verify that it has been paid (posting of receipts) and may or may not actually handle the incoming money. Very often, anesthesia practices or individuals who use a billing service (and even some who have inhouse billing staffs) will arrange that the actual payments go directly to a bank “lockbox,” which is a post office box for paper checks (better individual than shared, even if more expensive) to which the payments come and then go directly into a bank account for the practice, which is also where electronic payments are received. This system avoids the situation of having the people who generate the bill actually handle the incoming receipts, a practice that has led to theft and fraud in a few cases. Eventual decisions about how hard to try to collect from payers who deny coverage and then from patients directly will depend on the circumstances, including local customs, and the associated expense balanced against expected

returns.

Detailed summary statistics of the work done by an anesthesiology practice group are critical for logistic management of personnel, scheduling, and financial analysis. Spreadsheet and database computer programs customized for an individual practice's characteristics will be invaluable. A summary of the types of data an anesthesia practice should track is shown in [Table 2-1](#). Once all the data are assembled and reviewed, at least monthly analysis by a business manager or equivalent, as well as officers/leaders of the practice group, can spot trends very early in their development and allow appropriate correction or planning. Often the responsible members of an anesthesiology group question how effective their financial services operation is, particularly regarding net collections. This is a complex issue<sup>72</sup> that, again, often requires outside help. Routine internal audits can be useful but could be self-serving. No billing office or company that is honest and completely above board should ever object to a client, in this case the anesthesiology practice group, engaging an independent outside auditor to come in and thoroughly examine both the efficiency of the operation and also "the books" concerning correctness and completeness of collections.

Anesthesia billing and collecting are among the most complex challenges in the medical reimbursement field. Traditional anesthesia reimbursement is unique in all of medicine. The experience of many people over the years has suggested that it often is well advised to deal with an entity that is not only very experienced in anesthesia billing but also does anesthesia billing exclusively or as a large fraction of its efforts. It is very difficult for an anesthesiologist or a family member to do billing and collecting as a side activity to a normal life. This has led to inefficient and inadequate efforts in many cases, illustrating the value of paying a reasonable fee to a professional who will devote great time and energy to this challenging endeavor.

**Table 2-1** Types of Data an Anesthesiology Group Should Track and Maintain Concerning Its Own Practice

Types of Data the Anesthesiology Group's Computer System Should Track	Type of Information to Generate from These Data
<ul style="list-style-type: none"> <li>• Transaction-based system (track each case and charge as separate record)               <ul style="list-style-type: none"> <li>■ Track individual charges by CPT-4 code</li> <li>■ Track individual payments by payer</li> </ul> </li> <li>• Track all data elements on an interrelated basis               <ul style="list-style-type: none"> <li>■ By place of service</li> <li>■ By charge, broken down                   <ul style="list-style-type: none"> <li>○ By number of units (time and base)</li> <li>○ By ASA modifiers</li> <li>○ By number of lines</li> </ul> </li> <li>■ By CPT-4 code</li> <li>■ By payer</li> <li>■ By payment code (full payment, discount, write-off, or refund)</li> <li>■ By diagnosis (ICD-9 code)</li> <li>■ By surgeon</li> <li>■ By anesthesiologist</li> <li>■ By anesthesia care team provider</li> <li>■ By start and stop times</li> <li>■ By age</li> <li>■ By gender</li> <li>■ By employer</li> <li>■ By ZIP code</li> </ul> </li> </ul>	<ul style="list-style-type: none"> <li>• Aggregate number of cases per year for the group</li> <li>• Total number of cases per year for each provider within the group               <ul style="list-style-type: none"> <li>■ Number of cases performed by anesthesiologists</li> <li>■ Number of cases performed by the anesthesia care team</li> </ul> </li> <li>• Average number of units per case (as one measure of intensity per case)</li> <li>• Average number of units per CPT-4 code</li> <li>• Average time units per case and per CPT-4 code               <ul style="list-style-type: none"> <li>■ Group should be able to calculate time units per individual surgeon</li> </ul> </li> <li>• Average line charge per case</li> <li>• Charges per case by CPT-4 code</li> <li>• Payments per case by payer</li> <li>• Patient mix               <ul style="list-style-type: none"> <li>■ Percent traditional indemnity</li> <li>■ Percent managed care (broken down by each MCO for which services are provided)</li> <li>■ Percent self-pay</li> <li>■ Percent Medicare</li> <li>■ Percent Medicaid</li> </ul> </li> <li>• Collection rate for each population served</li> <li>• Overall collection rate</li> <li>• Costs per unit (total costs, excluding compensation + total units) (costs include liability insurance, rent, collection costs, and legal and accounting fees)</li> <li>• Compensation costs per unit (total compensation + total units) for MCO populations, utilization patterns by age, gender, and diagnosis</li> </ul>

## Antitrust Considerations

There can be antitrust implications of business arrangements involving anesthesiologists—particularly with all the realignments, consolidations, mergers, and contracts associated with the attempted implementation of managed care, expansion of health systems, the drive for cost efficiency and, more recently, the rise of ACOs. The applicable statutes and regulations are often poorly understood. Contrary to popular belief, the antitrust laws do not involve the rights of individuals to engage in business. Rather, the laws are concerned solely with the preservation of competition within a defined marketplace and the rights of the consumer, independent of whether any one vendor or provider of service is involved. When an anesthesiologist has been excluded from a particular hospital's staff or anesthesia group and then sues based on an alleged antitrust violation, the anesthesiologist loses virtually automatically. This is because there is still significant competition in the relevant medical care marketplace (community or region) and competition in that market is not threatened by the exclusion of one physician from one

staff.

In essence, if there are *several* hospitals offering relatively similar services to an immediate community (the market), denial of privileges to one physician by one hospital is not anticompetitive. If, on the other hand, there is only *one* hospital in a smaller market, then the same act, the same set of circumstances, could be seen very differently. In that case, there would be a limitation of competition because the hospital dominates and, in fact, may control the market for hospital services. Exclusion of one physician, then, could limit access by the consumers to alternative competing services and hence would likely be judged an antitrust violation.

The Sherman Antitrust Act is a federal law more than 100 years old. Section 1 deals with contracts, combinations, conspiracy, and restraint of trade. By definition, two or more separate economic entities must be involved in an agreement that is challenged as illegal for this section to apply. Section 2 prohibits monopolies or conspiracy to create a monopoly, and it is possible that this could apply to a single economic entity that has illegally gained domination of a market. Consideration of possible monopolistic domination of a market involves a situation in which a single entity controls at least 50% of the business in that market. The stakes are high in that the antitrust legislation provides for triple damages if a lawsuit is successful. The US Department of Justice and the Federal Trade Commission are keenly interested in the current rapid evolution and consolidation in the health-care industry, and thus are actively involved in evaluating situations of possible antitrust violations. The potential for a “whistle-blower” to file a lawsuit and receive a fractional payment out of the eventual financial penalties against a guilty party has in some cases provoked employees or former employees of a health system or group practice to institute such lawsuits.

There are two ways to judge violations. Under the *per se rule*, which is applied relatively rarely, conduct that is obviously limiting competition in a market is automatically illegal. The other type of violation is based on the *rule of reason*, which involves a careful analysis of the market and the state of competition. The majority of complaints against physicians are judged by this rule. The more competitors there are in a market, the less likely that any one act is anticompetitive. In a community with two hospitals, one smaller than the other, with an anesthesiology group practice exclusively at each, if the larger anesthesiology practice group buys out and absorbs the smaller, leaving only one group for the only two hospitals in the community, that may be anticompetitive, particularly if a new anesthesiologist seeks to practice solo at those hospitals and is refused privileges.

## **Legal Implications**

In the current era of rapidly evolving practice arrangements, the antitrust laws are important. If physicians (individuals or groups), who normally would be competitors because they are separate economic entities, meet and agree on the prices they will charge or the terms they will seek in a managed care, health system, or institutional contract, that can be anticompetitive, monopolistic, and hence possibly illegal. Note that sharing a common office and common billing service alone is not enough to constitute a true group. If, on the other hand, the same physicians join in a true economic partnership to form a new group (total integration), that is a single economic entity (and meets certain other criteria) that will set prices and negotiate contracts, that is perfectly legal. The other criteria are critical. There must be capital investment and also risk-sharing (if there is a profit or loss, it is distributed among the group members)—that is, total integration into a genuine partnership (that is usually incorporated, sometimes as a limited liability corporation). This issue is very important in considering the drive for new organizations to put together networks of physicians that then seek contracts with major employers to provide medical care. Sometimes, hospitals or clinics attempt to form a network comprising all the members of the medical staff so that the resulting entity can bid globally for total care contracts. Any network is a joint venture of independent practitioners. If the participating physicians of one specialty in a network are separate economic entities and the network advertises one price for their services, this would seem to suggest an antitrust violation (horizontal price fixing). In the past, if a network involved fewer than 20% of one type of medical specialist in a market, that was called a *safe harbor*, meaning that it was permissible for nonpartners to get together and negotiate prices. The federal government has tried to encourage formation of such networks to help reduce health-care costs, and as a result made some relevant exceptions to the application of these rules. As long as the network is nonexclusive (other nonnetwork physicians of a given specialty are free to practice in the same facilities and compete for the same patients), the network can comprise up to 30% of the physicians of one specialty in a market. Note specifically that this does not allow a local specialty society in a big city to serve as a bargaining agent on fees for its members because it is very likely that more than 30% of the specialists in an area will be members of the society. The only real exception to this provision is in thinly populated rural areas where there may be just one physician network. In such cases (which are, so far, less common because the major managed care, health system, and network activity has occurred mainly in more heavily populated urban areas), there is no limit on how many of one specialty can become network members and have the network negotiate fees, as long as the network is nonexclusive.

Relevant legislation, regulations, and court actions all happen rapidly and

often. Mergers among anesthesiology groups in a market area for the purposes of both efficiency and strength in negotiating fees have been very popular as a response to the rapidly changing marketplace. A list of questions must be answered to determine if such a merger would have anticompetitive implications. Some information may be available to ASA members, but it is important to consider independent expert advice and help. Obviously, anesthesiologists contemplating a merger or facing any one of a great number of other situations in the modern health-care arena must secure assistance from professional advisors, usually attorneys, whose job it is to be aware of the most recent developments, how they apply, and how best to forge agreements in formal contracts. Anesthesiologists hoping to find reputable advisors can start their search with word-of-mouth referrals from colleagues who have used such services. Local or state medical societies frequently know of attorneys who specialize in this area and it may be possible to get a referral through the ASA Washington, DC, office.

### **Exclusive Service Contracts**

Often, one of the larger issues faced by anesthesiologists in the traditional fee-for-service private practice model seeking to define practice arrangements concerns the desirability of considering an exclusive contract with a health-care facility to provide anesthesia services. An exclusive contract states that anesthesiologists practicing at a given facility must be members of the group holding the exclusive contract and, sometimes, that members of the group will practice nowhere else. A hospital may want to give an exclusive contract in return for a guarantee of coverage as part of the contract. Also, the hospital may believe that such a contract can help ensure the quality of the anesthesia professionals because the contract can contain credentialing and performance criteria. It is important to understand that the hospital likely will exercise a degree of control over the anesthesiologists with such a contract in force, such as requiring them to participate as providers in any contracts the hospital makes with third-party payers and also tying hospital privileges to the existence of the contract (the so-called “clean-sweep provision” that bypasses any due process of the medical staff should the hospital terminate the contract). Certain of these types of provisions constitute *economic credentialing*, which is defined as the use of economic criteria unrelated to the quality of care or professional competency of physicians in granting or renewing hospital privileges (such as the acceptance of below-market fees associated with a hospital-negotiated care contract or even requiring financial contributions in some form to the hospital).

The ASA in the past has opposed economic credentialing. However, the anesthesiologists involved may accept such an exclusive services contract to

guarantee that they alone will get the business from the surgeons on staff at that hospital, and hence the resulting income. There may be other considerations on both sides, and there is information on the ASA website (<http://www.asahq.org/.../06/exclusive-contracts-and-closed-open-departments/en/1>). However, it is critical that anesthesiologists faced with important practice management decisions, such as whether to enter into an exclusive contract, must seek outside advice and counsel. There are a great many nuances to these issues,<sup>73-75</sup> and anesthesiologists are at risk attempting to negotiate such complex matters alone, just as patients would be at risk if a contract attorney attempted to induce general anesthesia.

Denial of hospital privileges as a result of the existence of an exclusive contract with the anesthesiologists in place at the facility has been the source of many lawsuits, including the well-known Louisiana case of *Jefferson Parish Hospital District v Hyde*. In that case, the US Supreme Court found for the defendant anesthesiologists and the hospital, saying that there was no antitrust violation because there was no real adverse effect on competition as far as patients were concerned because there were several other hospitals within the market to which they could go, and therefore they could exercise their rights to take advantage of competition in the relevant market. Thus, existence of an exclusive contract only in the rare setting where anticompetitive effects on patients can be proved might lead to a legitimate antitrust claim by a physician denied privileges. This was proven true in the *Kessel v Monongahela County General Hospital* case in West Virginia in which an exclusive anesthesiology contract was held illegal. Therefore, again, these arrangements are by definition complex and fraught with hazard. Accordingly, outside advice and counsel are always necessary.

## **Hospital Subsidies**

Modern economic realities have forced a great number of anesthesiology practice groups (in both private and academic settings) to recognize that their patient care revenue, after overhead is paid, does not provide sufficient compensation to attract and retain the number and quality of staff necessary to provide the expected clinical service (and fulfill any other group/department missions). Attempting to do the same (or more) work with fewer staff may temporarily provide increased financial compensation. Cutting benefits (discretionary personal professional expenses, retirement contributions, or even insurance coverage) may also be a component of a response to inadequate practice revenue. However, the resulting decrements in personal security, in convenience, and in quality of life as far as acute and chronic fatigue, decreased family and recreation time, and tension among colleagues fearful that someone else is getting a “better deal” will quickly

overcome any brief advantage of a somewhat higher income. Therefore, many practice groups in such situations are requesting their hospital (or other health-care facility where they practice) pay them a direct cash subsidy that is used to augment practice revenue in order to maintain benefits and amenities while maintaining or even increasing the direct compensation to staff members, hopefully to a market-competitive level that will promote recruitment and retention of group members.

Obviously, requests by a practice group for a direct subsidy must be thoroughly justified to the facility administration receiving the petition. The group's business operation should already have been examined carefully for any possible defects or means to enhance revenue generation. Explanation of the general trend of declining reimbursements for anesthesia services should be carefully documented. Facts and figures on that and related topics can be obtained from journal articles and the ASA website and publications, including the *Monitor*. Demand for anesthesia coverage for the surgical schedule is a key component of this proposal. Scheduling and utilization, particularly if early-morning staffing is required for many ORs that are routinely unused later during the traditional work day, is a major issue to be understood and presented. Any other OR inefficiencies created by hospital support staff and previous efforts to deal with them should also be highlighted. Unfavorable payer mix, impact of contracts, and programs initiated by the hospital are also often major factors in situations of inadequate practice revenue. Always, 7 the group's good will with the surgeons and the community in general should be emphasized, as well as of the indirect or "behind the scenes" services and benefits the anesthesiology group provides to the hospital. Note that the necessity for such a subsidy request is precisely the time when the anesthesia professionals will benefit from being perceived as "good citizens" of the health-care facility. An overly aggressive effort beyond the bounds of logic could provoke the facility to consider alternative arrangements, even up to the point of putting out a request for proposal from other anesthesiology practice groups. Therefore, thoughtful calculations are required and a careful balance must be sought, seeking enough financial support to supplement practice revenues so that members' compensation is competitive but not so much as to be excessive. Supporting statements and documents about offers and potential earnings elsewhere must be completely honest and not exaggerated or credibility and good faith will be lost. Further, part of any agreement will be the full sharing of the group's detailed financial information with the facility administration, both at the time of the request and on an ongoing basis if the payment is more than a one-time "bail out." Plans for review and renewal should be made once a subsidy is paid.

Any subsidy will likely require a formal contract. There may be concern about malpractice liability implications for the hospital even though the

practice group stays an independent entity as before. There may be “inurement” or “private benefit” concerns that could be perceived as a threat to the tax-exempt status of a nonprofit hospital. Lack of understanding of the applicable laws may lead to fears that a subsidy could be an illegal “kickback” or a violation of the Stark II self-referral prohibition. As is almost always the case, expert outside professional consultant advice, usually from an attorney who specializes exclusively in health-care finance contracting, is mandatory in such circumstances. The ASA Washington, DC, office may be of help in identifying potential consultants, and the ASA has some basic information on subsidies to anesthesiology practice groups.<sup>76–78</sup>

## *Evolving Practice Arrangements*

Even though managed care plans have not had the major impact anticipated, various iterations still exist and have ongoing implications for anesthesiology practice. Further, concern about disproportionate increases in health-care spending as a percentage of US gross domestic product noted above and the fear of the postulated bankruptcy of Medicare and Medicaid fuel the persistent specter of new efforts to impose managed care (nationalized or decentralized) or other arrangements designed to control costs.

In the initial stages of the evolution of a managed care marketplace, 8 the MCO usually seeks contracts with providers based on discounted fee-for-service arrangements. This preserves the basic traditional idea of production-based physician reimbursement (do more, bill more) but the price of each act of services is lower (the providers are induced to give deep discounts with the promise of significant volumes of patients); also, the MCO gatekeeper primary care physicians and the MCO reviewers are strongly encouraged to limit complex and costly services as much as possible. There are other features intermittently along the way, such as the bundled payment models described above. In an application of the concept of risk-sharing (spend too much for patient care and lose income), this usually is initially manifest in the form of “withholds,” the practice of the MCO holding back a fraction of the agreed-upon payment to the providers (e.g., 10% or 15%) and keeping this money until the end of the fiscal year. At that time, if there is any money left in the risk pool or withhold account after all the (partial) provider fees and MCO expenses are paid, it is distributed to the providers in proportion to their degree of participation during the year. This is a clever and powerful incentive to providers to reduce health-care expenses. However, it is not as powerful as the stage of full risk-sharing. At one point in time, experts predicted that managed care marketplaces would mature and MCOs would grow and succeed, with the existing organizations and, especially, any new ones, intending to shift to the model of prospective capitated payments

for providers. Although it may be less likely today that this particular type of superstructure model will come to pass in the United States, the forces pushing cost control and fundamental reconfiguration of the US health-care establishment are powerful. It is valuable for anesthesiologists to understand one of the main models advocated by so-called reformers.

## **Prospective Payments**

Prospective capitated payments constitute an entirely new world to health-care providers, involving prospective capitated payments for large populations of patients, in which each group of providers in the MCO receives a fixed amount per enrolled covered life (member) per month (PMPM) and agrees, except in the most unusual circumstances, to provide whatever care is needed by that population for that prospective payment. The most unusual circumstances involve “carve-out” arrangements in which specific very costly and unusual conditions or procedures (such as the birth of a child with disastrous multiple congenital anomalies) are covered separately on a discounted fee-for-service basis. If there were to ever be full capitation, the entire financial underpinning of American medical care would do a complete about-face from the traditional rewards for giving more care and doing more procedures to new rewards for giving and doing less. Some managed care contracts contain other features intended to protect the providers against unexpected overutilization by patients that would stretch the providers beyond the bounds of the original contract with the MCO. The provisions setting the boundaries are called *risk corridors*, and the “stop-loss clauses” add some discounted fee-for-service payment for the excess care beyond the risk corridor (capitated contract limit). Providers who were used to getting paid more for doing more can suddenly find themselves getting paid a fixed amount no matter how much or how little they do with regard to a specified population—hence, the perceived incentive to do, and consequently spend, less. If the providers render too much care within the defined boundary of the contract, they essentially will be working for free, the ultimate in risk-sharing.

There are clearly potential internal conflicts in such a system, and how patients reacted initially to this radical change in attitude on the part of physicians where it was actually implemented demonstrated that this overall mechanism is unlikely to be readily embraced by the general public. Health-care providers (physicians, other health-care professionals, and facilities), in turn, allied themselves in a wide variety of organizations to create strength and desirable resources to present to the MCOs in contract negotiations. “Management service organizations” are joint-venture network arrangements that do not involve true economic integration among the practitioners, but

merely offer common services to physicians who may, as a loosely organized informal group, elect to seek MCO contracts. “Preferred provider organizations” are network arrangements of otherwise economically independent physicians who form a new corporate entity to seek managed care contracts in which there are significant financial incentives to patients to use the network providers and financial penalties for going to out-of-network providers. This has proved a relatively popular model and appeared to gain acceptance. Physician–hospital organizations are similar entities but involve understandings between groups of physicians and a hospital so that a large package or bundle of services can be constructed as essentially one-stop points of care. Independent practice associations are like preferred provider organizations but are specifically oriented toward capitated contracts for covered lives with significant risk-sharing by the providers. Groups (or clinics) “without walls” are collections of practitioners who fully integrate economically into a single fiscal entity (true partnership) and then compete for MCO contracts on the basis of risk-sharing incentives among the partners. Fully integrated groups or health maintenance organizations (such as Kaiser Permanente in California or Harvard Pilgrim Health in New England) house the group of partner provider physicians and associated support staff at a single location for the convenience of patients, a big selling point when they seek MCO or employer contracts.

### **Changing Paradigm**

MCOs are unlikely to contract with just one solo independent anesthesiologist. Further, smaller private practice groups of anesthesiologists may find themselves at a competitive disadvantage<sup>79</sup> unless they become part of a vertically integrated (multispecialty) or horizontally integrated (with other anesthesiologists) organization. Negotiations with MCOs require expert advice, probably even more so than the traditional exclusive contracts with hospitals as previously noted. Before any negotiation can even be considered, the MCO must provide significant amounts of information about the covered patient population. The projected health-care utilization pattern of a large group of white-collar workers (and their families) from major upscale employers in an urban area will be quite different from that of a relatively rural Medicaid population. Specific demographics and past utilization histories are absolutely mandatory for each proposed population to be covered, and this information should go directly to the advising experts for evaluation, whether the proposed negotiation is for discounted fee-for-service, a fee schedule, global bundled fees, or full capitation.

Significant questions were pointedly raised about the reimbursement implications for anesthesiologists of the putative managed care/practice

reorganization revolution. Much of that discussion has been rendered moot by the failure of the pure prospective capitated payment model to gain widespread adoption. However, if an anesthesia practice or its parent financial entity is ever asked to enter negotiation for a “per member per month” payment for anesthesia services, immediate consultation with independent experts should occur. Discounted fee-for-service arrangements are easier for anesthesiologists to understand because these are directly referable to existing traditional fee structures. Again, any negotiation requires outside help.

Another common feature of this discussion has been the tendency of private (nongovernmental) contracting organizations to attempt to tie their payments for professional services to the government’s Medicare rate for specific CPT-4 codes. It is common for both commercial indemnity insurance entities (e.g., Blue Shield, Aetna, Humana, United Health) and MCOs to offer primary care physicians, for example, 125% of the Medicare payment rate for specific services. Although groups of primary care physicians may view this as somewhat reasonable and, thus, they sign such contracts, anesthesiologists face unique challenges in this regard. Many leaders among anesthesia professionals believe that the Medicare reimbursement rate is unfairly low for the work involved in providing anesthesia care. The Medicare rate likely would remain less than half the per unit “conversion factor” that the large indemnity carriers traditionally have paid for anesthesia care in recent years. Therefore, 125% of what many anesthesia professionals consider woefully inadequate would still be inadequate. Thus, in spite of sometimes intense pressure, anesthesia professionals in many markets have been reluctant to accept indemnity insurance contract rates tied to Medicare rates. As always, anesthesia professionals faced with complex reimbursement situations and decisions should seek expert advice from the national offices of their professional practice organizations and from knowledgeable paid consultants and attorneys.

## **Pay for Performance**

Commercial indemnity insurance entities, MCOs, and particularly, the US federal CMS all now emphasize the concept of “performance-based payments” as a significant way to limit the growth of (and even reduce) health-care costs,<sup>80</sup> especially by reducing expensive complications of medical care. This “pay-for-performance” movement began with the federal Tax Relief and Healthcare Act of 2006 and continued with the Physician Quality Reporting Initiative in 2008. The potential implications for anesthesia practice are many.<sup>81</sup>

In general, CMS made strenuous efforts to attempt to define and

promulgate objective quality measures that could be documented as indicators of the “quality” of health care delivered. The main issue is the promotion of specific “best practices” care elements that help avoid expensive outcomes or complications that currently generate a disproportionate (preventable) fraction of health-care costs. The administration of aspirin and  $\beta$ -blockers within a fixed brief interval after the arrival of an acute myocardial infarction patient is a good example, as are various parameters in the care of patients with community-acquired pneumonia or congestive heart failure (all constituents of the CMS “core measures” on which quality is judged). Defining and validating objective and easily quantifiable so-called quality measures that will prevent expensive complications of anesthesia care has proved to be more difficult. The initial targeted parameter was somewhat indirect: the timing of the administration of prophylactic antibiotics prior to surgical incision. The anesthesia professional is judged to be in compliance when the antibiotic is administered within the prescribed limit prior to incision. This must be verifiably documented on the anesthesia record. Benchmark criteria such as 95% compliance for a specific financial entity billing Medicare and Medicaid must be met by members of the group or the reimbursement for anesthesia services by that financial entity will be reduced by a specific fraction (or a promised “bonus” will be withheld) as a compliance incentive, but also somewhat as an offset to the increased cost of the consequent complications associated with failure to comply. If performance is in compliance, CMS traditionally would pay the maximum allowable reimbursement (pay for performance).

The second target was catheter-related bloodstream infection, and the performance behavior expected of anesthesia professionals is observance of strict aseptic protocol during central vascular catheter placement (and avoiding the femoral route if at all possible). The third objective parameter of anesthesia care quality targeted temperature management of the surgical patient with the compliance behavior being met by achieving one of three possible goals: use of active warming intraoperatively or documented temperature 36°C or higher in either the last 30 minutes of anesthesia or the first 30 minutes in the PACU. Other potential objective performance criteria intended to encourage avoidance of costly complications of anesthesia care may include glucose control in major surgery, use of pencil-point spinal needles in obstetric anesthesia, (“meaningful”) use of EHRs, preoperative screening for sleep apnea, preoperative fasting instructions, meperidine administration for postoperative shivering, and several others. In all cases when a parameter is adopted, benchmark criteria for degree of compliance will be established and reimbursement will be reduced one way or another for failure to comply, as documented on the relevant records and self-reported by the billing financial entity (subject to audit, of course).

Hospitals will have even more at stake in the sense that the pay-for-performance movement has created paradigms in which hospitals will not receive reimbursements for care associated with preventable complications such as catheter-related sepsis (blood or urinary), ventilator-acquired pneumonia, and decubitus ulcers. This concept has several implications. One is that smaller hospitals often populated by less acute patients will be more likely and quicker to transfer sicker patients to larger referral facilities in order to avoid losing reimbursement associated with the development of patient complications. Concomitantly, documentation of the timing of the development of complications has become critical. If a hospital or department has documented the pre-existing presence of a complication at the time of a patient's admission, it should not be penalized for the development of that condition. In this context, anesthesia professionals can have an important role documenting the existence of pneumonia, sacral decubitus ulcers, or sepsis in their records when they first see a newly admitted patient, usually for preoperative evaluation. This will be perceived as excellent institutional citizenship by the anesthesia professional because it may prevent significant reimbursement reduction to the hospital.

### **Accountable Care Organizations**

The Patient Protection and ACA (nicknamed "ObamaCare") was signed into law in 2010. One area of significance to anesthesiology professionals concerned the creation of ACOs. After review of the 698-page final rule it became clear to ASA that there was little consideration to pre- and postoperative care. This was one of the original factors that led to the adaptation of the ACA-inspired "Patient-Centered Medical Home" (<http://www.hhs.gov/about/news/2014/08/26/the-affordable-care-act-supports-patient-centered-medical-homes-in-health-centers.html>) to a suggestion of the "Perioperative Surgical Home," discussed extensively in the opening section. As noted, in the PSH model, anesthesiologists are identified (and ultimately compensated) for their roles in preoperative evaluation of increasingly complex patient populations, intraoperative management of the anesthetic, and postoperative management of pain and critical care issues of the surgical patient. Included in this is the idea that even routine postoperative care of the patient is within the domain of the anesthesiologist, as is follow-up care for those patients suffering from subacute pain following surgical procedures. Clearly, in recent years, a growing number of institutions have come to rely on anesthesiologist-directed preoperative assessment clinics to ensure adequate preparation of the surgical patient for their procedure. Likewise most institutions have physicians (usually anesthesiologists) practicing pain medicine/management on staff. The PSH model merely seeks

to bring these elements along with critical care together to provide a vertical integration of care during the perioperative period. Although most academic anesthesiology departments and some large community hospitals can assemble these teams into a “PHS” model, it remains to be seen how this concept could be executed in the medium to small community hospital setting or what partnerships would have to be developed to accomplish these goals. Although the current language of the ACA deals with the concept of primary care and does not comment on surgical care, the ACO format would in essence be similar to the prospective payment paradigm described above with payment distributed to members of the care team based upon participation in care of the patient and any savings rendered from the efficient delivery of care distributed to the stakeholders in a given ACO.

### ***Management Intricacies***

The complexities of modern medical practice are significant and increasing rapidly. Management consultants, both large national firms that cross all industries and also boutique firms that specialize in only medical practices, are advertising their services to anesthesiology group practices. A recent analysis (that might seem more fitting as an MBA school case study) of business strategies relevant to anesthesiology group practices suggested there are key elements that detrimentally go unrecognized.<sup>82</sup> Whether a specific anesthesiology practice should consider bringing in an outside management consultant to help bolster the function, efficiency, and profitability of the practice obviously must be an individual carefully considered decision. However, even such a suggestion is a recent phenomenon, reflecting the tensions of the modern medical marketplace. As in other related caveats, whenever considering engaging outside help, a rigorous vetting process is required, especially including reference checks and discussion with previous practices served by that consultant.

### ***Health Insurance Portability and Accountability Act***

The 2003 implementation of the Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA) of 1996 required significant changes in how medical records and patient information are handled in the day-to-day delivery of health care. An update on the implications for anesthesiologists titled “Payment and Practice Management Memo, October 2013: You Can’t Be Too Careful When it Comes to HIPAA Privacy and Security” has been promulgated by the ASA ([http://www.asahq.org/.../tppm/Protected Health Information October 2013/en/1](http://www.asahq.org/.../tppm/ProtectedHealthInformationOctober2013/en/1)).

Attention is focused on “protected health information” (identifiable as

from a specific patient by name). Patients must be notified of their privacy rights. Usually this will be covered by the health-care facility in which anesthesia professionals work, but if separate private records are maintained, separate notification may be necessary. Privacy policies must be created, adopted, and promulgated to all practitioners, all of whom then must be trained in application of those policies. Often, anesthesiology groups can combine with the facilities in which they practice as an “organized health-care arrangement” so that the anesthesia practitioners can be covered in part by the HIPAA compliance activities of the facility. A “privacy officer” must be appointed for the practice group. Finally, and most importantly, medical records containing protected health information must be secured so they are not readily available to those who do not need them to render care.

One of the most obvious applications for many anesthesiologists is concern about the assembled preoperative information and charts for tomorrow’s cases that frequently were placed prominently in the OR holding area at the end of one work day in readiness for the next day’s cases. HIPAA provisions require that all that patient information be locked away overnight. Another classic example is what many ORs refer to as “the board.” Often, a large white dry-marker board occupies a prominent wall near the front desk of an OR suite, and the rooms, cases, and personnel assignments are inscribed thereon at the beginning of the day and modified or crossed off as the day progresses. Under HIPAA, patients’ names may not be used on such a board if there is any chance that anyone not directly involved in their care could see them. Alternatively, some facilities tape a copy of the day’s OR schedule (including patients’ names, ages, and operations) on the wall, which would also be a violation. The same is true for similar boards or posted schedules in OR holding areas and PACUs. Another issue often overlooked that is very problematic and probably the one that concerns patients the most is the obtaining of history information in a location, such as a “bed slot” behind just a curtain in the OR holding area, where sensitive medical and personal information is spoken out loud within earshot of other patients, other patients’ families, and noninvolved caregivers. This concern is difficult to address and there is no one universally applicable suggestion. However, anesthesia professionals who interact with patients in such environments should be as sensitive as physically possible to being overheard and also should bring such concerns to the attention of the facility administrators.

Further, many anesthesiology practices also must apply HIPAA provisions to their billing operations; the details will vary depending on the mechanisms used and a great deal will depend on which type of electronic claims submission software is being used by the billing entity actually submitting the claims. Telephone calls and faxes into offices must be handled specially if containing identifiable patient information. Presentation of patient

information for QA or teaching purposes must be free of all identifiers unless specific individual permission has been obtained on prescribed printed forms. Requests for patient information from a wide variety of outside entities, including insurance companies and collection agencies, must be processed in HIPAA-compliant ways. HIPAA policy and actions, as well as enforcement activities, have been developed over time and as situations develop. This system depends in part on patient complaints for both enforcement and policy evolution. In many practices and practice locations, there have been few or even no formal complaints of violations of patient privacy, indicating that the initial implementation of HIPAA compliance may have largely had the desired effect.

### *Electronic Medical (“Health”) Records*

Databases, spreadsheets, and electronic transfer of information are nonspecific features that have been applied to health care. Replacing the classic medical record, on the other hand, has required the creation of entirely new software in an attempt to duplicate and also expand the function of the handwritten or dictated traditional “chart.” This has afforded opportunities to multiple competing commercial entities to attempt to fill this need. Usually, competing proprietary systems are incompatible and do not “talk to each other.” This fact severely limits one of the highly touted benefits of medical practices “going electronic.” Cost is another great barrier, as is the formidable task of entering necessary information from the old paper records into the electronic system. There has been governmental and public pressure for health-care institutions, facilities, and practices to adopt electronic records because of the potential for increased legibility causing reduction in errors and confusion, greater speed of filing and retrieval, easy transmission of large amounts of information (such as from a surgeon’s office to an anesthesia practice’s booking office and also to a hospital’s preoperative clinic or OR holding area), and QA monitoring or auditing of vast databases. Increased ease of transmission and filing of reimbursement claims and cost savings from clerical staff downsizing are claims intended to encourage physician practice groups to adopt EHRs. However, experience has suggested that the commercially available software systems (both for institutions and practice groups) are not as robust or reliable as advertised by their often aggressive manufacturers. Accordingly, the expected benefits did not materialize quite as predicted, particularly in that costs have been great, often far in excess of estimates, and cost savings have been minimal at best. Nonetheless, there was a federal mandate that health-care facilities and practices must implement “meaningful use” of EMR or face penalties in the form of reduced payments from Medicare and Medicaid. Practice groups of anesthesia professionals should consider all

the noted points prior to investing in an EMR system (which can be called  “AIMS” for “anesthesia information management system”). At minimum, careful study and evaluation of the same system already in place in another anesthesiology practice should be undertaken. ASA has attempted to answer members’ questions (<http://www.asahq.org/.../Advocacy/Electronic Health Records/ASAEHRFAQ/en/1>) and there are multiple other resources on the ASA website, but the goal has seemed something of a moving target, so practitioners need to verify the most up-to-date information when they make decisions about EHRs.

If basic EHR implementation has been problematic for practices, true electronic AIMSs have been even more difficult. These include preoperative, intraoperative, postoperative, billing, and QA components. For the actual OR anesthesia record, several commercial versions are available. Various anesthesia professionals have various opinions about ease of implementation and subsequent use. Unless one massive bolus of fully integrated new technology from a single manufacturer is installed all at one time, integration of a new EHR with the existing anesthesia machines and monitors to ensure full accurate capture of all data parameters can often be difficult and frustrating. The function and value of electronic anesthesia records can be debated endlessly. All of them today will require computers on or in the anesthesia machine. These computers should be Internet-enabled so that demographic and billing information can be automatically uploaded to the facility’s and the practice’s database. Any such system must also integrate with the billing systems of the facility and the practice or the touted benefits will be largely negated. Likewise, such systems can be configured to report (upload) automatically case information (de-identified) to central repositories of clinical information, such as the QCDR and the NACOR, thus facilitating potential quality improvement projects and also satisfying requirements (EHR “meaningful use”) that should prevent payment penalties and potentially even qualify for payment bonuses.

Again, the best, and in some senses, the only way to evaluate seriously and thoroughly a proposed major investment of money, effort, and time is to visit a fully functioning installation of a given electronic AIMS and talk directly in detail with the users. The costs, in all senses of the word, are so great that it remains a significant gamble to be the first to purchase and implement such a system.

### *Expansion into Perioperative Medicine and Hospital Care*

The concept of the PSH is outlined in detail in the opening section and is being considered as a potential future model in some practices. Some anesthesiologists now practice for at least some of their time in preoperative

screening clinics because of the great fraction of OR patients who do not spend the night before surgery in the hospital or who do not come to a hospital at all. In such settings, these anesthesiologists frequently assume a role analogous to that of a primary care physician, planning and executing a workup of one or more significant medical or surgical problems before the patient can reasonably be expected to undergo surgery. Likewise, this concept can apply in the postoperative period. An anesthesiologist, on site in the hospital, immediately available and completely free of OR or other duties, could not only make at least twice-daily rounds on patients after surgery and provide exceedingly comprehensive pain management service but also follow the surgical progress and make reports (likely via an EHR, instant messaging, or e-mail) to the surgeon's office or smartphone. A fundamental aspect of the practice of anesthesiology is the management of acute problems in the hospital setting. Though controversial, it is suggested by some that it is logical to maintain that anesthesiologists would be among the physicians best suited to provide primary care for hospitalized surgical patients. It is intended that the PSH would make the overall surgical episode more efficient. The involved anesthesiologists would need close working relationships with the participating surgeons so that the surgeons could remain involved in the technical and surgical details of the postoperative phase with which the anesthesiologists would be less familiar. As noted, the financial aspects of such arrangements could be complex in that third-party payers are unlikely to agree to new costs for a new class of providers, and the surgeons may be reluctant to have their compensation proportionately reduced, even if the new arrangement would free up time for them to see more new patients and do more cases. It could be argued that an anesthesia group with great insight may well be willing to provide such labor-intense service without expecting additional compensation because doing so will help insure the security of their existing positions and traditionally relatively high incomes. In the Rovenstine Lecture at the 2005 ASA Annual Meeting,<sup>83</sup> there was an emphatic plea for significantly expanding the scope of practice for anesthesiologists in perioperative care, patient care in general, and in health systems (facilitated by increasing the number trained and increasing use of nonphysicians supervised by anesthesiologists to care for healthy patients) as a way to secure a role for anesthesiologists among the leaders of the future of American health care. The concepts were reinforced in the 2014 Rovenstine Lecture, in which the imperative for anesthesiologists to change or be pushed aside by the reality of the unsustainable costs of the US health-care system was very strongly emphasized (<https://education.asahq.org/drupal/2014/Rovenstine>). Overall, to date, it appears that there has been comparatively little progress in this regard. The challenge persists for the young and upcoming generation of

anesthesiologists.

An additional evolving opportunity within acute care hospitals is the creation and implementation of “rapid response teams.” In essence, studies have revealed that patients on general care nursing floors sometimes begin to deteriorate and, for one reason or another (but often because of the responsible physician being unavailable or at a considerable distance at that moment), the patients are not evaluated or treated in a timely manner and often not until they have further deteriorated, sometimes to a critical status. Therefore, a national trend has developed in which hospitals create a team of knowledgeable professionals (who have other regular responsibilities) who usually have no prior knowledge of the deteriorating patient but who will respond within a very few minutes to the call from (usually) a floor nurse who detects a deteriorating patient (e.g., rapidly increasing fever, relative hypotension and tachycardia, absent urine output). Frequently, the rapid response team institutes immediate symptomatic treatment, arranges for a higher acuity level of care, and contacts the primary responsible physician. Importantly, in larger hospitals, it has been suggested that the in-house anesthesiologists are uniquely qualified to be key members of the rapid response team because the interventions almost always involve acute “bread-and-butter” resuscitative care. Although many anesthesiologists may believe they already have plenty of work in the OR, such participation when possible would be an outstanding and highly visible contribution to the hospital’s mission of enhanced patient care. Also, such interventions theoretically could be separately billable encounters as consultations or, alternatively, excellent support in arguing for the maintenance or even increase of the hospital’s financial subsidy to its anesthesia professional group.

## Operating Room Management

The role of anesthesiologists in OR management has changed over time. Considering the potential shortage of anesthesia professionals, hospitals subsidizing many anesthesiology group practices, and an increasing workload, participation in OR management is essentially mandatory. The current emphasis on cost containment and efficiency is forcing anesthesiologists to take an active role in eliminating many dysfunctional aspects of OR practice that were previously ignored. First-case morning start times have changed from a hopeful suggestion to a genuine mandate. Delays of any sort are now often tracked electronically in real time and carefully scrutinized to eliminate waste and inefficiency. Together, anesthesiologists, surgeons, OR nurses and technicians, and increasingly, professional administrators/managers need to determine who is best qualified to be a leader in the day-to-day management of the OR.<sup>84</sup> Clearly, different groups have different perspectives. However, **9** anesthesiologists are in the best position to see the “big picture,” both overall and on any given day. Surgeons are commonly elsewhere before and after their individual cases (and sometimes for the beginning and the end of their cases); nurses and administrators may lack the medical knowledge to make appropriate, timely decisions, often “on the fly.” It is the anesthesiologist with the insight, overview, and unique perspective who is best qualified to provide leadership in an OR community. The subsequent recognition and appreciation from the other groups (especially hospital administration) will clearly establish the anesthesiologists as concerned physicians genuinely interested in the welfare of the OR and the institution.

### Organization

The symbiotic relationship between anesthesia professionals and surgeons remains unchanged. Both groups recognize this fact and also the common goal of having the OR function in a safe, expeditious manner. The age-old question, “Who is in charge of the OR?” still confronts many hospitals/institutions. Because some anesthesiology groups are subsidized by the hospital, the OR organization in such cases has changed accordingly. Many hospital administrators want to have input regarding who is in charge of the OR with an eye to increasing efficiency and throughput while reducing cost. Their wishes have an even added significance when more of their dollars are involved through the anesthesiology group subsidy. Sometimes there can be no real answer to, “Who’s in charge?” because of the complexity of the interpersonal relationships in the OR. Some institutions have a professional

manager (often a former OR registered nurse) whose sole job is to organize and run the OR. This individual may be vested with enough authority to be recognized by all as the person in charge. Other institutions ostensibly have a “medical director of the OR.” However, the implications to the surgeons that an anesthesiologist is in charge, or vice versa, have caused many institutions to abandon the title or retain the position but assign no authority to it. In such instances, institutions usually resolve disputes through some authority with a physician’s perspective. If there is no medical director with authority to make decisions stick, central authority usually resides with the OR committee, most often populated by physicians, senior nurses, and administrators. Every OR has this forum for major policy and fiscal decisions. As part of committee function, the standard practices of negotiation, diplomacy, and lobbying for votes are regularly carried out. The impact of such an OR committee varies widely among institutions.

Despite the constantly changing dynamics of the OR management and the attendant major frustrations, anesthesiologists should pursue a greater role in day-to-day management in every possible applicable practice setting. An anesthesiologist who is capable of facilitating the start of cases with minimal delays and solving problems “on the fly” as they arise will be in an excellent position to serve his or her department. Succeeding in this role will have a dramatic positive impact on all the OR constituents. The surgeons will be less concerned about who is in charge because their cases are getting done. The hospital administration will welcome the effort because they want something extra in return for any money they are now giving to the anesthesiology groups as a subsidy. Furthermore, the OR committee (or whatever system for dispute resolution is in place) is still functional and has not been circumvented (and will be thankful for the absence of disputes needing resolution).

Some institutions use the term *Clinical Director of the OR*. The person awarded this designation should be a senior-level individual with firsthand knowledge of the OR environment and function. Anesthesiologists have a better understanding of the perioperative process. They possess the medical knowledge to make appropriate decisions. Their intimate association with surgeons and their patients allows them to best allocate resources.

## **Contact and Communication**

An important issue for the anesthesia professionals in any OR setting is who among the group will be the contact person to interact with the OR and its related administrative functions. In situations in which everyone is an independent contractor, there may be a titular chief who by design is the contact person. The anesthesiologist in this role commonly changes yearly to spread the duties among all the members. Larger groups or departments that

function as the sole providing entity for that hospital/facility often identify an individual as the contact person to act as the voice for the department. Furthermore, these same groups delineate someone on a daily basis to be the operational clinical director, or the person “running the board.” Frequently, this position is best filled by one from a small dedicated fraction of the group (e.g., three people) rather than rotating the responsibility among every member of the group. Experienced “board runners” have an instinctually derived better perspective on the nuances of managing the operating schedule in real time. Certain procedures may require specific training (e.g., transesophageal echocardiography skills) that not all members of the group possess. Clearly, changes sometimes have to be made in real time to match the ability of the anesthesia provider and the requirements of the procedure when urgent or emergent cases are posted.

Another benefit of a very small number of daily clinical directors is a relative consistency in the application of OR policies, particularly in relationship to the scheduling of cases, especially add-ons. One of the most frustrating aspects to both surgeons and OR personnel is unpredictability and inconsistency in the decisions made by the anesthesia group/department members. A patient deemed unacceptable for surgery by anesthesiologist X on Monday may be perfectly acceptable, in the same medical condition, for anesthesiologist Y on Tuesday. Differences of opinion are inevitable in any large group. However, day-to-day OR function may be hampered by a large number of these situations. Having one member of a very small group in charge will lead to more consistency in this process, especially if the board runner/clinical director has the authority to switch personnel to accommodate the situation. Without stifling individual practices, philosophies, and comfort levels, a certain amount of consistency applied to similar clinical scenarios will improve OR function immeasurably. These few dedicated directors should be able to accomplish both goals better than a large rotating number of people.

A newer potential component of intra-OR communications is the concept of checklists and team briefings. Analogous to the now-required “time-out” in each OR prior to surgical incision, when the correct identity of the patient, the intended procedure, and any laterality involved are verified, some ORs are attempting to have a similar interprofessional communication involving all relevant OR personnel (the team) prior to the patient’s entering the OR. During this meeting the involved surgeon, anesthesia professional, circulating nurse, scrub person, and support persons each state a summary of what is projected to take place in this case, any anticipated need for extra or unusual resources or equipment, any anticipated difficulties or increased risks, and specific plans to deal with any feature of any of these points that would require intervention. In many models, a printed single-page checklist with

routine prompts and fill-in boxes is used to facilitate the process. One study reported a two-third reduction in “communication failures” that have otherwise likely caused problems, risks, or inefficiencies.<sup>85</sup>

The World Health Organization’s widely publicized “Surgery Safety Checklist” (<http://www.who.int/patientsafety/safesurgery/checklist/en>) is primarily an accident-prevention tool, but also promotes communication among everyone in the OR, particularly regarding planning—before, during, and after the actual operation—which is directly related to maximally efficient and safe conduct of the procedure.

## **Materials Management**

Usually, the institutional component of the anesthesia service creates, maintains, and staffs a location (“the workroom”) containing the specific supplies unique to the practice of anesthesia. Objectives necessary for efficient materials management include the standardization of equipment, drugs, and supplies. Volume purchasing, inventory reduction, and avoidance of duplication are also worthwhile. There needs to be coordination with the OR staff as to who is responsible for acquisition of routine hospital supplies such as syringes, needles, IV tubing, and IV fluids. Decisions as to which brands of which supplies to purchase ideally should be made as a group. Often, when several companies compete against each other in an open market, lower prices are negotiable. In many cases, however, hospitals belong to large buying groups that determine what brands and models of equipment and supplies will be available, with no exceptions possible except at greatly increased cost. Sometimes this is false economy if the provided items are inferior (cheap) or difficult to use—for example, if one must routinely open three or four intravenous cannulas to start a preoperative intravenous line as opposed to using a higher quality and reliable cannula that may cost more per unit but is less expensive overall because far fewer will be used. Dispassionate presentation of such logic by a respected team-player senior anesthesiologist to the OR committee or director of materials management may help resolve such conundrums.

## **Scheduling Cases**

Anesthesiologists need to participate in the OR scheduling process at their facility or institution. In some facilities the scheduling office and the associated clerical personnel work under the anesthesia group. Commonly, scheduling falls under the OR staff’s responsibility. Direct “control” of the schedule on a moment-to-moment basis often resides with the OR supervisor or charge person, frequently a nurse. Whatever the arrangements, the

anesthesia group must have input and a direct line of communication to the scheduling system. The necessary number of anesthesia professionals that must be supplied often changes on a daily basis depending on the caseload and sometimes because of institutional policy decisions. After-hours calls must be arranged, policy changes factored in, and additions/subtractions to the surgical load (day to day, week to week, and long term as surgical practices come and go in that OR) dealt with as well. These issues are important even when all the anesthesia professionals are independently contracted and are not affiliated with each other. In such situations, the titular chief of anesthesia should be the one to act as the link to the scheduling system. When the anesthesia group/department functions as a single entity, the chairman/chief, clinical director, or appointed spokesperson will be the individual who represents his or her group at meetings in which scheduling decisions are made in conjunction with the OR supervisors, surgeons, and hospital administrators.

There are as many different ways to create scheduling policies as there are OR suites. Most hospitals/facilities follow proprietary patterns established over the years. Despite all the efforts directed toward its creation, the OR schedule (both weekly time allotments and day-to-day scheduling of specific cases) remains one of the most contentious subjects for the OR. Recognizing the fact that it is impossible to satisfy everyone, the anesthesia group should endeavor to facilitate the process as much as possible. Initially, anesthesiologists need to be sympathetic toward all the surgeons' desires/demands (stated or implied) and attempt to coordinate these requests with the institution's ability to provide rooms, equipment, and staff. Secondly, the anesthesia group should make every possible effort to provide enough anesthesia services and personnel to realistically meet the goals of the institution. In light of the potential shortage of anesthesia professionals in this country, these efforts need to be made with a great deal of open communication among all parties of the OR committee as well as every member of the anesthesia group.

Regarding scheduling, surgeons essentially fall into one of three groups. One group wants to operate any time they can get their cases scheduled. This group wants the OR open 24/7. Another larger group wants "first case of the day" as often as possible so they can then get to their offices. A smaller third group wants either the first time slot or an opening following that time slot, a several-hour hiatus, then to return to the OR after office hours to complete additional cases; usually starting after 5 PM. Clearly a compromise among these disparate constituencies must be reached. Anesthesiologists who approach the OR committee regarding this dilemma with a nonconfrontational attitude will greatly facilitate agreement on a compromise.

## Types of Schedules

The majority of ORs use either block scheduling (preassigned guaranteed OR time for a surgeon or surgical service to schedule cases prior to an agreed-upon cut-off time; for example, 24 or 48 hours before) or, alternatively, open scheduling (first come, first serve). Most large institutions have a combination of both. Block scheduling inherently contains several advantages for creating a schedule. Block scheduling allows for more predictability in the daily OR function as well as an easy review of utilization of allotted time. Historic utilization data should be reviewed with surgeons, OR staff, and the OR committee to determine its validity. Many operating suites have found it useful to assemble rather comprehensive statistics about what occurs in each OR. Some computerized scheduling systems (see below) are part of a larger computerized perioperative information management system that automatically generates statistics. Graphic examples are 13-month “statistical control charts” or “run charts” that show the number of cases, number of OR minutes used for those cases (and when: such as in block, exceeding block, evenings, nights, weekends, and so forth), number of cancellations (and multiple other related parameters if desired) by service, by individual surgeon, and total for the current month and the 12 prior months, always with “control limits” (usually 2 standard deviations from the 13-month moving average) clearly indicated. All these data are valuable in that they generate a clear picture of what is actually going on in the OR. It is also extremely valuable in that block time allocation should be reviewed periodically and adjusted based on changes, degree of utilization, and projected needs. Inflexible block time scheduling can create a major point of contention if the assigned blocks are not regularly reevaluated. The surgeon or surgical service with the early starting block that habitually runs beyond his or her block time will create problems for the following cases. If this surgeon were made to schedule into the later block on a rotating basis, delays in his or her start caused by others may provoke improved accuracy of his or her subsequent early case postings. Adjustments in availability of block time can also be made in the setting of the “release time,” the time prior to the operative date that a given block is declared not filled and becomes available for open scheduling. Surgeons prefer as late a release time as possible in order to maintain their access to their OR block time. However, unused reserved block time wastes resources and prevents another service from scheduling. A single release time rarely fits all circumstances, but negotiating service-specific release times may lead to improved satisfaction for all. In the *ideal* system, enough OR time and equipment should exist to provide for each surgical service’s genuine needs while retaining the ability to add to the schedule (via open scheduling) as needed. Exactly such an environment does not exist. Invariably, in busy environments, surgical demand exceeds

available block and open time, leading services to request additional block time. When this time is not granted, services may perversely then schedule procedures in open time before filling their block time. Surgeons who prefer open time would then be shut out of OR time. Open scheduling may reward those surgeons who run an efficient service, but it also may be a source of problems to those surgeons who have a significant portion of their service's cases arrive unscheduled, such as orthopedic surgeons. Some degree of flexibility will be necessary whichever system is used. The anesthesia group should adopt a neutral position in these discussions while being realistic about what can be accomplished given the number of ORs and the length of the normal operating day.

The handling of the urgent/emergent case posting precipitates a great deal of discussion in most OR environments. No studies allow determination of exactly what rate of OR utilization is the most cost-effective. However, some institutions reportedly subscribe to following parameters: adjusted utilization rates averaging below 70% are not associated with full use of available block time, wasting resources, whereas rates above 90% are frequently associated with the need for overtime hours. Different OR constituencies have different comfort zones for degrees of utilization. Most institutions cannot afford to have one or two ORs staffed, open, and waiting unless there is a reliable steady supply of late open-schedule additions, that is, urgent cases/emergencies, during the regular work day. A previously agreed-upon, clear algorithm for the acceptance and ordering of these cases will need to be adopted. In general, critical life-threatening emergencies and elective add-ons are fairly straightforward and at the two ends of the spectrum. The critical emergency goes in the next available room, whereas the elective case gets added to the end of the schedule. The so-called "urgent" patient requires the most judgment. Individual services should provide guidelines and limitations for their expected urgent cases. These "add-on case policy" guidelines should be common knowledge to everyone involved in running the OR. Consequently, these cases, such as ectopic pregnancies, open fractures, the patient with obstructed bowel, and eye injuries, can then be triaged and inserted into the elective schedule as needed with minimal discussion from the delayed surgeon. The surgeons whose urgent case is presented as one that must immediately bump another service's patient, yet conversely could wait several hours if it is their own patient that will be delayed, will have to face their own previously agreed-upon standards in a future OR committee meeting. A simple way to express one logical policy for urgent cases (e.g., acute appendicitis, unruptured ectopic pregnancy, intestinal obstruction) is: (1) bump the same surgeon's elective scheduled case; (2) if none, bump a scheduled case on the same service; (3) if none, bump a scheduled case from an open-schedule surgical service; and (4) if none, bump a scheduled case

from a block schedule service. Some institutions require the attending surgeon of the posted urgent/emergent patient to speak personally with the surgeon of any bumped case.

Another area of burgeoning growth that must be accounted for in the daily work schedule is the non-OR “off-site” diagnostic test, or therapeutic intervention that requires anesthesia care. (In some locations, gastroenterologists expect anesthesia services for cases such as endoscopic retrograde cholangiopancreatography or other endoscopies on unusually sick patients, particularly after untoward emergencies beyond the capabilities of their sedation nurses have occurred and attracted attention in the facility.) In some instances the off-site procedures replace operations that, in the past, would have been posted on the OR schedule as urgent/emergency cases. For example, cerebral aneurysm coiling and computed tomography-guided abscess drainage, among other procedures, are done in imaging suites; some patients, adult as well as pediatric, require deep sedation or even general anesthesia for magnetic resonance imaging or computed tomography in radiology or for invasive procedures in catheterization laboratories. In addition, depending on distances involved and logistics, it may even be necessary to assign two people, a primary provider and an attending, exclusively to that one remote location when, had the case come to the OR, the attending may have been able to supervise one or more other cases also. Hospital administration or the OR committee may try to view these off-site cases as unrelated to OR function and, thus, purely a problem for the anesthesia group to solve. These cases must be treated the same as all the OR procedures.

In order to apportion hospital-based anesthesia resources reasonably, these off-site procedures should be subject to the same guidelines and processes for access and prioritization as any OR posting. Integration of the scheduling process with an institution-wide master program has been suggested as very helpful to maximize efficiency.<sup>86</sup> Most institutions have added at least one extra anesthetizing location (“line” on the printed schedule) to their formal operating schedule to designate these off-site procedures (occasionally with an imaginative classification such as “satellite,” “road show,” “outfield,” or “safari”—which is an acronym for “safe anesthesia for all remote interventions”). For some of these off-site cases, there may be less or no reimbursement for anesthesia care. For example, government plans and also private insurance carriers may well not pay for the claustrophobic adult to receive monitored anesthesia care or even a general anesthetic for an obviously needed diagnostic magnetic resonance image, even though the patient, the surgeon, and the hospital benefit from the test results. The anesthesia group, the OR committee, and the hospital administration need to reach compromises for off-site procedures, regarding scheduling, allocation of anesthesia resources that would otherwise go to the OR, and even

subsidization of the personnel costs in order to continue this obviously beneficial service that also does produce revenue for both the proceduralists and the facility.

## **Computerization**

Computerized scheduling will likely benefit every OR regardless of size. Whether this scheduling function should be one component of a comprehensive EHR system is a complex question, as noted. In the OR, however, computerization allows for a faster, more efficient method of case posting than any handwritten system. Changes to the schedule can be made quickly without any loss of information. Rearranging the daily schedule is much simpler on a computer than erasing and rewriting on a ledger sheet. Furthermore, most hospitals have adopted a computer-determined average time for a given surgical procedure for a particular surgeon. Commonly, this time is the average of the last 10 (or 10 of the last 12, with the longest and shortest discarded) of the specific procedure (e.g., total knee replacement) with the potential to add a modifier (e.g., it is a repeat surgery) that shows a material difference in the projected time length (almost always longer) for one particular patient type. Suppose surgeon X has block time of 8 hours on a given day and wants to schedule four procedures in that allotted time. The computerized scheduling program looks at surgeon X's past performances and determines a projected length for each of the procedures that are identified to the computer, usually by CPT-4 codes or possibly some other code developed locally for frequent procedures done by surgeon X. (Note that the recorded time length includes the turnover time, thus making the case time definition from the time the patient enters the OR until the time any following patient enters that OR [unless an "exception" is entered specifically for an unusual circumstance].) The use of agreed-upon codes instead of just text descriptions helps ensure accuracy because it eliminates any need for the scheduling clerk to guess what the surgeon intends to do. Bookings in most circumstances should not be taken without the accompanying codes (surgeons' offices objections notwithstanding). The computer then decides whether surgeon X will finish the four procedures in the allotted block time. If the computer concludes that the fourth case would finish significantly (the definition of which can be determined and entered into the program) beyond the available block time, it will not accept the fourth case into that room's schedule on that particular day. The surgeon will accept the computer's assigned times and adjust accordingly, planning only three cases, or appeal for an "exception" based on some factor not in the booking that is claimed will materially decrease the time needed for at least one of the four cases, which the surgeon must explain to the "exception czar" (anesthesiology clinical director or OR

charge nurse) of the day. An alternative method has the computer simply add (to each case except the last) a projected turnover time that is agreed upon by all involved at an (often contentious) OR committee meeting. Computerizing the scheduling process significantly reduces any personal biases and should smooth out the entire operating day. The longstanding ritual of mid-to-late-afternoon disputes between the surgeons and the anesthesia group and/or OR staff about whether or not to start the last scheduled case may be eliminated or at least reduced by this more realistic prospective OR scheduling method.

There are many variables to consider in any OR scheduling system. The patient population served and the nature of the institution dictate the overall structure of the OR schedule. Inner-city level 1 trauma centers must accommodate emergencies on a regular basis, 24 hours a day. These centers are unlikely to create a workable schedule more than a day in advance. An ambulatory surgery center serving elective plastic surgery patients may see only the rare emergency bring-back bleeding patient. Their schedule may be accurate many days in advance, with a high degree of expectation that the patient will arrive on time properly prepared for surgery. The anesthesia group at this ambulatory center may rarely have to make changes to the schedule, allowing them to proceed with a fairly predictable daily workload. At the inner-city trauma hospital, a great deal of flexibility and constant communication with the surgeons will be required in an attempt to get the cases done in a reasonable time frame with the inherent constraints placed on the OR staff's resources and the time available. These two extreme examples from opposite ends of the scheduling process spectrum can provide guidelines for the majority of the institutions that fall somewhere in between. Beyond open communication, how best to work toward this mutual understanding depends on the particulars of the people involved and the environment, but some ORs report benefits from team-building exercises, leadership retreats, and even OR-wide social events. ORs with a particularly malignant history of finger-pointing and bad feelings among the personnel groups may constitute one of the few instances an outside consultant may really be valuable in that there are workplace psychologists who specialize in analyzing dysfunctional work environments and implementing changes to improve the situation for all involved.

### **Preoperative Clinic**

An anesthesia preoperative evaluation clinic (APEC) that provides a comprehensive preoperative medical evaluation usually results in a more efficient running of the OR schedule.<sup>87-89</sup>

Unanticipated cancellations or delays are avoided when the anesthesia group evaluates complex patients prior to surgery. Even if the patient arrives

to the OR on time the day of surgery, inadequate preoperative clearance mandating the ordering of additional tests will consume precious OR time during the delay waiting for results. Cancellations or delays adversely affect the efficiency of any OR. Subsequent cases in the delayed room, whether for the same or a different surgeon, may get significantly delayed or forced to be squeezed into an already busy schedule on another day. The financial impact of delays or cancellations on the institution is considerable. Revenue is lost with no offsetting absence of expenses. Worse, expenses may actually increase when overtime has to be paid, or the sterile equipment has to be discarded or repackaged after having been opened for the canceled procedure. Even worse, the inconvenienced patient and/or surgeon may go to another facility.

Optimal timing for preoperative evaluation should be related to the institution's scheduling preferences, patient convenience, and the overall health of the patient. Earlier completion of the preoperative evaluation may not reduce the overall cancellation rate when compared with a more proximate evaluation. However, an early evaluation and clearance may well provide a larger pool of patients available to place on the OR schedule (block or open) resulting in a more efficient use of OR time. Further, early evaluation creates an opportunity to "prehabilitate," as mentioned above. Diabetes, hypertension, asthma, and even COPD that appeared problematic upon evaluation can often be beneficially treated in even a few days—sometimes soon enough so the originally booked OR date need not be moved back. In addition, a protocol-driven evaluation process can anticipate possible or likely need for time-consuming investigations (such as a cardiology evaluation for the patient with likely previously undiagnosed angina). Early recognition of a failed preoperative test and need for postponement allows time for another patient to be moved into the now-vacant time slot. Also, early identification of certain problems requiring special care on the day of surgery (e.g., preoperative epidural, nerve block, or invasive monitoring placement) should lead to fewer unanticipated delays. Unfortunately, many issues precipitating delays are traditionally discovered on the day of surgery. Some of these preventable delays are unrelated to the patients' health status. Seemingly simple administrative issues such as verification of a ride home or incomplete financial information also contribute to unexpected delays. A properly functioning APEC may also be able to eliminate a majority of these annoying causes of preventable delays.

Regardless of the institutional specifics surrounding the service provided by the APEC, further cost savings can be obtained through its proper usage by the anesthesia group. The APEC frequently reduces dramatically the number of preoperative tests performed by focusing on which diagnostic tests and medical consults are really required for any specific patient (as opposed to the "shotgun approach" by some surgeons or the PCPs/internists consulted to

give “medical clearance” who order excessive testing simply with the intent of trying to avoid some last-minute request, whatever it might be, for more data). In some circumstances, the APEC may also function as an additional source of revenue for the anesthesia group when a formal preoperative consult on a complicated patient is ordered well in advance by the surgeon, in the same manner as would have otherwise been directed to a primary care physician for the often nonreassuring “clearance for surgery.” The ability to centralize pertinent information including admission precertification/clearance, financial data, diagnostic and laboratory results, consult reports, and preoperative recommendations improves OR function by decreasing the time spent searching for all these items after changes have been made to the schedule. Patient and family education performed by the APEC frequently leads to an increase in patients’ overall satisfaction of the perioperative experience. In addition, patient anxiety may be reduced secondary to the more in-depth contact possibly inherent in the APEC process when compared with anesthesia practitioners meeting an ambulatory outpatient for the first time in an OR holding area immediately prior to surgery. The APEC model enables the anesthesia group to be more active and proactive in the perioperative process, improving their relations with the other OR constituents.

### *Anesthesiology Personnel Issues*

In light of the putative shortage of anesthesia professionals, creating, managing, and maintaining an adequate supply of anesthesia practitioners is a top priority. Numbers of applicants for residency positions appeared **10** robust in the first half of the second decade of the twenty-first century. The number of anesthesiology residency training programs remained fairly stable during this time. However, in 2016, there were approximately 100 fewer positions filled than in 2015 and a few programs did not fill all their slots. Anesthesiology training programs continue to be challenged in maintaining support of their educational missions.<sup>90</sup> Furthermore, the relative supply of nonphysician anesthesia professionals appears to be also decreasing. With the aging population of nurse anesthetists and the reportedly limited number of applications to schools in that profession, as well as the very limited number of training facilities for anesthesiology assistants, the overall supply of anesthesia professionals appeared potentially inadequate to meet current and, at least, short-term future demands. The need for anesthesia groups to create a flexible, attractive work environment in order to help retain professionals who might otherwise leave may increase. Note, however, that the “Great Recession” led to reduced turnover within practice groups for a few years because some anesthesia professionals, fearing economic

uncertainty, chose to continue in practice positions that they likely would have vacated during normal economic conditions.

Another issue is consideration of what is a reasonable work load for an anesthesiologist and how best to measure, if possible, the clinical productivity of an anesthesia group/department. These questions have been the subject of considerable discussion.<sup>91-93</sup> Beyond the simple number of full-time equivalents, cases, and OR minutes, there must be consideration of factors such as the nature of the facility, types of surgical practice, patient acuity, and speed of the surgeons to allow fair comparisons. Thoughtful filtering of resulting data should take place before dissemination of the aggregate information to all members of a group because of the understandable extreme sensitivity among stressed and fatigued anesthesiologists to a suggestion that they are not working as hard as their group/department peers.

Except in highly unusual circumstances, flexible scheduling of anesthesia professionals and also fulfilling the demands placed on the group by the institution continues to be a constant balancing act. This demand assumes added significance because institutions subsidize many anesthesia groups. Even when a majority of providers in a facility are independent contractors where it is required that a specific surgeon request their services, there are time conflicts ranging from no one at all being available to unwanted down time. When the anesthesia group/department accepts the responsibility of providing anesthesia services for an institution, they must schedule enough providers for that OR suite on each given day. Ideally, a sufficient number of professionals would be hired so that there would always be enough personnel to staff the minimum number of rooms scheduled on any given day, as well as after-hours call duty. This situation rarely exists because it would be financially disadvantageous to have an excess number of providers with no or minimal clinical activity. Having exactly the right number of anesthesia professionals in a group for the clinical load works well until one (or more) of them is out with an unplanned absence such as an extended illness or a family emergency. Many academic departments have a natural buffer with some clinicians assigned intervals of nonclinical time for research, teaching, or administrative duties. However, repeated loss of these nonclinical days because of inadequate clinical staffing in the OR leads to undermining the academic/research mission of the department. Continued loss of this time will eventually lead to faculty resignations (and possible migration to private practice), thus eliminating the original buffer. Consequently, anesthesia groups/departments need to anticipate available clinical personnel and match them to the OR demands. Ideally, this information should be accurate for several months into the future. Meeting this specification has become more difficult. Hospital administrators must offer reasonable assurances to the anesthesia group providing service that a given OR utilization rate is likely, as

well as accurate data regarding reimbursement (payer mix and any package contracts negotiated by the hospital). These data must be provided accurately and updated frequently if a health-care institution is to acquire and retain an anesthesia group staffed with the personnel to meet the expected demands.

## **Timing**

Each operating environment has its own personnel scheduling system and expectations for the anesthesia group. Daily coordination between the anesthesia group's clinical director and the OR supervisor permits the construction of a reasonable schedule showing the number of ORs that day and when the schedule expects each of them to finish. Invariably, some cases take longer than anticipated or add-ons are posted, requiring the OR to run into the late afternoon or early evening. Many anesthesia professionals accept this occurrence as a matter of course. Few anesthesia professionals will tolerate this sequence of events as an essentially daily routine whether they are paid extra or not. These practitioners become exhausted and resent the burdens continuously placed on them. If the OR schedule is such that add-ons frequently occur and elective cases run well into the evening, many anesthesia professionals will opt to protect their personal and family time and cut back their working hours or resign. Neither would be welcome in a tight market. Under these circumstances, hiring additional personnel who are scheduled to arrive at a later time, for example, 11:00 AM, and then providing lunch relief and staying late (e.g., 7:30 PM or later if needed) to finish the schedule may well be a very worthwhile investment.

Another possible solution to the demands of an extended OR schedule on an anesthesia group's personnel may involve employing part-time anesthesia professionals. Part-time opportunities could enhance a group's ability to attract additional staff. Some anesthesia personnel will have personal or family situations or obligations that prevent them from committing to a full-time position, but who want to practice on schedules that work for them. Making accommodations (including pay, perks and benefits appropriate to the time worked) for this potential valuable source of help can prevent strain on the full-time people and smooth the overall function of the group/department.

Scheduling after-hours coverage also adds to the personnel difficulties facing the anesthesia group. The variations of call schemes are endless. The nature of the institution and the workload determine the degree of late-night/over-night coverage. Major referral centers and level 1 trauma centers require inhouse primary providers. If these providers include residents and/or nurse anesthetists, then the supervising attending staff likely will also be inhouse 24 hours a day. A common solution employed at many institutions is

to staff the evening/night call shifts for an average workload based on historical statistics, recognizing that on some occasions there will be idle ORs, and, on other nights, the surgical demand will exceed the call team's numbers.

There are also medicolegal issues surrounding the call team's availability. Although this traditional model may be decreasing in numbers, it still exists: at a small community hospital with a limited number of independent anesthesiologists, these practitioners may agree to cover call on a rotating basis. The individuals not on call are usually not obligated to the OR and may well be truly unreachable. What happens then when the on-call anesthesiologist is administering an anesthetic and another true emergency case arrives in the OR suite and all the remaining staff anesthesiologists are legitimately unavailable? Does that anesthesiologist leave his or her current patient under the care of an OR nurse and go next door to tend to a more acutely (possibly critically) ill patient? Should the patient be transferred from the emergency department to another (hopefully nearby) hospital? These questions have no easy answers. Clearly, those practitioners on the scene have to assess in real time the relative risks and benefits and make the difficult decisions. Often in such settings, if at all possible, a second anesthesiologist will be on "back-up" call and available by pager or phone—with the understanding of being able to arrive within 30 minutes to help in a true emergency situation. In general, if the call duty requires the practitioner(s) frequently to work much or all of the night, leaving the individual(s) stressed and fatigued, they should not be required to work in the OR the next day during normal working hours.

A more complicated answer involves what to do when the call assignment rarely requires a long night's work and the on-call anesthesia professionals routinely have rooms assigned to them the next day, but at least one person has just finished a difficult 24-hour shift being awake and working all night. Anesthesia groups need to decide how to handle the possible call shift scenarios, with permutations and combinations, and clearly communicate prospectively their decisions to the OR committee before any difficult decision has to be made one morning. As always, the medicolegal aspects of any decision such as this need to be taken into consideration. Whether or not fatigue was a factor, the practitioner who worked throughout the night before and appeared to contribute to an anesthetic catastrophe the next morning would have a very difficult defense in court. Further, the anesthesiology group may also be held liable in that their practice/policy was in place, allegedly authorizing the supposedly dangerous situation.

## **Cost and Quality Issues**

As noted at the outset, one of the more pervasive aspects of American medical

care in today's environment is the drive to maintain and improve high-quality health care while simultaneously reducing the cost of that care. In 2015, health-care costs account for a remarkable 17.5% of the gross domestic product (CMS. National Health Expenditure Data: Historical. See: <https://www.cms.gov/research-statistics-data-and-systems/statistics-trends-and-reports/nationalhealthexpenddata/nationalhealthaccountshistorical.html>) nearly triple the fraction a generation ago. Even more alarming, if costs continue to increase at the current rate, by 2024, it will be 19.6% of the gross domestic product.<sup>94</sup> Consequently, all physicians, including anesthesiologists, are urged constantly to include cost-consciousness in decisions balancing the natural desire to provide the highest possible quality of care with the overall priorities of both the health-care system and the individual patient, all while facing increasingly limited resources. Complicated decisions are required regarding which patients are suitable for ambulatory surgery, what preoperative studies to order, what anesthetic drugs or technique is best for the patient, what monitors or equipment are reasonably required to run an OR, and the list goes on and on. With this as background, anesthesiologists legitimately can include economic considerations in their practice management decision processes. When presented with multiple options to provide for therapeutic intervention or patient assessment, one should not automatically choose the more expensive approach (just to “cover all the bases” or defend against later criticism or even a lawsuit) unless there is compelling evidence proving its value. Decisions that clearly materially increase cost should only be pursued when the benefit outweighs the risk. In anesthesia care as well as medicine in general, such decisions can be difficult regarding interventions that provide marginal benefit but contain significant cost increases. Because cost containment initially requires accurate cost awareness, anesthesiologists need to find out the actual costs and benefits of their anesthesia care techniques. Details will be unique to each practice setting. Because they will be excited that the anesthesiologists actually care, usually it is possible to get the cooperation of the facility administration's financial department members in researching and calculating the actual cost of anesthesia care so that thoughtful evaluations of potential reductions can be initiated.

Anesthesia drug expenses represent a small portion of the total perioperative costs (personnel costs being, by far, the greatest fraction). However, the great number of doses administered contributes significantly to aggregate total cost to the institution in actual dollars. Prudent drug selection combined with appropriate anesthetic technique can result in cost savings. Reducing fresh gas flow from 5 L/min to 2 L/min wherever possible has been estimated to potentially save approximately \$150 million (inflation adjusted) annually in the United States.<sup>95</sup> A majority of anesthesia professionals usually

attempt a practical approach to cost savings, but they are more frequently faced with difficult choices regarding methods of anesthesia that likely produce similar outcomes but at demonstrably different cost. When comparing the total costs of more expensive anesthetic drugs and techniques to lesser expensive ones, many variables need to be added to the formula. The cost of anesthetic drugs needs to include the costs of additional equipment such as extra infusion pumps and the associated maintenance, as well as the often-overlooked cost of anesthetic drug wastage in the OR.<sup>96,97</sup> There are other indirect costs that may be difficult to quantitate and are commonly overlooked. Some of these indirect costs include increased setup time, possibly increasing room turnover time, extended PACU recovery time, and additional expensive drugs required to treat side effects. Sometimes, more expensive techniques reduce indirect costs. A propofol infusion, although more expensive than inhaled vapor, commonly results in a decreased PACU stay after a short noninvasive procedure. If fewer PACU staff are needed or patient throughput is increased, the more expensive drug can possibly reduce overall cost. Conversely, using a comparatively expensive continuous propofol infusion for a long procedure definitely requiring postoperative admission to an ICU for which inhaled vapor would be just as good appears not to be cost justified. The impact of shorter-acting drugs and those with fewer side effects is context-specific. During long surgical procedures, such drugs may offer limited benefits over older, less expensive, longer-acting alternatives. Although newer, more expensive drugs may be easier to use, there is no objective evidence to support or refute the hypothesis that these drugs provide a “better” anesthetic experience when compared with carefully titrated older, less expensive, longer-acting drugs in the same class. This topic has been discussed for many years,<sup>98</sup> and likely will be for many to come.

Evaluation of outcomes and their subsequent application to cost analysis can be derived from two principle sources: data published in the literature and data collected from experience. As noted, computerized information management systems are useful tools to track outcomes and analyze the impact on the cost/benefit ledger, and large sophisticated databases with automatic input are in place and growing, with the intention of allowing “data mining” to reveal national trends. Using the collated data within a given institution in the same manner as for OR utilization and case load, practitioners can readily apply a statistical process to evaluate outcomes in their practice, possibly including correlation with cost. This information may take on added importance in that published incidence studies may not exist for the specific complication or outcome an anesthesia group is searching for. Cause-and-effect diagrams can track the parameters involved in the process and relate them to the various outcomes desired. An example could come from the extensive body of literature on the factors contributing to

postoperative nausea and vomiting and the various possible preventions and treatments, many of which involve expensive medications. Information would be collected and stored in the database (locally and nationally). Ideally, the database would identify and track as many variables as needed/possible to delineate sources for possible improvement and its ultimate cost analysis. Once these sources for improvement and the ensuing cost impact are known, the anesthesia group can determine whether or not to pursue changing their practice. Various adverse outcomes can also be monitored. If analysis reveals a significant difference in the rate of an adverse outcome among practitioners, after all the other variables such as surgeon, patient mix, and so forth are eliminated, the outcome database can investigate the anesthetic techniques used by that practitioner (or group if comparing in the national database). If significant variations are identified, practitioner(s) would be able to learn of these variations in a nonthreatening manner because computer-derived data are used as opposed to a specific case analysis, which might lead that practitioner(s) to feel singled out for public criticism. The database can become a tool both for QA and professional education. These basic concepts are the underpinnings of both the US federal government's program within CMS, the Physician Quality Reporting System,<sup>99</sup> and the multiple programs within the ASA that start with reporting to the NACOR.<sup>100</sup> Both these programs have financial implications for payment to anesthesia professionals for their clinical care, but the idea of using such databases for their potential of genuine quality assessment and improvement (which, of course, should reduce costs also) is significant and should be embraced by everyone within the profession of clinical anesthesia.

## Conclusion

Practice and OR “management” in anesthesiology today is more complex **11** and more important than ever before. Attention to details that previously did not exist, were unknown, or were perceived as unimportant can likely make the difference between success and failure in anesthesiology practice.

Outlined here are basic descriptions and understandings of many different administrative, organizational, financial, and personnel components and factors in the practice of anesthesiology today. Ongoing significant changes in the health-care system will provide a continuing and expanding array of challenges. Application of the knowledge and principles presented here will allow anesthesiologists to extrapolate creatively from these basics to their own individual circumstances and then forge ahead in anesthesiology practice that is safe, efficient, effective, productive, collegial, and even fun.

# 3 Occupational Health

JONATHAN D. KATZ • ROBERT S. HOLZMAN • AMY E. VINSON

## Introduction

### Physical Hazards

- Waste Anesthetic Gases
- Chemicals
- Allergic Reactions
- Radiation
- Noise Pollution
- Ergonomics/Human Factors
- Work Hours, Night Call, and Fatigue

### Infectious Hazards

- OSHA Standards, Standard Precautions, and Transmission-based Precautions
- Respiratory Viruses
- Enteric Infections
- DNA Viruses
- Rubella
- Measles (Rubeola)
- Viral Hepatitis
- Pathogenic Human Retroviruses
- Prion Diseases
- Tuberculosis
- Viruses in Smoke Plumes

### Emotional Considerations

- Stress
- Impact of Adverse Events
- Burnout
- Substance Use, Abuse, and Addiction
- Impairment and Disability
- The Aging Anesthesiologist
- Mortality Among Anesthesiologists
- Suicide

### Wellness

- Nutrition, Diet, and Fitness
- Implementing Lifestyle Interventions for Lifestyle-related Diseases
- Mindfulness

## Conclusion

### KEY POINTS

- 1 Exposure to waste anesthetic gases can be reduced to levels below those recommended by the National Institute for Occupational Safety and Health by using waste gas scavenging equipment, routinely maintaining anesthesia machines, and following appropriate work practices.
- 2 Vigilance is one of the most critical tasks performed by anesthesiologists and may be adversely affected by several occupationally related issues including poor equipment engineering and design, excessive noise, interpersonal conflict, production pressures, and fatigue.
- 3 Sleep deprivation and fatigue are common among anesthesiologists and can adversely affect patient safety due to deleterious effects on the physician's cognition, mood, and health.
- 4 The risk of exposure to infectious pathogens can be reduced by the routine use of standard precautions, transmission-based precautions for infected patients, and safety devices designed to prevent needlestick injuries.
- 5 Hepatitis B vaccine is recommended for all anesthesia personnel because of the increased risk for occupational transmission of this blood-borne pathogen.
- 6 Substance use disorder, or chemical dependency, is a significant, often lethal, occupational hazard among anesthesiologists. An incidence of controlled substance abuse of 1% to 2% has been repeatedly reported within anesthesia training programs. Rates have not changed despite educational and systematic interventions.
- 7 Anesthesiologists have a disproportionately high rate of suicide. Factors include pre-existing personality traits, substance use disorder, and stress.
- 8 Physician wellness is integral to occupational health and patient safety. There is an evolving professional commitment to optimizing physician work style and lifestyle, as well as physical health (e.g., through better nutrition, fitness, and rest).
- 9 Mindfulness-based stress reduction techniques can improve physician wellness, physician performance, and patient safety.

## Introduction

The health-care industry has the dubious distinction of being one of the most hazardous places to work in the United States. According to the U.S. Bureau of Labor, workers in the health-care and social assistance industry have the highest rate and greatest number of nonfatal occupational injuries among all

workers in the private industry sector.<sup>1</sup> Unfortunately, in contrast to other well-known hazardous workplaces, such as agriculture and construction, the frequency of occupational injuries in the health-care sector continues to rise.

In addition to the occupational risks incurred by other members of the health-care team, commonly recognized workplace hazards for anesthesia personnel include exposure to waste anesthetic gases (WAG), ionizing radiation, fires, and infectious agents. In addition, anesthesia personnel are vulnerable to emotional and psychological disorders such as burnout and substance use disorder.

Despite heightened awareness and concerted efforts to minimize these occupational diseases, many continue to occur at disproportionate rates among anesthesiologists. This chapter will discuss these hazards and the work being done both to reduce occupational risks in the workplace and to improve patient safety through promotion of physician wellness.

## Physical Hazards

### *Waste Anesthetic Gases*

#### **Levels of Waste Anesthetic Gases**

In the absence of adequate air exchange and scavenging of WAG, high levels of anesthetic vapors can be detected in the ambient air surrounding anesthetizing locations. In 1969, prior to the routine use of scavenging devices, Linde and Bruce<sup>2</sup> observed an average concentration of halothane of 10 ppm and nitrous oxide of 130 ppm in the air surrounding an active anesthesia machine, with end-expired air samples from anesthesiologists as high as 12 ppm of halothane. Subsequent studies have reported even higher concentrations in poorly ventilated and/or unscavenged locations.<sup>3</sup>

Citing health concerns, the National Institute for Occupational Safety and Health (NIOSH) in 1977 recommended exposure limits of 2 ppm for halogenated anesthetic agents when used alone or 0.5 ppm for a halogenated agent and 25 ppm of nitrous oxide when used together (Time Weighted Average [TWA] during the period of anesthetic administration).<sup>4</sup> Scavenging equipment specifications and methods for monitoring WAG concentrations were also included in the report.

In a subsequent publication, NIOSH issued an alert to health-care personnel that exposure to inhalation anesthetic agents, especially nitrous oxide, may produce “harmful effects” and included recommendations to monitor the air in operating rooms (ORs), implement appropriate engineering controls, enact certain work practices and equipment maintenance procedures, and institute a worker education program.<sup>5</sup> Other organizations, such as the American Conference of Governmental Industrial Hygienists, and some state

departments of health, have established their own occupational exposure limits for WAG, in many cases higher than those recommended by NIOSH.

**1** It has been well demonstrated that concentrations of WAG can usually be reduced to acceptable levels through strict compliance with the NIOSH recommendations.<sup>6</sup> However, there remain several potential sources for OR contamination and unavoidable situations, such as a mask induction (common in pediatric anesthesia), where levels of WAG can exceed these limits ([Table 3-1](#)).<sup>3</sup> Elevated levels of WAG have also been identified in the postanesthesia care unit (PACU),<sup>7</sup> typically occurring via exhaled gases from recovering patients.<sup>8</sup> Levels of WAG in the PACU can be reduced by ensuring adequate room ventilation and by discontinuing anesthetic gases in sufficient time before leaving the OR.

### **Health Consequences of WAG Exposure**

The first published report of specific toxic effects from chronic occupational exposure to WAG appeared in a 1967 article that described a high incidence of fatigue, nausea, headaches, and miscarriage among female Russian anesthesiologists.<sup>9</sup> Although the study methodology has been subsequently questioned, it opened an ongoing dialogue about whether or not chronic exposure to WAG renders anesthesia providers more vulnerable to cellular injury, organ toxicity, adverse reproductive outcomes, impairment of psychomotor skills, substance use disorder, and premature death.

It is not surprising that chemicals with such widespread and profound physiologic effects as anesthetic agents would evidence toxic properties if applied in adequate concentrations to tissues. For example, there is ample evidence that cellular damage can be caused by chronic exposure of cultured cells and experimental animals to high concentrations of many anesthetic gases.<sup>10-12</sup> However, the clinical literature remains inconclusive regarding causality between adverse health effects and the level of occupational exposure to WAG experienced by most anesthesia personnel. Some limitations of the clinical studies include occupational exposure in the study population to other risk factors such as radiation, long work hours, stress, and unhealthy personal habits, as well as potential reporter bias that can occur in retrospective studies.

**Table 3-1** Sources of Operating Room Contamination

<p><b>Anesthetic Techniques</b></p> <ul style="list-style-type: none"><li>• Filling of anesthesia vaporizers</li><li>• Flushing of the circuit</li><li>• Turning gas flow on before placing mask on patient</li><li>• Poorly fitting masks and laryngeal mask airways</li><li>• Uncuffed or leaking tracheal tubes</li><li>• Open pediatric circuits</li><li>• Failure to turn off gas flow control valves at the end of an anesthetic</li></ul> <p><b>Anesthesia Machine Delivery System and Scavenging System</b></p> <ul style="list-style-type: none"><li>• Open system</li><li>• Malfunction of hospital disposal system</li><li>• Leaks in high pressure hoses and connectors</li><li>• CO<sub>2</sub> absorbent canisters</li><li>• Mounting of gas tanks</li></ul> <p><b>Other Sources</b></p> <ul style="list-style-type: none"><li>• Cryosurgery units</li><li>• Cardiopulmonary bypass circuits</li></ul>
----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Most of the studies of possible health consequences to humans with occupational exposure to WAG have focused on cytotoxic changes, cancer, and reproductive outcomes. The reports on possible genotoxic effects of trace anesthetic exposure are conflicting. For example, in one study occupational exposure to sevoflurane ( $8.9 \pm 5.6$  ppm) and nitrous oxide ( $119 \pm 39$  ppm) was associated with increased levels of sister chromatid exchange (a marker of genotoxicity) with abnormal cytology returning to normal after 2 months of leave from the OR.<sup>13</sup> However, other studies have reported no findings of cellular damage among clinicians exposed to the levels of anesthetic gases that are encountered in an adequately ventilated and scavenged OR.<sup>14</sup> A conclusion that can be drawn from these conflicting reports is that the risk of genotoxicity is minimal under the low exposure to WAG usually experienced in a well-scavenged OR.<sup>15,16</sup>

The possibility of adverse reproductive outcomes has been the most intensively researched aspect of occupational WAG exposure. Early reports suggested an association between long-term occupational exposure to WAG and infertility, spontaneous abortions, and congenital abnormalities.<sup>17</sup> The American Society of Anesthesiologists (ASA) and NIOSH published a retrospective analysis in 1974 in which 49,585 OR personnel with occupational WAG exposure were compared with a nonexposed group of 23,911 health-care professionals.<sup>18</sup> Among the findings in this study was an increased risk of spontaneous abortion and congenital abnormalities in children of women who worked in the OR and an increased risk of congenital abnormalities in offspring of unexposed wives of male OR personnel.

In 1985, in response to criticism of the methodology and data analysis in this and other earlier reports, and in recognition of the fact that many of the

studies were conducted prior to routine WAG scavenging, the ASA commissioned a meta-analysis of the existing data.<sup>19</sup> This study reported that the relative risks of spontaneous abortion for female physicians and female nurses working in the OR were 1.4 and 1.3, respectively. The increased relative risk for congenital abnormalities was of borderline statistical significance for exposed physicians only. The overall risk created by WAG exposure was small compared with other, better-documented, maternal risk factors, such as cigarette smoking and long working hours. The review also pointed out that duration and levels of anesthetic exposure were not measured in any of the studies and that other confounding factors were not adequately controlled.

The importance of adequate scavenging was highlighted in a subsequent meta-analysis of the risk of spontaneous abortion among hospital workers, dental assistants, veterinarians, and veterinary assistants.<sup>20</sup> The study identified a significant risk of spontaneous abortion in those studies conducted prior to the era of scavenging but no increased risk among personnel who worked in environments where WAG were scavenged.

Reports of elevated risks for adverse reproductive outcomes have continued to appear. Most of these reports concern personnel in locations where adequate scavenging of WAG is not universally practiced. Female dental assistants<sup>21</sup> and female veterinarians who work in large animal hospitals<sup>22</sup> have been specifically identified as at-risk for adverse reproductive outcomes.

It is likely that other job-associated conditions besides exposure to trace anesthetic gases, such as stress, infections, long work hours, shift work, and radiation exposure, may account for many of the adverse reproductive outcomes. A survey of 3,985 Swedish midwives demonstrated that night work was significantly associated with spontaneous abortions after the 12th week of pregnancy (odds ratio 3.33), whereas exposure to nitrous oxide appeared to have no effect.<sup>23</sup> Preterm birth in obstetric and neonatal nurses was associated with increased work hours, hours worked while standing, and occupational fatigue.<sup>24</sup> In addition, in a study of female veterinarians, the risks of birth defects were highest among those exposed to radiation and long working hours (>45 hr/wk) but not to those exposed to WAG.<sup>22</sup>

The literature on this subject remains inconclusive. Many of the epidemiologic studies continue to suffer from important design flaws. For example, the level of exposure to WAG is frequently unknown or not reported and the retrospective nature of the questionnaire lends itself to reporter bias. Still, the evidence taken as a whole suggests that there is a slight increase in the relative risk of spontaneous abortion and congenital abnormalities in offspring of females exposed to WAG. This risk is minimized when appropriate waste gas scavenging technology is applied.<sup>25</sup>

One of the principal reasons identified by NIOSH in their original publication on WAG was concern about “decrements in performance, cognition, audiovisual ability and dexterity.”<sup>26</sup> The effect of WAG exposure on psychomotor performance among humans varies considerably depending upon the concentration of anesthetic gas to which the subjects are exposed. Temporary lethargy and fatigue are the most common symptoms described after brief exposures to subanesthetic concentrations of anesthetic gases. Longer exposures and higher concentrations have been associated with symptoms such as headache, depression, anxiety, loss of appetite, loss of memory, decreased reaction time, and decrements in cognitive function. Most of the measurable psychomotor and cognitive impairments produced by brief exposures are short-lived and disappear within 5 minutes of cessation of exposure.<sup>27</sup>

One other health consideration of WAG is the environmental impact and contribution to global warming. Among anesthetic gases, nitrous oxide is the greatest contributor to this effect because of the relatively large volumes that are used, the longer time period that it has been in use compared to other inhalation anesthetics, and the fact that nitrous oxide from a number of nonmedical sources is currently the dominant ozone-depleting gas.<sup>28</sup> Nitrous oxide from anesthetic use represents only a small fraction of that found in the stratosphere but nevertheless does contribute to the greenhouse effect.<sup>29</sup>

## **Chemicals**

Methyl methacrylate is commonly used in many surgical procedures. Known cardiovascular complications of methyl methacrylate in surgical patients include hypotension, bradycardia, and cardiac arrest. Reported risks from repeated occupational exposure to methyl methacrylate include skin irritation and burns, systemic allergic reactions, eye irritation, headache, neurologic signs, adverse reproductive outcomes, and organ damage. In one report, a dental technician suffered significant lower limb neuropathy after repeated occupational exposure to methyl methacrylate.<sup>30</sup> Reported levels in modern ORs using scavenging devices are well below the U.S. Environmental Protection Agency recommended limit of an 8-hour TWA exposure of 100 ppm.

## **Allergic Reactions**

Allergic reactions to volatile anesthetic agents and to some muscle relaxants have been associated with contact dermatitis, hepatitis, and anaphylaxis in individual anesthesiologists.<sup>31,32</sup> Analyses of sera from pediatric anesthesiologists exposed to halothane demonstrated an increased prevalence

of autoantibodies to cytochrome P450 2E1 and hepatic endoplasmic reticulum protein (ERp58).<sup>33</sup> The pathophysiology appears more complex than antibody development and may be more of a halogenated hydrocarbon autoimmune reaction injuring the liver. These autoantibodies are also detectable in about one-third of patients with advanced alcoholic liver disease and chronic hepatitis C.<sup>34</sup> Despite the presence of these autoantibodies, only 1 of 105 anesthesiologists had findings of any hepatic injury. Therefore, although autoantibodies may occur in anesthesiologists frequently exposed to volatile anesthetics, they do not appear to commonly cause anesthetic-induced hepatitis.

Latex in surgical and examination gloves has become a common source of allergic reactions among OR personnel. In many cases, medical personnel who are allergic to latex experience their first adverse reactions while they are patients undergoing surgery. Although the majority of symptoms are mild, urticaria, bronchospasm, and rhinitis can occur. More severe symptoms are significantly related to a positive history of individual or family atopy. The prevalence of latex sensitivity among medical personnel can be as great as 16% to 20%.<sup>35,36</sup> For anesthesiologists the rate is approximately 12%.<sup>37</sup>

The latex found in medical products is actually a composite of proteins, polyisoprenes, lipids, and phospholipids combined with preservatives, accelerators, antioxidants, vulcanizing compounds, and lubricating agents (such as cornstarch or talc). The protein content is responsible for most of the generalized allergic reactions to latex-containing surgical gloves. These reactions are exacerbated by the presence of powder that enhances aerosolization.

Irritant or contact dermatitis accounts for the majority of reactions resulting from wearing latex-containing gloves (Table 3-2). True allergic reactions present as T-cell-mediated contact dermatitis (type IV) or as an immunoglobulin E-mediated anaphylactic reaction (type I).

Anesthesiologists who believe that they are allergic to latex must avoid all direct contact with latex-containing products. It is also important that coworkers wear nonlatex or powderless, low latex-allergen gloves to limit the levels of ambient allergens.

**Table 3-2** Types of Reactions to Latex Gloves

Category	Symptoms	Signs	Cause	Management
Contact dermatitis	Irritation, itching, pain	Scaling, drying, cracking of skin	Powders, soaps, gloves	Identify reaction, avoid irritant, use glove liner, use alternative product
Type IV—delayed hypersensitivity	Irritation, itching, pain (delayed 6–72 h)	Scaling, drying, cracking of skin; blistering	Chemical additives used in manufacturing (such as accelerators)	Identify offending chemical, possibly use alternative product without chemical additive, possibly use glove liner
Type I—immediate hypersensitivity			Proteins found in natural rubber latex-containing products	Identify reaction; avoid latex-containing products; use by coworkers of nonlatex or powder-free, low-protein gloves
Localized contact urticaria	Itchiness in localized area of contact (immediate)	Localized urticaria in a contact pattern; redness and swelling of skin resembling a “poison ivy” type of rash		Antihistamines, topical/systemic steroids
Generalized reaction	Itching, stuffy nose, shortness of breath, sense of foreboding, itching	Hives, runny nose, wheezing, hypoxemia, cardiovascular instability including hypotension and shock		Anaphylaxis protocol emphasizing epinephrine in appropriate doses

## Radiation

Anesthesia personnel are at risk of radiation exposure from the primary x-ray beam and from scattered radiation reflected off surfaces such as tables, other equipment, and the patient. The biologic consequences of radiation exposure vary depending on age, gender, and the specific organ that is exposed. Well-documented consequences of radiation exposure include DNA damage, cell death, and organ injury. The development of cancer is an example of a radiation-induced injury with a long latency period and having no known threshold below which the risk entirely disappears.

The Occupational Safety and Health Administration (OSHA) has published occupational limits for workers exposed to ionizing radiation.<sup>38</sup> The annual limit is 5 rem with an allowable long-term limit of  $(N - 18) \times 5$  rem, where  $N$  is the age in years. The recommended maximum occupational exposure to a pregnant or lactating worker should not exceed a monthly limit of 0.5 rem (excluding medical and natural background radiation).

Early studies reported that the exposure to radiation among anesthesia personnel is safely below the OSHA limits.<sup>39</sup> However, studies conducted subsequent to the increased utilization of ionizing radiation in ORs, cardiac catheterization, and interventional radiology suites, have revealed a trend toward increased exposure among anesthesia personnel (although still well below OSHA limits).<sup>40,41</sup> In one study, there was a doubling of the aggregate radiation exposure to members of a department of anesthesiology in the year following the introduction of an electrophysiology laboratory.<sup>42</sup> Preventative

strategies for anesthesiologists to minimize their risk of radiation-induced injury include limiting the intensity and exposure time, distancing oneself from the source of the radiation, and using maximal shielding from both primary and scattered sources of radiation.

A second form of radiation with potential health consequence comes in the form of chronic exposure to low-frequency electromagnetic fields such as those emitted by magnetic resonance imaging (MRI) equipment.<sup>43</sup> Transient symptoms such as vertigo, nausea, dizziness, and visual phosphenes (light flashes) have all been reported. The severity of these symptoms is a function of the field strength of the scanner, the proximity to the scanner, and the rate of movement within the magnetic field. There are currently no published regulations in the United States that limit occupational exposure. Guidelines from the International Commission on Non-Ionizing Radiation Protection offer some suggestions regarding technique and worker practices to limit neurobehavioral effects.<sup>44</sup> No studies to date have identified any chronic adverse health effects from long-term exposure to high-intensity magnetic fields. However, until more information is available, it would seem prudent to conform to the general admonition regarding all forms of radiation exposure: keep it as low as reasonably achievable.

## Noise Pollution

The magnitude of noise is determined by both the intensity of the sound (measured in decibels) and the duration of the exposure to that sound. A commonly accepted standard for the maximum level of safe noise exposure is 90 dB for 8 hours.<sup>45</sup> Each increase in noise of 5 dB halves the permissible exposure time, so that 100 dB is acceptable for just 2 hours per day. The maximum peak allowable exposure in an industrial setting is 115 dB.

Average noise levels in a modern OR usually far surpass recommended levels (Table 3-3). Ambient noise levels as great as 90 dB commonly result from high capacity heating and air conditioning systems, ventilators, suction equipment, forced-air patient warming devices, music, and conversations. Sporadic clatter from dropped instruments, surgical saws and drills, and anesthetic alarms adds to this background noise so that in some ORs noise levels of 100 dB or greater occur for 40% of the time, with peak levels exceeding 120 dB.<sup>46</sup>

Excessive noise can be distracting, especially to trainees and inexperienced clinicians.<sup>47</sup> Noise also interferes with the critical ability of clinicians in the OR to hear conversations and vital tones and alarms.<sup>48,49</sup> In order for voices and other auditory signals to be heard and accurately interpreted, these sounds must be elevated to 20 dB above background noise.<sup>50</sup> Anesthesia providers are especially vulnerable to noise pollution through its adverse

effects on efficiency, short-term memory, and the ability to perform complex psychomotor tasks.<sup>51</sup> These hindrances can have their largest impact during induction and emergence, which are frequently the noisiest times in the OR.

Chronic exposure to excessive noise is a health hazard. The most direct complication of exposure to excessive noise is hearing loss.<sup>52</sup> The hearing loss occurs gradually, initially affecting higher frequencies (300 to 6,000 Hz), increases in severity with continued exposure, is frequently not realized until significant damage has occurred, and is irreversible. Although no direct causal relationship has been established with chronic exposure to excess noise in the OR, it is interesting that one study of hearing among anesthesiologists found that 66% had abnormal audiograms.<sup>53</sup> In 7% of those studied, the hearing impairment could potentially interfere with their ability to hear standard OR alarms. Other members of the surgical team, including surgeons and scrub nurses, have also been shown to suffer from accelerated hearing loss.<sup>54</sup>

One form of noise, music, deserves special consideration.<sup>55</sup> When properly selected, background music can help focus some members of the surgical staff and contribute toward work efficiency.<sup>56,57</sup> However, music also adds substantially to the already considerable ambient noise levels in the OR. Many members of the surgical team, particularly those in training or with limited experience, find music that is not self-selected distracting and a hindrance to their performance.<sup>58</sup> Anesthesiologists, in particular, frequently report that music can impair communication between team members and interfere with several of their tasks.<sup>59</sup> If music is to be played in the OR, the selection and the volume should be determined by mutual agreement of all of the parties present.

**Table 3-3** Comparative Noise Levels

Source	Noise Intensity
EPA recommendation	45 dB
Continuous suction	75–85 dB
Clang of instruments	75–85 dB
Surgical saw	80–105 dB
Music	75–105 dB
Average OR noise	77 dB
OSHA limit (8 h)	90 dB
Subway	100 dB
OSHA limit (0 h)	115 dB

EPA, Environmental Protection Agency; OSHA, Occupational Safety and Health Administration.

### **Ergonomics/Human Factors**

Human factor analysis, also called ergonomics, is the study of the interaction

between humans and machines and the impact of equipment design on its use. It is a multidisciplinary science that applies diverse principles gleaned from anthropometry, ethnography, biomechanics, industrial and social psychology, architecture, education, and information technology. Human factor analysis has gained its widest acceptance in industries such as aviation and nuclear power where many well-publicized catastrophes have been linked to human error. The work performed by an anesthesiologist shares many of the characteristics found in these industries, including the intricacy of the tasks, a narrow margin of error, and the vulnerability to human error.

A number of human factor shortcomings exist in the anesthesiologist's workplace. For example, anesthesia equipment is often poorly designed or positioned. Anesthesia monitors and electronic medical records are frequently placed so that the anesthesiologist's attention is diverted away from the surgical field. Among those tasks most vulnerable to the distractions of poor workstation design is vigilance,<sup>a</sup> a duty so critical to the conduct of a safe anesthetic that the seal of the ASA bears as its only motto "Vigilance."  

Other ergonomic factors can interfere with an anesthesiologist's ability to optimally perform his/her complex tasks. Any impediment that requires the expenditure of excessive mental or physical energy will eventually produce a decrement in performance. Poor engineering of the monitor displays, so that the manner of presentation is suboptimal, can increase the difficulty in extracting pertinent information and adversely influence the operator's performance. 

Even alarms that were developed with the specific goal of augmenting the task of vigilance can have considerable shortcomings. In general, alarms are nonspecific (the same alarm signaling as many as 12 different deviations from "normal"), and are susceptible to artifacts and false positives that can cause "alarm fatigue," and distract the observer from more clinically significant information. It is not unusual for distractive alarms to be ignored or inactivated.<sup>60</sup> A positive trend that is emerging in alarm technology is the development of "knowledge-based alarms" that can integrate information from more than one monitor and suggest a list of diagnostic and therapeutic possibilities.

Organizational issues, such as failed communication with other team members, can adversely impact an anesthesiologist's performance. The potential for disaster as a result of poor communication has been well illustrated in a number of airline catastrophes. The possibility for miscommunication and resultant error is heightened in the OR as a result of the overlapping realms of professional responsibility, which may be at odds with established hierarchy. Poor communication can lead to conflict and compromised patient safety and has been identified as a root cause of many 

anesthesia-related sentinel events. Crisis resource management training, well established in the aerospace industry, has emerged to address this issue.<sup>61,62</sup>

Effective conflict resolution is an important element of the teamwork necessary for successful surgical outcomes. Some degree of conflict occurs during the management of as many as 78% of patients in high-intensity areas such as ORs or critical care units.<sup>63</sup> Conflict and unpleasant interpersonal interactions among team members are among the most stressful aspects of the job of an anesthesiologist and can hinder safe anesthetic care.

Successful resolution of conflict is a skill that can be learned.<sup>64</sup> Mutual respect is required among team members along with a willingness to acknowledge differences of opinion. Intervention by a neutral third party is frequently helpful in finding an innovative solution. The airline industry has successfully implemented crew resource management programs to improve the performance of cockpit teams.<sup>65</sup> These can also be applied to OR personnel.

“Production pressure” has the potential to create an environment in which issues of productivity supersede those of safety, resulting in errors due directly to haste and/or deliberate deviations from safe practices.<sup>66</sup> The routine use of a preoperative checklist can help prevent multiple potential sources of error, including those directly related to production pressure.<sup>67</sup>

### *Work Hours, Night Call, and Fatigue*

A circadian pattern of alertness and sleep is a fundamental element of healthy human physiology. Inadequate sleep caused by any number of factors, including obstructive sleep apnea or disruptive work schedules, can contribute to adverse health effects including cardiovascular disease and psychological illness.

Sleep-deprived workers are at greater risk of committing workplace errors and suffer more work-related accidents.<sup>68</sup> Accident susceptibility extends beyond work hours to other activities of daily living, such as driving. The changes resulting from sleep deprivation bear a striking similarity to those seen with alcohol intoxication.<sup>69</sup> Significant individual variations in impairment due to fatigue have been identified.<sup>70</sup> The contribution of sleep loss and fatigue to accidents has been documented in many well-publicized industrial catastrophes. Sleep deprivation was a contributing factor in catastrophic industrial accidents such as those at Chernobyl and Three Mile Island, and on the Exxon-Valdez oil tanker and the Challenger space shuttle.

A number of reports have also identified sleep deprivation as a causative factor in errors occurring in the health-care industry.<sup>71</sup> As early as 1971, Friedman et al.<sup>72</sup> reported that interns made almost twice as many errors reading electrocardiograms after an extended work shift than after a night of

sleep. Intubation skills were reduced among emergency room physicians working night shifts when compared with other physicians working days, and physicians in both groups were more likely to commit errors during a simulated triage test toward the end of their work shifts.<sup>73</sup> In a study that examined the management by medical interns of medical admissions, 36% more medical errors occurred while on a “traditional” schedule (>24 hours work shifts) than when working a schedule that eliminated extended work shifts and reduced the number of hours worked per week.<sup>74</sup>

Anesthesiologists who take night call commonly suffer from each of the three well-defined classes of sleep deprivation: total, partial, and selective. Interruption of sleep during call frequently occurs between the hours of 2 AM and 4 AM when humans are most vulnerable to fatigue-induced errors.

**3** The precise role of sleep deprivation on the specific end point of clinical outcomes remains unclear. A number of studies have identified consequences of sleep deprivation that could adversely impact the conduct of a safe anesthetic, including impaired cognition, short-term memory and clinical decision-making, prolonged reaction time, and reduced attention, vigilance, and performance. In a report by Howard et al.,<sup>75</sup> sleep-deprived residents managing a 4-hour simulated anesthetic demonstrated progressive impairment of alertness, mood, and performance and had longer response latency to vigilance probes. In a study of American anesthesia caregivers, more than 50% reported having committed an error in medical judgment that they attributed to fatigue.<sup>76</sup> And 58% of New Zealand anesthesiologists reported they had exceeded their self-defined limit for safe continuous administration of anesthesia, with 86% reporting that they had committed a fatigue-related error.<sup>77</sup> Similar reports of fatigue-related complications appear in the surgical literature with as many as 16% of preventable adverse surgical events attributed to surgeon fatigue.<sup>78,79</sup>

However, others have reported no evidence of suboptimal clinical management or poor outcomes from sleep-deprived clinicians. Chu et al.<sup>80</sup> found no increase in mortality or major morbidity in 4,000 consecutive cardiac surgical procedures performed by surgeons who had varying degrees of sleep (ranging from 0 to >6 hours) the night before surgery. Other studies of surgeons and critical care specialists corroborated these findings.<sup>81,82</sup>

Several factors help to explain the apparent disparity between reports of fatigue-related performance impairment and the failure to conclusively link these with medical errors or adverse outcomes. Sleep deprivation is often arbitrarily defined, with varying characterizations of the nonrested state. Also, there is great difficulty in eliminating confounding variables such as the impact of loss of continuity of care, errors occurring during “hand-offs” of patients, and the reallocation of many medical tasks from physicians to nonphysician providers. Finally, it can be difficult to extrapolate findings

from simulation studies of volunteers in a laboratory to clinicians in real-life work conditions.

The health-care industry is slowly catching up with other industries, most notably the transport and airline industries, in identifying and regulating work practices that permit excessively long shifts. It was not until the well-publicized Libby Zion case in 1984 (which alleged that fatal, avoidable mistakes were made by exhausted, unsupervised residents) that medical organizations and state legislatures acted to limit excessive work hours among residents. In 2000, the Accreditation Council for Graduate Medical Education (ACGME) established the first set of standards to limit resident duty hours. These standards were revised by the ACGME in 2011 and updated in 2014.<sup>83</sup> The standards detail a list of work hours restrictions, including the well-known limit of 80 hours per week. Imposition of these standards has been controversial and a number of authors have commented on the failure of these changes to improve clinical outcomes. Somewhat ironically, at the end of a long list of duty hours restrictions, item VI.G.5.c states, “Residents in the final years of education must be prepared to enter the unsupervised practice of medicine and care for patients over irregular or extended periods.” This statement recognizes that these restrictions on duty periods apply only to trainees and that work hours in medical practice remain unregulated.

Prolonged work hours and sleep deprivation are a ubiquitous component of many anesthesiologists’ professional lives. Many academic faculty members now work longer hours than they did prior to house staff work hour limitations because of the shift of work from residents to faculty. A recent survey demonstrated an average work week of 57 hours among male and 51 hours among female American anesthesiologists.<sup>84</sup>

Several strategies have been devised to reduce fatigue and limit the adverse effects of sleep deprivation when long work periods are necessary. Recommendations include minimizing sleep debt by maximizing sleep before on-call shifts and utilizing maneuvers to overcome sleep inertia such as increasing ambient light levels, stretching, taking frequent breaks, and napping when possible. A number of pharmaceutical aids, such as caffeine and modafinil (a schedule IV drug), have been approved for military use and, if used under supervision and carefully monitored, may be helpful for clinicians with shift-work sleep disorder.<sup>85</sup>

## Infectious Hazards

Anesthesia personnel are at risk for acquiring infections from patients, their families, and from numerous other personnel in the health-care workforce. This risk is likely to increase because as antimicrobial agents become more effective, the pathogens develop resistance and new survival strategies.

Increasingly, immune-compromised patients become vectors for these resistant, opportunistic organisms. Furthermore, globalization brings increasing spread of organisms from less developed areas in the world, such as the 1999 outbreak in New York of West Nile Virus encephalitis and the 2003 epidemic of severe acute respiratory syndrome (SARS) in Hong Kong. Finally, diseases that were once thought to be noninfectious such as peptic ulcer disease (*Helicobacter pylori*), invasive cervical cancer (human papillomavirus), Kaposi's sarcoma (human herpesvirus type 8), and certain lymphomas such as Burkitt and non-Hodgkins (Epstein-Barr virus [EBV]) are now better understood as a long-term consequence of infection, making occupational health precautions even more important.

Viral infections are the most significant threat to medical personnel. Most commonly, these are spread through the respiratory route. Other infections are spread by hand-to-hand transmission and hand washing is the single most important protection strategy.<sup>86</sup> Immunity against some viral pathogens, such as hepatitis B, can be provided through vaccination.<sup>87</sup> Transmission of blood-borne pathogens such as hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) can be prevented with mechanical barriers. Current recommendations from the Centers for Disease Control and Prevention (CDC) for pre-employment screening, infection control practices, vaccination, postexposure treatment, and work restrictions for infected personnel should be consulted for specific information related to each pathogen.<sup>88,89</sup>

### ***OSHA Standards, Standard Precautions, and Transmission-based Precautions***

In the late 1980s the CDC formulated recommendations (“universal precautions”) for preventing transmission of blood-borne infections to medical personnel. The guidelines were based on the epidemiology of HBV as a worst-case model for transmission of blood-borne infections and available knowledge of the epidemiology of HIV and HCV. Since asymptomatic carriers of many blood-borne viruses cannot be identified, universal precautions were recommended for use during all patient contact. Although exposure to blood carries the greatest risk of occupationally related transmission of pathogens, it was recognized that universal precautions should also be applied to saliva, semen, vaginal secretions, human tissues, and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids. Subsequently, the CDC aggregated the major features of universal precautions into “standard precautions” (Table 3-4) that should be applied to all patients,<sup>90</sup> now updated to include Ebola (Table 3-5).<sup>91</sup>

**Table 3-4 Standard Precautions**

**Modes of Transmission**

Direct contact transmission	Transmission of an infectious agent directly from one person to another; may occur via contact of blood or secretions with mucous membranes, open cuts, or mites.
Indirect contact transmission	Transmission of an infectious agent via an intermediate object (fomite) that has been previously contaminated. This may include (but is not limited to) patient-care devices, environmental surfaces, and clothing.
<i>The particle size of emitted respiratory secretions is a continuum from aerosol size particles (<math>\leq 5 \mu\text{m}</math>) to droplets (<math>&gt; 5 \mu\text{m}</math>).</i>	
Droplet transmission	Droplets ( $> 5 \mu\text{m}$ ) remain suspended for short periods of time and tend to be deposited within 3 feet of where they are generated. The distance that a droplet travels may be affected by such things as temperature, humidity, and air currents. Droplets are preferentially deposited in the upper airways, whereas aerosols penetrate deeper into the lower respiratory tract.
Airborne transmission	Organisms that can remain infectious when disseminated over distance and time as the droplet nuclei ( $< 5 \mu\text{m}$ particles) are dispersed on air currents.

**Standard Precautions**

- Reduce the risk of transmission of infectious agents from patient to patient, patient to health-care worker (HCW), HCW to patient. Apply to all patients, as anyone may be infected or colonized with a transmissible disease.
- Wear gloves for all contact with blood, body fluids (except sweat), nonintact skin, and mucous membranes. Change gloves when they become soiled or when contact with a clean body part follows that with a contaminated part. Remove gloves after patient contact. Minimize environmental contamination.
- Perform hand hygiene before patient contact and upon removal of gloves.
- Gown, face, and eye protection should be worn if there is a risk of splash or spray.
- Environmental cleaning after contamination by body substances.
- Standard surgical mask when inserting a central line or performing neuraxial anesthesia.
- Needle and sharp safety:
  - Avoid recapping (when necessary, use one-handed technique).
  - Avoid bending or breaking used sharps. Sharp disposal in puncture-resistant containers.
- Practice and encourage respiratory hygiene/cough etiquette.

**Contact Precautions (in addition to standard precautions)**

- Signage outside room to indicate level of precautions.
- Gown and glove upon entering room and with any patient or environmental contact.
- Face and eye protection if there is a risk of splash or spray.
- Remove gloves and gown before exiting room. Avoid self-contamination when removing personal protective equipment (PPE).
- Perform hand hygiene after removal of PPE.
- Dedicated patient equipment whenever possible. Appropriately clean equipment prior to its use with other patients.
- Maintain contact precautions during transport and entire perioperative period.
- Communicate precaution level to those that will receive patient postoperatively.

**Droplet Precautions (in addition to standard precautions)**

- Single-patient room optimal. May cohort or keep patient with existing roommate when necessary.
- Spatial separation of patients of 3 feet. If curtain present, keep drawn.
- Signage outside room to indicate level of precautions.
- HCWs should wear standard surgical mask, gloves, gown, and eye protection as required under standard precautions.
- Patient should wear standard mask (if tolerated) when transport outside room required.
- Respiratory hygiene/cough etiquette.
- Maintain precautions throughout perioperative period.
- Communicate precaution level to those that will receive patient postoperatively.

**Airborne Precautions (in addition to standard precautions)**

- Place patient in an airborne infection isolation room (AIIR).
- Signage outside room to indicate level of precautions.
- N95 respirator or greater protection should be used when in the same room as the patient.
- Patient should remain in AIIR with door closed at all times, except for medically necessary procedures.
- Elective procedures should be postponed until patient no longer requires respiratory isolation.
- Patients should wear a standard surgical mask when transported outside the AIIR. The purpose of the mask is to prevent respiratory droplets from being expelled into the environment where they can become droplet nuclei.
- Operating rooms (ORs) are designed to have positive pressure in relation to the environment. Therefore, it is important to choose the most appropriate OR to minimize the risk of contaminating the OR suite. Options include the OR that is most remote from others, one with an antechamber, or installing a portable negative pressure isolation chamber at the OR door.
- The surgical procedure should be scheduled at a time when it will minimize exposure of other patients and medical staff to the airborne infectious disease.
- Postanesthesia recovery must take place with the same level of respiratory precautions.
- Communicate precaution level to receiving personnel.
- Room should remain vacant after the patient leaves until adequate time has elapsed to result in a 99.9% air turnover (duration dependent on number of air exchanges per hour in room).

Standard precautions include the appropriate application and use of hand washing, personal protective equipment (PPE), and respiratory hygiene/cough etiquette. The selection of specific barriers or PPE should be commensurate with the task being performed. Gloves may be sufficient during many procedures that involve contact with mucous membranes or oral fluids, such as routine endotracheal intubation or insertion of a peripheral intravenous catheter. However, additional personal protection, such as gown, mask, and face shield, may be required during endotracheal intubation when the patient has hematemesis or during bronchoscopy or endotracheal suctioning.

OSHA's Bloodborne Pathogens standard (29 CFR 1910.1030) prescribes safeguards to protect workers against the health hazards caused by blood-borne pathogens.<sup>92</sup> These standards require an exposure control plan specifically detailing the methods that the employer is providing to reduce employees' risk of exposure to blood-borne pathogens. The employer must encourage strategies to reduce blood exposures, furnish appropriate PPE (e.g.,

gloves, gowns), offer the HBV vaccine at no charge to personnel, and provide an annual education program to inform employees of their risk for blood-borne infection. Congressional testimony by OSHA reported an order of magnitude decrease in hepatitis B infection in a span of 8 years (1987–1995).<sup>93</sup>

The institution’s employee health service is required to obtain and record a contagious disease history from new employees and provide immunizations and annual purified protein derivative (PPD) skin testing. In addition, the employee health service must have protocols for dealing with workers exposed to contagious diseases and those exposed to the blood of patients infected with HIV or HBV or HCV. Free consultation is available from the CDC Post-Exposure Prophylaxis Hotline (PEpline) at 1-888-448(HIV)-4911.

**Table 3-5 Ebola Precautions**

<b><i>Ebola Hemorrhagic Fever</i></b>	
Site(s) of infection; transmission mode	As a rule infection develops after exposure of mucous membranes or RT, or through broken skin or percutaneous injury.
Incubation period	2–19 days, usually 5–10 days
Clinical features	Febrile illnesses with malaise, myalgias, headache, vomiting, and diarrhea that are rapidly complicated by hypotension, shock, and hemorrhagic features. Massive hemorrhage in <50% patients.
Diagnosis	Etiologic diagnosis can be made using RT-PCR, serologic detection of antibody and antigen, pathologic assessment with immunohistochemistry, and viral culture with EM confirmation of morphology.
Infectivity	Person-to-person transmission primarily occurs through unprotected contact with blood and body fluids; percutaneous injuries (e.g., needlestick) associated with a high rate of transmission; transmission in health-care settings has been reported but is prevented by use of barrier precautions.
Recommended precautions	Hemorrhagic fever-specific barrier precautions: If disease is believed to be related to intentional release of a bioweapon, epidemiology of transmission is unpredictable pending observation of disease transmission. Until the nature of the pathogen is understood and its transmission pattern confirmed, Standard, Contact, and Airborne Precautions should be used (see Table 3-4). Once the pathogen is characterized, if the epidemiology of transmission is consistent with natural disease, Droplet Precautions can be substituted for Airborne Precautions. Emphasize (1) use of sharps safety devices and safe work practices; (2) hand hygiene; (3) barrier protection against blood and body fluids upon entry into room (single gloves and fluid-resistant or impermeable gown, face/eye protection with masks, goggles or face shields); and (4) appropriate waste handling. Use N95 or higher respirators when performing aerosol-generating procedures. In settings where AIIRs are unavailable or the large numbers of patients cannot be accommodated by existing AIIRs, observe Droplet Precautions (plus Standard Precautions and Contact Precautions) and segregate patients from those not suspected of VHF infection. Limit blood draws to those essential to care.

RT, respiratory tract; PCR, polymerase chain reaction; EM, electron microscopy; AIIR, airborne infection isolation room; VHF, viral hemorrhagic fever.

## **Respiratory Viruses**

Respiratory viruses account for half or more of all acute illnesses and are usually transmitted by one of two routes. Small-particle aerosols from viruses such as influenza and measles are produced by coughing, sneezing, or talking and can be propelled over large distances. Large droplets that have been produced by coughing or sneezing can contaminate the donor’s hands or an inanimate surface. The virus is then transferred to the oral, nasal, or

conjunctival mucous membranes of a susceptible person by self-inoculation. Rhinovirus and human respiratory syncytial virus (HRSV) are spread by this process.

## **Influenza Viruses**

Influenza viruses (Orthomyxoviridae) are designated as type A, B, or C based on characteristics of the nucleoprotein (NP) and matrix (M) protein antigens. Influenza A viruses are subtyped on the basis of the surface hemagglutinin (H) and neuraminidase (N) antigens. Individual strains are designated according to the site of origin, isolate number, year of isolation, and subtype, for example, influenza A/California/07/2009 (the infamous H1N1 of 2009). Influenza A has 18 H subtypes and 11 N subtypes, of which only H1, H2, H3, N1, and N2 have been associated with epidemics of disease in humans. Influenza B viruses are not divided into subtypes but rather lineages and strains, whereas influenza C infections cause mild respiratory illness but are not associated with epidemics. Acutely ill patients shed virus for as long as 5 days after the onset of symptoms via small-particle aerosols. Because of their contact with nasopharyngeal secretions, anesthesiologists can easily become victims as well as vectors in the spread of influenza.

Influenza A (H1N1 or H3N2) and one or two influenza B viruses (depending on the vaccine) are included in each year's influenza vaccine. The CDC (Advisory Committee on Immunization Practices and the Healthcare Infection Control Practices Advisory Committee) recommends that all US health-care workers be immunized annually with the inactivated (killed virus) influenza virus vaccine. Through the efforts of the Society for Healthcare Epidemiology of America, there is evolving precedent to make this a condition of employment and medical staff credentialing.<sup>94,95</sup> Since the vaccine used in the United States and many other countries is produced in eggs, individuals with true hypersensitivity to egg products should be either desensitized or not vaccinated. A live attenuated influenza vaccine, approved for use in healthy nonpregnant persons 2 to 49 years of age and administered by intranasal spray, is now available. Inclusion and exclusion criteria are listed at <http://www.cdc.gov/flu/about/qa/nasalspray.htm>.

## **Influenza Pandemics**

Influenza outbreaks occur almost every year, although their extent and severity vary widely. In the past century there have been three influenza pandemics (1918, 1957, and 1968) with the "Great Influenza" in 1918 killing between 40 and 50 million people worldwide. The most recent pandemic emerged in March 2009 and was caused by an influenza A/H1N1 virus that rapidly spread worldwide over several months. Containment requires early

identification and isolation of infected individuals. NIOSH-certified respirators (N95 or higher) should be used by personnel during activities or procedures likely to generate infectious respiratory aerosols.

## **Avian Influenza A**

In 1997, human cases of influenza caused by avian influenza viruses (A/H5N1) were detected in Hong Kong during an extensive outbreak of influenza in poultry. Approximately 850 human cases have subsequently been reported worldwide with a mortality of more than 50%, nearly all associated with contact with infected poultry. Efficient person-to-person transmission has not been observed. Because of the absence of widespread immunity to the H5, H7, and H9 viruses, concern persists that avian-to-human transmission might contribute to the emergence of a pandemic strain.<sup>96</sup> A vaccine for prophylaxis against avian influenza H5N1 was approved for use in the United States in 2007.

## **Human Respiratory Syncytial Virus**

HRSV is the most common cause of serious bronchiolitis and lower respiratory tract disease in infants and young children worldwide. During periods when HRSV is prevalent in the community (late November through May in the United States), many hospitalized infants and children may carry the virus. Large amounts of virus are present in respiratory secretions of infected children. Viable virus can be recovered for up to 6 hours on contaminated environmental surfaces. The virus is readily inactivated with soap and water and disinfectants. Infection of susceptible people occurs by self-inoculation when HRSV in secretions is transferred to the hands, which then contact the mucous membranes of the eyes or nose. Although most children have been exposed to HRSV early in life, immunity is not permanent and reinfection is common. HRSV may also be a significant cause of illness in healthy elderly patients and those with chronic cardiac or pulmonary disease.<sup>96</sup> HRSV is shed for approximately 7 days after infection. Careful hand washing and the use of standard precautions have been shown to reduce HRSV infection in hospital personnel.

## **Severe Acute Respiratory Syndrome**

SARS is a respiratory tract infection produced by SARS-associated coronavirus (SARS-CoV). SARS typically presents with a fever greater than 38°C followed by symptoms of headache, generalized aches, and cough. Severe pneumonia may lead to acute respiratory distress syndrome and death. The mechanisms of transmission of SARS are incompletely understood. Spread may occur by

both large and small aerosols and perhaps by the fecal–oral route, as well as close person-to-person contact. Aerosolization of respiratory secretions during coughing or endotracheal suctioning has been associated with transmission of the disease to medical personnel, including anesthesiologists and critical care nurses.<sup>97</sup> After the first cases were reported from Asia in late 2002, the disease quickly spread globally in 2003 before being controlled. Since 2004, global surveillance for SARS-CoV has detected no confirmed cases.

## Enteric Infections

Diarrheal disease is second only to lower respiratory tract infections as the most common infectious cause of death worldwide. Infectious agents include viruses, bacteria, and parasites, acting via noninflammatory (enterotoxin), inflammatory (cytotoxin), or penetrating mechanisms. Traveler’s diarrhea is the most common travel-related infectious illness (20% to 50%), with *Escherichia coli* the most common organism. Rotavirus is most common among children less than 2 years of age, especially children in day care. Rotavirus can spread rapidly in day care centers and pediatric wards. *Giardia lamblia* is more common in older children, as is norovirus, and there is a high rate of secondary cases among family members. *Clostridium difficile* is the main cause of nosocomial diarrhea among adult inpatients in the United States. One-third of elderly patients in nursing homes develop a significant diarrheal illness each year, and more than half of these are caused by *C. difficile*, especially following antibiotic therapy. Personal hygiene on the part of clinicians is directed to limiting secondary fecal–oral spread.

## DNA Viruses

Herpes simplex viruses (HSV-1, HSV-2; *Herpesvirus hominis*) produce a variety of infections involving mucocutaneous surfaces, central nervous system (CNS), and visceral organs. Exposure to HSV at mucosal surfaces or abraded skin allows entry of the virus and initiation of viral replication. The primary infection with HSV type 1 is usually clinically inapparent but may involve severe oral lesions, fever, and adenopathy. After the primary infection subsides, the latent virus persists within the sensory nerve ganglion. Gingivostomatitis and pharyngitis are the most common clinical manifestations of first-episode HSV-1 infection, whereas recurrent herpes labialis is the most common clinical manifestation of reactivation HSV-2. Herpetic whitlow—HSV infection of the finger—may occur as a complication of primary oral or genital herpes by inoculation of virus through a break in the epidermal surface or by direct introduction of virus into the hand, a particularly important point for medical personnel. HSV infection of the eye is

a common cause of corneal blindness in the United States. Of all HSV-infected populations, infants younger than 6 weeks have the highest frequency of visceral and/or CNS infection. Of note for obstetrical anesthesia practice, antibody to HSV-2 has been detected in 32% of pregnant women with no history of genital herpes. Asymptomatic HSV shedding was detected in 0.43% of women in late pregnancy and during delivery, and a first episode of clinical genital herpes was recognized by 16% of women during their pregnancy.<sup>98</sup> Medical personnel may be inoculated by direct contact with body fluids laden with either HSV type 1 or 2.

Varicella–zoster virus (VZV) causes two distinct clinical diseases: varicella (chickenpox) and zoster (shingles). Chickenpox, ubiquitous and highly contagious, is usually a benign illness of childhood with transmission by the respiratory route. Reactivation of latent VZV (herpes zoster), most common after the sixth decade of life, presents as a markedly painful dermatomal vesicular rash. Infection during pregnancy may result in fetal death or (rarely) congenital defects. Patients and medical personnel with active VZV infection can transmit the virus to others. Anesthesiologists working in pain clinics may be exposed to VZV when caring for patients who have discomfort from herpes zoster. Communicability begins 1 to 2 days before the onset of the rash and ends when all the lesions are crusted, usually 4 to 6 days after the rash appears.<sup>99</sup> Respiratory isolation should be used for patients with chickenpox or disseminated herpes zoster.<sup>90</sup> Use of gloves to avoid contact with vesicular fluid is adequate to prevent VZV spread from patients with localized herpes zoster.

Most adults in the United States have protective antibodies to VZV. Since there have been many reports of nosocomial transmission of VZV, it is recommended that all medical personnel have immunity to the virus. Anesthesia personnel with a negative or unknown history of infection should consider being serologically tested.<sup>99</sup> All medical personnel with negative titers should be restricted from caring for patients with active VZV infection and should be offered immunization with two doses of the live, attenuated varicella vaccine.

Susceptible personnel with a significant exposure to an individual with VZV infection are potentially infective from 10 to 21 days after exposure and should not contact patients during this period. The postexposure period during which a patient may receive varicella–zoster immune globulin (VariZIG) was recently increased from 4 to 10 days, although VariZIG should be administered as soon as possible after exposure.<sup>100</sup>

EBV, also a member of the family *Herpesviridae*, is the cause of heterophile-positive infectious mononucleosis, characterized by fever, sore throat, lymphadenopathy, and atypical lymphocytosis. About 15% of cases of Burkitt lymphoma in the United States and 90% of those in Africa are

associated with EBV.<sup>101</sup> Anaplastic nasopharyngeal carcinoma is common in southern China and is uniformly associated with EBV. EBV has also been associated with Hodgkin disease, especially the mixed-cellularity type.

EBV is spread by contact with oral secretions. The virus is frequently transmitted from asymptomatic adults to infants and among young adults by transfer of saliva during kissing. Transmission by less intimate contact is rare. EBV has been transmitted by blood transfusion and bone marrow transplantation. More than 90% of asymptomatic seropositive individuals shed the virus in oropharyngeal secretions.

Cytomegalovirus (CMV) infects between 50% and 85% of individuals in the United States before age 40, with most infections producing minimal symptoms.<sup>102</sup> After the primary infection, the virus remains dormant, and recurrent disease only occurs with compromise of the individual's immune system. CMV is not readily spread by casual contact but rather by repeated or prolonged intimate exposure. It is unlikely that aerosols or small droplets play a role in CMV transmission.

Primary or recurrent CMV infection during pregnancy results in fetal infection in up to 2.5% of occurrences.<sup>103</sup> Congenital CMV syndrome may be found in up to 10% of infected infants. Thus, although CMV infection usually does not result in morbidity in healthy adults, it may have significant sequelae in pregnant women, and therefore becomes an occupational health concern for medical personnel.

The two major populations with CMV infection in the hospital include affected infants and immunocompromised patients. Routine infection control procedures (standard precautions) are sufficient to prevent CMV infection in health-care personnel.<sup>104</sup> Pregnant personnel should be made aware of the risks associated with CMV infection during pregnancy and of appropriate infection control precautions to be used when caring for high-risk patients.

## **Rubella**

Although most adults in the United States are immune to rubella, up to 20% of women of childbearing age are still susceptible, allowing the potential for viral replication in the placenta and infection of fetal organs (congenital rubella syndrome [CRS]). The infection is persistent throughout fetal development and for up to 1 year after birth. Therefore, only individuals immune to rubella should have contact with infants who have CRS or who are congenitally infected with rubella virus but are not showing signs of CRS.<sup>105</sup>

Rubella is transmitted by contact with nasopharyngeal droplets spread by infected individuals through coughing or sneezing. Patients are most contagious while the rash is erupting but can transmit the virus from 1 week before to 5 to 7 days after the onset of the rash. Droplet precautions should

be used to prevent transmission ([Table 3-6](#)).<sup>90</sup>

History is a poor indicator of immunity. Therefore, ensuring immunity at the time of employment (evidence of prior vaccination with live rubella vaccine or serologic confirmation) should prevent nosocomial transmission of rubella to personnel. A live, attenuated rubella virus vaccine (measles, mumps, rubella [MMR]) is available to produce immunity in susceptible personnel.<sup>106</sup> Many state or local health departments mandate rubella immunity for all medical personnel, and local regulations should be consulted.

### *Measles (Rubeola)*

Measles virus is highly transmissible by large droplets and by the airborne route. The virus is found in the mucus of the nose and pharynx of the infected individual and is spread by coughing and sneezing. The disease can be transmitted from 4 days prior to the onset of the rash to 4 days after its onset. Airborne precautions should be used for infected patients ([Table 3-6](#)).<sup>90,104</sup> Secondary attack rates in susceptible household and institutional contacts generally exceed 90%.<sup>107</sup> In 2014, a record number of measles cases were reported in the United States, with 668 cases from 27 states reported to CDC's National Center for Immunization and Respiratory Diseases (NCIRD).<sup>108</sup> This is the greatest number of cases since measles elimination was prematurely reported in the United States in 2000. From January to August 2015, 188 people from 24 states and the District of Columbia were reported to have measles.<sup>108</sup> More than half of these cases were part of a large multistate outbreak linked to an amusement park in California.<sup>108</sup>

Medical settings are well-recognized sites of measles virus transmission. Highly infectious children may present to health-care facilities during the prodrome when the diagnosis is not yet obvious. Medical personnel are at increased risk for acquiring measles and transmitting the virus to susceptible coworkers and patients. The CDC recommends that medical personnel have adequate immunity to measles, as documented by one of the following: evidence of two doses of live measles vaccine, a record of physician-diagnosed measles, or serologic evidence of measles immunity ([Table 3-6](#)).<sup>106</sup> Susceptible personnel born in or after 1957 should receive two doses of the live measles vaccine at the time of employment.<sup>109</sup>

### *Viral Hepatitis*

Many viruses produce hepatitis. The most common are type A (infectious hepatitis), type B (HBV, serum hepatitis), and type C (HCV and non-A, non-B hepatitis [NANBH]), which is responsible for most cases of parenterally transmitted hepatitis in the United States. Delta hepatitis (HDV), caused by an

incomplete virus, occurs only in people infected with HBV. Hepatitis E virus (HEV), previously labeled epidemic or enterically transmitted NANBH, is an enterically transmitted virus that occurs primarily in India, Asia, Africa, and Central America. In these locations, HEV is the most common cause of acute hepatitis. All types of viral hepatitis produce clinically similar illnesses. These range from asymptomatic and inapparent to fulminant and fatal infections, as well as subclinical to chronic persistent liver disease with cirrhosis and hepatocellular carcinoma, common to the blood-borne types (HBV, HCV, and HDV). The greatest risks of occupational transmission to anesthesia personnel are associated with HBV and HCV (Table 3-7).

**Table 3-6** Prevention of Occupationally Acquired Infections

Infection/Condition	Precautions	Comments
Abscess		
Draining/major	Contact	
Draining/minor	Standard	
Acquired immune deficiency virus (HIV)	Standard	Postexposure prophylaxis (PEP) for some exposures
Avian influenza	Droplet	Enhanced precautions (i.e., airborne may be recommended)
Bronchiolitis	Contact	
<i>Clostridium</i>		
<i>botulinum</i>	Standard	Not transmitted person to person
<i>difficile</i>	Contact	
<i>perfringens</i>	Standard	Not transmitted person to person
Conjunctivitis		
Bacterial	Standard	
Viral	Contact	Most commonly: adenovirus, enterovirus, coxsackievirus A24
Creutzfeldt–Jakob disease	Standard	Single-use equipment preferred, special cleaning (NaOH, heat, and time requirements) for contaminated instruments and environment
Diphtheria, pharyngeal	Droplet	Until two cultures >24 h apart are negative
<i>Escherichia coli</i>	Standard	Contact precautions if patient incontinent
<i>Haemophilus influenzae</i>		
Seasonal	Droplet	Single-patient room or cohort, gown, and glove
Pandemic	Droplet	Enhanced precautions (airborne may be recommended)
Hepatitis, viral		
A	Standard	Contact precautions for incontinent patients
B	Standard	
C	Standard	
E	Standard	Contact precautions for incontinent patients

Herpes, zoster (varicella-zoster)			
Disseminated	Airborne, contact		Health-care workers (HCWs) without immunity should not care for patient if immune HCW available.
Localized	Standard		
Impetigo	Contact		
Legionnaires' disease	Standard		Not transmitted person to person
Lice			
Head	Contact		
Body	Standard		
Pubic	Standard		
Lyme disease	Standard		
Malaria	Standard		
Measles	Airborne		Susceptible HCW should not care for patient if immune HCW available. Maintain precautions for 4 days after onset of rash. Nonimmune exposed individuals may be infectious from days 5 to 21 after exposure. PEP available (vaccine, immune globulin).
Meningitis			
Bacterial	Standard		
Fungal	Standard		
<i>Neisseria</i>	Droplet		
<i>Streptococcus</i>	Standard		PEP available
Multidrug-resistant organisms (MDROs: MRSA, VRE, VISA/VRSA, ESBLs, resistant <i>Streptococcus pneumoniae</i> )	Standard/contact		
Mumps	Droplet		Susceptible HCWs should not care for patient if immune HCW available.
Mycoplasma	Droplet		
<i>Mycobacterium tuberculosis</i>	Airborne		
Parainfluenza	Contact		
Pertussis	Droplet		Single-patient room or cohort. PEP available. Tdap recommended
Poliomyelitis	Contact		
Rabies	Standard		
Respiratory syncytial virus	Contact		Standard mask should be worn.
Rhinovirus	Droplet		
Rubella	Droplet		Susceptible HCW should not care for patient if immune HCW available. Vaccine available. Nonimmune exposed individuals may be contagious from days 5–21 after exposure.
<i>Salmonella</i>	Standard		Contact precautions for incontinent patients
SARS-CoV	Airborne, droplet, contact		Maintain precautions until 10 days after resolution of fever.
Shigella	Standard		Contact precautions for incontinent patients
Smallpox	Airborne, contact		Maintain precautions until all scabs have crusted and separated (3–4 wks). Nonvaccinated HCW should not care for patient if immune HCW available
Staphylococcal			
Major, wound	Contact		
Streptococcal			
Major, wound	Contact, droplet		

MRSA, methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococci; VISA/VRSA, vancomycin-intermediate/resistant *Staphylococcus aureus*; ESBL, extended-spectrum beta-lactamase-producing organisms; SARS-CoV, severe acute respiratory syndrome-associated corona virus.

Adapted from CDC Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Healthcare Settings, 2007. For a complete list of organisms, see Appendix A. Type and duration of precautions recommended for selected infections and conditions: <http://www.cdc.gov/ncidod/dhqp/pdf/guidelines/Isolation2007.pdf>.

**Table 3-7 Risk of Occupational Infection with Blood-Borne Pathogens**

1. The greatest risk of transmission of blood-borne infections with HIV, HBV, and HCV is from a blood-contaminated percutaneous injury.		
2. The risk depends on the type of pathogen involved and increases when the source patient has higher viral titers (for HIV, HBV, HCV, respectively: acute or terminal HIV illness; hepatitis Be antigen–positive source; increased HCV RNA titers) and with increased quantity of inoculum volume transferred from the patient source.		
Average risk after an accidental parenteral exposure (needlestick or cut):		
Known HIV-infected patient	0.3% <sup>a</sup>	
	Clinical hepatitis risk	Seroconversion risk
Known hepatitis B surface antigen (HBsAg) positive/hepatitis Be antigen (HBeAg) negative	1–6%	23–37%
Known hepatitis B surface antigen (HBsAg) positive/hepatitis Be antigen (HBeAg) positive	22–31%	37–62%
Known hepatitis C positive		0.3–0.74% <sup>b</sup>

<sup>a</sup>Exceeds 0.3% for an exposure involving a greater infectious dose resulting from transfer of a larger blood volume, a higher HIV titer in the source patient's blood, or both. (Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HBV, HCV, and HIV and Recommendations for Postexposure Prophylaxis.)

<sup>b</sup>Jagger J, Puro V, De Carli G. Occupational transmission of hepatitis C virus. *JAMA*. 2002;288:1469.

Hepatitis A virus is the cause of about 20% to 40% of viral hepatitis in adults in the United States. Hepatitis A is usually a self-limited illness, and no chronic carrier state exists. Spread is predominantly by the fecal–oral route, either by person-to-person contact or by ingestion of contaminated food or water. Outbreaks are usually found in institutions or other closed groups where there has been a breakdown in normal sanitary conditions. Hospital personnel do not appear to be at increased risk for hepatitis A and nosocomial transmission is rare. Personnel exposed to patients with hepatitis A should receive immune globulin intramuscularly as soon as possible but not more than 2 weeks after the exposure to reduce the likelihood of infection.<sup>110</sup>

Hepatitis B is a significant occupational hazard for nonimmune anesthesiologists and other medical personnel who have frequent contact with blood and blood products. The prevalence of hepatitis B in the United States during 1999 to 2006 (anti-HBc = 4.7% and hepatitis B surface antigen [HBsAg] = 0.27%) was not statistically different from what it was during 1988 to 1994 (5.4% and 0.38%, respectively).<sup>111</sup> Following a decline since 1990 as a result primarily of effective vaccination, in 2013 the number of acute cases increased by 5.4% in the United States.<sup>111</sup> Although the increase may reflect the growing number of drug-related and health-care-related outbreaks associated with hepatitis B transmission, it is probably too early to interpret the causes.<sup>111</sup>

Acute HBV infection may be asymptomatic and usually resolves without significant hepatic damage. Less than 1% of acutely infected patients develop fulminant hepatitis.<sup>112</sup> Approximately 10% become chronic carriers of HBV (serologic evidence for >6 months). Within 2 years, half of the chronic carriers resolve their infection without significant hepatic impairment. Chronic active hepatitis, which may progress to cirrhosis and is linked to hepatocellular carcinoma, is found most commonly in individuals with chronic

viral infection for more than 2 years.

The diagnosis and staging of HBV infection are made on the basis of serologic testing. The first marker is detectable in serum within 1 to 12 weeks (HBsAg). HBsAg becomes undetectable 1 to 2 months after the onset of jaundice and rarely persists beyond 6 months. After HBsAg disappears, antibody to HBsAg (anti-HBs) becomes detectable in serum and remains detectable indefinitely. Antibody to the surface antigen (anti-HBs) appears with resolution of the acute infection and confers lasting immunity against subsequent HBV infections (Fig. 3-1). Chronic HBV carriers are likely to have HBsAg and antibody to the core antigen (anti-HBc) present in serum samples. The presence of hepatitis B e antigen (HBeAg) in serum is indicative of active viral replication in hepatocytes.

Anesthesia personnel are at risk for occupationally acquired HBV infection as a result of accidental percutaneous or mucosal contact with blood or body fluids from infected patients. Patient groups with a high prevalence of HBV include immigrants from endemic areas, users of illicit parenteral drugs, homosexual men, and patients on hemodialysis.<sup>112</sup> Carriers are frequently not identified during hospitalization because the clinical history and routine preoperative laboratory tests may be insufficient for diagnosis. The risk for infection after an HBV-contaminated percutaneous exposure, such as an accidental needlestick, is 37% to 62% if the source patient is HBeAg-positive and 23% to 37% if HBeAg-negative (Table 3-7).<sup>112</sup> HBV can be found in saliva, but the rate of transmission is significantly less after mucosal contact with infected oral secretions than after percutaneous exposures to blood. HBV is a hardy virus that may be infectious for at least 1 week in dried blood on environmental surfaces.

**5** Hepatitis B vaccine is the primary strategy to prevent occupational transmission of HBV to anesthesia personnel and other health personnel at increased risk. Administration of three doses of vaccine results in the production of protective antibodies (anti-HBs) in more than 90% of healthy personnel. Hospitals or anesthesia departments should have policies for educating, screening, and counseling personnel about their risk of acquiring HBV infection and should make vaccination available for susceptible personnel.<sup>113</sup> If adequate postvaccination immunity is not confirmed, a second three-dose vaccine series should be administered. Nonresponders to vaccination remain at risk for HBV infection and should be counseled on strategies to prevent infections and the need for postexposure prophylaxis (PEP). Vaccine-induced antibodies decline over time. The CDC states that for vaccinated adults with normal immune status, routine booster doses are not necessary and periodic monitoring of antibody concentration is not recommended.<sup>113</sup>

**Figure 3-1** Clinical course and serologic profiles of acute and chronic hepatitis B. ALT, alanine aminotransferase. (Modified from Liang T. Hepatitis B: the virus and disease. *Hepatology*. 2009;49[5]:S13–S21.)

HCV causes most cases of parenterally transmitted NANBH and is a leading cause of chronic liver disease in the United States. Although antibody to HCV (anti-HCV) can be detected in most patients with hepatitis C, its presence does not correlate with resolution of the acute infection or progression of hepatitis, and it does not confer immunity against HCV infection.<sup>114</sup> Seropositivity for HCV RNA is a marker of chronic infection and continued viral presence. After HCV seroconversion, only 15% to 25% will clear the virus spontaneously.<sup>115</sup> Of those that develop chronic hepatitis, 20% will develop cirrhosis over the following 20 to 30 years and 1% to 2% of those will be diagnosed with hepatocellular carcinoma.<sup>115</sup>

Like HBV, HCV is transmitted through blood, but the rate of occupational HCV infection is less than for HBV. Although HCV transmission has been

documented in health-care settings, the prevalence of anti-HCV in medical personnel in the United States is not greater than that found in the general population (1.6%).<sup>113</sup> The greatest risk of occupational HCV transmission is associated with exposure to blood from an HCV-positive source. HCV has been transmitted through blood splashes to the eye and with exposure via nonintact skin. HCV in dried blood on environmental surfaces may remain infectious for up to 16 hours, but environmental contamination does not appear to be a common route of transmission. HCV can be found in the saliva of infected individuals, but it is not believed to represent a great risk for occupational transmission.<sup>113</sup>

Prevention of exposure remains the primary strategy for protection against HCV infection. Personnel who have had a percutaneous or mucosal exposure to HCV-positive blood should have counseling and serologic testing in accordance with the guidelines in the section on Postexposure Treatment and Prophylactic Antiretroviral Therapy.<sup>116</sup>

### **Pathogenic Human Retroviruses**

The family *Retroviridae* includes seven subfamilies, two of which produce disease in humans—human T lymphotropic viruses (HTLV)-I and HTLV-II, which are transforming retroviruses, and HIV-1 and HIV-2, which cause cytopathic effects either directly or indirectly. Tissue destruction may result directly from the viral infection or indirectly from malignant transformation of infected cells and an immune-deficient state in response to the virus, leading to neoplastic and infectious disease. HTLV-I infection is transmitted in at least three ways: from mother to child (especially via breast milk), through sexual activity, and parenterally via contaminated transfusions or contaminated needles. At the end of 2014, an estimated 36.9 million individuals were living with HIV infection according to the Joint United Nations Programme on HIV/AIDS (UNAIDS).<sup>117</sup> The global prevalence has increased approximately fourfold since 1990, reflecting the combined effects of continued high rates of new HIV infections and the beneficial (life-prolonging) impact of antiretroviral therapy. In 2014, there were an estimated 2 million new cases of HIV infection worldwide, including 220,000 in children under 15 years.<sup>117</sup> Approximately 1.1 million individuals in the United States are living with HIV infection; almost 20% are unaware of their infection.

The initial infection with HIV begins as a mononucleosis-like syndrome with lymphadenopathy and rash. Although the patient then enters an asymptomatic period, monocyte–macrophage cells serve as a viral reservoir and CD4+ T cells harbor the virus in the blood. Within a few weeks, an antibody may be detected by an enzyme immunoassay or rapid HIV antibody

test, but a positive result must be confirmed using Western blot or immunofluorescent assay. After a variable length period of asymptomatic HIV infection, there is an increase in viral titer and impaired host immunity, resulting in opportunistic infections and malignancies characteristic of Acquired Immune Deficiency Syndrome (AIDS).

## **Risk of Occupational HIV Infection**

There is a small but definite occupational risk of HIV transmission to medical personnel, laboratory personnel, and others who work with HIV-containing materials. An estimated 600,000 to 800,000 medical personnel are stuck with needles or other sharp medical instruments in the United States each year. Exposures that place personnel at potential risk of HIV infection are percutaneous injuries (a needlestick or cut with a sharp object) or contact of mucous membrane or nonintact skin with blood, tissue, or other potentially infectious body fluids. The risk of HIV transmission following skin puncture from a contaminated needle or a sharp object is 0.3% and after a mucous membrane exposure it is 0.09% if the injured and/or exposed person is not treated within 24 hours with antiretroviral drugs.<sup>118</sup> HIV transmission after nonintact skin exposure has been documented, but the average risk for transmission by this route has not been precisely determined. Transmission of HIV through intact skin has not been documented.

In the United States between 1985 and 2013, 58 medical personnel, for whom case investigations were completed, had confirmed seroconversions to HIV following occupational exposures; an additional 150 possible cases of occupationally acquired HIV infection were reported to CDC.<sup>119</sup> Since 1999, only one case has been reported. The routes of exposure were 49 percutaneous (puncture/cut injury); 5 mucocutaneous (mucous membrane and/or skin); 2 both percutaneous and mucocutaneous; and 2 of unknown route. The individuals with documented seroconversions included 20 laboratory workers (16 in clinical laboratories), 24 nurses, 6 physicians (nonsurgical), 2 surgical technicians, 1 dialysis technician, 1 respiratory therapist, 1 health aide, 1 embalmer/morgue technician, and 2 housekeeper/maintenance workers.<sup>119</sup>

Anesthesia personnel are frequently exposed to blood and body fluids during invasive procedures such as insertion of vascular catheters, arterial punctures, and endotracheal intubation.<sup>120–122</sup> Although many exposures are mucocutaneous and can be prevented by the use of PPE, these barriers do not prevent percutaneous exposures. Because of the tasks they perform, anesthesia personnel are likely to use and be injured by large-bore, hollow needles such as intravenous catheter stylets and needles on syringes. Needleless or protected needle safety devices can be used to replace standard

devices to reduce the risk of needlestick injuries. Safety devices usually are more expensive than a comparable nonsafety item but may be more cost-effective when the financial cost of needlestick injury investigation and medical care for infected personnel is considered.

The occupational risk of HIV infection is a function of the annual number of blood exposures, the rate of HIV transmission with each exposure to infected blood, and the prevalence of HIV infection in the specific patient population. Greene et al.<sup>120</sup> prospectively collected data on 138 contaminated percutaneous injuries to anesthesia personnel. The rate of contaminated percutaneous injuries per year per full-time equivalent anesthesia worker was 0.42, and the average annual risk of HIV and HCV infection was estimated to be 0.0016% (0.16:10,000) and 0.015% (1.5:10,000), respectively.

Although HIV can be recovered in low titers from saliva in a small number of infected subjects, there is no convincing evidence that saliva can transmit HIV infection, either through kissing or through other exposures, such as those that occur occupationally. Saliva contains several antiviral factors including HIV-specific immunoglobulins (IgA, IgG, and IgM isotypes). Moreover, there is no evidence that HIV transmission can occur as a result of exposure to tears, sweat, or urine. However, there have been isolated cases of transmission of HIV infection by body fluids that may or may not have been contaminated with blood.

Since the beginning of the HIV epidemic, there have been rare instances where transmission of infection from a medical personnel to patients seemed highly probable. An HIV-infected dentist in Florida may have infected as many as six of his patients, putatively through contaminated instruments.<sup>123,124</sup> Nevertheless, the risk of HIV transmission from medical personnel to patient is extremely low.

## Postexposure Treatment and Prophylactic Antiretroviral Therapy

When personnel have been exposed to patients' blood or body fluids, the incident should immediately be reported to the employee health service or the designated individual within the institution. Based on the nature of the injury, the exposed worker and the source individual should be tested for serologic evidence of HIV, HBV, and HCV infection.<sup>118</sup> Current local laws must be consulted to determine policies for testing the source patient, and confidentiality must be maintained. U.S. Public Health Service recommendations include<sup>118</sup>:

1. PEP is recommended when occupational exposures to HIV occur.
2. The HIV status of the exposure source patient should be determined, if possible, to guide need for HIV PEP.
3. PEP medication regimens should be started as soon as possible after

occupational exposure to HIV, and they should be continued for a 4-week duration.

4. PEP medication regimens should contain three (or more) antiretroviral drugs for all occupational exposures to HIV.
5. Expert consultation is recommended for any occupational exposures to HIV.
6. Close follow-up for exposed personnel should be provided that includes counseling, baseline and follow-up HIV testing, and monitoring for drug toxicity; follow-up appointments should begin within 72 hours of an HIV exposure.
7. If a newer fourth-generation combination HIV p24 antigen–HIV antibody test is utilized for follow-up HIV testing of the exposed medical personnel, HIV testing may be concluded 4 months after exposure; if a newer testing platform is not available, follow-up HIV testing is typically concluded 6 months after an HIV exposure.

The World Health Organization (WHO), in a push for early treatment and prevention, has revised its guidelines toward earlier treatment (as soon as possible after diagnosis) in substantially at-risk rather than high-risk individuals (pre-exposure prophylaxis [PrEP]) following the successful clinical trial of emtricitabine/tenofovir (Truvada).<sup>125</sup>

Failure of PEP has been attributed to a large viral inoculum, use of a single antiviral agent, drug resistance in the virus from the source patient, and delayed initiation or short duration of PEP therapy. For consultation on the treatment of occupational exposures to HIV and other blood-borne pathogens, the clinician managing the exposed patient can call the National Clinicians' Post-Exposure Prophylaxis Hotline (PEpline) at 1-888-448-4911.

## Prion Diseases

Prions (from *protein + infection*) are composed of misfolded protein without nucleic acid. They are responsible for the transmissible spongiform encephalopathies: Bovine spongiform encephalopathy or “mad cow disease” in cattle and Creutzfeldt–Jakob disease (CJD) in humans. All are untreatable and fatal. When a prion enters a healthy organism, it provides a template to guide the misfolding of normal protein into the extremely stable prion form, highly resistant to denaturation by chemical and physical agents. This makes disinfection and sterilization of reusable medical instruments a unique challenge because effective prion decontamination relies upon protein hydrolysis or destruction of protein tertiary structure.

Prions cause neurodegenerative disease by aggregating extracellularly within the CNS to form amyloid plaques resulting in the histologically characteristic spongy architecture. CJD, caused by an infectious protein or

prion, may be unsuspected in patients presenting with dementia.<sup>126</sup> There are specific guidelines for the disinfection and sterilization of prion-contaminated medical instruments.<sup>127</sup>

## Tuberculosis

Tuberculosis (TB) is a major cause of death worldwide and, if properly treated, almost always curable. When untreated, TB can be fatal within 5 years in 50% to 65% of cases.<sup>128</sup> More than 5.8 million new cases of TB were reported to the WHO in 2009; 95% of cases were reported from developing countries. In 2014, 9,421 US cases of TB (0.3:10,000) were reported to the CDC,<sup>129</sup> 66% of which occurred among foreign-born persons.

*Mycobacterium tuberculosis* is most commonly transmitted from a person with infectious pulmonary TB to others by aerosolized droplet nuclei via coughing, sneezing, or speaking. As many as 3,000 infectious nuclei per cough can remain suspended in the air for several hours and can reach the terminal air passages when inhaled. The most infectious patients have cavitary pulmonary disease or, much less commonly, laryngeal TB and produce sputum containing as many as  $10^5$  to  $10^7$  acid-fast bacilli (AFB)/mL. Other routes of transmission are uncommon. Clinical illness directly following infection is classified as *primary TB* and is common among children in the first few years of life and among immune-compromised persons.

The best way to prevent TB is to diagnose and isolate infectious cases rapidly and to administer appropriate treatment until patients are noninfectious, usually 2 to 4 weeks after the start of proper treatment. In low-prevalence countries with adequate resources, screening of high-risk groups such as immigrants from high-prevalence countries, migratory workers, prisoners, homeless individuals, substance abusers, and HIV-seropositive persons is recommended.

Outbreaks of TB in health-care facilities have been attributed to delayed diagnosis of TB in the source patient, delayed initiation or inadequate deployment of airborne precautions, lapses in precautions during aerosol-generating procedures, and lack of adequate respiratory protection in health-care personnel.

Effective prevention of spread to medical personnel requires early identification of infected patients and immediate initiation of airborne infection isolation (Table 3-4). Patients must remain in isolation until adequate treatment is documented. Personnel should wear fit-tested respiratory protective devices when they enter an isolation room or when performing procedures that may induce coughing, such as endotracheal intubation or tracheal suctioning. The CDC recommends that respiratory protective devices worn to protect against TB should be able to filter 95% of

particles 0.3  $\mu\text{m}$  in size at flow rates of 50 L/min and should fit the face with a leak rate of less than 10% around the seal, documented by fit testing.<sup>130</sup> High-efficiency particulate air (HEPA) respirators (classified as N95) are NIOSH-approved devices that meet the CDC criteria for respiratory protective devices against TB.<sup>131</sup> It is reasonable to postpone elective surgery until infected patients have had an adequate course of chemotherapy. If surgery prior to the completion of treatment is required, bacterial filters (HEPA filters) should be used on the anesthetic breathing circuit for patients with TB. Patients must be recovered in a room that meets all the requirements for airborne precautions.

Routine periodic screening of employees for TB is frequently a part of a hospital's employee health policy with the frequency of screening dependent on the prevalence of infected patients in the hospitalized population. When a new conversion is detected by skin testing, a history of exposure should be sought to determine the source patient. Treatment or preventive therapy is based on the drug-susceptibility pattern of the TB in the source patient, if known.

### *Viruses in Smoke Plumes*

The use of lasers and electrosurgical devices is associated with several hazards to patients and to OR personnel. Physical hazards include thermal burns, eye injuries, electrical hazards, fires, and explosions. Plume content consists of water and organic vapors, carbonized cell fragments, formaldehyde, acrolein, benzene, polyaromatic hydrocarbons, and carbon monoxide. Although airborne cancer cells have not been detected in laser plumes, potentially harmful particles varying from 0.5 to 5.0  $\mu\text{m}$  have been detected (for comparison, a red blood cell = 7.5  $\mu\text{m}$ ). Intact and infectious viral DNA can be detected with laser treatment of verrucae. Viable viruses are carried on large particles that travel lower than 100 mm from the site being vaporized.<sup>131,132</sup>

Smoke-vacuuming systems as well as PPE are recommended when personnel are in proximity to surgical smoke.<sup>133,134</sup> The smoke-vacuuming systems should be held as close as 1 cm to within the target because at 2 cm there is a 50% loss of the evacuation ratio. HEPA or ultralow penetration air filters should be used, and charcoal filters should be used for odor and gas absorption. Venting should be to the outdoors, if possible, and venting systems should have the ability to detect filter overloading (i.e., pressure drop). These filtration guidelines do not address fluid aspiration, which must be carried out independently. In addition, OR personnel working in the vicinity of the laser plume should wear gloves, goggles, and high-efficiency filter masks (N95 respirators).<sup>133</sup>

# Emotional Considerations

## Stress

Anesthesia practice is mentally, emotionally, and physically stressful. The stress is continuous, and changes dynamically across life and career stages. Several aspects of practice are predictably stressful: a perioperative catastrophe, medical malpractice, and interpersonal conflict. How one responds to these challenges, whether in a constructive or maladaptive manner, will determine the effect on the individual.

Occupational stress is unavoidable and often motivating, but when it exceeds the capabilities of the worker, it can lead to poor mental and physical health, accidents, and burnout. Hans Selye described a three-component stress syndrome: the stressor, the psychological appraisal, and the coping mechanisms employed to address the challenge.<sup>135</sup> This is notably individualistic: one person's stress can be another's recreation. Stress has been linked to cardiovascular, musculoskeletal, and gastrointestinal disease; sleep and mood disturbances; and disruption of personal relationships. Stress is also costly, forecasting higher absenteeism, injuries, disability and decreased productivity.

In response to an awareness of the prevalence of depression, suicide, and substance use disorders among anesthesiologists, Jackson examined individual factors relating to the stress.<sup>136</sup> He defined stress as the “nonspecific adaptive response of the body to any change, demand, pressure, challenge, threat or trauma,” and described the impact of personality type, gender, life cycle, and stress abatement programs on the personal response to stress. The perioperative environment supplies constant low-level stress, unpredictably punctuated by episodes of extreme stress, which are largely not controllable by anesthesiologists. Lack of an appropriate response can carry dire consequences, and anesthesiologists cite the following as particularly stressful: unpredictability of work, fear of an adverse event with a bad patient outcome, fear of litigation, need for sustained vigilance, production pressures, economic uncertainty, and strained relationships. Both resident and attending physicians have demonstrated objective evidence of stress at certain critical stages during anesthetic management.<sup>137,138</sup> There is evidence that acute stress can inhibit learning and working memory in the prefrontal cortex, making the appropriate management of stress critical for anesthesiologists.<sup>139</sup>

Personality traits like obsessive–compulsive behavior and dependence have been associated with maladaptive stress responses such as pessimism, self-doubt, internalization, and depression. These characteristics have correlated with future substance use disorder, psychiatric illness, and relational discord in undergraduate students.<sup>140,141</sup>

## *Impact of Adverse Events*

An adverse event with a bad outcome is among the most significant stressors for an anesthesiologist. The description of a “second victim” being the involved medical provider and the “third victim” being subsequently cared-for patients, was proposed by Wu<sup>142</sup> in a 2000 editorial. This followed investigations in the United Kingdom of the impact of such events on surgeons and anesthesiologists after the 1998 sentinel loss of two elective orthopedic patients on the same day. Following an intraoperative death, 27% of surgeons and 26% of anesthesiologists felt they should cease working for the remainder of the day, and 53% of surgeons and 22% of anesthesiologists discontinued patient care for the remainder of the day.<sup>143</sup>

In a study of American Society of Anesthesiologists members, 84% had encountered a “perioperative catastrophe,” with 88% requiring time to recover, 19% never fully recovering, 12% considering changing careers, 67% feeling care in the subsequent 4 hours was compromised and only 7% being given any time off.<sup>144</sup> An intense emotional response is normal following a medical error and conversations with peers was cited as the most helpful coping mechanism.<sup>145</sup> This was echoed in a study finding that peer support and individual meetings with department leadership were the most efficacious support modalities for residents following an adverse event.<sup>146</sup> Medical peer support systems have had varying degrees of participation and success.<sup>146–148</sup>

## *Burnout*

Stress and burnout, although causally related, are distinct entities. Burnout is “exhaustion of physical or emotional strength or motivation usually as a result of prolonged stress or frustration,”<sup>149</sup> outlining its multidimensional nature and motivational outcome. The concept of burnout was originally studied in the 1970s<sup>150</sup> with quantitative investigation beginning in the 1980s with the Maslach Burnout Inventory (MBI),<sup>151</sup> which stratifies three major characteristics of burnout: emotional exhaustion, depersonalization/cynicism, and a low sense of personal accomplishment. Burnout typically arises in service industries where interpersonal dynamics and stressors are left unbalanced by job satisfaction and work–life balance. Freudenberger describes a cascade of events culminating in the “burnout syndrome.”<sup>150</sup> Ironically, the initial steps are essentially requisite for successful medical school matriculation, starting with a compulsion to prove oneself, to work harder, and to neglect personal needs, and ending with withdrawal, behavior change, depersonalization, and depression. According to Maslach, engagement is the psychological converse to burnout.<sup>152</sup>

The effects of burnout on physicians are significant. Shanafelt published

the first large study (7,288 respondents) of US physicians' burnout levels, finding that 45.8% of physicians expressed 1 or more major symptoms of burnout, a level much higher than the background rate of nonphysicians.<sup>153</sup> Amongst all physicians, anesthesiologists scored above the mean for burnout and near the mean for work–life balance. In subsequent reports, burnout has been shown in anesthesiologists (40% at risk for burnout),<sup>154</sup> academic anesthesiology chairs,<sup>155</sup> program directors,<sup>156</sup> nurse anesthetists,<sup>157</sup> and anesthesiologists globally.<sup>158–160</sup>

The health consequences of burnout (cardiovascular, musculoskeletal, and psychological maladies, substance use disorder and altered cortisol expression) have been well documented.<sup>161–163</sup> A correlation has also been shown between burnout and medical malpractice,<sup>164</sup> perceived medical errors and patient care in internal medicine residents,<sup>165,166</sup> empathy, suicidal ideation and professional conduct in medical students,<sup>167,168</sup> and career satisfaction and medical errors among surgeons.<sup>169,170</sup> Dyrbye<sup>171</sup> asserted that burnout is a threat to health-care reform and Wallace<sup>172</sup> proposes physician wellness as a quality indicator. A Canadian model revealed a greater than \$200-million-dollar burnout impact, mostly in the form of reduced work hours and early retirement.<sup>173</sup> A population-based cohort study in Finland linked burnout to sickness absences and initiation of disability payments.<sup>174,175</sup>

Myriad solutions have been proposed to address the crisis of burnout in health care; the solution will likely involve an individualized “bundle” of interventions.

### ***Substance Use, Abuse, and Addiction***

Although drug proclivities have changed over time, society continues to struggle with the issue of substance use disorders. *Abuse* implies the use of a substance despite negative consequences and *addiction* is characterized by continued abuse despite attempts to curtail use, the need for increasing doses, physical dependence (withdrawal occurring in the absence of the substance), and increasing energy expended seeking the substance. Currently the skyrocketing use, misuse, and addiction to prescription opiate pain relievers (OPRs) has led to a quadrupling of deaths from OPR overdose between 1999 and 2011.<sup>176</sup> It is estimated that 10% to 12% of physicians will, at some point in their careers, develop a form of substance use disorder.<sup>177</sup> Although this prevalence is similar to the general US population, the drugs chosen are more often prescription and controlled medications,<sup>178</sup> with some studies suggesting higher rates than the general population.<sup>179–181</sup>

The medical community has held a longstanding concern for substance use disorder in physicians, and particularly among anesthesiologists.<sup>182,183</sup> Intriguingly, this issue does not spare the luminaries of medicine, with

Sigmund Freud, Freeman Allen, and William Halsted being examples of high profile, yet addicted, physicians.<sup>182,184</sup> Data has even suggested that academic excellence (e.g., high test scores and Alpha Omega Alpha membership) is an independent predictor of admission for substance use disorder treatment.<sup>185,186</sup> Improved data collection began in the 1980s and the Medical Association of Georgia's Impaired Physician Program found that in their first 1,000 participants, anesthesiologists were disproportionately represented (12.1% of participants, but only 3.9% of US physicians; 33.7% of resident participants, but 4.6% of US residents). Further, anesthesiologists were much more likely to abuse narcotics, abuse multiple substances, and utilize the intravenous route than other physicians, who are more likely to abuse ethanol.<sup>181</sup> Recently, propofol has emerged as a drug of abuse, highlighting the more treacherous nature of the substances abused by anesthesiologists.<sup>180,187-189</sup> Unlike alcohol abuse, intravenous narcotic and hypnotic abuse has a short initiation to discovery phase and a high mortality and involves drug diversion.

When queried in a 2002 report, academic anesthesiology program 6 chairs revealed a *known* incidence of drug abuse of 1% in faculty and 1.6% in residents.<sup>190</sup> More recent data substantiates this finding by following the outcomes of all physicians entering anesthesia residencies over a 40-year period. Substance use disorder occurred in 2.16 out of 1,000 resident-years, with the highest incidence occurring since 2003, despite educational, treatment, and drug accounting interventions. Of the 384 residents identified as having a substance use disorder (0.86% of the cohort), 28 died during their training period (all from drug-related causes). If one is to consider substance use disorder-related death an occupational hazard of anesthesia, the profession is more dangerous than being a firefighter.<sup>191,192</sup>

The disproportionate prevalence in anesthesiology residents is concerning and has been repeatedly shown.<sup>181,190,193</sup> In a retrospective study of 260 graduates of a single anesthesia program, 32% admitted to prior illicit drug use, 15.8% reported a history of problematic substance abuse, and 20% reported observing compromised teaching due to substance use by faculty.<sup>194</sup>

It is unclear why anesthesiologists appear particularly prone to substance use disorders, though a vulnerable host exposed to a "favorable" environment may account for a majority of the risk. Documented factors include a history of recreational drug use or other high-risk behaviors that are proven to make one susceptible to chemical dependency. Theorized factors include a stressful work environment, lack of external recognition, and low self-esteem, but there is no predictive tool that can identify all of those at risk for substance use disorders.<sup>195</sup> Additional explanations for the prevalence of substance use disorder among anesthesiologists include the availability of controlled substances as a motivator for pursuing an anesthetic career,<sup>193,196</sup> the ease of

access and longstanding exposure to anesthetic agents,<sup>197</sup> and the actual personal administration of potent psychoactive medications. Drugs of choice among anesthesiologists have changed with availability. Initial reports indicated the popularity of meperidine, diazepam, and barbituates,<sup>178</sup> then synthetic opiates and inhalational agents,<sup>190</sup> and more recently propofol.<sup>189</sup>

Early recognition of addiction is critical to implementing life-saving interventions. It is important that anesthesiologists be able to recognize, not only in themselves but also in their colleagues, the constellation of physiologic, behavioral, and relational characteristics exhibited in substance use disorders (Table 3-8). Professional and personal withdrawal, while maintaining a façade of normality at work so as to preserve the access to drugs, is typical. By the time impairment is evident to most colleagues, the disease is in its end stages and often fatal.

**Table 3-8** Signs of Substance Abuse and Dependence

<p>Within the practice of anesthesia</p> <ul style="list-style-type: none"> <li>• Signing out increasing quantities of narcotics/hypnotics (often inappropriately high for the case)</li> <li>• Volunteering for cases requiring high-dose narcotics</li> <li>• Arriving early, staying late, taking extra call, and offering extra breaks to gain access to drugs (or calling in sick in the case of alcoholics)</li> <li>• Refusing lunch or breaks, personally administering medications in the recovery room, and preferring to work alone to mask drug diversion behavior</li> <li>• Asking for additional bathroom breaks, or staying in bathroom for long periods to use drugs</li> <li>• Being difficult to locate after breaks, as naps often follow drug use</li> <li>• Wearing long sleeves to hide needle marks</li> <li>• Illegible or sloppy charting</li> <li>• Frequent changes in job to maintain the secret</li> </ul> <p>Behavioral changes</p> <ul style="list-style-type: none"> <li>• Mood swings and emotionally labile</li> <li>• Social withdrawal (from people and previously enjoyed activities)</li> <li>• Increased impulsivity</li> <li>• Leaving drug paraphernalia (bloody swabs, needles, etc.) in common areas</li> <li>• Decreased sexual drive</li> <li>• Increased domestic strife</li> </ul> <p>Physical signs</p> <ul style="list-style-type: none"> <li>• Pinpoint pupils</li> <li>• Long sleeves worn due to cold sensitivity (associated with narcotics)</li> <li>• Alcohol odor on the breath or witnessing IV drug use</li> <li>• Weight loss and pallor</li> <li>• Narcotic withdrawal (sweating, tremors)</li> <li>• Coma and death—unfortunately a not uncommon presenting symptom</li> </ul>
----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Compared to internists, anesthesiologists have an increased relative rate (RR) of suicide from all causes (RR 1.45), drug-related suicide (RR 2), and

drug-related death (RR 2.79).<sup>198</sup> Notably, drug-related deaths were far more prevalent in the 5 years subsequent to medical school graduation and account for 2,000 life-years lost for anesthesiologists younger than 65 years old. Warner found 28 drug-related deaths in residents who had been re-enrolled in anesthesia residencies following chemical dependency treatment,<sup>191,192</sup> echoing a study reporting 9 deaths in 100 residents returning to anesthesia residency after treatment.<sup>193</sup> Those re-entering and surviving residency training showed a significantly higher risk of death, with a hazard ratio of 7.9.<sup>192</sup>

There exist many state-specific legal ramifications to physician chemical impairment, which may be mitigated if the involved physician voluntarily seeks treatment. Failing to report impaired colleagues may even carry disciplinary and criminal penalties in certain states. By federal law, the National Practitioner Data Bank must be notified of disciplinary action taken against an impaired physician. There is a reluctance to seek help rooted deeply in physician culture, reinforced by years of self-denial required to complete training and practice medicine. A well-developed defense mechanism enables many physician-addicts to minimize evolving impairment and delay treatment, with often devastating consequences.<sup>199</sup>

One strategy aimed at prevention and early detection of substance use disorders is compulsory pre-employment and random drug screening of anesthesiologists, a practice standard in other high-profile industries (aviation, military, nuclear).<sup>199</sup> Although random drug screening is an element of re-entry contracts, few anesthesia departments randomly screen anesthesiologists.<sup>200</sup> Despite lingering questions regarding the legality and effectiveness of this approach, many academic anesthesiology chairs are in favor of testing.<sup>194</sup>

Controversy persists over the appropriate disposition of an anesthesiologist who has successfully completed substance use disorder treatment. Although the prognosis for sustained recovery is higher for physicians than the general public,<sup>201</sup> relapse is often fatal in those returning to practice in anesthesia. Death rates as high as 9% for anesthesia residents returning to training after substance use disorder treatment<sup>193</sup> are sobering and fuel the argument of a risk too great to take.<sup>202</sup> Countering that argument is that a risk stratification approach may be used, taking into account the three greatest factors linked to relapse<sup>203</sup>: family history of substance abuse, a major opioid as the abused drug, and a coexisting psychiatric disorder.<sup>204</sup> Return to practice can be achieved with relapse rates similar to other medical specialties for anesthesiologists following a rigorous treatment regimen.<sup>205</sup>

Re-entry into practice for a recovering physician must be collaborative, involving the recovering physician, the treating addiction counselor, occupational health, department leadership, organizational credentialing

board, and others. Federal laws, such as the Americans with Disabilities Act, impose additional considerations. A carefully worded contract is essential and should include considerations for the following:

- Continued monitoring of sobriety (e.g., random drug screening, opiate antagonists)
- Continued treatment (addiction counseling, Alcoholics Anonymous [AA] or Narcotics Anonymous [NA])
- A period of supervised practice (e.g., not personally handling narcotics) or reduced call (e.g., no nights/weekends)

Despite precautions, relapse must be anticipated and the advice of a physician treatment center may be helpful. Those with the highest chance of successful re-entry into practice accept and understand their disease, have no concomitant psychiatric illness, have strong social support, are sponsored, are committed to their recovery, and have bonded with AA (<http://www.aa.org/>) or NA (<http://www.na.org/>). In addition, their department and hospital must support their return. Those with active disease, severe psychiatric comorbidities, prolonged intravenous substance use, or with prior relapses or treatment failures should be redirected to another specialty.<sup>206,207</sup>

Substance use disorder prevention requires strict control of substances of abuse. Meticulous controlled substance regulation and accounting is essential, especially with the advent of conveniences like satellite pharmacies and automated drug dispensing machines. Systems are being developed to detect patterns and episodes of drug diversion.<sup>208,209</sup>

There is limited data linking substance abuse disorder and poor patient care.<sup>210</sup> However, the impact of the disease on the affected individual physician is great. The burden of substance use disorder is particularly great in anesthesiology and does not appear to be abating. Efforts must be made on multiple fronts to decrease this tragic occupational hazard, including education, controlled substance accounting, and systems of discovery, treatment, and recovery.

## ***Impairment and Disability***

Impairment<sup>b</sup> and disability<sup>c</sup> can arise from physical, mental, emotional, sensory, or developmental causes. The onset can be sudden, as occurs with injury or acute illness, or more gradual, as is the case with many chronic diseases.

Data regarding the number of impaired physicians<sup>d</sup> are difficult to obtain. Many cases of physician impairment are the result of substance-related disorders (see earlier). Other factors that can result in physician impairment include physical or mental illness. Unwillingness or inability to keep up with current literature and techniques can be considered a form of impairment.

Depression is a prominent finding among impaired physicians. Unfortunately, many of the personality traits that ensure success as a physician, such as self-sacrifice, competitiveness, achievement orientation, denial of feelings, and intellectualization of emotions, may also serve as risk factors for depression. Observations of alcoholic physicians have provided some insight into the association of achievement orientation and emotional disturbance. In one study, more than half of the alcoholic physicians graduated in the upper one-third of their medical school class, 23% were in the upper one-tenth of their class, and only 5% were in the lower one-third of their class.<sup>211</sup> Similarly, a report on alcohol use in medical school demonstrated better first-year grades and higher scores on Part I National Board of Medical Examiners tests among those students identified as alcohol abusers.<sup>186</sup>

It can be very challenging to appropriately respond to all of the problems imposed by the impaired or unsafe anesthesiologist.<sup>212</sup> Management protocols for dealing with the impaired physician are covered in a series of articles by Canavan and Baxter.<sup>213</sup>

### *The Aging Anesthesiologist*

The natural and inevitable changes that accompany the aging process can impact the practice of anesthesiology.<sup>214</sup> Most notable are commonly observed anatomical and functional changes that appear in the CNS, such as decreases in short-term memory, creative thinking, and problem-solving abilities. Intellectual quickness, on-the-spot reasoning, learning, and reaction time all slow. These are frequently accompanied by other physiologic changes including impairments in hearing and vision that can exacerbate any cognitive impairment. The older anesthesiologist who is experiencing these neurologic changes is potentially more prone to difficulties in assimilation and application of new knowledge, rapid processing of information, complex decision making, and proper response initiation.<sup>215</sup> These potential deficiencies are especially exposed in the stressful environment of an OR.

There are also important changes in the cardiovascular and musculoskeletal systems that commonly occur and can affect the practice of an aging anesthesiologist. Older anesthesiologists may lack the strength to perform some of the more physically demanding aspects of practice, such as prolonged work shifts and night call, and may be more susceptible to late night errors. Failing eyesight, arthritic joints, and tremor may impair the anesthesiologist's ability to perform precision procedures such as vascular access or neural blockade.

These and other common physiologic changes associated with normal aging that might handicap an anesthesiologist are often accompanied by other

changes that can provide an advantage. These include wisdom, judgment, and experience. There is a strong positive correlation between these attributes and certain elements of clinical performance.<sup>215</sup> It is less clear that this advantage extends to some of the more complex cognitive skills required to administer a safe anesthetic. As pointed out by Weinger,<sup>216</sup> experience is not synonymous with expertise.

Aging among all physicians, but particularly anesthesiologists, raises complex legal and ethical issues. Neither state licensure nor hospital privileges are specifically limited by the chronologic age of the practitioner. In many cases, the decision to limit or retire from practice remains at the discretion of the individual physician. A number of federal laws impact the aging physician's rights and responsibilities regarding continuation of work. These include the Age Discrimination Act, Title VII of the Civil Rights Act, the Medical and Family Leave Act, the Fair Labor Standards Act, and the Employee Retirement Income Security Act.

Age is an important factor in decisions about retirement. The median age of retirement for anesthesiologists as of 2012 was approximately 64 years.<sup>217</sup> Commonly cited reasons for retirement among older anesthesiologists include on-call responsibilities, financial considerations, lack of professional satisfaction, health concerns, and changes in governmental policies and the health-care operating environment. The decision to retire from anesthesiology is frequently precipitated by concerns about deteriorating clinical skills. In many cases, the retiring anesthesiologist just "felt it was time."<sup>218</sup> Older anesthesiologists who postpone retirement cite career satisfaction, unmet financial obligations, and the need to maintain health insurance for family members as the primary reason to remain in the workforce.

### *Mortality among Anesthesiologists*

There have been a number of conflicting reports regarding how and at what age anesthesiologists most commonly die. Almost all of the studies report an increased rate of suicide.<sup>198,219</sup> Some earlier studies also reported an increased incidence of cancer, specifically leukemia and lymphoma, attributed at the time to chronic exposure to WAG, radiation, and stress.<sup>18,19,220</sup> Subsequent reports have failed to confirm an increased risk for cancer related mortality but continue to cite a disproportionate number of drug-related deaths and suicide.<sup>198,221,222</sup>

There are also contradictory reports about the average longevity of anesthesiologists. Using different databases, control populations, and methodologies, these studies have variously reported a shortened,<sup>198,223</sup> an average,<sup>224,225</sup> or a prolonged life expectancy.<sup>219,222</sup> A 2006 study reported a significant increase in longevity among anesthesiologists who had died

throughout the 10-year study period 1992 to 2001, such that the average age at death in the last year of the study was 78 years, the same as the national average for all Americans.<sup>226</sup>

## Suicide

There is a disproportionately high incidence of suicide among **7** physicians.<sup>227,228</sup> Anesthesiologists have been singled out as being particularly vulnerable.<sup>198</sup> A partial explanation for this alarming observation lies with the high degree of stress that is an integral part of the job. There are a number of personality characteristics that may make an individual more susceptible to suicidal thoughts under extreme stress. These characteristics include high anxiety, insecurity, low self-esteem, impulsiveness, and poor self-control. In one study that examined personality traits among anesthesiologists, 20% manifested psychological profiles that reflected a predisposition to behavioral disintegration and attempted suicide when placed under extremes of stress.<sup>229</sup> This study raises the discomfiting notion that “premorbid” personality characteristics exist before entering specialty training that could be identified during the admission process.

One specific type of stress for anesthesiologists, that resulting from a catastrophic adverse anesthetic outcome, and/or a malpractice lawsuit, may have a direct causative association with suicide.<sup>144,230</sup> Substance abuse among anesthesia personnel is another potential contributor to the increased suicide rate. Individuals with chemical dependence, who are not identified and are in the end stages of the disease, may die of drug overdose, a cause of death that can be difficult to distinguish from suicide. Drug abuse is among the highest causes of death and the most frequent method of suicide among anesthesiologists.<sup>198</sup> Drug overdose and death was the initial relapse symptom in 16% (13 of 79) of the parenteral opioid abusers who had reentered their residency in anesthesiology.<sup>231</sup> In a more recent survey that examined outcomes for residents who developed substance use disorder, 14.1% were dead within 12 years of onset of the disease.<sup>192</sup> Physicians who are impaired from substance abuse and whose privileges to practice medicine have been revoked are also at heightened risk for attempting suicide.<sup>232</sup>

## Wellness

Sir William Osler said that “in no relationship is the physician more often **8** derelict than in his duty to himself.”<sup>233</sup> An emphasis on wellness has emerged as a codified component of anesthesia training internationally,<sup>234</sup> and in the United States with the adoption of the ACGME Milestones Project,<sup>235</sup> mandating that a trainee should demonstrate a “responsibility to

maintain personal emotional, physical, and mental health.” Despite the emphasis, little concrete guidance is offered regarding education and implementation, and varying wellness challenges encountered at different life-cycle stages further obfuscates the subject. External stressors, such as disease, disability, divorce, death, malpractice, and financial distress, may provoke maladaptive coping mechanisms with profound short- and long-term consequences.<sup>136</sup>

Half of the deaths in the United States are estimated to be premature and potentially “deferrable” with the modification of 10 behaviors: tobacco use, dietary pattern, physical activity level, alcohol consumption, exposure to microbial agents, exposure to toxic agents, use of firearms, sexual behavior, motor vehicle crashes, and illicit use of drugs.<sup>236,237</sup>

### ***Nutrition, Diet, and Fitness***

By the year 2025, it is predicted that the obesity pandemic will comprise 380 million cases.<sup>238</sup> More than a quarter (27.7%) of US workers fulfill BMI criteria for obesity, with working greater than 40 hours per week and in the health-care setting being independent risk factors for obesity.<sup>239</sup> Clearly anesthesiologists are not exempt from this health crisis.

At a cellular level, the beneficial effects of physical activity are evident. Nitric oxide (NO), one of the body’s major bulwarks to oxidative stress, is increased in both sedentary and active men participating in both acute and chronic exercise. Those who exercise consistently have higher basal levels of NO.<sup>240</sup> In a rat model, physical activity led to modulation in hippocampal regenerative sprouting, implying improved learning capacity.<sup>241</sup>

A large (n = 17,549), longitudinal study of men entering Harvard College between 1916 and 1950 demonstrated a significant survival benefit to higher levels of physical activity with a 32% reduction in death rate between the lower and upper thirds.<sup>242</sup> A study of residents and fellows demonstrated 31% of participants adhered to U.S. Department of Health and Human Services levels of physical activity with 23% of invited trainees enrolling in an exercise program.<sup>243</sup> Those who participated in the exercise program had a higher objective quality of life and trended toward decreased burnout. A longitudinal study of Swedish health-care workers utilizing objective measures of physical activity, burnout, depression, and anxiety showed that physical activity, particularly increases in physical activity, were associated with improved mental health.<sup>244</sup>

If the thought of becoming an elite athlete is daunting, there exists encouraging data that longer periods of moderate physical activity (e.g., walking) carry a similar overall survival benefit to shorter extremes of activity (e.g., running), with fewer injuries (Fig. 3-2).<sup>245</sup>

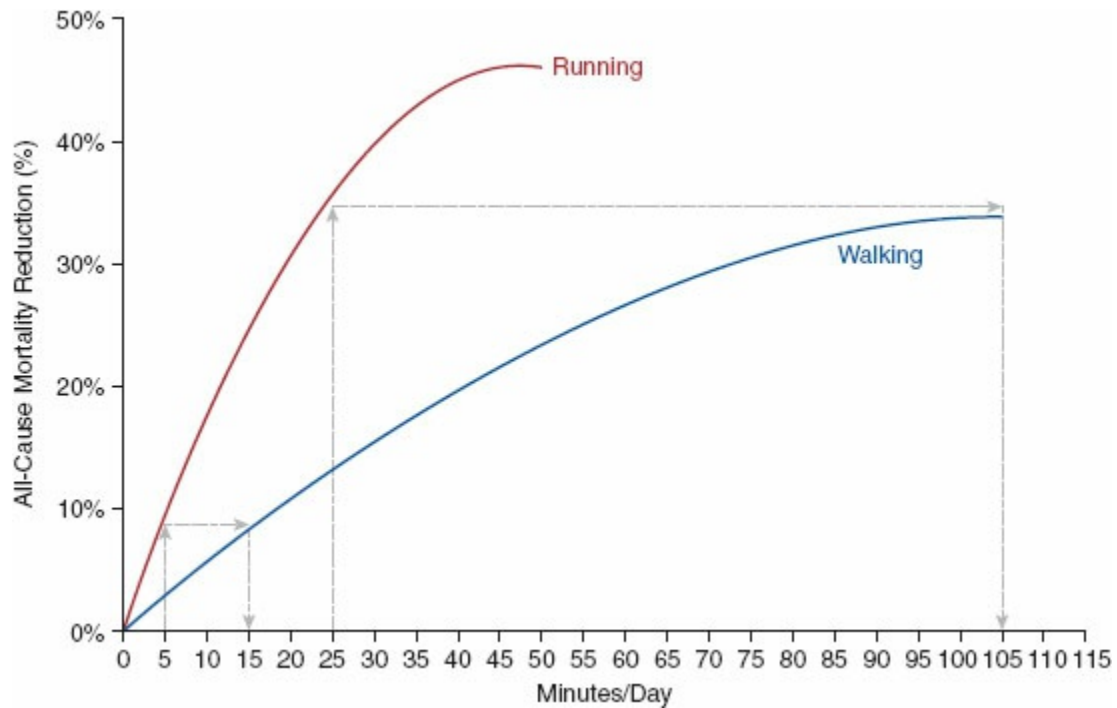

## Implementing Lifestyle Interventions for Lifestyle-related Diseases

Given the number of premature preventable deaths due to tobacco use, sedentary lifestyle, and poor diet, lifestyle changes should focus on these factors.<sup>236,237</sup> A Cochrane review demonstrated that a multifaceted approach to weight loss involving counseling coupled with behavioral, dietary, and exercise components, yielded 3 to 4 kg of sustainable weight loss.<sup>246</sup> A meta-analysis of 33 trials revealed that dieting and exercise yielded greater weight loss than dieting alone and a greater likelihood of sustained weight loss.<sup>247</sup> Strategies to decrease and/or modify caloric intake (e.g., low-glycemic index foods, Mediterranean diet, reduced portions) can improve cardiovascular risk factors, prevent type 2 diabetes, improve hypertension, and lead to sustained weight loss.<sup>248</sup>

Smoking cessation is a difficult endeavor. A review and meta-analysis of 26 studies, showed that those who successfully quit smoking had improved mental health (less anxiety, depression, and stress), a more positive mood, and an overall improved quality of life.<sup>249</sup> There is currently controversy over the practice of not hiring smokers. Some argue discrimination, whereas others praise this as potentially lifesaving.<sup>250,251</sup> Regardless of the motivation, the practice of cessation is difficult, but can be successful by employing integrated pharmacologic and nonpharmacologic approaches.<sup>252</sup>

### Mindfulness

Mindfulness, with its roots in Buddhist meditation practice, is an intentional, nonjudgmental practice of attention meant to cultivate awareness of the present moment.<sup>253</sup> The introduction of mindfulness-based stress reduction (MBSR) techniques to improve quality of life, decrease burnout, and supplement integrative approaches to medical therapy began appearing in the medical literature in the 1980s due largely to the work of Jon Kabat-Zinn.<sup>254–256</sup> Meditation techniques have been shown to change transcription profiles and the biochemical milieu (particularly in buffering oxidative stress and repairing cellular damage),<sup>257–259</sup> as well as affecting cortical structure and function (particularly relating to learning, memory, emotional stability, and positivity).<sup>260–262</sup> The use of MBSR with health-care providers has shown promise in decreasing burnout and improving physical and mental health.<sup>263</sup> A program designed to improve mindful communication in medical students led to decreased burnout, increased empathy, and overall enhancement of patient-centered care.<sup>264</sup>

**Figure 3-2** Demonstration of a similar reduction in all-cause mortality from longer periods of moderate physical activity when compared to shorter periods of vigorous activity. (Modified from Wen CP, Wai JPM, Tsai MK, et al. Minimal amount of exercise to prolong life: to walk, to run, or just mix it up? *J Am Coll Cardiol.* 2014;64[5]:482–484.)

Mindful practice requires mentoring and guidance through progressive phases from denial to generalizations, insight, new behaviors, compassion, and presence.<sup>254</sup> Many health-care organizations are rightfully pursuing the goal of becoming a “high reliability organization,”<sup>265</sup> which has been characterized as a consequence of “collective mindfulness.”<sup>266</sup> The argument has been made that, in the name of patient safety, mindful practice is our ethical responsibility as anesthesiologists.<sup>267</sup>

## Conclusion

The perioperative and critical care environments potentially expose anesthesiologists to physical hazards such as toxic chemicals, WAG, various forms of radiation and infectious agents. In addition, the sustained cognitive, emotional, and psychological demands can have significant bearing on performance and professional deportment. This chapter has reviewed some of the ongoing as well as emerging areas related to occupational illness and wellness of anesthesia personnel in these settings.

---

<sup>a</sup>Vigilance is the ability to detect changes in a stimulus during prolonged monitoring

tasks when the subject has no prior knowledge of whether or when any changes might occur.

<sup>b</sup>Impairment is any loss of use of any body part, organ system, or organ function.

<sup>c</sup>Disability is an impairment that substantially limits one or more major life activities.

<sup>d</sup>An impaired physician is one whose performance as a professional person and as a practitioner of the healing arts is impaired because of alcoholism, drug abuse, mental illness, senility, or disabling disease.

# 4 Anesthetic Risk, Quality Improvement, and Liability

## KEY POINTS

- 1 Anesthetic mortality has decreased, but potentially preventable deaths and disabling complications still occur.
- 2 Risk management programs are broadly oriented toward reducing the liability exposure of the organization. Risk management programs complement quality improvement programs in minimizing liability exposure while maximizing quality of patient care.
- 3 Continuous quality improvement is a systems approach to identifying and improving quality of care. Quality improvement programs focus on improving the structure, process, and outcome of care.
- 4 Quality improvement programs are generally guided by the requirements of the Joint Commission that accredits health-care organizations and the reporting and performance requirements of the Centers for Medicare and Medicaid Services.
- 5 Medical malpractice refers to the legal concept of professional negligence. The patient-plaintiff must prove that the anesthesiologist

owed the patient a duty and failed to fulfill this duty, that the anesthesiologist's actions caused an injury, and that the injury resulted from a breach in the standard of anesthesia care.

- 6 The most common lawsuits against anesthesiologists (excluding dental injuries) are for death, brain damage, nerve damage, and airway injury. Chronic pain management is the source of an increasing number of malpractice claims against anesthesiologists.

In anesthesia, as in other areas of life, everything does not always go as planned. Undesirable outcomes can occur regardless of the quality of care provided. Continuous quality improvement (CQI) programs are intended to maximize the collective learning from past near misses and undesirable outcomes to prevent their future occurrence. An anesthesia risk management program can work in conjunction with a program for quality improvement to minimize the liability risk of practice. Payers such as the Centers for Medicare and Medicaid Services (CMS) are increasingly depending on accreditation through bodies such as the Joint Commission to ensure that mechanisms are in place to deliver quality and safe care to all patients. In addition, there has been a move toward linking reimbursement to performance measurement and reporting. The legal aspects of American medical practice are important to the anesthesia community as the public turns to the courts for economic redress when their expectations of medical treatment are not met.

This chapter discusses anesthetic mortality and morbidity, risk management, CQI, performance measurement, and medical liability. The chapter provides background for the practitioner concerning the role of risk management activity in minimizing and managing liability exposure. Also described are the medical legal system, the most frequent causes of lawsuits for anesthesiologists, and appropriate actions for physicians to take in the event of a malpractice suit.

## Anesthesia Risk

### *Mortality and Major Morbidity Related to Anesthesia*

Estimates of anesthesia-related morbidity and mortality are difficult to quantify. Not only are there difficulties obtaining data on complications, but also different methods yield different estimates of anesthesia risk. Studies differ in their definitions of complications, in length of follow-up, and especially in approaches to evaluation of the contribution of anesthesia care to patient outcomes. A comprehensive review of anesthesia complications is beyond the scope of this chapter. A sampling of studies of anesthesia mortality and morbidity will be presented to provide historical

perspective plus a limited overview of relatively recent findings.

Early studies estimated the anesthesia-related mortality rate as 1 per 1,560 anesthetics.<sup>1</sup> More recent studies use data from the 1990s, and later estimate the anesthesia-related death rate in the United States to be lower than 1 per 10,000 anesthetics.<sup>2-7</sup> Some examples of modern estimates of anesthesia-related death from throughout the world are provided in [Table 4-1.2-25](#) **1** Differences in estimates may be influenced by different reporting methods, definitions, anesthesia practices, and patient populations, as well as actual differences in underlying complication rates. A systematic review and meta-analysis of mortality attributable to general anesthesia (GA) from before the 1970s through 2011 suggested a decrease worldwide, especially in developed countries.<sup>8</sup> This lends support to the generally accepted belief that anesthesia safety has improved over the past 50+ years.

**Table 4-1** Estimates of Anesthesia-related Death

Reference	Country	Time	Data Sources/Methods	Rate of Death
Bainbridge et al. <sup>6</sup>	Global	1940s–2011 a. pre-1970s b. 1970s–1980s c. 1990s–2000s	Systematic review and meta-analysis of published studies in any language with a sample size over 3,000 of rates of anesthesia-related mortality of surgical patients who had undergone general anesthesia. ( <i>n</i> = 87 studies including 21.4 million general anesthetics for patients undergoing surgery)  Anesthetic mortality by national development status using the United Nations Human Development Index (HDI) over time to assess impact of country development on anesthetic mortality	Anesthetic solely attributable mortality: a. 3.57/10,000 b. 0.52/10,000 c. 0.34/10,000  Anesthetic contributory mortality: a. 6.5/10,000 b. 3.23/10,000 c. 1.43/10,000  Anesthetic solely attributable mortality: a. High HDI 3.57/10,000, Low HDI not reported b. High HDI 0.32/10,000, Low HDI 1.01/10,000 c. High HDI 0.25/10,000, Low HDI 1.41/10,000  Anesthetic contributory mortality: a. High HDI 6.84/10,000, Low HDI 3.26/10,000 b. High HDI 2.34/10,000, Low HDI 4.32/10,000 c. High HDI 0.85/10,000, Low HDI 4.67/10,000
Flick et al. <sup>2</sup>	USA	1988–2005	Perioperative cardiac arrest in pediatric patients at a tertiary referral hospital ( <i>n</i> = 92,881 anesthetics)	Anesthesia-attributed deaths—0.22/10,000 anesthetics
Biboulet et al. <sup>9</sup>	France	1989–1995	ASA 1–4 patients undergoing anesthesia ( <i>n</i> = 101,769 anesthetics); cardiac arrest within 12 h postanesthesia ( <i>n</i> = 24)	Anesthesia-related death—0.6/10,000 anesthetics

Newland et al. <sup>3</sup>	USA	1989–1999	Cardiac arrests within 24 h of surgery ( <i>n</i> = 72,959 anesthetics) in a teaching hospital	Death related to anesthesia-attributable perioperative cardiac arrest—0.55/10,000 anesthetics
Eagle and Davis <sup>10</sup>	Western Australia	1990–1995	Deaths within 48 h or deaths in which anesthesia was considered a contributing factor ( <i>n</i> = 500 deaths)	Anesthesia-related death—0.025/10,000 anesthetics
Lagasse <sup>4</sup>	USA	a. 1992–1994 b. 1995–1999	a. Suburban teaching hospital ( <i>n</i> = 115 deaths; <i>n</i> = 37,924 anesthetics) b. Urban teaching hospital ( <i>n</i> = 232 deaths; <i>n</i> = 146,548 anesthetics)	Anesthesia-related death: a. 0.79/10,000 anesthetics b. 0.75/10,000 anesthetics
Khan and Khan <sup>11</sup>	Pakistan	1992–2003 a. 1992–1998 b. 1999–2003	University hospital. Deaths within 24 h of anesthesia ( <i>n</i> = 111,289 anesthetics)	3.14/10,000 anesthetics; deaths totally attributable to anesthesia 0.35/10,000; anesthesia partially responsible for death 0.7/10,000 a. 0.68/10,000 anesthetics b. 0.18/10,000 anesthetics
Ahmed et al. <sup>12</sup>	Pakistan	1992–2006	Perioperative cardiac arrest in pediatric patients at a university hospital ( <i>n</i> = 20,216 anesthetics)	Deaths primarily anesthesia-related 0.49/10,000 anesthetics
Davis <sup>13</sup>	Australia	1994–1996	Deaths reported to the committee ( <i>n</i> = 8,500,000 anesthetics)	Anesthesia-related death—0.16/10,000 anesthetics
Murray et al. <sup>5</sup>	USA	1994–1997	Pediatric patients from 63 hospitals ( <i>n</i> = 1,089,200 anesthetics)	Anesthesia-related death—0.36/10,000 anesthetics
Kawashima et al. <sup>14</sup>	Japan	1994–1998	Questionnaires to training hospitals ( <i>n</i> = 2,363,038 anesthetics)	Death totally attributable to anesthesia—0.21/10,000 anesthetics
Arbous et al. <sup>15</sup>	Netherlands	1995–1997	All deaths within 24 h or patients who remained unintentionally comatose 24 h postanesthesia ( <i>n</i> = 811 in 869,483 anesthetics)—64 hospitals	Anesthesia-related death—1.4/10,000 anesthetics
Braz et al. <sup>16</sup>	Brazil	1996–2005	Tertiary general teaching hospital ( <i>n</i> = 53,718 anesthetics)	Anesthesia-related death—1.12/10,000 anesthetics Totally attributed—0.56/10,000 Partially attributed—0.56/10,000
Lienhart et al. <sup>17</sup>	France	1999	Nationwide survey of anesthesia-related deaths	Death totally related to anesthesia—0.069/10,000 Death partially related to anesthesia—0.47/10,000
Kawashima et al. <sup>18</sup>	Japan	1999	Questionnaires to training hospitals ( <i>n</i> = 793,840 anesthetics)	Death totally attributable to anesthesia—0.13/10,000 anesthetics
Irita et al. <sup>19</sup>	Japan	1999–2002	Deaths as a result of life-threatening events in the operating room ( <i>n</i> = 3,855,384 anesthetics) in training hospitals	Death totally attributable to anesthetic management—0.1/10,000 anesthetics
Li et al. <sup>6</sup>	USA	1999–2005	Deaths with anesthesia-related complication codes from death certificate data a. Population data from census records b. National hospital discharge survey data (inpatients)	Anesthesia-related deaths a. 1.1/million population/year b. 8.2/million hospital surgical discharges

Ellis et al. <sup>7</sup>	USA	1999–2009	Cardiac arrests within 24 h of surgery ( <i>n</i> = 217,365 anesthetics) in a single hospital	Death due to anesthesia-attributable cardiac arrest—0.2/10,000 anesthetics Death due to anesthesia-contributable cardiac arrest—0.7/10,000 anesthetics
Charuluxananan et al. <sup>20</sup>	Thailand	2003–2004	Perioperative deaths within 24 h of surgery—20 hospitals ( <i>n</i> = 163,403 anesthetics)	Death directly related to anesthesia—1.7/10,000 Death partially related to anesthesia—4.0/10,000
Gibbs <sup>21</sup>	Australia	2003–2005	Deaths reported to Anesthesia Mortality Committees ( <i>n</i> = 5,983,704 anesthetics)	Anesthesia-related deaths 0.19/10,000
Rukewe et al. <sup>22</sup>	Nigeria	2005–2010	Cardiac arrest during surgery ( <i>n</i> = 12,143) in a university hospital	Mortality related to anesthesia 11.5/10,000 anesthetics
Gonzalez et al. <sup>23</sup>	Brazil	2005–2010	Anesthesia related (totally or partially) pediatric cardiac arrest and mortality in a university hospital ( <i>n</i> = 10,469)	Anesthesia-related mortality 0.0/10,000
van der Griend et al. <sup>24</sup>	Australia	2003–2008	Anesthesia related deaths in children ≤18 years from a single pediatric hospital ( <i>n</i> = 101,885)	Anesthetic related death 0.98/10,000
De Bruin et al. <sup>25</sup>	Netherlands	2006–2012	Reported 30-day postoperative in-hospital mortality children <18 yrs from a single pediatric hospital- ( <i>n</i> = 45,182 anesthetics)	Partially anesthesia-related mortality within 24 h 0.7/10,000 Partially anesthesia-related mortality within 30 days 1.1/10,000

Other complications related to anesthesia that have received relatively recent attention include postoperative nerve injury, awareness during GA, eye injuries and visual deficits, dental injury, postoperative cognitive dysfunction in elderly patients, and long-term cognitive impacts in pediatric patients (Table 4-2).<sup>26–60</sup> The incidence of ulnar neuropathy has been estimated to be 47 per 10,000 patients.<sup>27</sup> Lower-extremity neuropathy following surgery in the lithotomy position was observed in 151 per 10,000 patients.<sup>28</sup> Permanent neurologic injury following neuraxial anesthesia was estimated at 0 to 4.2 per 10,000 spinal anesthetics and 0 to 7.6 per 10,000 epidural anesthetics.<sup>26,30,31</sup> Peripheral nerve injury following peripheral nerve blocks (PNBs) was estimated to occur at a rate of 1.7 to 4.2 per 10,000 anesthetics.<sup>29,30,33</sup> Postoperative neurologic symptoms related to ultrasound-guided PNBs were estimated to occur at a rate 18/10,000 and 9/10,000 for symptoms lasting shorter than 5 days and greater than 6 months, respectively.<sup>32</sup> Awareness during GA has been estimated to occur in 15 to 100 per 10,000 patients.<sup>34–41</sup> The incidence of *patient reported* awareness during GA was 0.51 to 14.9 per 10,000 in the National Audit Project in Great Britain and Ireland.<sup>41</sup>

**Table 4-2** Rates of Selected Anesthesia Complications

Complication	Reference	Country	Time	Specific Complication	Results
Nerve injury	Brull et al. <sup>26</sup>	Various	1987–1999	Radiculopathy or peripheral neuropathy after spinal anesthesia	3.78/10,000 spinal anesthetics
				Radiculopathy or peripheral neuropathy after epidural anesthesia	2.19/10,000 epidural anesthetics
				Permanent neurologic injury after spinal anesthesia	0–4.2/10,000 spinal anesthetics
				Permanent neurologic injury after epidural anesthetic	0–7.6/10,000 epidural anesthetics
	Warner et al. <sup>27</sup>	USA	1995	Transient neurologic deficit after interscalene block	2.84/10,000 anesthetics
				Ulnar neuropathy in adults following noncardiac surgery ( <i>n</i> = 1,502)	47/10,000
	Warner et al. <sup>28</sup>	USA	1997–1998	Lower extremity neuropathy in adult patients ≥18 under general anesthesia (GA) while in lithotomy position ( <i>n</i> = 991)	151/10,000
	Welch et al. <sup>29</sup>	USA	1997–2007	Peripheral nerve injury within 48 h of sedation or anesthesia ( <i>n</i> = 380,680)	2.9/10,000
	Auroy et al. <sup>30</sup>	France	1998–1999	Serious peripheral neuropathy related to regional anesthesia	Nonobstetric spinal blocks (SBs) ( <i>n</i> = 35,439): 3.4/10,000 Obstetric SBs ( <i>n</i> = 5,640): 3.5/10,000 Upper limb peripheral nerve blocks (PNBs) ( <i>n</i> = 23,784): 1.7/10,000 Lower limb PNBs ( <i>n</i> = 20,162): 4/10,000
	de Sèze et al. <sup>31</sup>	France	2000	Incapacitating neurologic complications lasting ≥3 months after central neuraxial blockade	Nonobstetric SBs ( <i>n</i> = 67,884): 0.15/10,000; Nonobstetric epidural blocks (EBs) ( <i>n</i> = 65,464): 0.015/10,000 Obstetric EBs ( <i>n</i> = 116,639): 0.09/10,000
Sites et al. <sup>32</sup>	USA	2003–2011	Postoperative sensory or motor dysfunction after ultrasound guided PNB with anatomic basis to support possible block contribution ( <i>n</i> = 12,668)	Symptoms lasting >5 days 18/10,000 Symptoms lasting >6 months 9/10,000	
Barrington et al. <sup>33</sup>	USA	2006–2008	Late neurologic complications after PNB or plexus block ( <i>n</i> = 7,156 blocks)	4.2/10,000 PNBs	
Awareness	Errando et al. <sup>34</sup>	Spain	1995–1997 and 1998–2001	Awareness during GA ( <i>n</i> = 3,921)	99.5/10,000
	Sandin et al. <sup>35</sup>	Sweden	1997–1998	Awareness associated with GA ( <i>n</i> = 11,785)	15.3/10,000 procedures

Vallejo et al. <sup>59</sup>	USA	2001–2008	Dental injuries in patients receiving anesthesia care at multiple locations of a large university hospital system (n = 816,690)	Overall incidence 4.4/10,000 GA 5.7/10,000 Monitored anesthesia care 0.8/10,000
Mourao et al. <sup>60</sup>	Portugal	2011	Prospective study of dental damage diagnosed by a dentist after classic direct laryngoscopy at a university hospital (n = 536)	2,500/10,000

Eye injuries are a risk of anesthesia, including corneal abrasions as well as more rare complications such as blindness from ischemic optic neuropathy (ION) or central retinal artery occlusion.<sup>42–52</sup> Corneal abrasion has occurred at a rate of 1.4 to 15.1 per 10,000 procedures.<sup>42,44,50</sup> ION has been observed at 0.57 to 2.8 per 10,000 spine surgeries.<sup>42,45</sup> Risk factors for ION after spinal fusion have recently been identified and include a variety of patient, surgical, and anesthetic factors.<sup>61</sup> Among these include use of a Wilson surgical bed frame, obesity, and long anesthetic durations. All can contribute to increased venous congestion in the optic canal and potentially reduce optic nerve perfusion pressure. There was insufficient evidence to conclude that intraoperative anemia or transient periods of hypotension were causative factors. There is some evidence that the incidence of postoperative visual loss has been decreasing in the United States.<sup>47</sup>

Damage to teeth or dentures is the most common injury leading to anesthesia malpractice claims. Dental injury complaints are usually resolved by a hospital risk management department. Dental injuries after general endotracheal anesthesia were observed in approximately 1 per 2,000 to 3,000 patients in the United States.<sup>53,54</sup> A prospective study of dental damage diagnosed by a dentist after classic direct laryngoscopy in Portugal reported a high rate of 2,500/10,000.<sup>60</sup>

There has been increasing concern about the potential effect of anesthesia on cognitive function, especially among pediatric and elderly patients. It is difficult to sort out the potential contributions of surgery, anesthesia, and illness on neurocognitive function. Cognitive dysfunction, usually short term, has been observed in many adult patients after major surgery, and it has been hypothesized that the elderly may be at more significant risk for long-term cognitive problems.<sup>62</sup> While the role of anesthesia in postoperative cognitive dysfunction has not been definitively determined, recent evidence based on twin studies suggests that major surgery with anesthesia results in a negligible effect on cognitive function in middle-aged and elderly patients.<sup>63</sup> There is concern but limited data about the long-term cognitive impacts of pediatric anesthesia. One randomized controlled trial found no evidence for

increased risk of neurodevelopment deficits at 2 years of age after 1 hour of GA in healthy infants undergoing inguinal herniorrhaphy. Follow-up at 5 years of age is pending.<sup>64</sup> For up-to-date research findings and a consensus statement from a diverse group of experts on the use of anesthetic drugs in infants and toddlers, see the web site for SmartTots at [smarttots.org](http://smarttots.org). SmartTots is a public/private partnership between the U.S. Food and Drug Administration and the International Anesthesia Research Society.

## Risk Management

### Conceptual Introduction

Risk management and quality improvement programs work hand in hand to minimize liability exposure while maximizing quality of patient care. Although the functions of these programs vary from one institution to another, they overlap in their focus on patient safety. They can generally be distinguished by their basic difference in orientation. A hospital risk management program is broadly oriented toward reducing the liability exposure of the organization. This includes not only professional liability (and therefore patient safety) but also contracts, employee safety, public safety, and any other liability exposure of the institution. Quality improvement programs have as their main goal the continuous maintenance and improvement of the quality of patient care. These programs may be broader in their patient safety focus than strictly risk management. Quality improvement (sometimes called *patient safety*) departments are responsible for providing the resources to provide safe, patient-centered, timely, efficient, effective, and equitable patient care.<sup>65</sup>

### Risk Management in Anesthesia

Those aspects of risk management that are most directly relevant to the liability exposure of the anesthesiologist include prevention of patient injury, adherence to standards of care, documentation, and patient relations.

The key factors in the prevention of patient injury are vigilance, adequate monitoring, and up-to-date knowledge.<sup>66</sup> Physiologic monitoring of cardiopulmonary function, combined with monitoring of equipment function, might be expected to reduce anesthetic injury to a minimum. This was the rationale for the adoption by the American Society of Anesthesiologists (ASA) of *Standards for Basic Anesthetic Monitoring*.<sup>67</sup> Detailed information on anesthesia monitoring techniques can be found in [Chapter 26](#), Commonly Used Monitoring Techniques.

The ASA website is an accessible resource that can be reviewed periodically for any changes in the published *Guidelines and Statements*. It

should be noted that although membership in the ASA is not required for the practice of anesthesiology, expert witnesses will, with virtual certainty, hold any practitioner to the ASA standards. It is also possible that as a risk management strategy, a professional liability insurer or hospital may hold an individual anesthesiologist to standards higher than those promulgated by the ASA.

Another risk management tool is the use of checklists to prevent errors. Since the first checklists for pilots were developed for the military, checklists have been adopted by many industries wherein processes are too numerous and/or complex to rely on human memory. A checklist is a simple, yet powerful, tool that ensures no important detail is forgotten, and it removes variability, enhances consistency, and decreases likelihood of error. This patient safety tool helps to remind providers of key steps and thus works to facilitate safe and effective health-care delivery. Incorporation of checklists for routine anesthesia into regular anesthesia workflow processes has been advocated to improve patient safety.<sup>68</sup>

Historically, checklists have been used in anesthesia for anesthesia machine checkout procedures. Information pertaining to anesthesia workstation preuse procedures as well as safety considerations for workstations can be found in [Chapter 25](#), The Anesthesia Workstation and Delivery Systems for Inhaled Anesthetics. Recently, checklists for clinical care have been promoted to improve patient safety and medical management in various clinical settings, for example, central venous catheterization, intraoperative emergencies, and perioperative care. Catheter-related bloodstream infections were reduced significantly with the implementation of a standardized process that included a checklist for catheter placement and management.<sup>69</sup> The ASA developed an algorithm for central venous catheter access.<sup>70</sup> During simulated emergency scenarios, checklists have improved performance in the management of local anesthesia systemic toxicity<sup>71</sup> and improved management of intraoperative crises such as malignant hyperthermia, massive hemorrhage, air embolism, and cardiac arrest.<sup>72,73</sup>

Perioperative use of the surgical safety checklist in a variety of global hospital settings reduced surgical complications and mortality.<sup>74</sup> In a staged fashion (prior to induction, prior to skin incision, prior to wound closure, and prior to patient leaving the OR), this checklist confirms patient information and presence of personnel, addresses potential case-specific concerns, and incorporates significant processes ranging from a surgical time-out to a postprocedural briefing ([Table 4-3](#)). The surgical safety checklist has been widely incorporated into practice in the United States. Specific anesthesia preinduction checklists have also been developed and tested to improve information exchange and patient safety.<sup>75</sup>

**Table 4-3** World Health Organization Surgical Safety Checklist Elements

<b>Preinduction</b>
Patient confirms identity, site, procedure, and consent
Site marked
Anesthesia machine and medication check
Pulse oximeter on and functioning
Does the patient have:
Known allergy?
Risk for difficult airway or aspiration?
<b>Before Incision</b>
Team members introduce themselves by name and role
Confirm patient identity, procedure, and incision site
Antibiotics within last 60 min
Anticipated critical events:
Critical or nonroutine steps in procedure
Anticipated duration of surgery
Anticipated blood loss
Anesthesia concerns
Sterility confirmed
Equipment issues or concerns
Essential imaging displayed
<b>Before Patient Leaves Operating Room</b>
Confirm procedure
Complete instrument, sponge, and needle counts
Specimens labeled
Address equipment problems
What are the key concerns for recovery?

Adapted from the WHO Surgical Safety Checklist, [http://whqlibdoc.who.int/publications/2009/9789241598590\\_eng\\_Checklist.pdf](http://whqlibdoc.who.int/publications/2009/9789241598590_eng_Checklist.pdf).

Although it may seem obvious, qualified anesthesia personnel should be in continuous attendance during the conduct of all anesthetics. The only exceptions should be those that lay people (i.e., judge and jury) can understand, such as radiation hazards or an unexpected life-threatening emergency elsewhere. Even then, provisions should be made for monitoring the patient adequately. Adequate supervision of nurse anesthetists and residents is also important, as is good communication with surgeons when adverse anesthetic outcomes occur.

## **Informed Consent**

Informed consent regarding anesthesia should be documented with a general surgical consent, which should include a statement to the effect that “I understand that all anesthetics involve risks of complications, serious injury, or, rarely, death from both known and unknown causes.” In addition, there should be a note in the patient’s record that the risks of anesthesia and alternatives were discussed and that the patient accepted the proposed anesthetic plan. A brief documentation in the record that the common complications and material risk of the proposed technique were discussed is helpful. In some institutions and states, a separate written anesthesia consent form must be used, which may include more detail about risks. If it is

necessary to change the agreed-on anesthesia plan significantly after the patient is premedicated or anesthetized, the reasons for the change should be documented in the record.

Informed consent is problematic in that standard forms are often difficult for patients to understand, and patients often differ from physicians in their expectations and understanding of the risks and benefits associated with their treatments.<sup>76-78</sup> Patient complaints are commonly grounded in elements of informed consent, absorbing valuable health-care system resources even if they do not lead to a malpractice complaint.<sup>79</sup> Patient complaints can be leveraged to identify high-risk providers to target for interventions to improve communication skills.<sup>80,81</sup>

Shared decision-making is an enhanced form of informed consent applicable in elective situations when options for treatment are available to the patient. Shared decision-making is a strategy to empower the patient to actively make an evidence-based choice in his/her treatment.<sup>82</sup> In shared decision-making, evidence-based information is shared with the patient using educational materials (“decision-aids”), and patient preferences and values are elicited during the decision-making process. When all parties are satisfied that they understand the options and expectations, an informed decision can be made regarding treatment.<sup>83,84</sup>

There is an increasing body of evidence to suggest that sharing of information with patients, particularly when there may have been an adverse outcome, perhaps involving a medical error, can be beneficial. Effective disclosure can improve doctor–patient relations, facilitate better understanding of systems, and potentially decrease medical malpractice costs.<sup>85</sup>

## **Record Keeping**

Good records can form a strong defense if they are adequate; however, records can be disastrous if inadequate. The anesthesia record itself should be as accurate, complete, and neat as possible. In addition to documenting vital signs at least every 5 minutes, special attention should be paid to ensure that the patient’s ASA classification, monitors used, fluids administered, and doses and times of all administered drugs are accurately charted. Because the principal causes of hypoxic brain damage and death during anesthesia are related to ventilation and/or oxygenation, all respiratory variables that are monitored should be documented accurately. It is important to note when there is a change of anesthesia personnel during the conduct of a case. Sloppy, inaccurate anesthesia records, with gaps during critical events, can be extremely damaging to the defense when enlarged and placed before a jury.

The use of electronic health records (EHRs) has been mandated in health

care, and currently in the United States anesthesia information management systems (AIMS) have supplanted the traditional anesthesia paper record in the majority of the operating rooms. CMS has implemented bonuses for practitioners who can demonstrate “meaningful use” of an EHR which may be followed by financial penalties for those who do not meet the standard. Some areas of anesthesia practice have received an exemption from the requirement to meaningfully use an EHR in their practices but it is unclear whether this will continue. Basic AIMS are connected to the patient monitors and the anesthesia machine and capture perioperative data specific to anesthesia (e.g., vital signs, times of induction, intubation and emergence, medications and fluids). There is improved patient care and cost savings at institutions where EHR are fully incorporated.<sup>86</sup> When properly configured, AIMS can increase provider efficiency,<sup>87</sup> improve quality of care,<sup>88</sup> improve coding and billing accuracy,<sup>89,90</sup> decrease paperwork, and be a legible, chronologic documentation of clinical care. Use of AIMS has substantial potential as a clinical-decision support mechanism.<sup>91</sup> AIMS can process information from multiple devices and the EHR, incorporate algorithms to remind physicians to perform critical clinical processes on time,<sup>92,93</sup> and alert physicians to changes in patient status.<sup>94</sup>

Some physicians are wary of EHRs and the possible increased risk of exposure to litigation. Concerns have been raised about the profuse amounts of data and the risk of electronic discovery being used in litigation.<sup>95,96</sup> Although there is a growing body of data and opinion, no definitive conclusions can yet be made regarding the impact of EHRs and the risk of malpractice.<sup>97</sup> EHRs were associated with fewer paid malpractice claims in one study.<sup>98</sup> The digital data reviewed in court may be detrimental to the physician-defendant case when shortcuts are taken and anomalies in time-stamped entries cast doubt on the integrity of the record; for example, engaging in the practice of documenting events before they actually occur.<sup>99</sup> Outside the operating room, in the documentation of preoperative assessments, pain management, and critical care consultation notes, the EHR presents a medicolegal and billing compliance risk if the practitioner engages in the use of copying and pasting, cloning, or carrying forward information from other notes without very careful review of those notes for accuracy and relevance to the care encounter they purport to document.

## **What to Do after an Adverse Outcome**

If a critical incident occurs during the conduct of an anesthetic, the anesthesiologist should document, in narrative form, what happened, which drugs were used, the time sequence, and who was present. If there is no space or format appropriate to adequately summarize a complex catastrophic intra-

anesthetic event in the usual anesthesia record, it should be documented in the patient's progress notes. The critical incident note should be written as soon as possible. For events where the etiology is unclear, speculation in the record regarding causation should be limited only to the generation of a differential diagnosis that might contribute to the ongoing care of the patient. The report should be as consistent as possible with concurrent records, such as the anesthesia, operating room, recovery room, and cardiac arrest records. If significant inconsistencies exist, they should be explained. Records should never be altered after the fact. If an error is made in record keeping, a line should be drawn through the error, leaving it legible, and the correction should be initialed and timed. Litigation is a lengthy process, and a court appearance to explain the incident to a jury may be years away, when memories have faded.

Whenever an anesthetic complication becomes apparent, appropriate consultation should be obtained quickly, and the departmental or institutional risk management group should be notified. If the complication is apt to lead to prolonged hospitalization or permanent injury, the liability insurance carrier should be notified. The patient should be followed closely while in the hospital, with telephone follow-up, if indicated, after discharge. The anesthesiologist(s), surgeon(s), consulting physicians, and the institution should coordinate and be consistent in their explanations to the patient or the patient's family as to the cause of any complication.

If anesthetic complications occur, the anesthesiologist should be honest with both the patient and the family about the cause. The providers should provide the facts about the event, express regret to the patient and family about the outcome, and give a formal apology if the unanticipated outcome is the result of an error or system failure.<sup>85,100</sup> Some states have laws mandating disclosure of serious adverse events to patients, and disclosure has been incorporated into quality reporting. Some states prohibit use of disclosure discussions as evidence in malpractice litigation. Disclosure is considered the ethically right thing to do, and may reduce malpractice risk,<sup>101</sup> although malpractice risk reduction through disclosure is still subject to debate.<sup>102</sup> Some institutions, health systems, and insurers have adopted formal "communication and resolution" approaches to adverse events.<sup>103,104</sup> These approaches vary in their details but share the underlying premise that early disclosure and an offer of compensation may provide satisfactory resolution to the patient and avoid formal litigation proceedings.<sup>105</sup>

### **Special Circumstances: "Do Not Resuscitate" and Jehovah's Witnesses**

It is important to recognize that patients have well-established rights, and that among these is the right to refuse specific treatments. Two situations most

relevant to anesthesia care are “Do Not Resuscitate” (DNR) orders and the special circumstance of blood transfusion for Jehovah’s Witnesses.

Patients with severe medical conditions may elect to forgo resuscitation attempts in the event of cardiac arrest. Such DNR orders may be specified at hospital admission or may be in place in the form of an advance directive prior to admission. DNR orders or advance directives may be general or specific, such as refusal of tracheal intubation or mechanical ventilation. When a patient with DNR status presents for anesthesia care, it is important to discuss this with the patient or patient’s surrogate to clarify the patient’s intentions. In many hospitals, the institutional policy is to suspend the DNR order during the immediate perioperative period since the cause for a cardiac arrest may be easily identified and treated. In other institutions, the patient may choose to suspend the DNR order during the entire perioperative period. It should be clarified when the DNR order should be reinstated (e.g., discharge from recovery or possibly later, when the patient has recovered from the procedure) and documented in the patient’s chart. The perioperative status of DNR orders should also be clarified with the surgeon and other providers who will be involved in the patient’s perioperative care. The ASA has published *Ethical Guidelines of the Anesthesia Care of Patients with Do-Not-Resuscitate Orders or Other Directives That Limit Treatment*.<sup>106</sup>

In the case of Jehovah’s Witnesses, the treatment that may be refused is the administration of blood or blood products.<sup>107</sup> A central religious belief of many Jehovah’s Witnesses is that the faithful will be forbidden salvation if they receive blood or blood products. Thus, for them to receive a transfusion is a mortal sin, and many Jehovah’s Witnesses would rather die in grace than live with no possibility of salvation. Anesthesiologists must recognize and respect these beliefs, but also be cognizant that these convictions may conflict with their own personal, religious, or ethical codes.

As a general rule, physicians are not obligated to treat all patients who apply for treatment in elective situations. It is well within the rights of a physician to decline to care for any patient who wishes to place burdensome constraints on the physician or to unacceptably limit the physician’s ability to provide optimal care. When presented with the opportunity to provide elective care for a Jehovah’s Witness, the physician may decline to provide any care or may limit, by mutual consent with the patient, his or her obligation to adhere to the patient’s religious beliefs. If such an agreement is reached, it must be documented clearly in the medical record, and it is desirable to have the patient co-sign the note. Not all Jehovah’s Witnesses have identical beliefs regarding blood transfusions or which methods of blood preservation or sequestration will be allowed. Some patients will not allow any blood that has left the body to be reinfused, yet others will accept autotransfusion if their blood remains in constant contact with the body (via

tubing).<sup>107</sup> Therefore, it is important to reach a clear understanding of which techniques for blood preservation are to be used and to document this plan in the record. Parents of a minor child may not legally prevent that child from receiving blood. It may be necessary to obtain a court order in this circumstance.

### ***National Practitioner Data Bank***

It is usually the obligation of the hospital risk management department to make reports and inquiries to the National Practitioner Data Bank (NPDB),<sup>108</sup> a nationwide information system that theoretically allows licensing boards and hospitals a means of detecting adverse information about physicians.<sup>109</sup> Simply moving into another state does not provide safe haven for incompetent physicians.

The NPDB requires notification of various adverse actions including medical malpractice payments, license actions by medical boards or states, negative actions or findings by a peer review organization or private accreditation entity, adverse clinical privilege actions, and adverse professional membership society actions.<sup>110</sup> There has been a great deal of effort to establish a minimum malpractice payment below which no report is necessary, but to date, any payment made on behalf of a physician in response to a written complaint or claim must be reported. Settlements made by cancellation of bills or settlements made on verbal complaints are not considered reportable payments.

Once a report has been submitted, the physician is notified and may dispute the accuracy of the report. At this time, the reporting entity may correct the form or void it. Failing that, the physician has the option of putting a brief statement in the file or appealing to the US Secretary of Health and Human Services, who may also either correct or void the form. A practitioner may make a query about his or her file at any time. A physician may also add a statement to a report at any time. Such statements will be included in any reports that are sent in response to inquiries. The existence of the NPDB reporting requirements has made physicians reluctant to allow settlement of nuisance suits because it will cause their names to be added to the data bank.

## **Quality Improvement and Patient Safety in Anesthesia**

Quality is a concept that has continued to elude precise definition in medical practice. However, it is generally accepted that attention to quality will improve patient safety and satisfaction with anesthesia care. The field of quality improvement is continually evolving, as is the terminology used to

describe such efforts. A more recent trend is emphasis on patient safety, the prevention of harm from medical care. At the time of this writing, patient safety initiatives are evolving and “pay for performance (P4P)” (direct linkage between care processes and outcomes and reimbursement) has been adopted by CMS. These will be discussed in a separate section.

Anesthesia quality improvement programs at the service level are generally guided by requirements of the Joint Commission that accredits hospitals and health-care organizations. Quality improvement programs are basically oriented toward improvement of the structure, process, and outcome of health-care delivery. An understanding of the fundamental principles of quality improvement may clarify the relationship between the continually evolving Joint Commission requirements and mandated quality improvement and other reporting initiatives.

### **Structure, Process, and Outcome: The Building Blocks of Quality**

Although quality of care is difficult to define, it is generally accepted that it is composed of three components: structure, process, and outcome.<sup>111</sup> *Structure* refers to the setting in which care was provided, for example, personnel and facilities used to provide health-care services and the manner in which they are organized. This includes the qualifications and licensing of personnel, ratio of practitioners to patients, standards for the facilities and equipment used to provide care, and the organizational structure within which care is delivered. The *process* of care includes the sequence and coordination of patient care activities, that is, what was actually done. Was a preanesthetic evaluation performed and documented? Was the patient continuously attended and monitored throughout the anesthetic? *Outcome* of care refers to changes in health status of the patient following the delivery of medical care. A quality improvement program focuses on measuring and improving these basic components of care.

**3** CQI takes a systems approach to identifying and improving quality of care.<sup>112,113</sup> The operator is just one part of a complex system. An important underlying premise is that poor results may be a result of either random or systematic error. Random errors are inherently difficult to prevent and programs focused in this direction are misguided. System errors, however, should be controllable and strategies to minimize them should be within reach. CQI is basically the process of continually evaluating anesthesia practice to identify systematic problems (opportunities for improvement) and implementing strategies to prevent their occurrence.

A CQI program may focus on undesirable outcomes as a way to identify opportunities for improvement in the structure and process of care. The focus is not on blame but rather on identification of the causes of undesirable

outcomes. Instead of asking which practitioners have the highest patient mortality rates, a CQI program may focus on the relationship between the process of care and patient mortality. What proportion of deaths was related to the patient's disease process or debilitated condition? Are these patients being appropriately evaluated for anesthesia and surgery? Were there any controllable causes, such as lack of extra help during resuscitation? The latter may lead to a modification of personnel resources (structure) or assignments (process) to be sure that adequate personnel are available at all times.

Formally, the process of CQI involves the identification of opportunities for improvement through the continual assessment of important aspects of care. It is a process that is instituted from the bottom up, by those who are actually involved in the process to be improved, rather than from the top down by administrators. Identification of opportunities for improvement may be carried out by various means, from brainstorming sessions focusing on a systematic evaluation of care activities to the careful measurement of indicators of quality (such as morbidity and mortality). In any event, once areas are identified for improvement, their current status is measured and documented. This may involve measurement of outcomes, such as delayed recovery from anesthesia or peripheral nerve injury. The process of care leading to these problems is then analyzed. If a change is identified that should lead to improvement, it is implemented. After an appropriate time, the status is then measured again to determine whether improvement actually resulted. Attention may then be directed to continuing to improve this process or turning to a different process to target for improvement.

### ***Difficulty of Outcome Measurement in Anesthesia***

Improvement in quality of care is often measured by a reduction in the rate of adverse outcomes. However, adverse outcomes are relatively rare in anesthesia, making measurement of improvement difficult. For example, if an institution lowers its mortality rate of surgery patients from 1 in 1,000 to 0.5 in 1,000, this difference may not be statistically significant. In other words, it may be impossible to know if the change in outcome resulted from changes in care or is simply random fluctuation. Many adverse outcomes in anesthesia are sufficiently rare to render them problematic as quality improvement measures.

To complement outcome measurement, anesthesia CQI programs can focus on critical incidents, sentinel events, and human errors. *Critical incidents* are events that cause, or have the potential to cause, patient injury if not noticed and corrected in a timely manner. For example, a partial disconnect of the breathing circuit may be corrected before patient injury occurs, yet has the potential for causing hypoxic brain injury or death. Critical incidents are more

common than adverse outcomes. Measurement of the occurrence rate of important critical incidents may serve as a proxy measure for rare outcomes in anesthesia in a CQI program designed to improve patient safety and prevent injury.

*Sentinel events* are single, isolated events that may indicate a systemic problem. The Joint Commission has a specific definition of sentinel events (any unexpected occurrences involving death or serious physical or psychological injury or risk thereof) that will be discussed later. In general, a sentinel event may be a significant or alarming critical incident that did not result in patient injury, such as a syringe swap and administration of a potentially lethal dose of medication that was noted and treated promptly, avoiding catastrophe. Or a sentinel event may be an unexpected significant patient injury such as intraoperative death. In either case, a CQI program may investigate sentinel events in an attempt to uncover systemic problems in the delivery of care that can be corrected. For example, a syringe swap may be analyzed for confusing or unclear labeling of medications or unnecessary medications routinely stocked on the anesthesia cart, setting the scene for unintended mix-up. In the case of death, all aspects of the patient's hospital course from selection for surgery to anesthetic management may be analyzed to determine if similar deaths can be prevented by a change in the care delivery system.

Human error has garnered much attention since a 1999 government report that 98,000 Americans may die annually from medical errors in hospitals.<sup>114</sup> Human errors are inevitable yet potentially preventable by appropriate system safeguards. Errors of planning involve use of a wrong plan to achieve an aim. Errors of execution are the failure of a planned action to be completed as intended. Modern anesthesia equipment is designed with safeguards such as alarm systems to detect errors that could lead to patient injury. Other anesthesia care processes are also amenable to human factors design principles, such as color coding of drug labels. A quality improvement program may identify human errors and institute safety systems to aid in error prevention.

Recently, many institutions have implemented "Communication and Resolution Programs" which have been shown to significantly reduce the incidence of medical errors.<sup>115</sup> In these institutions, when an error has occurred, the involved parties (including medical personnel, risk management, medical liability insurers, and the patient) immediately communicate with one another, the cause of the error is thoroughly investigated, the patient is rapidly remunerated financially (if necessary), and mechanisms are instituted to prevent recurrence of a similar error. Data from these institutions have shown a significant reduction in the incidence of error, dramatically reduced litigation, and improved patient satisfaction.

## *Joint Commission Requirements for Quality Improvement*

The Joint Commission is a nonprofit organization that has its roots in an early twentieth century initiative of the American College of Surgeons. The organization became the Joint Commission on Accreditation of Hospitals in 1951 and then the Joint Commission on Accreditation of Healthcare Organizations in 1987 when it expanded its accreditation activities to facilities other than hospitals. The name of the organization was shortened to The Joint Commission in 2007.<sup>116</sup> Although Joint Commission accreditation of hospitals and surgery centers is officially voluntary, it is a requirement in order to participate in Medicaid billing in many states.

Joint Commission requirements for quality improvement activities are updated on an annual basis and are available online. In general, a hospital must adopt a method for systematically assessing and improving important functions and processes of care and their outcomes in a cyclical fashion. The general outline for this CQI cycle is the design of a process or function, measurement of performance, assessment of performance measures through statistical analysis or comparison with other data sources, and improvement of the process or function. Then the cycle repeats. The Joint Commission provides specific standards that must be met, with examples of appropriate measures of performance. The goal of this cycle of design, measurement, assessment, and improvement of performance of important functions and

**4** processes is to improve patient safety and quality of care.

Many of the specific Joint Commission requirements are outlined in its National Patient Safety Goals.<sup>117</sup> These include performance elements for all aspects of hospital care including processes for delivering perioperative care, such as medication labeling, the prevention of infections associated with urinary and central venous catheters, and the preprocedure “time-out.”<sup>117</sup> The time-out is meant to ensure that the entire team (anesthesiologist, surgeon, nursing staff) agrees that the procedure, patient, and procedural details are correct. The surgical check list, described earlier in this chapter, is often used for this purpose. Since 2006 Joint Commission accreditation visits are unannounced or conducted on short notice and involve the inspection team watching patient care to see that safe and acceptable practices are routinely implemented. Surveyors may also talk to any staff member about organizational policies and procedures. Although the accreditation visits are by necessity episodic, the ORYX Performance Measurement Initiative<sup>118</sup> is a longstanding Joint Commission program that changed the focus of the accreditation process from simply taking a snapshot of institutional performance at the time of an inspection to a continuous process of reporting performance data using the ORYX tool. Unlike most programs in the quality arena that are primarily known by their acronyms, ORYX is named after the

animal whose swiftness and graceful appearance was intended to be both memorable and evocative of positive attributes.<sup>118</sup>

The Joint Commission also requires all sentinel events (any unexpected occurrences involving death or serious physical or psychological injury or risk thereof) to undergo root cause analysis.<sup>119</sup> A root cause analysis is typically facilitated by the hospital and includes everyone involved in the care of the affected patient in reconstructing the events to identify system process flaws that facilitated medical error. Any surgery on the wrong patient or wrong body part is included in this policy. The Joint Commission publishes sentinel event alerts so health-care organizations can learn from the experiences of others and prevent future medical errors.

### *Alternative Payment Models and Pay for Performance*

Alternative Payment Models (APMs) are part of the move away from traditional volume driven fee-for-service systems to other payment formulas that are intended to promote quality, patient value, and efficiency in health care. The models attempt to do this by shifting some of the down-side risk of excess costs due to complications and inefficient care to the providers through capitation and/or bundled payments. Some models also share the upside risk of cost savings gained through improved efficiency with the providers. A full exploration of this trend in reimbursement and health-care organization and its potential impact on the manner in which anesthesiologists will practice in the future is beyond the scope of this chapter and is mentioned here due to its importance as part of the forces shaping quality improvement programs.

Pay for Performance (P4P) is a broad term that encompasses programs and initiatives aimed at improving the quality and efficiency of health care by providing financial incentives to hospitals and health-care professionals to measure and report health-care outcomes and to meet specific goals and standards for outcomes and processes. There are a large number of initiatives in the private sector but historically the best known P4P programs have been those of the CMS; the Value-Based Purchasing program for hospitals and institutions and the Physician Quality Reporting System (PQRS) for individual health professionals and group practices. Within these programs performance parameters were divided into the domains of: clinical process of care, structure, outcome, efficiency, and patient experience. The programs were initially introduced with a formula that paid a percentage bonus to institutions and providers for having reported and met applicable performance goals. As the programs have evolved negative payment adjustments or penalties were introduced for participants that failed to report data or did not meet performance goals. Performance parameters directly applicable to the delivery of perioperative care are only a small subset of all

the parameters in these programs. An item-specific, comprehensive outline of the parameters and goals relevant to perioperative care will not be included here as these have changed and will continue to change, such that they may not be relevant over the longer term. For example, one of the previously perennial performance parameters, which had also been aligned with the Joint Commission's Surgical Care Improvement Project (SCIP) was the delivery of antibiotic prophylaxis for surgical infection prevention within 60 minutes prior to incision. This parameter was dropped by CMS because adherence was close to 100%, so it was no longer providing information that could discriminate between the practices of participating providers.<sup>120,121</sup>

The next CMS P4P program on the horizon in 2018 will combine and streamline the PQRS program and the Value-Based Purchasing program into one system created under the Medicare Access and CHIP Reauthorization Act (MACRA). Over a 10-year timeline this system will incentivize practitioners through Merit-Based Incentive Payments (MIPS) or through participation in APMs to replace traditional fee-for-service payments. The MIPS system will assess individual physician performance in four categories: quality, resource use, meaningful use of certified EHR technology, and clinical practice improvement activities to generate a composite score on a 0- to 100-point scale. After full implementation of the program in 2019 physicians participating in the MIPS will have their Medicare payments adjusted positively or negatively according to their ranking above or below the mean composite score. Because APMs have already ostensibly been created to move practitioners from volume to quality-based practice, those practitioners who receive a "significant portion" of their Medicare payments through an eligible APM entity, will be exempt from the MIPS requirements and will be considered "qualifying APM participants."

The concept of P4P has been around for a sufficient length of time that there is evidence accumulating on how well the idea has performed in meeting the intended goals. This evidence primarily pertains to general initiatives, rather than the parameters that apply specifically to the delivery of perioperative care. The evidence is mixed as to whether processes and practitioner behavior are changed by P4P initiatives and there are very limited data to support the idea that patient outcomes are improved. A study of hospitals in the United Kingdom<sup>122</sup> found that the mortality due to pneumonia was improved after the introduction of P4P initiatives. However, a major study in the United States<sup>123</sup> did not demonstrate any similar improvements and a Cochrane Review<sup>124</sup> did not find any evidence for the effectiveness of P4P programs. Some investigators have suggested that there are major gaps between the documentation of care and the delivery of care,<sup>125</sup> and that P4P incentivizes providers to focus more on the documentation of certain elements of care but may divert resources and

efforts from the actual delivery of care.<sup>121</sup> Regardless of any present lack of evidence for the effectiveness of these measures, MACRA and MIPS will ensure that they will remain part of the health-care landscape and anesthesiologists should adopt a proactive approach to shaping and improving any future P4P programs.

The Anesthesia Quality Institute (AQI) has developed a National Anesthesia Clinical Outcomes Registry (NACOR) that can serve as a benchmarking resource for anesthesiologists. The AQI is a resource chartered by ASA in 2009.<sup>126</sup> The AQI was developed to assist members in maintaining certification and meeting emerging standards and to collect digital case information. NACOR is the registry of accumulated digital data acquired through periodic transfer of case-specific data directly from one electronic system (electronic billing and health records, EHR, AIMS, etc.) to another. NACOR data can be used to meet current CMS P4P measures. The NACOR registry is a rich bank of data for future outcomes analysis that may be used for personal benchmarking, comparing quality of care, maintaining licensure and certification, and research. Through NACOR, acquired data (practice demographics, case-specific data, outcome data, and risk adjustment data) can be analyzed, changes can be implemented, and health care can be improved.

## Professional Liability

This section addresses the basic concepts of medical liability. A more detailed discussion of liability issues and the steps of the lawsuit process and appropriate actions for physicians to take when sued is available in the ASA Manual on Professional Liability.<sup>127</sup>

### The Tort System

Although physicians may become involved in the criminal law system in a professional capacity, they more commonly become involved in the legal system of civil laws. Civil law is broadly divided into *contract law* and *tort law*. A tort may be loosely defined as a civil wrongdoing; negligence is one type of tort. *Malpractice* actually refers to any professional misconduct, but its use in legal terms typically refers to professional negligence. 5

To be successful in a malpractice suit, the patient-plaintiff must prove four things:

1. Duty: That the anesthesiologist owed the patient a duty
2. Breach of duty: That the anesthesiologist failed to fulfill his or her duty
3. Causation: That a reasonably close causal relation exists between the anesthesiologist's acts and the resultant injury

4. Damages: That actual damage resulted because of a breach of the standard of care.

Failure to prove any one of these four elements will result in a decision for the defendant-anesthesiologist.

## **Duty**

As a physician, the anesthesiologist establishes a duty to the patient when a doctor–patient relationship exists. When the patient is seen preoperatively and the anesthesiologist agrees to provide anesthesia care for the patient, a duty to the patient has been established. In the most general terms, the duty the anesthesiologist owes to the patient is to adhere to the *standard of care* for the treatment of the patient. Because it is virtually impossible to delineate specific standards for all aspects of medical practice and all eventualities, the courts have created the concept of the *reasonable and prudent* physician. For all specialties, there is a national standard that has displaced the local standard.

## **Breach of Duty**

In a malpractice action, expert witnesses will review the medical records of the case and determine whether the anesthesiologist acted in a reasonable and prudent manner in the specific situation and fulfilled his or her duty to the patient. If they find that the anesthesiologist either did something that should not have been done or failed to do something that should have been done, then the duty to adhere to the standard of care has been breached. Therefore, the second requirement for a successful suit will have been met.

## **Causation**

Judges and juries are interested in determining whether the breach of duty was the *proximate cause* of the injury. If the odds are better than even that the breach of duty led, however circuitously, to the injury, this requirement is met.

There are two common tests employed to establish causation. The first is the *but for* test and the second is the *substantial factor* test. If the injury would not have occurred but for the action of the defendant-anesthesiologist, or if the act of the anesthesiologist was a substantial factor in the injury despite other causes, then proximate cause is established.

Although the burden of proof of causation ordinarily falls on the patient-plaintiff, it may, under special circumstances, be shifted to the physician-defendant under the doctrine of *res ipsa loquitur* (literally, “the thing speaks for itself”). Applying this doctrine requires proving the following:

1. The injury is of a kind that typically would not occur in the absence of negligence.
2. The injury must be caused by something under the exclusive control of the anesthesiologist.
3. The injury must not be attributable to any contribution on the part of the patient.
4. The evidence for the explanation of events must be more accessible to the anesthesiologist than to the patient.

Because anesthesiologists render patients insensible to their surroundings and unable to protect themselves from injury, the doctrine of *res ipsa loquitur* may be invoked in anesthesia malpractice cases. If the plaintiff can successfully argue that the injury would not have occurred in the absence of negligence, then the defendant-anesthesiologist must prove that he/she was not negligent in the case under consideration.

## **Damages**

The law allows for three different types of damages. *General damages* are those such as pain and suffering that directly result from the injury. *Special damages* are those actual damages that are a consequence of the injury, such as medical expenses, lost income, and funeral expenses. *Punitive damages* are intended to punish the physician for negligence that was reckless, wanton, fraudulent, or willful. Punitive damages are exceedingly rare in medical malpractice cases. More likely in the case of gross negligence is a loss of the license to practice anesthesia. In extreme cases, criminal charges may be brought against the physician, although this is rare. Determination of the dollar amount is usually based on some assessment of the plaintiff's condition versus the condition he or she would have been in had there been no negligence. Plaintiffs' attorneys generally charge a percentage of the damages and will, therefore, seek to maximize the award given. Some states have legislated caps on damages. Such caps are more common for general damages, although some states cap total compensation for malpractice awards.

## **Standard of Care**

Because medical malpractice usually involves issues beyond the comprehension of lay jurors and judges, the court establishes the standard of care in a particular case by the testimony of *expert witnesses*. These witnesses differ from factual witnesses mainly in that they may give opinions. The trial court judge has sole discretion in determining whether a witness may be qualified as an expert. Although any licensed physician may be an expert, information will be sought regarding the witness's education and training, the nature and scope of the person's practice, memberships and affiliations, and

publications. The purpose in gathering this information is not only to establish the qualifications of the witness to provide expert testimony but also to determine the weight to be given to that testimony by the jury. In many cases the success of a lawsuit depends primarily on the stature and believability of the expert witnesses.

Unfortunately, there is a tendency for experts to link severe injury with inappropriate care (i.e., a bias that “bad outcomes mean bad care”). To investigate the influence of the severity of the injury on the assessment of standard of care, a group of 112 practicing anesthesiologists judged appropriateness of care in 21 cases involving adverse anesthetic outcomes.<sup>128</sup> The original outcome in each case was either temporary or permanent. For each original case, a matching alternate case was created that was identical to the original in every respect, except that a plausible outcome of the opposite severity was substituted. Reviewers judged the standard of care in each case. Knowledge of the severity of injury produced a significant inverse effect on the judgment of appropriateness of care.<sup>128</sup> The proportion of ratings for appropriate care decreased when the outcome was changed from temporary to permanent and increased when the outcome was changed from permanent to temporary. These results suggest that outcome bias in the assessment of standard of care may contribute to the frequency and size of payments.

In certain circumstances, the standard of care may also be determined from published societal guidelines, written policies of a hospital or department, or textbooks and monographs. Some medical specialty societies have carefully avoided applying the term *standards* to their guidelines in the hope that no binding behavior or mandatory practices have been created. The essential difference between standards and guidelines is that guidelines *should* be adhered to and standards *must* be adhered to. The ASA has a searchable database of all standards, guidelines, and practice parameters on their website.<sup>67</sup> The ASA also has extensive material on quality improvement and practice management on their website.<sup>129</sup>

## Causes of Anesthesia-related Lawsuits

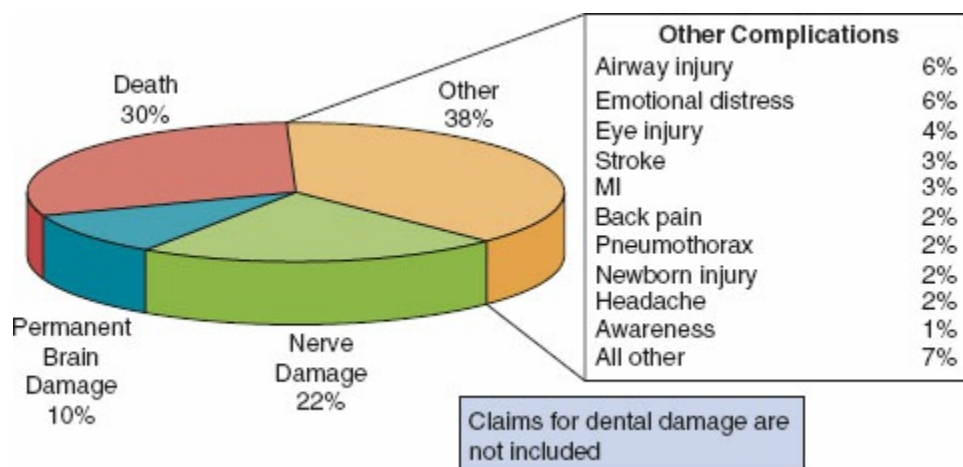

Relatively few adverse outcomes end up in a malpractice suit. It has been estimated that less than 1 of 25 patient injuries result in malpractice litigation.<sup>130</sup> The ASA Committee on Professional Liability has conducted a nationwide analysis of malpractice claims against anesthesiologists, excluding dental damage, since 1985 (i.e., the *Closed Claims Project*).<sup>131–133</sup> While most malpractice claims continue to be associated with surgical anesthesia care, obstetric anesthesia, acute pain management, and chronic pain management together represent one-third of anesthesia malpractice claims (Fig. 4-1).

The leading injuries in anesthesia-related malpractice claims in the

2000s were death (30%), nerve damage (22%), permanent brain damage (10%), and airway injury (6%) (Fig. 4-2). Burns from cautery fires, especially during monitored anesthesia care, increased over previous decades.<sup>134,135</sup> The causes of death and permanent brain damage were predominantly problems in airway management (e.g., inadequate ventilation, difficult intubation, premature extubation) and other complications such as pulmonary embolism, inadequate fluid therapy, stroke, hemorrhage, and myocardial infarction.<sup>136</sup> Nerve damage, especially to the ulnar nerve, often occurs despite apparently adequate positioning.<sup>137,138</sup> Nerve injury was also the most common complication leading to claims after PNBs.<sup>139</sup> Spinal cord injury was the most common cause of nerve damage claims against anesthesiologists in the 1990s.<sup>137</sup>

**Figure 4-1** Types of anesthesia care in malpractice claims in the year 2000 or later. Most claims are associated with surgical anesthesia care. Anesthesia Closed Claims Project ( $n = 10,546$ ). OB, obstetric.

**Figure 4-2** The most common injuries leading to anesthesia malpractice claims in the year 2000 or later. Damage to teeth and dentures excluded. Anesthesia Closed Claims Project ( $n = 10,546$ ). MI, myocardial infarction.

Chronic pain management is an increasing source of malpractice claims against anesthesiologists.<sup>133,140,141</sup> Cervical spine interventions for chronic pain management were the most common nonneurolytic injections in the 2000s, representing 27% of recent pain medicine malpractice claims. Permanent nerve injury, generally to the spinal cord, was the outcome in 54% of these claims.<sup>141,142</sup> Medication management represented 17% of recent chronic pain management claims, with death as the most common outcome.<sup>141,143</sup> Lumbar injections decreased over time, representing 17% of pain medicine claims in the 2000s, with permanent disabling nerve injury the outcome in 26% of lumbar injection claims.<sup>141</sup> Claims associated with implanted devices increased over time, representing 16% of pain medicine claims in the 2000s.<sup>141</sup>

The anesthesiologist is likely to be the target of a lawsuit if an untoward outcome occurs because the physician–patient relationship is usually tenuous at best. The patient rarely chooses the anesthesiologist, the preoperative visit is brief, and the anesthesiologist who sees the patient preoperatively may not actually anesthetize the patient. Communication between anesthesiologists and surgeons about complications is often lacking, and the tendency is for the surgeon to “blame anesthesia.” In addition, anesthesiologists are often sued along with the surgeon in the case of an adverse outcome. This may occur even if the outcome was in no way related to the anesthetic care. However, as mentioned earlier, there is an increasing body of evidence that early full disclosure of adverse events to patients, probably best done by individuals properly trained in the process of disclosure, may significantly reduce the incidence of malpractice claims.<sup>85,100,115</sup>

### **What to Do When Sued**

A lawsuit begins when the patient-plaintiff’s attorney files a *complaint* and demands for jury trial with the court. The anesthesiologist is then served with the complaint and a summons requiring an answer to the complaint. Until this happens, no lawsuit has been filed. Insurance carriers must be notified immediately after the receipt of the complaint. The anesthesiologist will need assistance in answering the complaint, and there is a time limit placed on the response.

Specific actions at this point include the following:

1. Do not discuss the case with anyone, including colleagues who may have been involved, operating room personnel, or friends. (Although in many jurisdictions the courts will look favorably upon a physician who speaks to the patient soon after an adverse outcome occurs, and offers sympathy and an apology without necessarily admitting guilt.)<sup>115</sup>

2. Never alter any records.
3. Gather together all pertinent records, including a copy of the anesthetic record, billing statements, and correspondence concerning the case.
4. Make notes recording all events recalled about the case.
5. Cooperate fully with the attorney provided by the insurer.

The first task the anesthesiologist must perform with an attorney is to prepare an answer to the complaint. The complaint contains certain facts and allegations with which the defense may either agree or disagree. Defense attorneys rely on the frank and totally candid observations of the physician in preparing an answer to the complaint. Physicians should be willing to educate their attorneys about the medical facts of the case, although most medical malpractice attorneys will be knowledgeable and medically sophisticated.

The next phase of the malpractice suit is called *discovery*. The purpose of discovery is the gathering of facts and clarification of issues in advance of the trial. In all likelihood the anesthesiologist will initially receive a written interrogatory, which will request factual information. In consultation with the defense attorney, the interrogatory should be answered in writing because carelessly or inadvertently misstated facts can become troublesome later.

Depositions are a second mechanism of discovery. The defendant-anesthesiologist will be deposed as a fact witness, and depositions will be obtained from other anesthesiologists who will act as expert witnesses. A nationally recognized expert in the area in question, recommended by the defendant but who is not a personal friend, and who agrees with the defense position, may be very valuable.

The plaintiff's attorney, not the defense attorney, will depose the anesthesiologist. Despite the apparent informality of the deposition, the anesthesiologist must be constantly aware that what is said during the deposition carries as much weight as what would be said in court. It is important to be factually prepared for the deposition by review of personal notes, the anesthetic record, and the medical record. The physician should dress conservatively and professionally because appearance and image are very important. The opposition is assessing the physician to see how he or she will appear to a jury. Answer only the question asked, and do not volunteer information. Rely on one's attorney for assistance when preparing for a deposition.

There will be depositions from expert witnesses, both for the plaintiff and for the defense. The anesthesiologist should work with his or her attorney to suggest questions and rebuttals. The better educated the attorney is about the medical facts, the reasons the anesthesiologist did what was done, and the alternative approaches, the better able the attorney will be to conduct these expert depositions.

If there is some merit in the case but the damages are minimal, or if proof of innocence will be difficult, there will probably be a settlement offer. There is a high cost incurred by both plaintiffs and defendants in pursuing a malpractice claim up through a jury trial. Unless there is a strong probability of a large dollar award, reputable plaintiffs' attorneys are not likely to pursue the claim. Thus, even if physicians believe that they are totally innocent of any wrongdoing, they should not be offended or angered about settling of the case: This is solely a matter of money, not medicine.

If a settlement is not reached during the discovery phase, a trial will occur. Only about 1 in 20 malpractice cases ever reach the point of a jury trial. Only those cases in which both sides think they can win, and which are likely to have significant financial impact, will proceed to trial.

The discussion of deposition testimony also applies to testimony in court, but there are a few additional points to consider during the trial. The members of the jury will not be as sophisticated medically as the attorneys who deposed the anesthesiologist during discovery. However, do not underestimate the intelligence of the jury. Talking down to them will create an unfavorable impression. If the answer to a question is not known, avoid guessing. If specific facts cannot be remembered, say so. Nobody expects total recall of events that may have occurred years before.

The defendant-physician should be present during the entire trial, even when not testifying, and should dress professionally. Displays of anger, remorse, relief, or hostility will hurt the physician in court. The physician should be able to give his or her testimony without using notes or documents. When it is necessary to refer to the medical record, it will be admitted into evidence. The anesthesiologist's goal is to convince the jury that he or she behaved in this case as any other competent and prudent anesthesiologist would have behaved.

It is important to keep in mind that *proof* in a malpractice case means only "more likely than not." The patient-plaintiff must "prove" the four elements of negligence, not to absolute certainty, but only to a probability greater than 50%. On the positive side, this means that the defendant-anesthesiologist must only show that his or her actions were, more likely than not, within an acceptable standard of care.

## Fire Safety

## KEY POINTS

- 1 A basic principle of electricity is known as *Ohm's law* (Voltage = current  $\times$  resistance).
- 2 To have the completed circuit necessary for current flow, a closed loop must exist and a voltage source must drive the current through the impedance.
- 3 To receive a shock, one must contact the electrical circuit at two points, and there must be a voltage source that causes the current to flow through an individual.
- 4 In electrical terminology, *grounding* is applied to two separate concepts:

- the grounding of electrical power and the grounding of electrical equipment.
- 5 To provide an extra measure of safety from gross electrical shock (macroshock), the power supplied to most operating rooms (ORs) is ungrounded.
  - 6 The line isolation monitor is a device that continuously monitors the integrity of an isolated power system.
  - 7 The ground fault circuit interrupter is a popular device used to prevent individuals from receiving an electrical shock in a grounded power system.
  - 8 An electrically susceptible patient (i.e., one who has a direct, external connection to the heart) may be at risk from very small currents; this is called *microshock*.
  - 9 Problems can arise if the electrosurgical return plate is improperly applied to the patient or if the cord connecting the return plate to the electrosurgical unit is damaged or broken.
  - 10 Fires in the OR are just as much a danger today as they were 100 years ago when patients were anesthetized with flammable anesthetic agents.
  - 11 The necessary components for a fire consist of the triad of heat or an ignition source, a fuel, and an oxidizer.
  - 12 The two major ignition sources for OR fires are the electrosurgical unit and the laser.
  - 13 It is known that desiccated carbon dioxide absorbent can, in rare circumstances, react with sevoflurane to produce a fire.
  - 14 All OR personnel should be familiar with the location and operation of fire extinguishers.

The myriad of electrical and electronic devices in the modern operating room (OR) greatly improve patient care and safety. However, these devices also subject both the patient and OR personnel to increased risks. To reduce the risk of electrical shock, most ORs have electrical systems that incorporate special safety features. It is incumbent upon the anesthesiologist to have a thorough understanding of the basic principles of electricity and an appreciation of the concepts of electrical safety applicable to the OR environment.

## Principles of Electricity

A basic principle of electricity is known as *Ohm's law*, which is represented by the equation:

$$E = I \times R$$

where  $E$  is electromotive force (in volts),  $I$  is current (in amperes), and  $R$  is resistance (in ohms). Ohm's law forms the basis for the physiologic equation  $BP = CO \times SVR$ ; that is, blood pressure (BP) is equal to the cardiac output (CO) times the systemic vascular resistance (SVR). In this case, the BP of the vascular system is analogous to voltage, the CO to current, and the SVR to the forces opposing the flow of electrons. Electrical power ( $P$ ) is measured in watts ( $W$ ). Power is the product of the voltage ( $E$ ) and the current ( $I$ ), as defined by the formula:

$$P = E \times I$$

The amount of electrical work done is measured in watts multiplied by a unit of time. The watt-second (a joule,  $J$ ) is a common designation for electrical energy expended in doing work. The energy produced by a defibrillator is measured in watt-seconds (or joules). The kilowatt-hour is used by electrical utility companies to measure larger quantities of electrical energy.

Power can be thought of as a measure not only of work done but also of heat produced in any electrical circuit. Substituting Ohm's law in the formula:

$$\begin{aligned} P &= E \times I \\ P &= (I \times R) \times I \\ P &= I^2 \times R \end{aligned}$$

Thus, power is equal to the square of the current  $I^2$  (amperage) times the resistance  $R$ . Using these formulas, it is possible to calculate the number of amperes and the resistance of a given device if the wattage and the voltage are known. For example, a 60-W light bulb operating on a household 120-V circuit would require 0.5 A of current for operation. Rearranging the formula so that:

$$I = P/E$$

We have:

$$\begin{aligned} I &= (60 \text{ watts})/120 \text{ volts} \\ I &= 0.5 \text{ ampere} \end{aligned}$$

Using this in Ohm's law:

$$R = E/I$$

The resistance can be calculated to be 240 ohms:

$$R = (120 \text{ volts}) / (0.5 \text{ ampere})$$

$$R = 240 \text{ ohms}$$

It is obvious from the previous discussion that 1 V of electromotive force (EMF) flowing through a 1-ohm resistance will generate 1 A of current. Similarly, 1 A of current induced by 1 V of EMF will generate 1 W of power.

## Direct and Alternating Currents

Any substance that permits the flow of electrons is called a *conductor*. Current is characterized by electrons flowing through a conductor. If the electron flow is always in the same direction, it is referred to as *direct current* (DC). However, if the electron flow reverses direction at a regular interval, it is termed *alternating current* (AC). Either of these types of current can be pulsed or continuous in nature.

The previous discussion of Ohm's law is accurate when applied to DC circuits. However, when dealing with AC circuits, the situation is more complex because the flow of the current is opposed by a more complicated form of resistance, known as *impedance*.

## Impedance

Impedance, designated by the letter  $Z$ , is defined as the sum of the forces that oppose electron movement in an AC circuit. Impedance consists of resistance (ohms) but also takes capacitance and inductance into account. In actuality, when referring to AC circuits, Ohm's law is defined as:

$$E = I \times Z$$

An *insulator* is a substance that opposes the flow of electrons. Therefore, an insulator has a high impedance to electron flow, whereas a conductor has a low impedance to electron flow.

In AC circuits, the capacitance and inductance can be important factors in determining the total impedance. Both capacitance and inductance are influenced by the frequency (cycles per second or hertz, Hz) at which the AC current reverses direction. The impedance is directly proportional to the frequency ( $f$ ) times the inductance (IND):

$Z \propto (f \times IND)$  and the impedance is inversely proportional to the product of the frequency ( $f$ ) and the capacitance (CAP):

$$Z \propto 1 / (f \times CAP)$$

As the AC current increases in frequency, the net effect of both capacitance and inductance increases. However, because impedance and capacitance are inversely related, total impedance decreases as the product of the frequency and the capacitance increases. Thus, as frequency increases, impedance falls and more current is allowed to pass.

## Capacitance

A *capacitor* consists of any two parallel conductors that are separated by an insulator (Fig. 5-1). A capacitor has the ability to store charge. *Capacitance* is the measure of that substance's ability to store charge. In a DC circuit the capacitor plates are charged by a voltage source (i.e., a battery) and there is only a momentary current flow. The circuit is not completed and no further current can flow unless a resistance is connected between the two plates and the capacitor is discharged.

In contrast to DC circuits, a capacitor in an AC circuit permits current flow even when the circuit is not completed by a resistance. This is because of the nature of AC circuits, in which the current flow is constantly being reversed. Because current flow results from the movement of electrons, the capacitor plates are alternately charged—first positive and then negative with every reversal of the AC current direction—resulting in an effective current flow as far as the remainder of the circuit is concerned, even though the circuit is not completed.

Since the effect of capacitance on impedance varies directly with the AC frequency in hertz, the greater the AC frequency, the lower the impedance. Therefore, high-frequency currents (0.5 to 2 million Hz), such as those used by electrosurgical units (ESUs), will cause a marked decrease in impedance.

Electrical devices use capacitors for various beneficial purposes. There is, however, a phenomenon known as *stray capacitance*—capacitance that was not designed into the system but is incidental to the construction of the equipment. All AC-operated equipment produces stray capacitance. An ordinary power cord, for example, consisting of two insulated wires running next to each other will generate significant capacitance simply by being plugged into a 120-V circuit, even though the piece of equipment is not turned on. Another example of stray capacitance is found in electric motors. The circuit wiring in electric motors generates stray capacitance to the metal housing of the motor. The clinical importance of capacitance will be emphasized later in the chapter.

**Figure 5-1** A capacitor consists of two parallel conductors separated by an insulator. The capacitor is capable of storing charge supplied by a voltage source.

## Inductance

Whenever electrons flow in a wire, a magnetic field is induced around the wire. If the wire is coiled repeatedly around an iron core, as in a transformer, the magnetic field can be very strong. *Inductance* is a property of AC circuits in which an opposing EMF can be electromagnetically generated in the circuit. The net effect of inductance is to increase impedance. Since the effect of inductance on impedance also depends on AC frequency, increases in frequency will increase the total impedance. Therefore, the total impedance of a coil will be much greater than its simple resistance.

## Electrical Shock Hazards

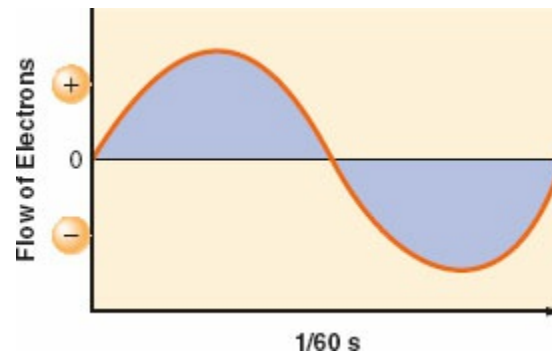

### Alternating and Direct Currents

Whenever an individual contacts an external source of electricity, an electrical shock is possible. An electrical current can stimulate skeletal muscle cells to contract, and thus can be used therapeutically in devices such as pacemakers or defibrillators. However, casual contact with an electrical current, whether AC or DC, can lead to injury or death. Although it takes approximately three times as much DC as AC to cause ventricular fibrillation, this by no means renders DC harmless. Devices such as an automobile battery or a DC defibrillator can be sources of DC shocks.

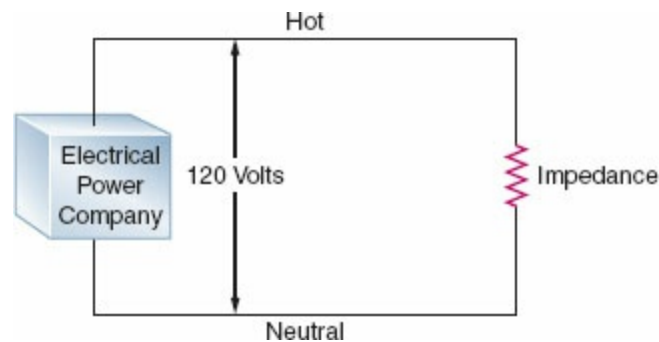

In the United States, utility companies supply electrical energy in the form of ACs of 120 V at a frequency of 60 Hz. The 120 V of EMF and 1 A of current are the effective voltage and amperage in an AC circuit. This is also referred to as *RMS* (root-mean-square). It takes 1.414 A of peak amperage in the sinusoidal curve to give an effective amperage of 1 A. Similarly, it takes 170 V ( $120 \times 1.414$ ) at the peak of the AC curve to get an effective voltage of 120 V. The 60 Hz refers to the number of times in 1 second that the current reverses its direction of flow. Both the voltage and current waveforms form a sinusoidal pattern (Fig. 5-2).

**2** To have the completed circuit necessary for current flow, a closed loop must exist and a voltage source must drive the current through the

impedance. If current is to flow in the electrical circuit, there has to be a *voltage differential*, or a drop in the driving pressure across the impedance. According to Ohm's law, if the resistance is held constant, then the greater the current flow, the larger the voltage drop must be.

**Figure 5-2** Sine wave flow of electrons in a 60-Hz AC.

**Figure 5-3** A typical AC circuit where there is a potential difference of 120 V between the hot and neutral sides of the circuit. The current flows through a resistance, which in AC circuits is more accurately referred to as *impedance*, and then returns to the electrical power company.

The power company attempts to maintain the line voltage constant at 120 V. Therefore, by Ohm's law, the current flow is inversely proportional to the impedance. A typical power cord consists of two conductors. One, designated as *hot* carries the current to the impedance; the other is *neutral*, and it returns the current to the source. The potential difference between the two is effectively 120 V (Fig. 5-3). The amount of current flowing through a given device is frequently referred to as the *load*. The load of the circuit depends on the impedance. A very high impedance circuit allows only a small current to flow and thus has a small load. A very low impedance circuit will draw a large current and is said to be a large load. A *short circuit* occurs when there is a zero impedance load with a very high current flow.<sup>1</sup>

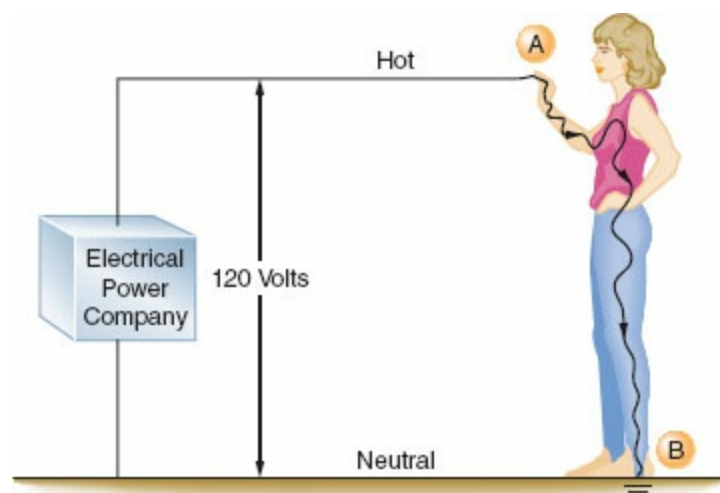

### Source of Shocks

Electrical accidents or shocks occur when a person becomes part of, or

completes, an electrical circuit. To receive a shock, one must contact the electrical circuit at two points, and there must be a voltage source that causes the current to flow through an individual (Fig. 5-4).

When an individual contacts a source of electricity, damage occurs in one of two ways. First, the electrical current can disrupt the normal electrical function of cells. Depending on its magnitude, the current can contract muscles, alter brain function, paralyze respiration, or disrupt normal heart function, leading to ventricular fibrillation. The second mechanism involves the dissipation of electrical energy throughout the body's tissues. An electrical current passing through any resistance raises the temperature of that substance. If enough thermal energy is released, the temperature will rise sufficiently to produce a burn. Accidents involving household currents usually do not result in severe burns. However, in accidents involving very high voltages (i.e., power transmission lines), severe burns are common.

The severity of an electrical shock is determined by the amount of current (number of amperes) and the duration of the current flow. For the purpose of this discussion, electrical shocks are divided into two categories. *Macroshock* refers to large amounts of current flowing through a person, which can cause harm or death. *Microshock* refers to very small amounts of current and applies only to the electrically susceptible patient. This is an individual who has an external conduit that is in direct contact with the heart. This can be a pacing wire or a saline-filled catheter such as a central venous or pulmonary artery catheter. In the case of the electrically susceptible patient, even minute amounts of current (microshock) may cause ventricular fibrillation.

**Figure 5-4** An individual can complete an electric circuit and receive a shock by coming in contact with the hot side of the circuit (point A). This is because he or she is standing on the ground (point B) and the contact point A and the ground point B provide the two contact points necessary for a completed circuit. The severity of the shock that the individual receives depends on his or her skin resistance.

Table 5-1 shows the effects typically produced by various currents following a 1-second contact with a 60-Hz current. When an individual contacts a 120-V household current, the severity of the shock will depend on his or her skin resistance, the duration of the contact, and the current density. Skin resistance can vary from a few thousand to 1 million ohms. If a person with a skin resistance of 1,000 ohms contacts a 120-V circuit, he or she would receive 120 mA of current, which would probably be lethal. However, if that same person's skin resistance is 100,000 ohms, the current flow would be 1.2 mA, which would barely be perceptible.

**Table 5-1** Effects of 60-Hz Current on an Average Human for a 1-Second Contact

Current	Effect
<i>Macroshock</i>	
1 mA (0.001 A)	Threshold of perception
5 mA (0.005 A)	Accepted as maximum harmless current intensity
10–20 mA (0.01–0.02 A)	“Let-go” current before sustained muscle contraction
50 mA (0.05 A)	Pain, possible fainting, mechanical injury; heart and respiratory functions continue
100–300 mA (0.1–0.3 A)	Ventricular fibrillation will start, but respiratory center remains intact
6,000 mA (6 A)	Sustained myocardial contraction, followed by normal heart rhythm; temporary respiratory paralysis; burns if current density is high
<i>Microshock</i>	
100 $\mu$ A (0.1 mA)	Ventricular fibrillation
10 $\mu$ A (0.01 mA)	Recommended maximum 60-Hz leakage current

A, amperes; mA, milliamperes;  $\mu$ A, microamperes.

$$I = E/R = (120 \text{ volts})/(1,000 \text{ ohms}) = 120 \text{ mA}$$

$$I = E/R = (120 \text{ volts})/(100,000 \text{ ohms}) = 1.2 \text{ mA}$$

The longer an individual is in contact with the electrical source, the more dire the consequences, because more energy will be released and more tissue damaged. Also, there will be a greater chance of ventricular fibrillation from excitation of the heart during the vulnerable period of the electrocardiogram (ECG) cycle.

*Current density* is a way of expressing the amount of current that is applied per unit area of tissue. The diffusion of current in the body tends to be in all directions. The greater the current or the smaller the area to which it is applied, the higher the current density. In relation to the heart, a current of 100 mA (100,000  $\mu$ A) is generally required to produce ventricular fibrillation when applied to the surface of the body. However, only 100  $\mu$ A (0.1 mA) is

required to produce ventricular fibrillation when that minute current is applied directly to the myocardium through an instrument having a very small contact area, such as a pacing wire electrode. In this case, the current density is 1,000-fold greater when applied directly to the heart; therefore, only 1/1,000 of the energy is required to cause ventricular fibrillation. In this case, the electrically susceptible patient can be electrocuted with currents well below 1 mA, which is the threshold of perception for humans. The frequency at which the current reverses is also an important factor in determining the amount of current an individual can safely contact. Utility companies in the United States produce electricity at a frequency of 60 Hz. They use 60 Hz because higher frequencies cause greater power loss through transmission lines and lower frequencies cause a detectable flicker from light sources.<sup>2</sup> The “let-go” current is defined as that current above which sustained muscular contraction occurs and at which an individual would be unable to let go of an energized wire. The let-go current for a 60-Hz AC power is 10 to 20 mA,<sup>1,3,4</sup> whereas at a frequency of 1 million Hz, up to 3 A (3,000 mA) is generally considered safe. It should be noted that very high frequency currents do not excite contractile tissue; consequently, they do not cause cardiac dysrhythmias.

It can be seen that Ohm’s law governs the flow of electricity. For a completed circuit to exist, there must be a closed loop with a driving pressure to force a current through a resistance, just as in the cardiovascular system there must be a BP to drive the CO through the peripheral resistance. [Figure 5-5](#) illustrates that a hot wire carrying a 120-V pressure through the resistance of a 60-W light bulb produces a current flow of 0.5 A. The voltage in the neutral wire is approximately 0 V, whereas the current in the neutral wire remains at 0.5 A. This correlates with our cardiovascular analogy, where a mean BP decrease of 80 mmHg between the aortic root and the right atrium forces a CO of 6 L/min through an SVR of 13.3 resistance units. However, the flow (in this case, the CO, or in the case of the electrical model, the current) is still the same everywhere in the circuit. That is, the CO on the arterial side is the same as the CO on the venous side.

## Grounding

To fully understand electrical shock hazards and their prevention, one must have a thorough knowledge of the concepts of grounding. These concepts of **4** grounding probably constitute the most confusing aspects of electrical safety because the same term is used to describe several different principles. In electrical terminology, grounding is applied to two separate concepts. The first is the grounding of electrical *power*, and the second is the grounding of electrical *equipment*. Thus, the concepts that (1) power can be

grounded or ungrounded and that (2) power can supply electrical devices that are themselves grounded or ungrounded are not mutually exclusive. It is vital to understand this point as the basis of electrical safety (Table 5-2). Whereas electrical *power* is grounded in the home, it is usually ungrounded in the OR. In the home, electrical *equipment* may be grounded or ungrounded, but it should always be grounded in the OR.

**Figure 5-5** A 60-W light bulb has an internal resistance of 240 ohms and draws 0.5 A of current. The voltage drop in the circuit is from 120 in the hot wire to 0 in the neutral wire, but the current is 0.5 A in both the hot and neutral wires.

## Electrical Power: Grounded

Electrical utilities universally provide power that is grounded (by convention, the earth-ground potential is zero, and all voltages represent a difference between potentials). That is, one of the wires supplying the power to a home is intentionally connected to the earth. The utility companies do this as a safety measure to prevent electrical charges from building up in their wiring during electrical storms. This also prevents the very high voltages used in transmitting power by the utility from entering the home in the event of an equipment failure in their high-voltage system.

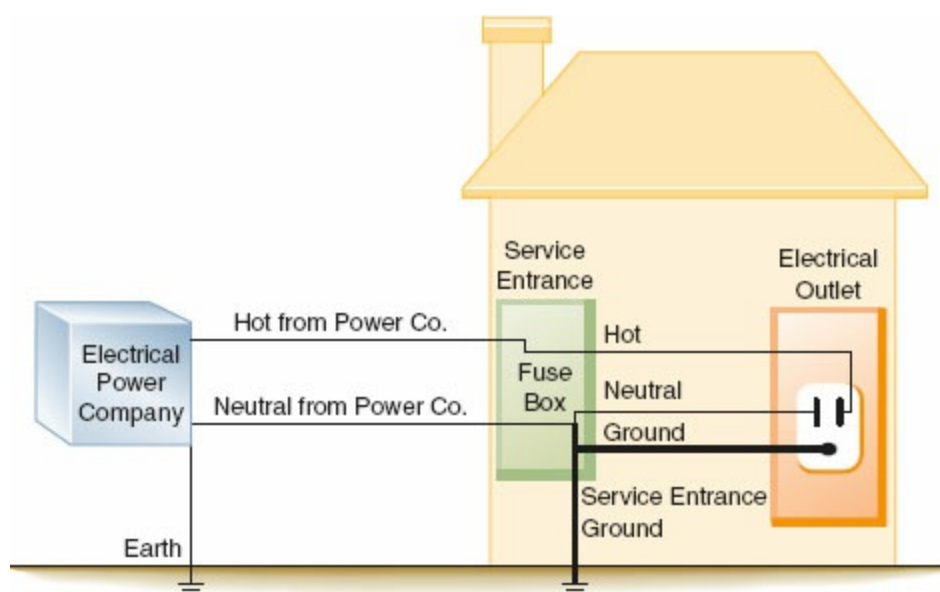

**Table 5-2** Differences Between Power and Equipment Grounding in the Home and the Operating Room

	Power	Equipment
Home	+	±
Operating room	-	+

+, grounded; -, ungrounded; ±, may or may not be grounded.

The power enters the typical home via two wires. These two wires are attached to the main fuse or the circuit breaker box at the service entrance.

The “hot” wire supplies power to the “hot” distribution strip. The neutral wire is connected to the neutral distribution strip and to a service entrance ground (i.e., a pipe buried in the earth; Fig. 5-6). From the fuse box, three wires leave to supply the electrical outlets in the house. In the United States, the hot wire is color-coded black and carries a voltage 120 V above ground potential. The second wire is the neutral wire color-coded white; the third wire is the ground wire, which is either color-coded green or uninsulated (bare wire). The ground and the neutral wires are attached at the same point in the circuit breaker box and then further connected to a cold-water pipe (Figs. 5-7 and 5-8). Thus, this grounded power system is also referred to as a *neutral grounded power system*. The black wire is not connected to the ground, as this would create a short circuit. The black wire is attached to the hot (i.e., 120 V above ground) distribution strip on which the circuit breakers or fuses are located. From here, numerous branch circuits supply electrical power to the outlets in the house. Each branch circuit is protected by a circuit breaker or fuse that limits current to a specific maximum amperage. Most electrical circuits in the house are 15- or 20-A circuits. These typically supply power to the electrical outlets and lights in the house. Several higher amperage circuits are also provided for devices such as an electric stove or an electric clothes dryer. These devices are powered by 240-V circuits, which can draw from 30 to 50 A of current. The circuit breaker or fuse will interrupt the flow of current on the hot side of the line in the event of a short circuit or if the demand placed on that circuit is too high. For example, a 15-A branch circuit will be capable of supporting 1,800 W of power.

**Figure 5-6** In a neutral grounded power system, the electric company supplies two lines to the typical home. The neutral wire is connected to ground by the power company and again connected to a service entrance ground when it enters the fuse box. Both the neutral and ground wires are connected together in the fuse box at the neutral bus bar, which is also attached to the service entrance ground.

**Figure 5-7** Inside a fuse box with the circuit breakers removed. The *arrowheads* indicate the hot wires energizing the strips where the circuit breakers are located. The *arrows* point to the neutral bus bar where the neutral and ground wires are connected.

$$P = E \times I$$

$$P = 120 \text{ volts} \times 15 \text{ amperes}$$

$$P = 1,800 \text{ watts}$$

Therefore, if two 1,500-W hair dryers were simultaneously plugged into one outlet, the load would be too great for a 15-A circuit, and the circuit breaker would open (trip) or the fuse would melt. This is done to prevent the supply wires in the circuit from melting and starting a fire. The amperage of the circuit breaker on the branch circuit is determined by the thickness of the wire that it supplies. If a 20-A breaker is used with wire rated for only 15 A, the wire could melt and start a fire before the circuit breaker would trip. It is important to note that a 15-A circuit breaker does not protect an individual from lethal shocks. The 15 A of current that would trip the circuit breaker far exceeds the 100 to 200 mA that will produce ventricular fibrillation.

**Figure 5-8** The *arrowhead* indicates the ground wire from the circuit breaker box

attached to a cold-water pipe.

**Figure 5-9** An older style electrical outlet consisting of just two wires (a hot and a neutral). There is no ground wire.

The wires that leave the circuit breaker supply the electrical outlets and lighting for the rest of the house. In older homes, the electrical cable consists of two wires, a hot and a neutral, which supply power to the electrical outlets (Fig. 5-9). In newer homes, a third wire has been added to the electrical cable (Fig. 5-10). This third wire is either green or uninsulated (bare) and serves as a ground wire for the power receptacle (Fig. 5-11). On one end, the ground wire is attached to the electrical outlet (Fig. 5-12); on the other, it is connected to the neutral distribution strip in the circuit breaker box along with the neutral (white) wires (Fig. 5-13).

It should be realized that in both the old and new situations, the power is grounded. That is, a 120-V potential exists between the hot (black) and the neutral (white) wire and between the hot wire and ground. In this case,  the ground is the earth (Fig. 5-14). In modern home construction, there is still a 120-V potential difference between the hot (black) and the neutral (white) wire as well as a 120-V difference between the equipment ground wire (which is the third wire), and between the hot wire and earth (Fig. 5-15).

**Figure 5-10** Modern electrical cable in which a third, or ground wire has been added.

**Figure 5-11** Modern electrical outlet in which the ground wire is present. The *arrowhead* points to the part of the receptacle where the ground wire connects.

**Figure 5-12** Detail of modern electrical power receptacle. The *arrow* points to the ground wire (bare wire), which is attached to the green grounding screw on the power

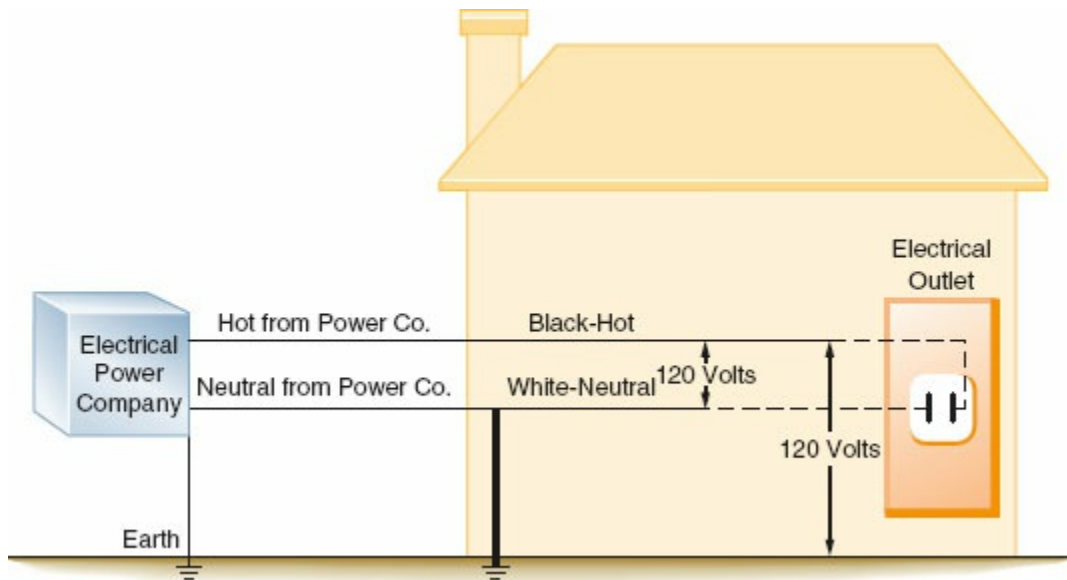

receptacle.

**Figure 5-13** The ground wires (bare wires) from the power outlet are run to the neutral bus bar, where they are connected with the neutral wires (white wires) (*arrowheads*).

A 60-W light bulb can be used as an example to further illustrate this point. Normally, the hot and neutral wires are connected to the two wires of the light bulb socket, and throwing the switch will illuminate the bulb (Fig. 5-16). Similarly, if the hot wire is connected to one side of the bulb socket and the other wire from the light bulb is connected to the equipment ground wire, the bulb will still illuminate. If there is no equipment ground wire, the bulb will still light if the second wire is connected to any grounded metallic object such as a water pipe or a faucet. This illustrates the fact that the 120-V potential difference exists not only between the hot and the neutral wires but also between the hot wire and any grounded object. Thus, in a grounded power system, the current will flow between the hot wire and any conductor with an earth ground.

As previously stated, current flow requires a closed loop with a source of voltage. For an individual to receive an electric shock, he or she must contact the loop at two points. Because we may be standing on the ground or be in contact with an object that is referenced to ground, only one additional contact point is necessary to complete the circuit and thus receive an electrical shock. This is an unfortunate and inherently dangerous consequence of grounded power systems. Modern wiring systems have added the third wire, the equipment ground wire, as a safety measure to reduce the severity of a potential electrical shock. This is accomplished by providing an alternate, low-resistance pathway through which the current can flow to ground.

**Figure 5-14** Diagram of a house with older style wiring that does not contain a ground wire. A 120-V potential difference exists between the hot and the neutral wires, as well as between the hot wire and the earth.

**Figure 5-15** Diagram of a house with modern wiring in which the third, or ground, wire has been added. The 120-V potential difference exists between the hot and neutral wires, the hot and the ground wires, and the hot wire and the earth.

**Figure 5-16** A simple light bulb circuit in which the hot (*black*) and neutral (*white*) wires are connected with the corresponding wires from the light bulb fixture.

Over time, the insulation covering wires may deteriorate. It is then possible for a bare, hot wire to contact the metal case or frame of an electrical device. The case would then become energized and constitute a shock hazard to someone coming in contact with it. [Figure 5-17](#)  illustrates a typical short circuit, where the individual has come in contact with the hot case of an instrument. This illustrates the type of wiring found in older homes. There is no ground wire in the electrical outlet, nor is the electrical apparatus equipped with a ground wire. Here, the individual completes the circuit and receives a severe shock. [Figure 5-18](#) illustrates a similar example, except that now the equipment ground wire is part of the electrical distribution system. In this example, the equipment ground wire provides a pathway of low impedance through which the current can travel; therefore, most of the current would travel through the ground wire. In this case, the person may get a shock, but it is unlikely to be fatal.

The electrical power supplied to homes is always grounded. A 120-V potential always exists between the hot conductor and the ground or earth. The third or equipment ground wire used in modern electrical wiring systems does not normally have current flowing through it. In the event of a short circuit, an electrical device with a three-prong plug (i.e., a ground wire connected to its case) will conduct the majority of the short-circuited or “fault” current through the ground wire and away from the individual. This provides a significant safety benefit to someone accidentally contacting the defective device. If a large enough fault current exists, the ground wire also will provide a means to complete the short circuit back to the circuit breaker or fuse, and this will either melt the fuse or trip the circuit breaker. Thus, in a grounded power system, it is possible to have either grounded or ungrounded equipment, depending on when the wiring was installed and whether the

electrical device is equipped with a three-prong plug containing a ground wire. Obviously, attempts to bypass the safety system of the equipment ground should be avoided. Devices such as a “cheater plug” (Fig. 5-19) should never be used because they defeat the safety feature of the equipment ground wire.

**Figure 5-17** When a faulty piece of equipment without an equipment ground wire is plugged into an electrical outlet not containing a ground wire, the case of the instrument will become hot. An individual touching the hot case (point A) will receive a shock because he or she is standing on the earth (point B) and completes the circuit. The current (*dashed line*) will flow from the instrument through the individual touching the hot case.

**Figure 5-18** When a faulty piece of equipment containing an equipment ground wire is properly connected to an electrical outlet with a grounding connection, the current (*dashed line*) will preferentially flow down the low-resistance ground wire. An individual touching the case (point A) while standing on the ground (point B) will still complete the circuit; however, only a small part of the current will go through the individual.

## Electrical Power: Ungrounded

Numerous electronic devices, together with power cords and puddles of saline solutions on the floor, make the OR an electrically hazardous environment for both patients and personnel. Bruner et al.<sup>5</sup> found that 40% of electrical accidents in hospitals occurred in the OR. The complexity of electrical equipment in the modern OR demands that electrical safety be a factor of paramount importance. To provide an extra measure of safety from **5** macroshock, the power supplied to most ORs is ungrounded. In this ungrounded power system, the current is isolated from the ground potential. The 120-V potential difference exists only between the two wires of the isolated power system (IPS), but no circuit exists between the ground and either of the isolated power lines.

Supplying ungrounded power to the OR requires the use of an *isolation transformer* (Fig. 5-20). This device uses electromagnetic induction to induce a current in the ungrounded or secondary winding of the transformer from energy supplied to the primary winding. There is no direct electrical connection between the power supplied by the utility company on the primary side and the power induced by the transformer on the ungrounded or secondary side. Thus, the power supplied to the OR is isolated from the **3** ground (Fig. 5-21). Since the 120-V potential exists only between the two wires of the isolated circuit, neither wire is hot nor neutral with reference to ground. In this case, they are simply referred to as line 1 and line 2 (Fig. 5-22). Using the example of the light bulb, if one connects the two wires of the bulb socket to the two wires of the IPS, the light will illuminate. However, if one connects one of the wires to one side of the isolated power and the other wire to the ground, the light will not illuminate. If the wires of the IPS are connected, the short circuit will trip the circuit breaker. In comparing the two systems, the standard grounded power has a direct connection to ground, whereas the isolated system imposes a very high impedance to any current flow to ground. The added safety of this system can be seen in [Figure 5-23](#). In this case, a person has come in contact with one side of the IPS (point A). Since standing on the ground (point B) does not constitute a part of the isolated circuit, the individual does not complete the loop and will not receive a shock. This is because the ground is part of the primary circuit (*solid lines*), and the person is contacting only one side of the isolated secondary circuit (*cross-hatched lines*). The person does not complete either circuit (i.e., have two contact points); therefore, this situation does not pose an electric shock hazard. Of course, if the person contacts both lines of the IPS (an unlikely event), he or she would receive a shock.

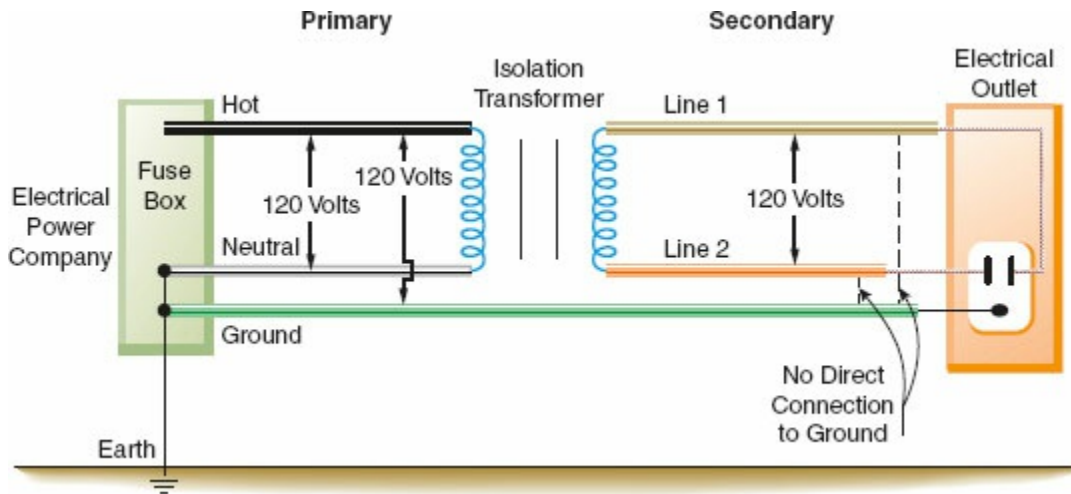

**Figure 5-19** **Right:** a “cheater plug” that converts a three-prong power cord to a two-prong cord. **Left:** The wire attached to the cheater plug is rarely connected to the screw in the middle of the outlet. This totally defeats the purpose of the equipment ground wire.

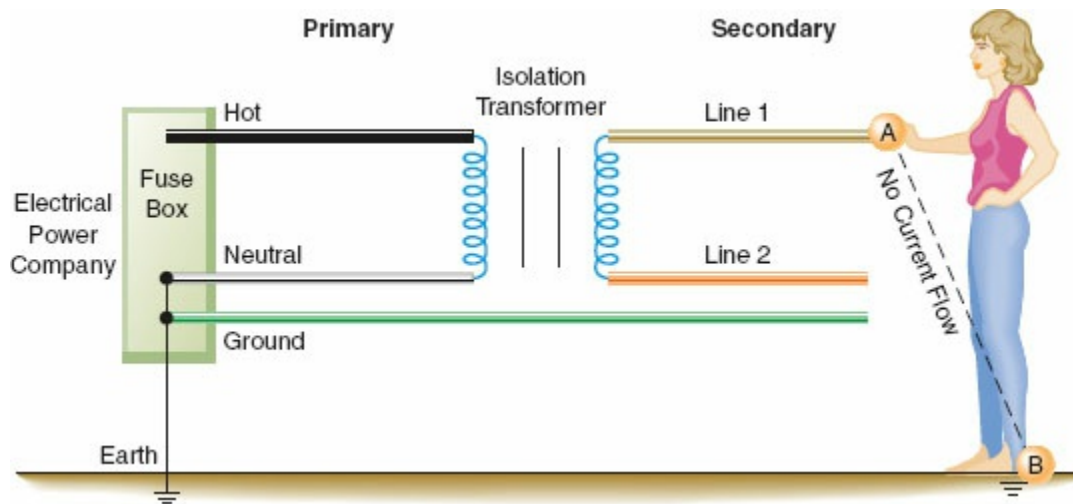

**Figure 5-20** **A:** Isolated power panel showing circuit breakers, LIM, and isolation transformer (*arrow*). **B:** Detail of an isolation transformer with the attached warning lights. The *arrow* points to ground wire connection on the primary side of the transformer. Note that no similar connection exists on the secondary side of the transformer.

**Figure 5-21** In the OR, the isolation transformer converts the grounded power on the primary side to an ungrounded power system on the secondary side of the transformer. A 120-V potential difference exists between line 1 and line 2. There is no direct connection from the power on the secondary side to ground. The equipment ground wire, however, is still present.

**Figure 5-22** Detail of the inside of a circuit breaker box in an isolated power system. The *bottom arrow* points to ground (*green*) wires meeting at the common ground terminal. *Arrows 1 and 2* indicate lines 1 and 2 (*orange and brown*) from the isolated power circuit breaker. Neither line 1 nor line 2 is connected to the same terminals as the ground wires. This is in marked contrast to [Figure 5-13](#), where the neutral and ground wires are attached at the same point.

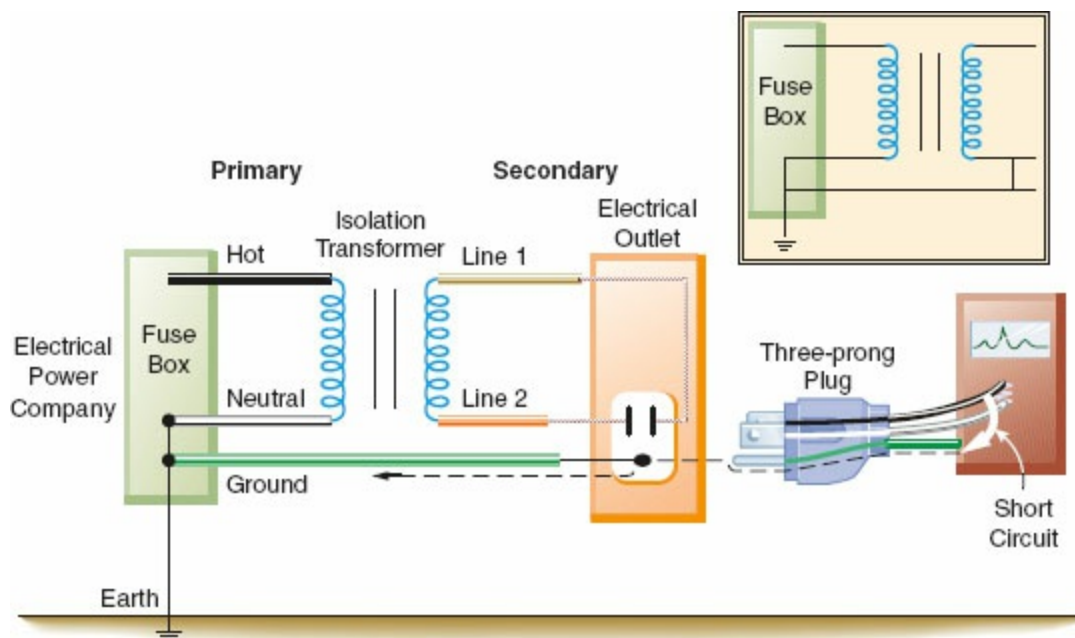

**Figure 5-23** A safety feature of the isolated power system is illustrated. An individual contacting one side of the isolated power system (point A) and standing on the ground (point B) will not receive a shock. In this instance, the individual is not contacting the circuit at two points and thus is not completing the circuit. Point A is part of the isolated power system, and point B is part of the primary or grounded side of the circuit.

If a faulty electrical appliance with an intact equipment ground wire is plugged into a standard household outlet, and the home wiring has a properly connected ground wire, then the amount of electrical current that will flow through the individual is considerably less than what will flow through the low-resistance ground wire. Here, an individual would be fairly well protected from a serious shock. However, if that ground wire were broken, the individual might receive a lethal shock. No shock would occur if the same faulty piece of equipment were plugged into the IPS, even if the equipment ground wire were broken. Thus, the IPS provides a significant amount of protection from macroshock. Another feature of the IPS is that the faulty piece of equipment, even though it may be partially short-circuited, will not usually trip the circuit breaker. This is an important feature because the faulty piece of equipment may be part of a life-support system for a patient. It is important to note that even though the power is isolated from ground, the case or frame of all electrical equipment is still connected to an equipment ground. The third wire (equipment ground wire) is necessary for a total electrical safety program.

**Figure 5-24** illustrates a scenario involving a faulty piece of equipment connected to the IPS. This does not represent a hazard; it merely converts the isolated power back to a grounded power system as exists outside the OR. In fact, a *second* fault is necessary to create a hazard.

The previous discussion assumes that the IPS is perfectly isolated from ground. Actually, perfect isolation is impossible to achieve. All AC-operated power systems and electrical devices manifest some degree of capacitance. As previously discussed, electrical power cords, wires, and electrical motors exhibit capacitive coupling to the ground wire and metal conduits and “leak”

small amounts of current to the ground (Fig. 5-25). This so-called *leakage current* partially ungrounds the IPS. This does not usually amount to more than a few milliamperes in an OR. So an individual coming in contact with one side of the IPS would receive only a very small shock (1 to 2 mA). Although this amount of current would be perceptible, it would not be dangerous.

**Figure 5-24** A faulty piece of equipment plugged into the isolated power system does not present a shock hazard. It merely converts the isolated power system into a grounded power system. The figure inset illustrates that the isolated power system is now identical to the grounded power system. The *dashed line* indicates current flow in the ground wire.

## The Line Isolation Monitor

**6** The *line isolation monitor* (LIM) is a device that continuously monitors the integrity of an IPS. If a faulty piece of equipment is connected to the IPS, this will, in effect, change the system back to a conventional grounded system. Also, the faulty piece of equipment will continue to function normally. Therefore, it is essential that a warning system be in place to alert the personnel that the power is no longer ungrounded. The LIM continuously monitors the isolated power to ensure that it is indeed isolated from ground, and the device has a meter that displays a continuous indication of the integrity of the system (Fig. 5-26). The LIM is actually measuring the impedance to the ground of each side of the IPS. As previously discussed, with perfect isolation, impedance would be infinitely high and there would be no current flow in the event of a first fault situation ( $Z = E/I$ ; if  $I = 0$ , then  $Z = \infty$ ). Because all AC wiring and all AC-operated electrical devices have

some capacitance, small leakage currents are present that partially degrade the isolation of the system. The meter of the LIM will indicate (in milliamperes) the total amount of leakage in the system resulting from capacitance, electrical wiring, and any devices plugged into the IPS.

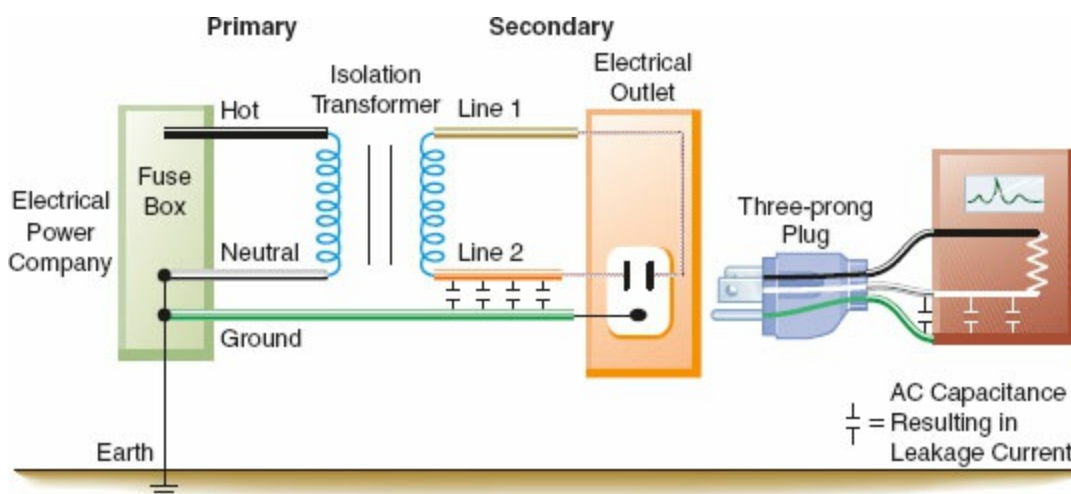

The reading on the LIM meter does not mean that current is actually flowing; rather, it indicates how much current would flow in the event of a first fault. The LIM is set to alarm at 2 or 5 mA, depending on the age and brand of the system. Once this preset limit is exceeded, visual and audible alarms are triggered to indicate that the isolation from the ground has been degraded beyond a predetermined limit (Fig. 5-27). This does not necessarily mean that there is a hazardous situation, but rather that the system is no longer totally isolated from ground. It would require a second fault to create a dangerous situation.

For example, if the LIM were set to alarm at 2 mA, using Ohm's law, the impedance for either side of the IPS would be 60,000 ohms:

$$Z = E/I$$

$$Z = (120 \text{ volts}) / (0.002 \text{ ampere})$$

$$Z = 60,000 \text{ ohms}$$

**Figure 5-25** The capacitance that exists in alternating current (AC) power lines and AC-operated equipment results in small “leakage currents” that partially degrade the isolated power system.

Therefore, if either side of the IPS had less than 60,000 ohms impedance to the ground, the LIM would trigger an alarm. This might occur in two situations. In the first situation, a faulty piece of equipment is plugged into the IPS. In this case, a true fault to ground exists from one line to ground. Now the system would be converted to the equivalent of a grounded power system. This faulty piece of equipment should be removed and serviced as soon as possible. However, this piece of equipment could still be used safely if it were essential for the care of the patient. It should be remembered,

however, that continuing to use this faulty piece of equipment would create the potential for a serious electrical shock. This would occur if a second faulty piece of equipment were simultaneously connected to the IPS.

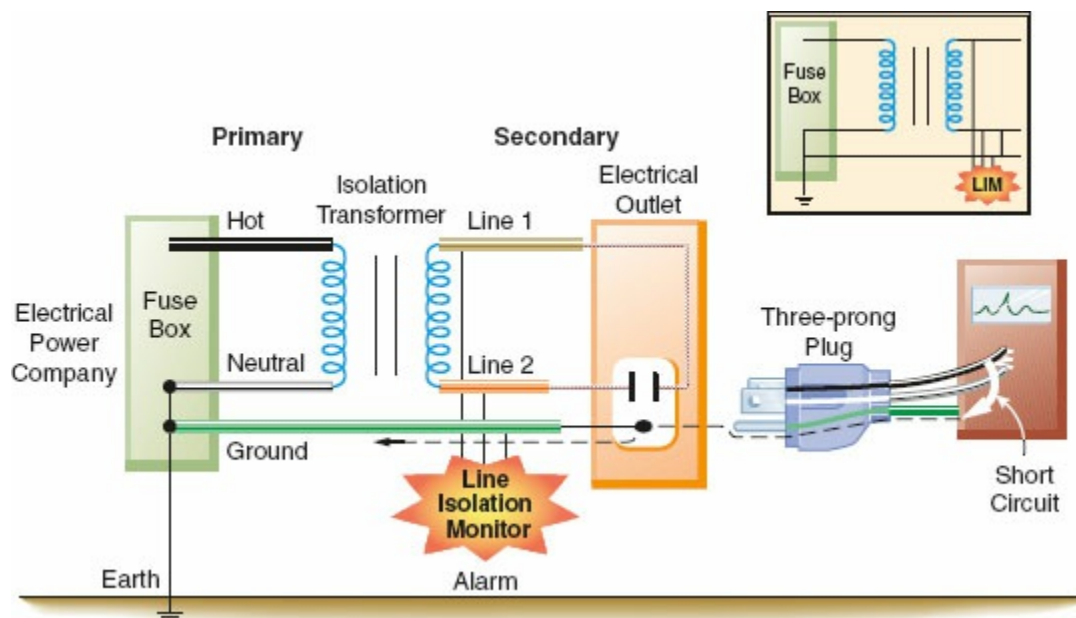

The second situation involves connecting many perfectly normal pieces of equipment to the IPS. Although each piece of equipment has only a small amount of leakage current, if the total leakage exceeds 2 mA, the LIM will trigger an alarm. Assume that in the same OR there are 30 electrical devices, each having 100  $\mu$ A of leakage current. The total leakage current ( $30 \times 100 \mu\text{A}$ ) would be 3 mA. The impedance to ground would still be 40,000 ohms ( $120/0.003$ ). The LIM alarm would sound because the 2 mA set point was violated. However, the system is still safe and represents a state significantly different from that in the first situation. For this reason, the newer LIMs are set to alarm at 5 mA instead of 2 mA.

The newest LIMs are referred to as *third-generation monitors*. The first-generation monitor, or static LIM, was unable to detect balanced faults (i.e., a situation in which there are equal faults to ground from both line 1 and line 2). The second-generation, or dynamic, LIM did not have this problem but could interfere with physiologic monitoring. Both of these monitors would trigger an alarm at 2 mA, which led to annoying “false” alarms. The third-generation LIM corrects the problems of its predecessors and has the alarm threshold set at 5 mA.<sup>6</sup> Proper functioning of the LIM depends on having both intact equipment ground wires as well as its own connection to ground. First- and second-generation LIMs could not detect the loss of the LIM ground connection. The third-generation LIM can detect this loss of ground to the monitor. In this case the LIM alarm would sound and the red hazard light would illuminate, but the LIM meter would read zero. This condition will alert the staff that the LIM needs to be repaired. However, the LIM still cannot detect broken equipment ground wires. An example of the third-generation LIM is the *Iso-Gard* made by the Square D Company (Monroe, NC).

The equipment ground wire is again an important part of the safety system. If this wire is broken, a faulty piece of equipment that is plugged into an outlet would operate normally, but the LIM would not alarm. A second fault could therefore cause a shock, without any alarm from the LIM. Also, in the event of a second fault, the equipment ground wire provides a low-resistance path to ground for most of the fault current (Fig. 5-24). The LIM will only be able to register leakage currents from pieces of equipment that are connected to the IPS and have intact ground wires.

**Figure 5-26** The meter of the LIM is calibrated in milliamperes. If the isolation of the power system is degraded such that more than 2 mA (5 mA in newer systems) of current could flow, the hazard light will illuminate and a warning buzzer will sound. Note the button for testing the hazard warning system. **A:** Older LIM that will trigger an alarm at 2 mA. **B:** Newer LIM that will trigger an alarm at 5 mA. **C:** The LIM alarm is triggered, and the red hazard stripe is illuminated, and the number on the right shows 9.9 mA of potential current flow.

**Figure 5-27** When a faulty piece of equipment is plugged into the isolated power system, it will markedly decrease the impedance from line 1 or line 2 to ground. This will be detected by the line isolation monitor (LIM), which will sound an alarm.

If the LIM alarm is triggered, the first thing to do is to check the gauge to determine if it is a true fault. The other possibility is that too many pieces of electrical equipment have been plugged in and the 2 mA limit has been exceeded. If the gauge is between 2 and 5 mA, it is probable that too much electrical equipment has been plugged in. If the gauge reads greater than 5 mA, most likely there is a faulty piece of equipment present in the OR. The next step is to identify the faulty equipment, which is done by unplugging each piece of equipment until the alarm ceases. If the faulty piece of equipment is not of a life-support nature, it should be removed from the OR. If it is a vital piece of life-support equipment, it can be safely used. (Note: If a critical piece of life support equipment—like the cardio-pulmonary bypass machine—is suspected as causing the alarm, do not disconnect it until it is no longer needed.) However, it must be remembered that the protection of the IPS and the LIM is no longer operative. Therefore, if possible, no other electrical equipment should be connected during the remainder of the case, or until the faulty piece of equipment can be safely removed.

## Ground Fault Circuit Interrupter

**7** The ground fault circuit interrupter (GFCI, or occasionally abbreviated as GFI) is another popular device used to prevent individuals from receiving an electrical shock in a grounded power system. Electrical codes for most new construction require that a GFCI circuit be present in potentially hazardous (e.g., wet) areas such as bathrooms, kitchens, or outdoor electrical outlets. The GFCI may be installed as an individual power outlet (Fig. 5-28) or may

be a special circuit breaker to which all the individual protected outlets are connected at a single point. The special GFCI circuit breaker is located in the main fuse/circuit breaker box and can be distinguished by its red test button (Fig. 5-29). As Figure 5-5 demonstrates, the current flowing in both the hot and neutral wires is usually equal. The GFCI monitors both sides of the circuit for the equality of current flow; if a difference is detected, the power is immediately interrupted. If an individual should contact a faulty piece of equipment such that current flowed through the individual, an imbalance between the two sides of the circuit would be created, which would be detected by the GFCI. Since the GFCI can detect very small current differences (in the range of 5 mA), the GFCI will open the circuit in a few milliseconds, thereby interrupting the current flow before a significant shock occurs. Thus, the GFCI provides a high level of protection at a very modest cost. If the OR has a GFCI that tripped, then one should first attempt to reset it by pushing the reset button. This is because a surge may have caused the GFCI to trip. If it cannot be reset, then the equipment must be removed from service and checked by the biomedical engineering staff. It is essential that when GFCIs are used in an OR, only one outlet be protected by each GFCI. They should never be “daisy-chained,” so that one GFCI protects multiple outlets. This was illustrated in a report by Courtney et al.<sup>7</sup> when they lost all power to their monitors and the anesthesia machine. The cause was a power cord to a warming blanket that got pinched in the OR table causing a short circuit. The GFCI tripped and shut off the power to the warming blanket. However, that GFCI also controlled the outlets where the anesthesia machine and monitors were connected.

**Figure 5-28** A GFCI electrical outlet with integrated test (*black*) and reset (*red*) buttons.

**Figure 5-29** Special GFCI circuit breaker. The *arrowhead* points to the distinguishing red test button.

The disadvantage of using a GFCI in the OR is that it interrupts the power without warning. A defective piece of equipment could no longer be used, which might be a problem if it were of a life-support nature, whereas if the same faulty piece of equipment were plugged into an IPS, the LIM would alarm but the equipment could still be used.

## Double Insulation

There is one instance in which it is acceptable for a piece of equipment to have only a two-prong and not a three-prong plug. This is permitted when the instrument has what is termed *double insulation*. These instruments have two layers of insulation and usually have a plastic exterior. Double insulation is found in many home power tools and is seen in hospital equipment such as infusion pumps. Double-insulated equipment is permissible in the OR with IPSs. However, if water or saline should get inside the unit, there could be a hazard because the double insulation is bypassed. This is even more serious if the OR has no isolated power or GFCIs.<sup>8</sup>

**Figure 5-30** The electrically susceptible patient is protected from microshock by the presence of an intact equipment ground wire. The equipment ground wire provides a low-impedance path in which the majority of the leakage current (*dashed lines*) can flow. R, resistance.

## Microshock

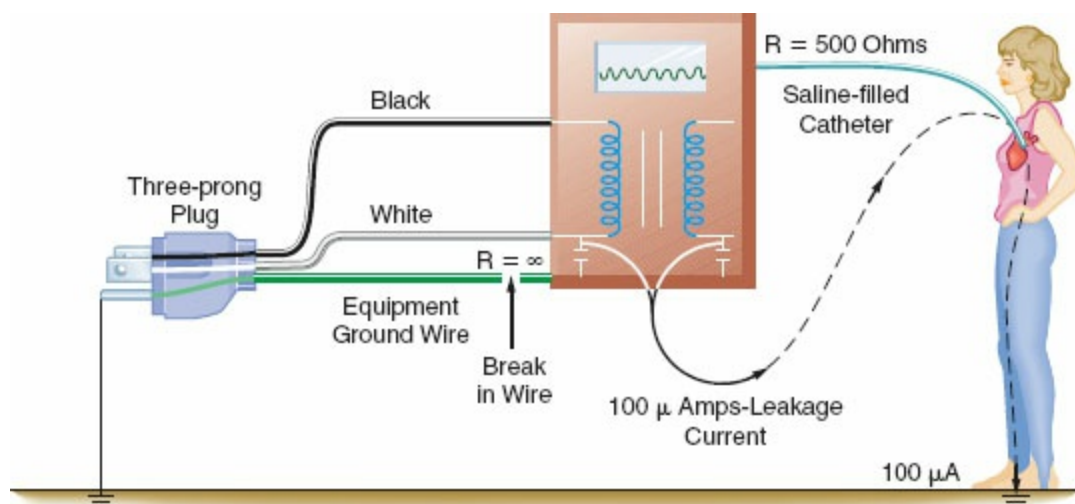

As previously discussed, macroshock involves relatively large amounts of current applied to the surface of the body. The current is conducted through all the tissues in proportion to their conductivity and area in a plane perpendicular to the current. Consequently, the “density” of the current (amperes per meter squared) that reaches the heart is considerably less than what is applied to the body surface. However, an electrically susceptible patient (i.e., one who has a direct, external connection to the heart, such as through a central venous pressure catheter or transvenous cardiac pacing wires) may be at risk from very small currents; this is called *microshock*.<sup>9</sup> The catheter orifice or electrical wire with a very small surface area in contact with the heart produces a relatively large current density at the heart.<sup>10</sup> Stated another way, even very small amounts of current applied directly to the myocardium will cause ventricular fibrillation. Microshock is a particularly difficult problem because of the insidious nature of the hazard.

In the electrically susceptible patient, ventricular fibrillation can be produced by a current that is below the threshold of human perception. The exact amount of current necessary to cause ventricular fibrillation in this type of patient is unknown. Whalen et al.<sup>11</sup> were able to produce fibrillation with 20 μA of current applied directly to the myocardium of dogs. Raftery et al.<sup>12</sup> produced fibrillation with 80 μA of current in some patients. Hull<sup>13</sup> used data obtained by Watson et al.<sup>14</sup> to show that 50% of patients would fibrillate at currents of 200 μA. Since 1,000 μA (1 mA) is generally regarded as the threshold of human perception with 60-Hz AC, the electrically susceptible patient can be electrocuted with one-tenth the normally perceptible currents.

This is not only of academic interest but also of practical concern because many cases of ventricular fibrillation from microshock have been reported.<sup>15-19</sup>

The stray capacitance that is part of any AC-powered electrical instrument may result in significant amounts of charge buildup on the case of the instrument. If an individual simultaneously touches the case of an instrument where this has occurred and the electrically susceptible patient, he or she may unknowingly cause a discharge to the patient that results in ventricular fibrillation. Once again, the equipment ground wire constitutes the major source of protection against microshock for the electrically susceptible patient. In this case, the equipment ground wire provides a low-resistance path by which most of the leakage current is dissipated instead of stored as a charge.

Figure 5-30 illustrates a situation involving a patient with a saline-filled catheter in the heart with a resistance of approximately 500 ohms. The ground wire with a resistance of 1 ohm is connected to the instrument case. A leakage current of 100  $\mu\text{A}$  will divide according to the relative resistances of the two paths. In this case, 99.8  $\mu\text{A}$  will flow through the equipment ground wire and only 0.2  $\mu\text{A}$  will flow through the fluid-filled catheter. This extremely small current does not endanger the patient. However, if the equipment ground wire were broken, the electrically susceptible patient would be at great risk because all 100  $\mu\text{A}$  of leakage current could flow through the catheter and cause ventricular fibrillation (Fig. 5-31). Currently, electronic equipment is permitted 100  $\mu\text{A}$  of leakage current.

**Figure 5-31** A broken equipment ground wire results in a significant hazard to the electrically susceptible patient. In this case, the entire leakage current can be conducted to the heart and may result in ventricular fibrillation. R, resistance.

Modern patient monitors incorporate another mechanism to reduce the risk of microshock for electrically susceptible patients.<sup>20</sup> This mechanism

involves electrically isolating all direct patient connections from the power supply of the monitor by placing a very high impedance between the patient and any device. This limits the amount of internal leakage through the patient connection to a very small value. The standard currently is less than 10  $\mu\text{A}$ . For instance, the output of an ECG monitor's power supply is electrically isolated from the patient by placing a very high impedance between the monitor and the patient's ECG leads.<sup>21</sup> Isolation techniques are designed to inhibit hazardous electrical pathways between the patient and the monitor while allowing the passage of the physiologic signal.

An intact equipment ground wire is probably the most important factor in preventing microshock. There are, however, other things that the anesthesiologist can do to reduce the incidence of microshock. One should never simultaneously touch an electrical device and a saline-filled central catheter or external pacing wires. Whenever one is handling a central catheter or pacing wires, it is best to insulate oneself by wearing rubber gloves. Also, one should never let any external current source, such as a nerve stimulator, come into contact with the catheter or wires. Finally, one should be alert to potential sources of energy that can be transmitted to the patient. Even stray radiofrequency current from the ESU (cautery) can, with the right conditions, be a source of microshock.<sup>22</sup> It must be remembered that the LIM is not designed to provide protection from microshock. The microampere currents involved in microshock are far below the LIM threshold of protection. In addition, the LIM does not register the leakage of individual monitors, but rather indicates the status of the total system. The LIM reading indicates the total amount of leakage current resulting from the entire capacitance of the system. This is the amount of current that would flow to ground in the event of a first-fault situation.

The essence of electrical safety is a thorough understanding of all the principles of grounding. The objective of electrical safety is to make it difficult for electrical current to pass through people. For this reason, both the patient and the anesthesiologist should be isolated from ground as much as possible. That is, their resistance to current flow should be as high as is technologically feasible. In the inherently unsafe electrical environment of an OR, several measures can be taken to help protect against contacting hazardous current flows. First, the grounded power provided by the utility company can be converted to ungrounded power by means of an isolation transformer. The LIM will continuously monitor the status of this isolation from ground and warn that the isolation of the power (from ground) has been lost in the event that a defective piece of equipment is plugged into one of the isolated circuit outlets. In addition, the shock that an individual could receive from a faulty piece of equipment is determined by the capacitance of the system and is limited to a few milliamperes. Second, all equipment plugged

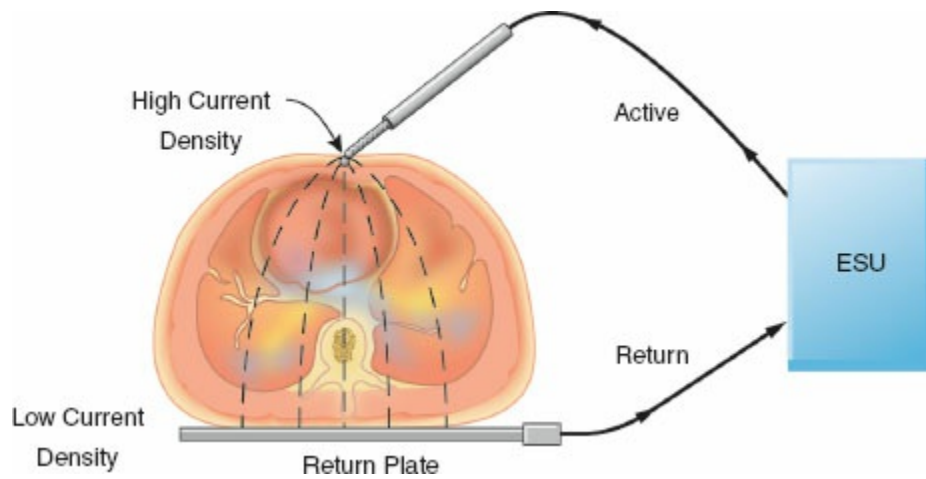

into the IPS has an equipment ground wire that is attached to the case of the instrument. This equipment ground wire provides an alternative low-resistance pathway enabling potentially dangerous currents to flow to ground. Thus, the patient and the anesthesiologist should be as insulated from ground as possible and all electrical equipment should be grounded.

The equipment ground wire serves three functions. First, it provides a low-resistance path for fault currents to reduce the risk of macroshock. Second, it dissipates leakage currents that are potentially harmful to the electrically susceptible patient. Third, it provides information to the LIM on the status of the ungrounded power system. If the equipment ground wire is broken, a significant factor in the prevention of electrical shock is lost. In addition, the IPS will appear safer than it actually is because the LIM is unable to detect broken equipment ground wires.

Because power cord plugs and receptacles are subjected to greater abuse in the hospital than in the home, the Underwriters Laboratories (Melville, NY) has issued a strict specification for special “hospital-grade” plugs and receptacles (Fig. 5-32). The plugs and receptacles that conform to this specification are marked by a green dot.<sup>23</sup> The hospital-grade plug is one that can be visually inspected or easily disassembled to ensure the integrity of the ground wire connection. Molded opaque plugs are not acceptable. Edwards<sup>24</sup> reported that of 3,000 non-hospital-grade receptacles installed in a new hospital building, 1,800 (60%) were defective after 3 years. When 2,000 of the non-hospital-grade receptacles were replaced with ones of hospital grade, no failures occurred after 18 months of use.

**Figure 5-32** **A:** A hospital-grade plug that can be visually inspected. The *arrow* points to the equipment ground wire whose integrity can be readily verified. Note that the prong for the ground wire (*arrow*) is longer than the hot or neutral prong, so that it is the first to enter the receptacle. **B:** The *arrows* point to the green dot denoting a hospital-grade power outlet. The red outlet on the right is connected to the emergency power (generator) system.

**Figure 5-33** A properly applied electrocautery unit (ESU) return plate. The current density at the return plate is low, resulting in no danger to the patient.

## Electrosurgery

On that fateful October day in 1926 when Dr. Harvey W. Cushing first used an ESU machine invented by Professor William T. Bovie to resect a brain tumor, the course of modern surgery and anesthesia was forever altered.<sup>25</sup> The ubiquitous use of electrosurgery attests to the success of Professor Bovie's invention. However, this technology was not adopted without a cost. The widespread use of electrocautery has, at the very least, hastened the elimination of explosive anesthetic agents from the OR. In addition, as every anesthesiologist is aware, few things in the OR are immune to interference from the "Bovie." The high-frequency electrical energy generated by the ESU interferes with everything from the ECG signal to CO computers, pulse oximeters, and even implanted cardiac pacemakers.<sup>26</sup>

The ESU operates by generating very-high-frequency currents (radiofrequency range) of anywhere from 500,000 to 1 million Hz. These currents pass through tissue, and heat is created by the resistance of the tissues to current flow. The amount of heat ( $H$ ) produced is proportional to the square of the current and inversely proportional to the area through which the current passes ( $H = I^2/A$ ).<sup>27</sup> By concentrating the energy at the tip of the "Bovie pencil," the surgeon can produce either a cut or a coagulation at any given spot. This very-high-frequency current behaves differently from the standard 60-Hz AC current and can pass directly across the precordium without causing ventricular fibrillation.<sup>27</sup> This is because high-frequency currents have a low tissue penetration and do not excite contractile cells.

The term electrocautery is often mistakenly used interchangeably with electrosurgery. Electrocautery is usually a small, hand held, battery operated device that uses an electrical current to heat a metal wire. The heated wire is then applied directly to the tissue to achieve a desired effect.

Although the ESU is used safely hundreds of thousands of times each year,

there is evidence that under certain circumstances it has been the cause of ventricular fibrillation.<sup>28-31</sup> The mechanism is thought to be low frequency (50 to 60 Hz) “stray current” that is generated when the ESU is activated. Current in the 50- to 60-Hz range can cause ventricular fibrillation. These cases have been associated with the use of the coagulation mode, when the surgeon is using the device near the heart, and when the patient has a conductor in the heart such as a CVP or pulmonary artery catheter. However, the exact mechanism has not been elucidated.

The large amount of energy generated by the ESU can pose other problems to the operator and the patient. Dr. Cushing became aware of one such problem. He wrote, “Once the operator received a shock which passed through a metal retractor to his arm and out by a wire from his headlight, which was unpleasant to say the least.”<sup>32</sup> The ESU cannot be safely operated unless the energy is properly routed from the ESU through the patient and back to the unit. Ideally, the current generated by the active electrode is concentrated at the ESU tip, constituting a very small surface area. This energy has a high current density and is able to generate enough heat to produce a therapeutic cut or coagulation. The energy then passes through the patient to a dispersive electrode of large surface area that returns the energy safely to the ESU (Fig. 5-33).

One unfortunate quirk in terminology concerns the return (dispersive) plate of the ESU. This plate, often incorrectly referred to as a *ground plate*, is actually a dispersive electrode of large surface area that safely returns the generated energy to the ESU via a low current density pathway. When inquiring whether the dispersive electrode has been attached to the patient, OR personnel frequently ask, “Is the patient grounded?” As the aim of electrical safety is to isolate the patient from the ground, this expression is worse than erroneous; it can lead to confusion. Because the area of the return plate is large, the current density is low; therefore, no harmful heat is generated and no tissue destruction occurs. In a properly functioning system, the only tissue effect is at the site of the active electrode that is held by the surgeon.

Problems can arise if the electrosurgical return plate is improperly applied to the patient or if the cord connecting the return plate to the ESU is damaged or broken. In these instances, the high-frequency current generated by the ESU will seek an alternate return pathway. Anything attached to the patient, such as ECG leads or a temperature probe, can provide this alternate return pathway. The current density at the ECG pad will be considerably higher than normal because its surface area is much less than that of the ESU return plate. This may result in a serious burn at this alternate return site. Similarly, a burn may occur at the site of the ESU return plate if it is not properly applied to the patient or if it

9

becomes partially dislodged during the operation (Fig. 5-34). This is not merely a theoretical possibility but is evidenced by the numerous case reports involving patients who have received ESU burns.<sup>33-39</sup>

The original ESUs were manufactured with the power supply connected directly to the ground by the equipment ground wire. These devices made it extremely easy for ESU current to return by alternate pathways. The ESU would continue to operate normally even without the return plate connected to the patient. In most modern ESUs, the power supply is isolated from ground to protect the patient from burns.<sup>40</sup> It was hoped that by isolating the return pathway from ground, the only route for current flow would be via the return electrode. Theoretically, this would eliminate alternate return pathways and greatly reduce the incidence of burns. However, Mitchell<sup>41</sup> found two situations in which the current could return via alternate pathways, even with the isolated ESU circuit. If the return plate were left either on top of an uninsulated ESU cabinet or in contact with the bottom of the OR table, then the ESU could operate fairly normally and the current would return via alternate pathways. It will be recalled that the impedance is inversely proportional to the capacitance times the current frequency. The ESU operates at 500,000 to more than 1,000,000 Hz, which greatly enhances the effect of capacitive coupling and causes a marked reduction in impedance. Therefore, even with isolated ESUs, the decrease in impedance allows the current to return to the ESU by alternate pathways. In addition, the isolated ESU does not protect the patient from burns if the return electrode does not make proper contact with the patient. Although the isolated ESU does provide additional patient safety, it is by no means foolproof protection against the patient receiving a burn.

**Figure 5-34** An improperly applied electrosurgical unit (ESU) return plate. Poor contact with the return plate results in a high current density and a possible burn to the patient.

Preventing patient burns from the ESU is the responsibility of all professional staff in the OR. Not only the circulating nurse, but also the

surgeon and the anesthesiologist must be aware of proper techniques and be vigilant to potential problems. The most important factor is the proper application of the return plate. It is essential that the return plate has the appropriate amount of electrolyte gel and an intact return wire. Reusable return plates must be properly cleaned after each use, and disposable plates must be checked to ensure that the electrolyte has not dried out during storage. In addition, it is prudent to place the return plate as close as possible to the site of the operation. ECG pads should be placed as far from the site of the operation as is feasible. OR personnel must be alert to the possibility that pools of flammable “prep” solutions such as alcohol and acetone can ignite when the ESU is used. If the ESU must be used on a patient with a demand pacemaker, the return electrode should be located below the thorax, and preparations for treating potential dysrhythmias should be available, including a magnet to convert the pacemaker to a fixed rate, a defibrillator, and an external pacemaker. It is best to keep the pacemaker out of the path between the surgical site and the dispersal plate.

The ESU has also caused other problems in patients with pacemakers, including reprogramming and microshock.<sup>42,43</sup> If the surgeon requests higher than normal power settings on the ESU, this should alert both the circulating nurse and the anesthesiologist to a potential problem. The return plate and cable must be immediately inspected to ensure that it is functioning and properly positioned. If this does not correct the problem, the return plate should be replaced.<sup>44,45</sup> If the problem remains, the entire ESU should be taken out of service. Finally, an ESU that is dropped or damaged must be removed immediately from the OR and thoroughly tested by a qualified biomedical engineer. Following these simple safety steps will prevent most patient burns from the ESU.

The previous discussion concerned only *unipolar* ESUs. There is a second type of ESU, in which the current passes only between the two blades of a pair of forceps. This type of device is referred to as a *bipolar* ESU. Because the active and return electrodes are the two blades of the forceps, it is not necessary to attach another dispersive electrode to the patient, unless a unipolar ESU is also being used. The bipolar ESU generates considerably less power than the unipolar and is mainly used for ophthalmic and neurologic surgery.

In 1980, Mirowski et al.<sup>46</sup> reported the first human implantation of a device to treat intractable ventricular tachydysrhythmias. This device, known as the *automatic implantable cardioverter-defibrillator* (AICD), is capable of sensing ventricular tachycardia and ventricular fibrillation and then automatically defibrillating the patient. Since 1980, thousands of patients have received AICD implants.<sup>47,48</sup> Because some of these patients may present for noncardiac surgery, it is important that the anesthesiologist be aware of

potential problems.<sup>47</sup> The use of a unipolar ESU may cause electrical interference that could be interpreted by the AICD as a ventricular tachydysrhythmia. This would trigger a defibrillation pulse to be delivered to the patient and would likely cause an actual episode of ventricular tachycardia or ventricular fibrillation. The patient with an AICD is also at risk for ventricular fibrillation during electroconvulsive therapy.<sup>49</sup> In both cases, the AICD should be disabled by placing a magnet over the device or by use of a specific protocol to shut it off. Therefore, it is best to consult with someone experienced with the device before starting surgery. The device can be reactivated by reversing the process. Also, an external defibrillator and a noninvasive pacemaker should be in the OR whenever a patient with an AICD is anesthetized.

Electrical safety in the OR is a matter of combining common sense with some basic principles of electricity. Once OR personnel understand the importance of safe electrical practice, they are able to develop a heightened awareness to potential problems. All electrical equipment must undergo routine maintenance, service, and inspection to ensure that it conforms to designated electrical safety standards. Records of these test results must be kept for future inspection because human error can easily compound electrical hazards. Starmer et al.<sup>50</sup> cited one case concerning a newly constructed laboratory where the ground wire was not attached to a receptacle. In another study, Albisser et al.<sup>51</sup> found a 14% (198/1,424) incidence of improperly or incorrectly wired outlets. Furthermore, potentially hazardous situations should be recognized and corrected before they become a problem. For instance, electrical power cords are frequently placed on the floor where they can be crushed by various carts or the anesthesia machine. These cords could be located overhead or placed in an area of low traffic flow. Multiple-plug extension boxes should not be left on the floor where they can come in contact with electrolyte solutions. These could easily be mounted on a cart or the anesthesia machine. Pieces of equipment that have been damaged or have obvious defects in the power cord must not be used until they have been properly repaired. If everyone is aware of what constitutes a potential hazard, dangerous situations can be prevented with minimal effort.

Sparks generated by the ESU may provide the ignition source for a fire with resulting burns to the patient and OR personnel. This is a particular risk when the ESU is used in an oxygen-enriched environment as may be present in the patient's airway or in close proximity to the patient's face. The administration of high-flow nasal oxygen to a sedated patient during procedures on the face and eye is particularly hazardous. Most plastics such as tracheal tubes and components of the anesthetic breathing system that would not burn in room air will ignite in the presence of oxygen and/or nitrous oxide. Tenting of the drapes to allow dispersion of any accumulated oxygen

and/or its dilution by room air will decrease the risk of ignition from a spark generated by a nearby ESU. The risk of fire can also be reduced by use of a circle anesthesia breathing system with minimal to no leak of gases around the anesthesia mask.

### **Conductive Flooring**

In past years, conductive flooring was mandated for ORs where flammable anesthetic agents were being administered. This would minimize the buildup of static charges that could cause a flammable anesthetic agent to ignite. The standards have now been changed to eliminate the necessity for conductive flooring in anesthetizing areas where flammable agents are no longer used.

### **Environmental Hazards**

There are a number of potential electrically related hazards in the OR that are of concern to the anesthesiologist. There is the potential for electrical shock not only to the patient but also to OR personnel. In addition, cables and power cords to electrical equipment and monitoring devices can become hazardous. Finally, all OR personnel should have a plan of what to do in the event of a power failure.

In today's OR, there are literally dozens of pieces of electrical equipment. It is not uncommon to have numerous power cords lying on the floor, where they are vulnerable to damage. If the insulation on the power cable becomes damaged, it is fairly easy for the hot wire to come in contact with a piece of metal equipment. If the OR does not have isolated power, that piece of equipment would become energized and be a potential electrical shock hazard.<sup>52</sup> Having isolated power minimizes the risk to the patient and OR personnel. Clearly, getting electrical power cords off the floor is desirable. This can be accomplished by having electrical outlets in the ceiling or by having ceiling-mounted articulated arms that contain electrical outlets. Also, the use of multioutlet extension boxes that sit on the floor can be hazardous and should be avoided. These can be contaminated with fluids, which could easily trip the circuit breaker. In one case, it apparently tripped the main circuit breaker for the entire OR, resulting in a loss of all electrical power except for the overhead lights.<sup>53</sup>

Modern monitoring devices have many safety features incorporated into them. Virtually all of them have isolated the patient input from the power supply of the device. This is frequently done with optocoupler isolation circuits, which transfer electrical signals by utilizing light waves. This was an important feature that was lacking from the original ECG monitors. In the early days, patients could actually become part of the electrical circuit of the

monitor. There have been relatively few problems with patients and monitoring devices since the advent of isolated inputs. However, between 1985 and 1994, the Food and Drug Administration (FDA) received approximately 24 reports in which infants and children had received an electrical shock (including five children who died by electrocution).<sup>54,55</sup> These electrical accidents occurred because the electrode lead wires from either an ECG monitor or an apnea monitor were plugged directly into a 120-V electrical outlet instead of the appropriate patient cable. In 1997, the FDA issued a new performance standard for electrode lead wires and patient cables that requires that the exposed male connector pins from the electrode lead wires be eliminated. Therefore, the lead wires must have female connections and the connector pins must be housed in a protected patient cable (Fig. 5-35). This effectively eliminates the possibility of the patient being connected directly to an AC source since there are no exposed connector pins on the lead wires.

All health-care facilities are required to have a source of emergency power. This generally consists of one or more electrical generators. These generators are configured to start up automatically and provide power to the facility within 10 seconds after detecting the loss of power from the utility company. The facility is required to test these generators on a regular basis. However, in the past, not all health-care facilities tested them under actual load. There are numerous anecdotal reports of generators not functioning properly during an actual power failure. If the generators are not tested under actual load, it is possible that many years will pass before a real power outage puts a severe demand on the generator. If the facility has several generators and one of them fails, the increased demand on the others may be enough to cause them to fail in rapid succession.<sup>56</sup> Hospitals (under the current National Fire Protection Association [NFPA] 99 standards) must test their emergency power supply systems (generators) under connected load once a month for at least 30 minutes. If the generator is oversized for the application and cannot be loaded to at least 30% of its rating, it must be load-banked and run for a total of 2 hours every year. A fairly recent requirement is for emergency power supply systems to be tested once every 3 years for 4 continuous hours, with a recommendation that this be performed during peak usage of the system.<sup>57,58</sup>

**Figure 5-35** The current standard for patient lead wires (**top**) requires a female connector. The patient cable (**bottom**) has shielded connector pins that the lead wires plug into.

Although all hospitals are required to have emergency generators to power essential equipment in the event of a power failure, these generators do not function in every circumstance. If there is a loss of power from the electrical utility, then this is detected by a relay switch, which in turn causes a series of events to activate the transfer of the power generation to the backup system. This usually happens seamlessly. However, if the transfer switch or the generator fails, then there will be no backup electricity.

Another cause of partial or total power failure has to do with construction mishaps.<sup>56</sup> As hospitals frequently remodel, add new wings, or upgrade existing facilities, there is always a chance that the power will be accidentally interrupted. This may be due to a worker tripping a GFI, a relay failure that caused a power transfer to a nonworking generator, or a fire in the electrical vault of the hospital.<sup>59-61</sup> Since the electrical utility is still supplying power, the generators may not be activated.

The causes of a power failure are numerous. Local events can usually be corrected in a few hours. However, the effects of a natural disaster can be devastating. A hospital may have to operate on emergency power for days or even several weeks. If the power cannot be restored in a reasonable time frame, some or all of the patients may have to be evacuated.

Some disasters, like a hurricane will allow the hospital several days to prepare. However, a tornado or an earthquake will strike without warning. OR managers need to know what equipment will operate on emergency power. While the ventilation system will usually be powered by the generators, the air conditioning systems may not operate. This can be devastating on hot humid summer days. How long will the generators operate? Two days is a minimum, but is there fuel for them to run longer?<sup>62</sup>

During a major hurricane and the flood that followed, a major New York City hospital had its generators safely located on an upper level. However, the fuel pumps for the generators were located in the basement which flooded, and left the hospital with no emergency power.

It is vitally important that each OR has a contingency plan for a power failure. There should be a supply of battery-operated light sources available in each OR. A laryngoscope can serve as a readily available source of light that allows one to find flashlights and other pieces of equipment. The overhead lights in the OR should also be connected to some sort of battery-operated lighting system. Traditional anesthesia machines have a backup battery that will last 30 to 60 minutes. If the power failure lasts longer than that, the anesthesiologist must make plans on how to continue the anesthetic. The newer electronic machines may be more problematic than older traditional machines, since they may have electronic gas or vaporization systems. The department should have a supply of battery-powered monitors, but it is unlikely that there will be enough for every OR. Syringe pumps typically have a battery, and BPs can be taken with a manual sphygmomanometer. Since many ORs employ automated drug dispensing systems, these devices will not work without power and a communication link to the hospital information system.

Modern anesthesia workstations are heavily dependent on electrical power to function properly. Therefore, all have a battery backup system. Typically, these batteries can power the workstation for 1 to 2 hours. Once the battery is exhausted, only basic functions are available to the anesthesiologist. This would include emergency oxygen which can be used with a conventional vaporizer to provide inhalational anesthesia. However, the Desflurane Tec 6 vaporizer and many of the newer electronic vaporizers cannot deliver anesthetic agent without electrical power. The Arkon Workstation (Spacelabs Healthcare, Snoqualmie, WA) has a unique feature. The workstation has the capability to hold up to 4 batteries which extend the usable function up to 4 hours. These batteries can be easily added or changed by the user during a power failure.

In reality, the backup generators will usually supply power in the event of an emergency. However, there are many circumstances where the hospital can experience partial or total power loss. The cost of these contingencies is relatively small but the benefits can be incomparable in an emergency.

## **Electromagnetic Interference**

Rapid advances in technology have led to an explosion in the number of wireless communication devices in the marketplace. These devices include cellular telephones, cordless telephones, walkie-talkies, and wireless Internet

access devices. All of these devices have something in common: They emit electromagnetic interference (EMI). This most commonly manifests itself when traveling on airplanes. Most airlines require that these devices be turned off when the plane is taking off or landing or, in some cases, during the entire flight. There is concern that the EMI emitted by these devices may interfere with the plane's navigation and communication equipment.

In recent years, the number of people who own these devices has increased exponentially. Indeed, in some hospitals, they form a vital link in the regular or emergency communication system. It is not uncommon for physicians, nurses, paramedics, and other personnel to have their own cellular telephones. In addition, patients and visitors may also have cellular telephones and other types of communication devices. Hospital maintenance and security personnel frequently have walkie-talkie-type radios and some hospitals have even instituted an in-house cellular telephone network that augments or replaces the paging system. There has been concern that the EMI emitted by these devices may interfere with implanted pacemakers or various types of monitoring devices and ventilators in critical care areas.<sup>63</sup> One case of a patient death has been reported when a ventilator malfunctioned secondary to EMI.<sup>64</sup>

Several studies have been done to find out if cellular telephones cause problems with cardiac pacemakers. One report by Hayes et al.<sup>65</sup> studied 980 patients with five different types of cellular telephones. They conducted more than 5,000 tests and found that in more than 20% of the cases they could detect some interference from the cellular telephone. Patients were symptomatic in 7.2% of the cases, and clinically significant interference occurred in 6.6% of the cases. When the telephone was held in the normal position over the ear, clinically significant interference was not detected. In fact, the interference that caused clinical symptoms occurred only if the telephone was directly over the pacemaker. Other studies have demonstrated changes such as erroneous sensing and pacemaker inhibition.<sup>66,67</sup> Again, these occurred only when the telephone was close to the pacemaker. The changes were temporary, and the pacemaker reverted to normal when the cellular telephone was moved to a safe distance. Currently, the FDA guidelines are that the cellular telephones be kept at least 6 inches from the pacemaker. Therefore, a patient with a pacemaker should not carry a cellular telephone in the shirt pocket, which is adjacent to the pacemaker. There appears to be little risk if hospital personnel carry a cellular telephone and if they ensure that it is kept at a reasonable distance from patients with a pacemaker.

AICDs comprise another group of devices of concern to biomedical engineers. Fetter et al.<sup>68</sup> conducted a study of 41 patients who had AICDs. They concluded that the cellular telephones did not interfere with the AICDs. They did, however, recommend keeping the cellular telephone at least 6

inches from the device.

EMI extends well beyond that of cellular telephones. Walkie-talkies, which are frequently used by hospital maintenance and security personnel, paging systems, police radios, and even televisions all emit EMI, which could potentially interfere with medical devices of any nature. Although there are many anecdotal reports, the amount of available scientific information on this problem is scant. Reports of interference include ventilator and infusion pumps that have been shut down or reprogrammed, interference with ECG monitors, and even an electronic wheelchair that was accidentally started because of EMI. It is a difficult problem to study because there are many different types of devices that emit EMI and a vast array of medical equipment that has the potential to interact with these devices. Even though a device may seem “safe” in the medical environment, if two or three cellular telephones or walkie-talkies are brought together in the same area at the same time, there may be unanticipated problems or interference.

Any time a cellular telephone is turned on, it is actually communicating with the cellular network, even though a call is not in progress. Therefore, the potential to interfere with devices exists. The ECRI Institute reported in October 1999 that walkie-talkies were far more likely to cause problems with medical devices than cellular telephones.<sup>69</sup> This is because they operate on a lower frequency than cellular telephones and have a higher power output. The ECRI recommends that cellular telephones be maintained at a distance of 1 m from medical devices, while walkie-talkies be kept at a distance of 6 to 8 m.

Some hospitals have made restrictive policies on the use of cellular telephones, particularly in critical care areas.<sup>70</sup> These policies are supported by little scientific documentation and are nearly impossible to enforce. The ubiquitous presence of cellular telephones carried by hospital personnel and visitors makes enforcing a ban virtually impossible. Even when people try to comply with the ban, failure is nearly inevitable because the general public is usually unaware that a cellular telephone in the standby mode is still communicating with the tower and generating EMI.

The real solution is to “harden” devices against EMI. This is difficult to do because of the many different frequencies on which these devices operate. Education of medical personnel is essential. When working in an OR or critical care area, all personnel must be alert to the fact that electronic devices and pacemakers can be interfered with by EMI. Creating a restrictive policy would certainly irritate personnel and visitors, and in some cases, may actually compromise emergency communications.<sup>71</sup>

## **Construction of New Operating Rooms**

Frequently, an anesthesiologist is asked to consult with hospital administrators and architects in designing new, or remodeling older, ORs. In the past, a strict electrical code was enforced because of the use of flammable anesthetic agents. This code included a requirement for IPSs and LIMs. The NFPA revised its standard for health-care facilities in 1984 (NFPA 99–1984). These standards did not require IPS or LIMs in areas designated for use of nonflammable anesthetic agents only.<sup>72,73</sup> Although not mandatory, NFPA standards are usually adopted by local authorities when revising their electrical codes.

This change in the standard created a dilemma. The NFPA 99–2012 and NFPA 99–2015—*Health Care Facilities Code*, mandates that “wet procedure locations shall be provided with special protection against electrical shock.” Section 6.3.2.2.8.2 further states that “this special protection shall be provided as follows: (1) Power distribution system that inherently limits the possible ground-fault current due to a first fault to a low value, without interrupting the power supply, (2) power distribution system in which the power supply is interrupted if the ground-fault current does, in fact, exceed the trip value of a Class A GFCI.”<sup>74</sup>

The decision of whether to install isolated power hinged on two factors. The first was whether or not the OR was considered a wet location, and, if so, whether an interruptible power supply was tolerable. When power interruption was tolerable, a GFCI was permitted as the protective means. However, the standard also stated that “the use of an isolated power system (IPS) shall be permitted as a protective means capable of limiting ground fault current without power interruption.”

Most people who have worked in an OR would attest to its being a wet procedure location. The presence of blood, body fluids, and saline solutions spilled on the floor all contribute to making this a wet environment. The cystoscopy suite serves as a good example.

Once the premise that the OR is a wet location is accepted, it must be determined whether a GFCI can provide the means of protection. The argument against using GFCIs in the OR is illustrated by the following example. Assume that during an open heart procedure, the cardiopulmonary bypass pump and the patient monitors are plugged into outlets on the same branch circuit. Also assume that during bypass, the circulating nurse plugs in a faulty headlight. If there is a GFCI protecting the circuit, the fault will be detected and the GFCI will interrupt all power to the pump and the monitors. This undoubtedly would cause a great deal of confusion and consternation among the OR personnel and may place the patient at risk for injury. The pump would have to be manually operated while the problem was being resolved. In addition, the GFCI could not be reset (and power restored) until the headlight is identified as the cause of the fault and unplugged from the

outlet. However, if the OR were protected with an IPS and LIM, the same scenario would cause the LIM to alarm, but the pump and patient monitors would continue to operate normally. There would be no interruption of power and the problem could be resolved without risk to the patient.

It should be realized that a GFCI is an active system. That is, a potentially hazardous current is already flowing and must be actively interrupted, whereas the IPS (with LIM) is designed to be safe during a first-fault situation. Thus, it is a passive system because no mechanical action is required to activate the protection.<sup>75</sup>

Many hospital administrators and engineers wanted to eliminate IPSs in new OR construction by advocating that it was unnecessary and costly. They also grossly inflated the maintenance costs of the IPS. In fact, the maintenance costs of modern systems are minimal, and the installation costs are approximately 1% to 2% of the cost of constructing a new OR. The American Society of Anesthesiologists (ASA) and others, however, had advocated for the retention of IPSs.<sup>75–78</sup> In 2006, the ASA, through its representatives to NFPA 99 and its technical committee on Electrical Systems, launched a major campaign to have ORs default to being a wet procedure location. This was vigorously opposed by the American Hospital Association and the American Society of Healthcare engineers. The final version of the NFPA 99–2012 and NFPA 99–2015 edition, contains the following language: “Section 6.3.2.2.8.4 ORs shall be considered to be a wet procedure location, unless a risk assessment conducted by the health care governing body determines otherwise.” In addition section 6.3.2.2.8.7 states: “Operating rooms defined as wet procedure locations shall be protected by either isolated power or ground fault circuit interrupters.” Although, this code applies only to new or remodeled ORs, it is nonetheless a major victory for ASA, our patients, and OR personnel. In the event that the health-care facility wants to classify an OR as a “dry” location, then they have to do a risk assessment, and the NFPA 99 annex (A.6.3.2.2.8.4) states that among others this should include clinicians.<sup>74</sup>

Although not perfect,<sup>79</sup> the IPS and LIM do provide both the patient and OR personnel with a significant amount of protection in an electrically hazardous environment. IPSs provide clean stable voltages, which is important for sensitive diagnostic equipment.<sup>80</sup> Also, modern LIMs, which are microprocessor-based, require only yearly instead of monthly testing.

The value of the IPS is illustrated in a report by Day<sup>81</sup> in 1994. He reported four instances of electrical shock to OR personnel in a 1-year period. The operating suite had been renovated and the IPS removed, and it was not until the OR personnel received a shock that a problem was discovered. Also, in 2010, Wills et al.<sup>82</sup> reported an incident where an OR nurse received a severe electrical shock while plugging in a piece of equipment. This case

further illustrates the consequences of having a wet floor in an OR with no IPS or GFCIs.

Anesthesiologists need to be aware of these new regulations and strongly encourage that new ORs be constructed with IPSs. The relatively small cost savings that the alternative would represent do not justify the elimination of such a useful safety system. The use of GFCIs in the OR environment can be acceptable if carefully planned and engineered. In order to avoid the loss of power to multiple instruments and monitors at one time, each outlet must be an individual GFCI. If that is done, then a fault will result in only one piece of equipment losing power. Using GFCIs also precludes the use of multiple plug strips in the OR.

Finally, in 2011, August reported on the opening of 24 new ORs in his facility. To their dismay, they found that the electrical service panels outside each OR were locked, and that the ORs had been reclassified as “dry” locations, without the knowledge of the anesthesia department.<sup>83</sup> Barker also reported an incident where a PACU monitor overheated and was billowing smoke. An attempt to shut off the power, was met with a locked circuit breaker box.<sup>84</sup> He too, commented on the need to have ORs designated as wet procedure locations.

Hopefully, with the new NFPA 99 code, there will be far fewer incidents of new ORs being designated as “dry” locations, especially without the knowledge of the anesthesia department. Electrical safety should be the concern of everyone in the OR. Accidents can be prevented only if proper installation and maintenance of the appropriate safety equipment in the OR have occurred and the OR personnel understand the concepts of electrical safety and are vigilant in their efforts to detect new hazards.<sup>85</sup>

## Fire Safety

**10** Fires in the OR are just as much a danger today as they were 100 years ago when patients were anesthetized with flammable anesthetic agents.<sup>86,87</sup> Because the potential consequences of a fire or explosion with ether or cyclopropane were well known and potentially devastating, OR fire safety practices were routinely followed.<sup>88,89</sup>

Today, the risk of an OR fire is probably as great or greater than the days when ether and cyclopropane were used, in part because of the routine use of potential sources of ignition (including electrosurgical cauteries) in an environment rich in fuel sources (i.e., flammable materials) and oxidizers (e.g., oxygen and nitrous oxide). Although the number of OR fires that occur annually in the United States is unknown, some estimates suggest that there are 550 to 650 fires each year, with as many as 5% to 10% associated with serious injury or death.<sup>90</sup> In contrast to the era of flammable anesthetics,

there currently appears to be a lack of awareness of the potential for an OR fire. In response to the risks presented by this situation, in 2008 and updated in 2013, the ASA released a Practice Advisory on the Prevention and Management of Operating Room Fires (Table 5-3).<sup>91</sup>

**Table 5-3** Recommendations for The Prevention and Management of Operating Room Fires

<p><b>Preparation</b></p> <ul style="list-style-type: none"><li>• Train personnel in operating room fire management</li><li>• Practice responses to fires (fire drills)</li><li>• Assure that fire-management equipment is readily available</li><li>• Determine if a high-risk situation exists</li><li>• Team decides how to prevent/manage a fire</li><li>• Each person assigned a task (e.g., remove endotracheal tube or disconnect circuit)</li></ul> <p><b>Prevention</b></p> <ul style="list-style-type: none"><li>• Allow flammable skin preparations to dry before draping</li><li>• Configure surgical drapes to avoid buildup of oxidizer</li><li>• Anesthesiologist collaborates with team throughout the procedure to minimize oxidizer-enriched environment near ignition source</li><li>• Keep O<sub>2</sub> concentration as low as clinically possible</li><li>• Avoid N<sub>2</sub>O</li><li>• Notify surgeon if oxidizer ↔ ignition source are in proximity to each other</li><li>• Moisten gauze and sponges that are near an ignition source</li></ul> <p><b>Management</b></p> <ul style="list-style-type: none"><li>• Look for early warning sign of a fire (e.g., pop, flash, or smoke)</li><li>• Stop procedure and each team member immediately carries out assigned task</li></ul>
----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

### **Airway Fire**

- *Simultaneously* remove the endotracheal tube and stop gases/disconnect circuit
- Pour saline into airway
- Remove burning materials
- Mask ventilate patient, assess injury, consider bronchoscopy, reintubate

### **Fire on the Patient**

- Turn off gases
- Remove drapes and burning materials
- Extinguish flames with water, saline, or fire extinguisher
- Assess patient's status, devise care plan, assess for smoke inhalation

### **Failure to Extinguish**

- Use CO<sub>2</sub> fire extinguisher
- Activate fire alarm
- Consider evacuation of room: Close door and do not reopen
- Turn off medical gas supply to room

### **Risk Management**

- Preserve scene
- Notify hospital risk manager
- Follow local regulatory reporting requirements
- Treat fire as an adverse event
- FIRE DRILLS

Adapted from: Practice Advisory for the Prevention and Management of Operating Room Fires: An updated report by the American Society of Anesthesiologists Task Force on Operating Room Fires: American Society of Anesthesiologists: Schaumburg, IL. Approved by the ASA House of Delegates in October 2012; published in *Anesthesiology*, February 2013.

**Figure 5-36** The fire triangle. (Copyright © ECRI Institute. Used with permission.)

For a fire to start, three components are necessary. The limbs of the “fire

11 triad” are a heat or ignition source, fuel, and an oxidizer (Fig. 5-36).<sup>92</sup> A  
6 fire occurs when there is a chemical reaction of a fuel rapidly  
12 combining with an oxidizer to release energy in the form of heat and  
light. In the OR, there are many heat or ignition sources, such as the ESU,  
lasers, and the ends of fiberoptic light cords. The main oxidizers in the OR  
are air, oxygen, and nitrous oxide. Oxygen and nitrous oxide function equally  
well as oxidizers, so a combination of 50% oxygen and 50% nitrous oxide  
would avidly support combustion, as would 100% oxygen. Fuel for a fire can  
be found everywhere in the OR. Paper drapes, which have largely replaced  
cloth drapes, are much easier to ignite and can burn with greater  
intensity.<sup>93,94</sup> Other sources of fuel include gauze dressings, endotracheal  
tubes, gel mattress pads, and even facial or body hair (Table 5-4).<sup>95</sup>

Fire prevention is accomplished by not allowing all three of the elements  
of the fire triad to come together at the same time.<sup>96</sup> The challenge in the OR  
is that frequently each of the limbs of the fire triad is controlled by a different  
individual. For instance, the surgeon is frequently in charge of the ignition  
source, the anesthesiologist is usually administering the oxidizer, and the OR  
nurse frequently controls the fuel sources. It is not always evident to any one  
individual that all of these elements may be coming together at the same  
time. This is especially true in any case in which there is the possibility of  
oxygen or an oxygen–nitrous oxide mixture being delivered around the  
surgical site. In these circumstances, the risk of an OR fire is markedly  
increased and the need for communication among the surgeon, the  
anesthesiologist, and the OR nurses throughout the procedure is essential.

There are several dangers that may result from an OR fire. The most  
obvious is that the patient and OR personnel can suffer severe burns.  
However, a less obvious but potentially more deadly risk can be posed by the  
products of combustion (called *toxicants*). When materials, such as plastics,  
burn a variety of injurious compounds can be produced. These include carbon  
monoxide, ammonia, hydrogen chloride, and even cyanide. Toxicants can  
produce injury by damaging airways and lung tissue, and can cause asphyxia.  
OR fires can often produce significant amounts of smoke and toxicants, but  
may not cause enough heat to activate overhead sprinkler systems. If enough  
smoke is produced, the OR personnel may have to evacuate the area.  
Therefore, it is essential to have an evacuation plan for both the OR personnel  
and the patient, which was planned and carefully considered before a fire  
could occur.

OR fires can be divided into two different types. The more common type  
of fire occurs *in* or *on* the patient, especially during high-risk procedures  
in which an ignition source is used in an oxidizer-rich environment. These  
would include airway fires (including endotracheal tube fires, fires in the  
oropharynx, which may occur during a tonsillectomy, fires in the

breathing circuit), and fires during laparoscopy. In 2005, Katz and Campbell<sup>97</sup> reported on a fire during a thoracotomy. A dry gauze lap pad was set on fire, because 100% oxygen was present in the thoracic cavity while the surgeon was using the electrocautery. Cases that involve stripping of the pleura or resection of pulmonary blebs, tracheobronchopleural fistula, can easily result in high concentrations of oxygen in the thoracic cavity when the lung is reinflated due to gas leakage.<sup>98,99</sup> Solutions to this problem include making sure that the lap pads are always wet, and if the surgeon needs the lung inflated, then doing CPAP with air instead of oxygen will greatly reduce the risk of a fire.

Fires occurring on the patient mainly involve head and neck surgery done under regional anesthesia (RA) or monitored anesthesia care (MAC) when the patient is receiving high flows of supplemental oxygen. Because these fires occur in an oxygen-enriched environment, items such as surgical towels, drapes, or even the body hair can be readily ignited and produce a severe burn. The ECRI Institute warns that “oxygen enriched atmospheres lower the temperature at which a fuel will ignite.”<sup>90</sup> In addition, these fires will burn more vigorously, and spread faster. The other type of OR fire is one that is remote from the patient. This would include an electrical fire in a piece of equipment, or a carbon dioxide (CO<sub>2</sub>) absorber fire. A report by Lepiane describes a case where the power cord to the OR table was trapped beneath the base of the table. When the bed control was activated, a shower of sparks arose and ignited the sheets on the bed.<sup>100</sup>

All materials burn in the presence of an oxygen-enriched environment. Wolf et al.<sup>101</sup> tested a number of surgical drape materials in 21%, 50%, and 95% oxygen. They found that the higher the concentration of oxygen, the more readily the material could be set on fire. In 50% and 95% O<sub>2</sub>, all the materials burned. In the case of the cotton huck towel, the time to ignition in 21% O<sub>2</sub> was a mean of 12 seconds. The same material ignited in 0.1 seconds in 95% O<sub>2</sub>. Recent studies by Goldberg<sup>102</sup> and Culp et al.<sup>103</sup> showed similar results with a variety of common OR materials. Namely, that all materials ignited in an oxygen-enriched environment, and there was a dramatic increase in flammability especially with 100% oxygen.

In an editorial accompanying the Culp article, Eichhorn urged the elimination of open oxygen delivery in MAC cases involving the head and neck or upper body. He stressed that anesthesiologists must stop the routine administration of oxygen in these cases simply because “it’s the way we always do it.”<sup>104</sup>

The two major ignition sources for OR fires are the ESU and the laser. However, the ends of some fiberoptic light cords can also become hot enough to start a fire if they are placed on paper drapes. Although the ESU is responsible for igniting the majority of the fires,<sup>105</sup> it is the laser that has

generated the most attention and research. Laser is the acronym for *light amplification by stimulated emission of radiation*. A laser consists of an energy source and material that the energy excites to emit light.<sup>106–108</sup> The material that the energy excites is called the *lasing medium* and provides the name of the particular type of laser. Laser light has several important properties. It is coherent radiation (meaning all the waves have the same frequency and phase), it is monochromatic (of a single color or wavelength), and it is collimated (the beam does not disperse as the distance from the source increases). This coherent light can be focused into very small spots that have very high power density.

**Table 5-4** Fuel Sources Commonly Found in the Operating Room

"Prep" agents	Nitropaste (Nitro-Bid)
Alcohol	EMLA
Degreasers (acetone, ether)	Lip balms
Adhesives (tincture of benzoin, Aeroplast)	Anesthesia equipment
Chlorhexidine digluconate (Hibitane)	Breathing circuit hoses
Iodophor (Dura-Prep)	Masks
Drapes and covers	Endotracheal tubes
Patient drapes (paper, plastic, cloth)	Oral and nasal airways
Equipment drapes (paper, plastic, cloth)	Laryngeal mask airways
Blankets and sheets	Nasogastric tubes
Pillows, mattresses, and padding	Suction catheters and tubing
Gowns	Scavenger hoses
Masks	Volatile anesthetics
Shoe covers	CO <sub>2</sub> absorbers
Gloves (latex, nonlatex)	Intravenous tubing
Clothing	Pressure monitor tubing and plastic transducers
Compression (antiembolism) stockings	Other equipment
Patient	Charts and records
Hair	Cardboard, wooden, and particleboard boxes and cabinets
Alimentary tract gases (methane, hydrogen)	Packing materials (cardboard, expanded polystyrene [Styrofoam])
Desiccated tissue	Fiberoptic cable covers
Dressings	Wire covers and insulation
Gauze and sponges	Fiberoptic endoscope coverings
Petrolatum-impregnated dressings	Sphygmomanometer cuffs and tubing
Xeroform	Pneumatic tourniquet cuffs and tubing
Adhesive tape (cloth, plastic, paper)	Stethoscope tubing
Elastic bandages	Vascular shunts (Gore-Tex, Dacron)
Stockinettes	Dialysis and extracorporeal circulation circuits
Sutures	Wound drains and collection systems
Steri-strips	Mops and brooms
Collodion	Textbooks and instruction manuals
Ointments	
Petrolatum	
Antibiotics (bacitracin, neomycin, polymyxin B)	

There are many different types of medical lasers, and each has a specific application. The argon laser is used in eye and dermatologic procedures because it is absorbed by hemoglobin and has a modest tissue penetration of between 0.05 and 2.0 mm. The potassium titanyl phosphate (KTP) or frequency-doubled yttrium aluminum garnet (YAG) lasers are also absorbed by hemoglobin and have tissue penetrations similar to that of the argon laser. The tunable dye laser has a wavelength that is easily changed and can be used

in different applications, particularly in dermatologic procedures. The neodymium-doped yttrium aluminum garnet (Nd:YAG) laser is the most powerful of the medical lasers. Since the tissue penetration is between 2 and 6 mm, it can be used for tumor debulking, particularly in the trachea and main stem bronchi, or in the upper airway. The energy can be transmitted through a fiberoptic cable that is placed down the suction port of a fiberoptic bronchoscope (FOB). The laser can then be used in a contact mode to treat a tumor mass. The CO<sub>2</sub> laser has very little tissue penetration and can be used where great precision is needed. It is also absorbed by water, so that minimal heat is dispersed to surrounding tissues. The CO<sub>2</sub> laser is used primarily for procedures in the oropharynx and in and around the vocal cords. The helium–neon (He–Ne) laser produces an intense red light and thus can be used for aiming the CO<sub>2</sub> and the Nd:YAG lasers. It has very low power and thus will present no significant danger to OR personnel.

One of the most devastating types of OR fires occurs when an endotracheal tube is ignited *in* the patient.<sup>109–114</sup> If the patient is being ventilated with oxygen and/or nitrous oxide, the endotracheal tube will essentially emit a blowtorch type of flame that can result in severe injury to the trachea, lungs, and surrounding tissues (Fig. 5-37). Red rubber, polyvinyl chloride, and silicone endotracheal tubes all have oxygen-flammability indices (defined as the minimum O<sub>2</sub> fraction in N<sub>2</sub> that will just support a candle-like flame for a given fuel source using a standard ignition source)<sup>115</sup> of less than 26%.<sup>116</sup> Historically, anesthesiologists attempted to improve the safety of these tubes by wrapping red rubber or polyvinyl chloride tubes with some sort of reflective tape. However, taped–wrapped tubes often became kinked, gaps in the tape exposed areas of the tube to the laser, and non–laser-resistant tape was sometimes unintentionally used. To prevent these problems during high-risk procedures, “laser-resistant” endotracheal tubes have been developed.<sup>117–119</sup> Anesthesiologists can now use an endotracheal tube that is designed to be resistant to ignition by the specific type of laser that will be used during surgery. For instance, when using the CO<sub>2</sub> laser, the LaserFlex (Mallinckrodt, Pleasanton, CA) (Fig. 5-38) is an excellent choice. This is a

flexible metal tube that has two cuffs that can be inflated with saline colored with methylene blue. The methylene blue enables the surgeon to easily recognize if he or she has accidentally penetrated one of the cuffs.

The LaserFlex tube is highly resistant to being struck by the laser. If the Nd:YAG laser is being used, then the Lasertubus (Rüsch Inc., Duluth, GA) can be used (Fig. 5-39). The Lasertubus has a soft rubber shaft that is covered by a corrugated silver foil that is in turn covered in a Merocel sponge jacket. In order to provide maximum protection, the Merocel must be kept moist with saline. It should be noted that only the portion of the tube covered with the Merocel is laser resistant.

**Figure 5-37 A:** A burning ET tube with a high concentration of O<sub>2</sub> or O<sub>2</sub>/N<sub>2</sub>O will exhibit a “blowtorch” effect. (Copyright © ECRI Institute. Used with permission.) **B:** A burning ET tube will produce a large amount of debris. (Copyright © ECRI Institute. Used with permission.)

Another potential source of ignition for an OR fire is the ESU.<sup>120,121</sup> A typical example of how an ESU could cause ignition would be during a tonsillectomy in a child in whom the anesthesiologist was using an uncuffed, flammable endotracheal tube. In this case, the oxygen or oxygen–nitrous oxide mixture could leak around the endotracheal tube and pool at the operative site, providing an oxidizer-enriched environment. When the surgeon uses the ESU (or laser) to cauterize the tonsil bed, the combination of a high concentration of oxidizer (oxygen or oxygen–nitrous oxide mixture), fuel (endotracheal tube), and ignition source (the ESU or laser) could easily start a fire.<sup>122–124</sup>

The best way to prevent this type of fire is to take steps to prevent the three legs of the fire triad from coming together. For example, mixing the oxygen with air will keep the inspired oxygen concentration as low as possible, thus reducing the available oxidizer. Another possibility would be to place wet pledgets around the endotracheal tube, which would prevent the escape of oxygen or oxygen–nitrous oxide mixture from the trachea into the operative field. This reduces the available oxidizer and would keep the endotracheal tube and tissues from becoming desiccated, thus reducing their suitability as fuel sources. However, the pledgets must be kept moist, lest they dry out and become an additional source of fuel for a fire.

A related situation that requires a different solution can arise when a critically ill patient requires a tracheostomy.<sup>125–128</sup> These patients may require very high concentrations of inspired oxygen to maintain tissue oxygenation so that any decrease in inspired oxygen concentration or interruption of ventilation would not be tolerated. In this circumstance, the best option for preventing a fire would be to avoid the use of electrocautery (ignition source) when the surgeon enters the trachea. The Nd:YAG laser can be used to treat tumors of the lower trachea and main stem bronchi. Most

commonly, the surgeon will use a FOB and pass the laser fiber through the suction port of the bronchoscope. The FOB can be used in conjunction with a rigid metal bronchoscope or passed through an 8.5 or 9.0 mm polyvinyl chloride endotracheal tube. A special laser-resistant tube would not be used in this circumstance because the FOB and laser fiber pass through the endotracheal tube and focus on tissue distal to the tube. Fire safety precautions available in this setting include titrating the concentration of inspired oxygen to as low a concentration as the patient can tolerate while maintaining a saturation of between 90% and 95% (ideally keeping the inspired oxygen below 30%), keeping the tip of the endotracheal tube and FOB away from the site of surgery and out of the “line of fire” of the laser, and removing charred and desiccated tissue from the surgical field.

**Figure 5-38** LaserFlex laser resistant ET tube.

**Figure 5-39** Lasertubus laser resistant ET tube.

The use of a rigid metal bronchoscope instead of an endotracheal tube will

eliminate the possibility of setting the tube on fire but does not eliminate the possibility of setting the FOB on fire. This would also necessitate the use of a jet Venturi system to ventilate the patient, which would, in turn, deliver an inspired oxygen concentration of between 40% and 60%.

There are a number of basic safety precautions that should be taken whenever a laser is used in surgery. Since laser light can be reflected off any metal surface, it is important that all OR personnel wear protective goggles that are specific to the type of laser being used. The anesthesiologist needs to be aware that the laser goggles may make it difficult to read certain monitor displays. In addition, it is important that the patient's eyes be covered with wet gauze or eye packs. OR personnel should also wear high filtration masks because the laser "plume" may contain vaporized virus particles or chemical toxins. Finally, all doors to the OR should have warning signs that a laser is in use, and all windows should be covered with black window shades.

Laparoscopic surgery in the abdomen is another potential risk for a surgically related fire. Ordinarily, the abdomen is inflated with CO<sub>2</sub>, which does not support combustion. It is important to verify that, indeed, only CO<sub>2</sub> is being used, as erroneous inclusion of oxygen can be disastrous.<sup>129,130</sup> Also, nitrous oxide administered to the patient as part of the anesthetic can, over 30 minutes, diffuse into the abdominal cavity and attain a concentration that could support combustion.<sup>131</sup> In fact, when sampling the abdominal gas contents after 30 minutes, the mean nitrous oxide concentration was 36%; however, in certain patients it reached a concentration of 47%. Both methane and hydrogen are flammable gases that are frequently present in bowel gas in significant concentrations. Methane concentration in bowel gas can be up to 56% and hydrogen has been reported as high as 69%. With the maximum abdominal concentration of 47% nitrous oxide mixed with CO<sub>2</sub>, it would require the maximum of 56% of methane to be flammable. Therefore, this represents a relatively small hazard. In contrast, a concentration of 69% hydrogen is flammable if the nitrous oxide concentration is above 29%. Therefore, a fire is possible if the surgeon, while using the ESU, enters the bowel with a high concentration of hydrogen and the intra-abdominal nitrous oxide content is more than 29%. The risk is greater during emergent colon surgery, when an unprepped or ruptured colon can release hydrogen or methane that can be ignited by the ESU.<sup>132</sup> In recent years, fires *on* the patient have become the most frequent type of OR fire. These cases occur most often during surgery in and around the head and neck, where the patient is receiving MAC and supplemental oxygen is being administered by either a face mask or nasal cannulae.<sup>133–137</sup> The higher the oxygen flow rate, the higher the oxygen concentration will be under the drapes, and the longer it will take to dissipate.<sup>138,139</sup> In these cases, the oxygen can collect under the drapes if not properly vented, and when the surgeon uses the ESU or the

laser, a fire can easily start. Placing a modified nasal cannula into a nasopharyngeal airway, has been shown to reduce the oxygen concentration under the drapes.<sup>140,141</sup>

There are many things that can act as fuel, such as the surgical towels, paper drapes, disinfecting preparation solutions, sponges, plastic tubing from the oxygen face mask, and even the body hair. These fires start very quickly and can turn into an intense blaze in only a few seconds. Even if the fire is quickly extinguished, the patient will usually sustain a significant burn.

Currently, the majority of OR fires occur with MAC during head and neck surgery. Invariably, this involves an oxygen-enriched atmosphere since the majority of surgical fires are oxygen enriched. Currently, the Anesthesia Patient Safety Foundation (APSF), and ECRI Institute recommend that there be no open delivery of oxygen during these cases.<sup>90,142</sup> If the patient needs increased levels of sedation during a time when the surgeon is using the ESU or laser, then the airway needs to be secured with an LMA or an endotracheal tube. Occasionally, there are cases during which the patient and the anesthesiologist need to communicate. An example of this might be an awake craniotomy or a carotid endarterectomy under RA. In these cases it is prudent to use an FiO<sub>2</sub> of less than 30%. Preferably, the patient should receive only room air during these cases.

The ASA Closed Claims Study provides some further insights into the problem.<sup>143</sup> They have maintained a database of closed malpractice claims since 1985. Analysis of the database showed there were 103 claims for OR fires between 1985 and 2009. This amounted to 1.9% of the total claims (n = 5,297). Of those, 78 (76%) occurred during MAC or RA. Twenty-five (24%) of the cases happened when the patient was receiving general anesthesia.

The ESU was found to be the ignition source in 90% of the fire cases. There has been an increase in the incidence of the ESU being the ignition source in recent years. From 1985 to 1994, these totaled 1% of all surgical claims, but increased to 4.4% of claims from 2000 to 2009. Eighty-five percent (85%) of the ESU fires involved the head, neck, or upper chest, and 97% of the MAC/RA fires occurred in the head, neck, or upper chest region. Oxygen was the oxidizer in 95% of the ESU-induced fires, and in 84% there was open delivery of oxygen.

The most important principle that the anesthesiologist has to keep in mind to minimize the risk of fire is to titrate the inspired oxygen to the lowest concentration necessary to keep patient's oxygenation within safe levels. If the anesthesia machine has the ability to deliver air, then the nasal cannula or face mask can be attached to the anesthesia circuit by using a small no. 3 or no. 4, 15-mm endotracheal tube adapter.<sup>144</sup> This is attached to the right-angle elbow of the circuit. If the anesthesia machine is equipped with an auxiliary oxygen flowmeter that has a removable nipple adapter, then a humidifier can

be installed in place of the nipple adapter. The humidifier has a Venturi mechanism through which room air is entrained and thus the oxygen concentration that is delivered to the face mask can be varied from 28% to 100%. Finally, if this machine has a common gas outlet that is easily accessible, a nasal cannula or face mask can be attached at this point using the same small 3- or 4-mm endotracheal tube adaptor (Fig. 5-40). If it is necessary to deliver more than 30% oxygen to the patient, then delivering 5 to 15 L/min of air under the drapes will dilute the oxygen.<sup>145</sup> The oxygen should always be discontinued at least 1 minute before the surgeon uses the ESU. Also the bipolar ESU is preferable to the monopolar ESU. It is important that the drapes be arranged in such a manner that there is no oxygen buildup beneath them. Venting the drapes and having the surgeon use an adhesive sticky drape that seals the operative site from the oxygen flow are steps that will help reduce the risk of a fire.<sup>146</sup> However, the seal of the adhesive drape may break down during the case and allow oxygen into the operative field. Therefore, this technique cannot be counted on to reliably protect the patient.

**Figure 5-40** A nasal cannula connected to the alternate fresh gas outlet (arrow) on a GE-Datex-Ohmeda Aestiva anesthesia machine.

It is potentially possible to discontinue the use of oxygen before the surgeon plans to use the electrocautery or laser. This would have to be done several minutes beforehand in order to allow any oxygen that has built up to dissipate. If the surgeon is planning to use the electrosurgery or laser during the entire case, this may not be practical. Also the bipolar ESU is preferable to the monopolar ESU.

Some newer surgical preparation solutions can contribute to surgically related fires.<sup>147-150</sup> These solutions typically come prepackaged in a “paint stick” applicator with a sponge on the end (e.g., DuraPrep, 3M, St. Paul, MN; ChlorPrep or Prevail, Becton Dickinson, Franklin Lakes, NJ). They consist of

an Iodophor or CHG mixed with at least 70% isopropyl alcohol. This is highly flammable and can easily be the fuel for an OR fire. In 2001, Barker and Polson<sup>133</sup> reported such a case. In a laboratory recreation, they found that if the DuraPrep had been allowed to dry completely (4 to 5 minutes), the fire did not occur (Fig. 5-41). The other problem with these types of preparation solutions is that small pools of the solution can accumulate if the person doing the preparation is not careful. The alcohol in these small puddles will continue to evaporate for a period of time, and the alcohol vapors are also extremely flammable. Flammable skin preparation solutions should be allowed to dry at least 3 minutes, and puddles removed before the site is draped (Fig. 5-42). If the preparation solution gets into the patient's hair, then drying can take up to 60 minutes.

It is important to bear in mind that halogenation of hydrocarbon anesthetics confers relative, but not absolute, resistance to combustion. Even the newer, "nonflammable" volatile anesthetics can, under certain circumstances, present fire hazards. For example, sevoflurane is nonflammable in air, but can serve as a fuel at concentrations as low as 11% in oxygen and 10% in nitrous oxide.<sup>151</sup> In addition, sevoflurane and desiccated CO<sub>2</sub> absorbent (either soda lime or Baralyme) can undergo exothermic chemical reactions that have been implicated in several fires that involved the anesthesia breathing circuit.<sup>152-155</sup> In 2003, the manufacturer of sevoflurane published a "Dear Health Care Provider" letter and advisory alert.<sup>156</sup> To prevent future fires, the manufacturer of sevoflurane has recommended that anesthesiologists employ several measures, including avoiding the use of desiccated CO<sub>2</sub> absorbent and monitoring the temperature of the absorbers and the inspired concentration of sevoflurane; if elevated temperature or an inspired sevoflurane concentration that differed unexpectedly from the vaporizer setting is detected, it is recommended that the patient be disconnected from the anesthesia circuit and monitored for signs of thermal or chemical injury, and that the CO<sub>2</sub> absorbent be removed from the circuit and/or replaced. 13

Another way to prevent this type of fire is to use a CO<sub>2</sub> absorbent that does not contain a strong alkali, as do soda lime and Baralyme (Chemetron Medical Division, Allied Healthcare Products, St. Louis, Missouri). Amsorb (Armstrong Medical Limited, Coleraine, Northern Ireland) is a CO<sub>2</sub> absorbent that contains calcium hydroxide and calcium chloride, but no strong alkali.<sup>157</sup> In experimental studies, it was found that Amsorb is unreactive with currently used volatile anesthetics and does not produce carbon monoxide or Compound A with desiccated absorbent. Therefore, it would not interact with sevoflurane and undergo an exothermic chemical reaction.<sup>155</sup>

If a fire does occur, it is important to extinguish it as soon as possible. The first step is to interrupt the fire triad by removing one component. This is

usually best accomplished by removing the oxidizer from the fire. Therefore, if a tracheal tube is on fire, disconnecting the circuit from the tube or disconnecting the inspiratory limb of the circuit will usually result in the fire immediately going out. Simultaneously the surgeon should remove the burning endotracheal tube. Once the fire is extinguished, the airway is inspected via bronchoscopy, and the patient reintubated.

If the fire is on the patient, then extinguishing it with a basin of saline may be the most rapid and effective method to deal with this type of fire. There is also a method to use a sheet or towel to extinguish the fire. If the drapes are burning, particularly if they are paper drapes, then they must be removed and placed on the floor. Paper drapes are impervious to water; thus, throwing water or saline on them will do little to extinguish the fire. Once the burning drapes are removed from the patient, the fire can then be extinguished with a fire extinguisher. In most OR fires, the sprinkler system is not activated. This is because the sprinklers are not located directly over the OR table and because OR fires seldom get hot enough to activate the sprinklers.

All OR personnel should receive OR fire safety education, which should include training in institutional fire safety protocols and learning the location and operation of the fire extinguishers. Fire safety education, including fire drills, allows each member of the OR team to learn and practice what his or her responsibilities and actions should be if a fire were to occur.<sup>158</sup> Fire drills are an important part of the plan and can help personnel become familiar with the exits, evacuation routes, location of fire extinguishers, and how to shut off medical gas and electrical supplies. Although institutional fire safety protocols vary, the general principles of responding to an OR fire can be summarized by the mnemonic ERASE: *Extinguish, rescue, activate, shut, and evaluate*. In sequence: First, the team should generally attempt to extinguish a fire on, in, or near the patient. Depending on the situation, this may include the use of saline or a CO<sub>2</sub> fire extinguisher (see later discussion). If the initial attempts at extinguishing the fire are unsuccessful, the patient and all other persons at risk should be rescued and the OR evacuated, if possible, and the fire alarm should be activated. Once the OR is emptied of personnel, the doors should be shut and the medical gas supply to the room should be shut off. The patient should then be evaluated and any injuries should be appropriately managed.

**Figure 5-41** Simulation of fire caused by ESU electrode during surgery. **A:** Mannequin prepared and draped for surgery. Electrosurgical unit monopolar pencil electrode applied to operative site at start of surgery. **B:** Six seconds after electrosurgical unit application. Smoke appears from under the drapes. **C:** Fourteen seconds after electrosurgical unit application. Flames burst through the drapes. **D:** Twenty-four seconds after electrosurgical unit application. Entire patient head and drapes in flames. (Reprinted with permission from Barker SJ, Polson JS. Fire in the operating room: A case report and laboratory study. *Anesth Analg.* 2001;93:960. Copyright © 2001, International Anesthesia Research Society.)

**Figure 5-42** A demonstration of the intense heat and flame that is present in an alcohol

fire. (Photograph courtesy of Mark Bruley of Emergency Care Research Institute. Reprinted with permission, Copyright 2009, ECRI Institute. [www.ecri.org](http://www.ecri.org).)

Preventing an OR fire should be the hallmark of all fire safety programs and training. The first step is to determine whether a high risk situation exists. This can be accomplished by doing a “fire time out” prior to starting the case. The risk factors include: (1) open delivery of oxygen/oxygen-enriched environment; (2) an ignition/heat source, such as ESU, laser, or electrocautery; (3) surgery in the head, neck, or upper chest area; (4) an alcohol prep solution. If three or more of these factors are present, then a high fire risk situation exists, and the team should take necessary steps to prevent a fire.

Other safety measures to prevent a fire include keeping the oxygen concentration as low as clinically possible. Notify the surgeon if an oxygen-enriched environment is in proximity to an ignition source. Allow sufficient time for the oxygen-enriched environment to dissipate before activating the ESU or laser. Ensure that alcohol preps are dry before draping the patient, and moisten all sponges that are in proximity to an ignition source.<sup>159–161</sup>

**Figure 5-43** The figure shows the CO<sub>2</sub> fire protection device. Panels **A** and **B** illustrate a 3-dimensional model, and Panels **C** and **D** show the polymer prototype. Number 1, is the barrel for the ESU; Number 2 is the inlet for the CO<sub>2</sub>; Numbers 3 to 6 are the sleeve and exit ports for the CO<sub>2</sub>. (Reprinted with permission from Culp WC Jr, Kimbrough BA, Luna S, et al. Operating room fire prevention: creating an electrosurgical unit fire safety device. *Annals of Surgery*. 2014;260:214–217.)

The ESU has been implicated as the ignition source in as many as 90% of OR fires.<sup>143</sup> This is exacerbated when there is an oxygen-enriched environment, as fuel sources will ignite more rapidly, and burn faster and

hotter. If there was an engineering solution to mitigate this problem, then fire safety would be greatly enhanced.<sup>162</sup> Culp et al.<sup>163,164</sup> might have developed just such a device. Their device consists of a polymer sleeve that fits over an ESU pencil. They then connected a continuous flow of carbon dioxide to the sleeve which flowed around the ESU pencil tip. The CO<sub>2</sub> acted as a fire suppressant and in laboratory tests none of the tested materials was ignited even in the presence of 100% oxygen (Fig. 5-43 and Fig. 5-44.).

Fire extinguishers are divided into three classes, termed A, B, and C, based on the types of fires for which they are best suited. Class A extinguishers are used on paper, cloth, and plastic materials; Class B extinguishers are used for fires when liquids or grease are involved; Class C extinguishers are used for energized electrical equipment. A single fire extinguisher may be useful for any one, two, or all three types of fires. Probably the best fire extinguisher for the OR is the CO<sub>2</sub> extinguisher. This can be used on Class B and C fires and some Class A fires. Other extinguishers are water mist and new environmentally friendly fluorocarbons that replaced the Halon fire extinguisher. Finally, many ORs are equipped with a fire hose that supplies pressurized water at a rate of 50 gallons per minute. Such equipment is best left to the fire department to use, unless there is a need to rescue someone from a fire. In order to effectively use a fire extinguisher, the acronym "PASS" can be used. This stands for *pull* the pin to activate the fire extinguisher, *aim* at the base of the fire, *squeeze* the trigger, and *sweep* the extinguisher back and forth across the base of the fire. When responding to a fire, the acronym RACE is useful. This stands for *rescue*; *alarm*; *confine*; *extinguish*. Clearly, having a plan that everyone is familiar with will greatly facilitate extinguishing the fire and minimizing the harm to the patient and equipment.

**Figure 5-44** The CO<sub>2</sub> fire protection device with white smoke exiting the device (simulating carbon dioxide flow) and surrounding the ESU pencil tip. (Reprinted with permission from Culp WC Jr, Kimbrough BA, Luna S, et al. Operating room fire prevention: creating an electrosurgical unit fire safety device. *Annals of Surgery*.

However, neither fire drills nor the presence and use of fire extinguishers should be relied on to provide a fire-safe operating environment. Only through heightened awareness, continuing education, and ongoing communication can the legs of the fire triad be kept apart and the risk of an OR fire minimized.

### Conclusions and Future Directions

### Acknowledgments

## KEY POINTS

- 1 Candidate gene studies and recent genome-wide association studies suggest that susceptibility to a range of common adverse perioperative events including cardiac (myocardial infarction, ventricular dysfunction, atrial fibrillation), neurologic, and renal, among others, is genetically and epigenetically determined. Ongoing emphasis is placed on prioritizing genetic variants that warrant clinical action.

- 2 Potential applications of biomarkers in perioperative medicine include prognosis, diagnosis and monitoring of adverse events, as well as informing therapeutic decisions. Very few have been rigorously evaluated to demonstrate incremental discriminatory accuracy when added to existing risk stratification models (clinical validity), or change therapy (clinical utility). Among the most promising are natriuretic peptides and C-reactive protein (CRP) for cardiovascular risk prediction, postoperative troponin surveillance to diagnose myocardial injury, and procalcitonin to assess infection in the critically ill.
- 3 Interindividual variability in response to anesthetic agents is as high as 24%, and has underlying genetic mechanisms.
- 4 Individual variability in analgesic responsiveness is attributed to genetic control of peripheral nociceptive pathways and descending central pain modulatory pathways.
- 5 Pharmacogenomic variation in genes modulating drug actions explains part of the variability in drug response, and has shown promising clinical utility for several classes of drugs used perioperatively.
- 6 To facilitate translation to medical practice, systematic evaluation of existing genomic evidence for clinical decisions in the perioperative continuum, updating the practice guidelines, as well as identifying the revenue sources to reimburse the generation and use of genomic information are still required.

## Scientific Rationale for Perioperative Precision Medicine

Intrinsic variability exists across the human population in morphology, behavior, physiology, development, and disease susceptibility. Of particular relevance to our specialty, responses to stressful stimuli and drug therapy are also variable. As we appreciate in our daily practices in the operating rooms and intensive care units, one hallmark of perioperative physiology is the wide range of patient responses to the acute and sometimes repeated exposures to a collection of robust perturbations to homeostasis induced by surgical injury, hemodynamic challenges, vascular cannulations, mechanical circulatory support, intra-aortic balloon counterpulsation, mechanical ventilation, partial/total organ resection, transient limb/organ ischemia-reperfusion, transfusions, anesthetic agents, and the pharmacopoeia used in the perioperative period (the *perioperative exposome*). This translates into substantial interindividual variability in immediate adverse perioperative events (mortality or incidence/severity of organ dysfunction), as well as long-term outcomes (i.e., phenotypes; [Table 6-1](#)). For decades we have attributed this variability only to factors that increase an individual's biologic susceptibility or reduce resilience to surgical trauma (such as age, gender,

frailty, cardiopulmonary fitness, nutritional state, comorbidities)—what we colloquially call “protoplasm”—or to heterogeneity in the intensity of exposure to perioperative stressors. Now we are beginning to appreciate that genomic and epigenomic variation is also partially responsible for this observed variability in patient vulnerability and outcomes. An individual’s susceptibility to adverse perioperative events stems not only from genomic contributions to the development of co-morbid risk factors (such as coronary artery disease or reduced preoperative cardiopulmonary reserve) during his or her lifetime, but also from genomic variability in specific biologic pathways participating in the host response to surgical injury (Fig. 6-1). With increasing evidence suggesting that genomic and epigenomic regulation can significantly modulate risk of adverse perioperative events,<sup>1-7</sup> the emerging field of *perioperative genomics* aims to apply functional genomic approaches to uncover biologic mechanisms that explain why similar patients have such dramatically different outcomes after surgery, and is justified by a unique combination of exposures to environmental insults and postoperative phenotypes that characterize surgical and critically ill patient populations.

**Table 6-1** Categories of Perioperative Phenotypes

Immediate perioperative outcomes	<ul style="list-style-type: none"><li>• Inhospital mortality</li><li>• Perioperative myocardial infarction</li><li>• Perioperative low cardiac output syndrome/acute decompensated heart failure/ventricular dysfunction</li><li>• Perioperative vasoplegic syndrome</li><li>• Perioperative arrhythmias (atrial fibrillation, QTc prolongation)</li><li>• Postoperative bleeding</li><li>• Perioperative venous thrombosis</li><li>• Acute postoperative stroke</li><li>• Postoperative delirium</li><li>• Perioperative acute kidney injury</li><li>• Acute perioperative lung injury/prolonged postoperative mechanical ventilation</li><li>• Acute allograft dysfunction/rejection</li><li>• Postoperative sepsis</li><li>• Multiple organ dysfunction syndrome</li><li>• Postoperative nausea and vomiting</li><li>• Acute postoperative pain</li><li>• Variability in response to anesthetics, analgesics and other perioperative drugs</li><li>• Intermediate phenotypes (plasma biomarker levels)</li></ul>
Long-term postoperative outcomes	<ul style="list-style-type: none"><li>• Event-free survival/major adverse cardiac events</li><li>• Progression of vein graft disease</li><li>• Chronic allograft dysfunction/rejection</li><li>• Postoperative cognitive dysfunction</li><li>• Postoperative depression</li><li>• Transition from acute to chronic pain</li><li>• Cancer progression</li><li>• Quality of life</li></ul>

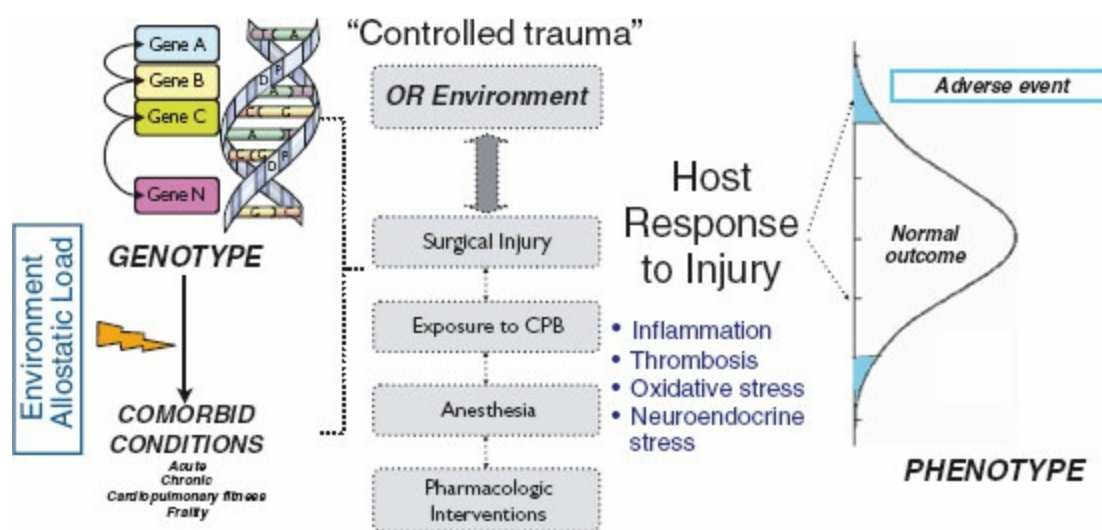

Traditional epidemiologic approaches have been limiting our ability to examine factors contributing to such differential individual susceptibility to adverse perioperative events, often having to generalize from otherwise limited homogenous cohorts to the effects on the overall population. However, it has become apparent that heterogeneity in response at the individual level tends to “stretch out” the population-level response distribution curve (Fig. 6-1).<sup>9</sup> *Precision medicine* is an emerging approach for disease prevention and treatment that takes into account individual variability in genes, environment, and lifestyle for each patient. Although not new, this concept has been recently brought within our reach by three converging opportunities: a rapid and significant expansion of large-scale biologic databases (such as the reference human genome, catalogs of human genetic variation, RNA and protein databases, and curated biologic pathway databases); powerful methods to characterize and monitor patients (including the ability to conduct molecular profiles at the genome, proteome, metabolome and microbiome levels, cellular assays, multiparameter data

streaming, mobile health technologies, patient-activated social networks); and refinement of computational tools for managing and analyzing large datasets (“Big Data” analytics).<sup>10</sup> The presidential Precision Medicine Initiative, launched in 2015, seeks to extend precision medicine to all diseases by building a national research cohort of more than 1 million participants reflecting the diversity of the US population, with commitment to protecting participant privacy, regulatory modernization, and public–private partnerships.

Several unique characteristics of the perioperative continuum suggest it may represent an ideal acute care paradigm to implement precision medicine strategies. First, as a planned event (for the most part), surgery allows for preemptive molecular or genetic profiling that can inform preoperative optimization strategies. Second, the perioperative environment involves intense perturbations and stressors that can unmask underlying genetic susceptibilities. A third unique feature of the perioperative setting is the dynamic decision-making process, which involves multiple decision points over a relatively short period of time, several medications amenable to pharmacogenomics-driven decision support in order to improve their efficacy and safety, and a clinical need for such guidance regarding patient-specific drug choices and dosing (Fig. 6-2). Fourth, the acuity of the initial surgical episode is similarly followed by a rapid convalescence period or a short time to developing adverse events, thus allowing for rapid assessment of clinical outcomes and interventions.<sup>1</sup> Perioperative physicians are generally familiar with risk prediction tools, their implementation in clinical practice including incorporating interindividual variability into risk decisions, communicating risks, and the intricacies of managing longitudinal care transitions throughout the perioperative continuum. Finally, perioperative health-care delivery systems have been early adopters of electronic medical records (EMRs), with several large multi-institutional data integration efforts like the Multicenter Perioperative Group ([www.mpogresearch.org](http://www.mpogresearch.org)) and the Anesthesiology Performance Improvement and Reporting Exchange ([www.aspirecqi.org](http://www.aspirecqi.org)) well underway to enable perioperative medicine research, improve adherence to evidence-based standards of care, and reduce variability in both clinical practice and in common adverse postoperative outcomes, hospital length of stay, and cost.

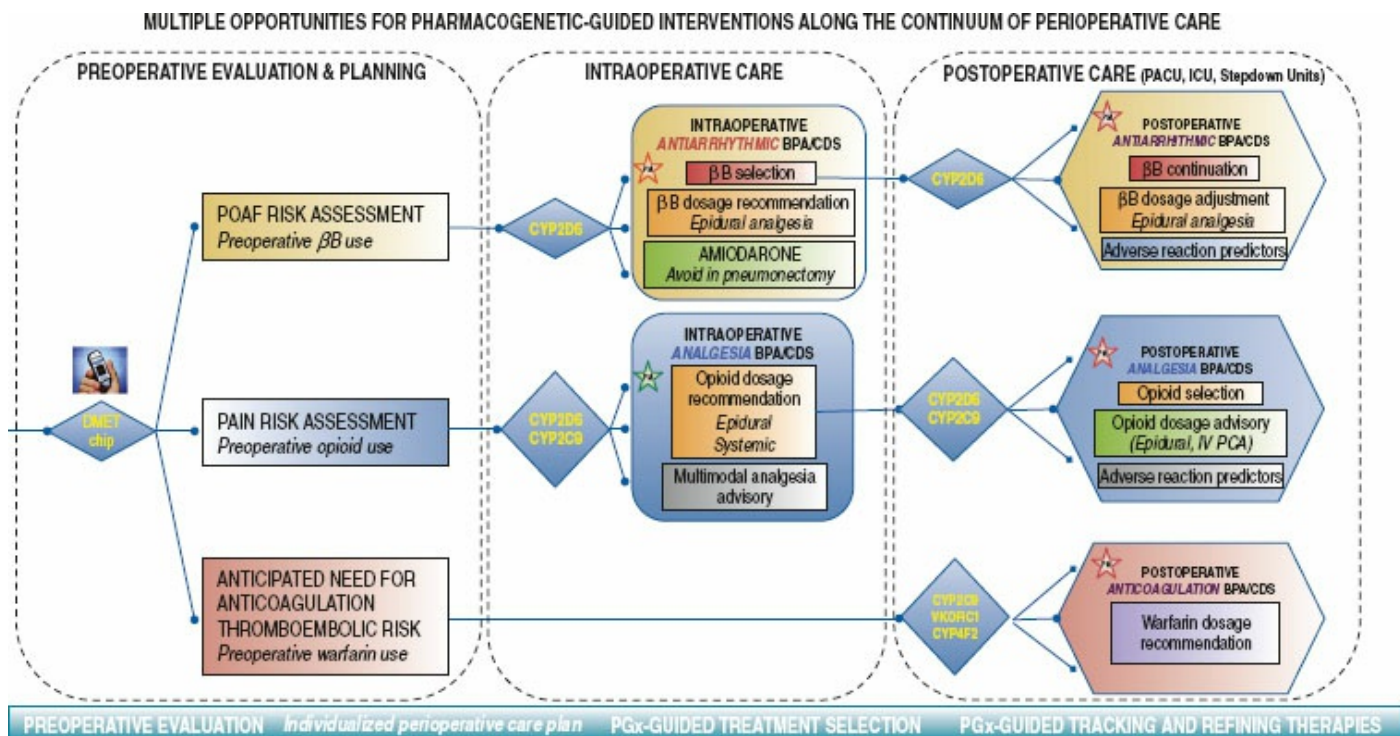

Perioperative precision medicine aims to classify individuals into subpopulations that differ in their susceptibility to develop certain adverse perioperative events, in the biology or prognosis of these adverse outcomes, or in their responses to specific treatments and interventions throughout the perioperative period. Decisions regarding preventive or therapeutic interventions, informed by precision medicine molecular and analytical approaches, would then be concentrated on patients likely to benefit, sparing

expense and side effects for those who will not. Adoption of this new generation of molecular tests into clinical practice is predicated, however, on perioperative physicians becoming increasingly familiar with several key concepts, including patterns of human genome variation, gene regulation, basic population genetic methodology, gene and protein expression analysis, and most importantly the general principles for evaluating biomarker performance. This chapter serves as a primer in genomic and precision medicine by highlighting the evolving applications of genomic technologies to refine perioperative risk stratification, outcome prediction, understanding the complex biologic mechanisms underlying surgical stress responses, as well as identification and validation of novel targets for perioperative organ protection.

**Figure 6-1** The perioperative period represents a unique and extreme example of gene–environment interactions. Perioperative adverse events are complex traits, characteristically involving an interaction between acute exposures to robust operative environmental perturbations (surgical trauma, hemodynamic challenges, exposure to extracorporeal circulation, drug administration—the *perioperative exposome*) occurring on a landscape of susceptibility determined by an individual’s clinical and genetic characteristics (constitutive factors). The observed variability in perioperative outcomes can be in part attributed to genetic and epigenetic variability modulating the host response to surgical injury. Adverse outcomes will develop only in patients whose combined burden of genetic and environmental risk factors exceeds a certain threshold, which may vary with age. In fact, physiologic stress associated with life-threatening injury exposes genetic anomalies that might otherwise go unnoticed. Identification of such genetic contributions not only to disease causation and susceptibility but also to the individual patient’s *responses* to disease and drug therapy, and incorporation of genetic risk information in clinical decision-making, may lead to improved health outcomes and reduced costs. However, some individuals are more sensitive than others to any given exposure to perioperative stressors, making them more susceptible to develop adverse events. Heterogeneity in response at the individual level tends to

“stretch out” the population-level dose–response curve for any perioperative stress exposure.<sup>8</sup> The occurrence of perioperative adverse events is further determined by the effectiveness of adaptive (hormetic) responses to perioperative stressors, which can mitigate injurious systemic host responses. OR, operating room; CPB, cardiopulmonary bypass.

**Figure 6-2** Multiple opportunities exist for implementation of a set of actionable, accessible, and sustainable clinical decision support tools to provide pharmacogenomics (PGx)-guided drug prescription along the continuum of perioperative care, under a new clinical paradigm to reduce hospital length of stay and cost. POAF, postoperative atrial fibrillation;  $\beta$ B, beta blocker; PACU, postanesthesia care unit; ICU, intensive care unit; PCA, patient-controlled analgesia.

## Human Genomic Variation

In elucidating the genetic basis of disease, much of what has been investigated in the pre-Human Genome Project era focused on identifying rare genetic variants (*mutations*) responsible for more than 1,500 monogenic disorders such as hypertrophic cardiomyopathy, long-QT syndrome, sickle cell anemia, cystic fibrosis, or familial hypercholesterolemia. However, most of the genetic diversity in the population is attributable to more widespread DNA sequence variations (*polymorphisms*), typically single nucleotide base substitutions (*single nucleotide polymorphisms*, SNPs), or to a broader category of *structural genetic variants* which include short sequence repeats (*microsatellites*), insertion/deletion (I/D) of one or more nucleotides (*indels*), inversions, and copy number variants (*CNVs*, large segments of DNA that vary

in number of copies),<sup>11</sup> all of which may or may not be associated with a specific phenotype (Fig. 6-3). In addition to the nuclear genome, the mitochondrial genome encodes for 37 genes essential to mitochondrial function. Variability in the mitochondrial DNA is implicated in a growing number of diseases including neurodegenerative, myopathic, cardiovascular, and metabolic conditions, with important implications for perioperative and critical care management.<sup>12</sup> To be classified as a polymorphism, the DNA sequence alternatives (i.e., *alleles*) must exist with a frequency greater than 1% in the population. About 15 million SNPs are estimated to exist in the human genome, approximately once every 300 base pairs, located in genes as well as in the surrounding regions of the genome. Polymorphisms may directly alter the amino acid sequence and therefore potentially alter protein function, or alter regulatory DNA sequences that modulate protein expression. Sets of nearby SNPs on a chromosome are inherited in blocks, referred to as *haplotypes*. As it will be shown later, haplotype analysis is a useful way of applying genotype information in disease gene discovery.

**Figure 6-3** Categories of common human genetic variation. **A:** *Single nucleotide polymorphisms (SNP)* can be silent or have functional consequences: changes in amino acid sequence or premature termination of protein synthesis (if they occur in the coding regions of the gene) or alterations in the expression of the gene, resulting in more or less protein (if they occur in regulatory regions of the gene such as the promoter region or the intron/exon boundaries). Structural genetic variants include: **B:** *Microsatellites* with varying number of dinucleotide (CA)<sub>n</sub> repeats; **C:** *Insertions-deletions*; **D:** *Copy number variation (CNV)*, A-D are long DNA segments, segment D shows variation in copy number. Glossary: *locus*, the location of a gene/genetic marker; *alleles*, alternative forms of a gene/genetic marker; *genotype*, the

observed alleles for an individual at a genetic locus; *heterozygous*, two different alleles are present at a locus; *homozygous*, two identical alleles are present at a locus. An SNP at position 1691 of a gene, with alleles G and A would be written as 1691G>A.

## **Profiling the Regulatory Genome to Understand Perioperative Biology and Discover Biomarkers of Adverse Outcomes**

Genomic approaches are anchored in the “central dogma” of molecular biology, the concept of transcription of messenger RNA (mRNA) from a DNA template, followed by translation of RNA into protein (Fig. 6-4). Since transcription is a key regulatory step that may eventually signal many other cascades of events, the study of RNA abundance in a cell or organ (i.e., quantifying gene expression) can improve the understanding of a wide variety of biologic systems. Furthermore, although the human genome contains only about 26,000 genes, functional variability at the protein level is far more diverse, resulting from extensive posttranscriptional and posttranslational modifications. It is believed that there are approximately 200,000 distinct proteins in humans, further subjected to a wide array of dynamic posttranslational modifications (such as phosphorylation, glycosylation, acetylation, S-nitrosylation, carbonylation, SUMOylation, and disulfide structures, among others), which are implicated in protein stability, coordinate protein–protein interactions, and serve key regulatory functions. Increasing evidence suggests that variability in gene expression levels underlies complex disease and is determined by regulatory DNA polymorphisms affecting transcription, splicing, and translation efficiency in a tissue- and stimulus-specific manner.<sup>13</sup> Thus, in addition to the assessment of genetic variability at the DNA sequence level (*static genomics*), analysis of large-scale variability in the pattern of RNA and protein expression both at baseline and in response to exposure to the multidimensional perioperative stimuli (*dynamic genomics*) using microarray, next-generation sequencing, and proteomic approaches provides a much needed understanding of the overall regulatory networks involved in the pathophysiology of adverse postoperative outcomes (Table 6-2). Such dynamic genomic markers can be incorporated in genomic classifiers and used clinically to improve perioperative risk stratification or monitor postoperative recovery.<sup>14</sup> An example of using the interplay between static genomic and dynamic genomic information for perioperative risk prediction in the case of thoracic aortic disease follows. Although surgical repair of thoracic aortic aneurysms is typically recommended when the aortic diameter reaches 5.0 to 5.5 cm, studies indicate that 60% of aortic dissections occur at aortic diameters smaller than 5.5 cm. However, DNA variants in specific genes (static genomics) can not only distinguish patients at risk for thoracic aortic disease

but also predict the risk of early dissection at diameters smaller than 5.0 cm, thus potentially personalizing the timing of aortic surgery.<sup>15</sup> Moreover, combined genomic and proteomic analysis (dynamic genomics) using expression patterns of 138 genes from peripheral blood leukocytes and levels of seven circulating plasma proteins accurately discriminated patients who developed multiple organ dysfunction syndrome (MODS) after thoracoabdominal aortic aneurysm repair from those who did not. Importantly, these genome-wide gene expression and plasma protein concentration patterns were observed *before* surgical trauma and visceral ischemia-reperfusion injury, suggesting that patients who developed MODS differed preoperatively in either their genetic predisposition or pre-existing inflammatory state.<sup>16</sup>

**Figure 6-4** Increasing complexity of the central dogma of molecular biology. Protein expression involves two main processes: RNA synthesis (*transcription*) and protein synthesis (*translation*), with many intermediate regulatory steps. A single gene can give rise to multiple protein products (isoforms) via processing of preRNA molecules yielding multiple RNA products, including microRNA (miRNA) and small interfering RNA (siRNA) molecules, as well as alternative splicing and RNA editing. Thus functional variability at the protein level, ultimately responsible for biologic effects, is the cumulative result of genetic variability as well as extensive transcriptional, posttranscriptional, translational, and posttranslational modifications.

**Table 6-2** Summary of Gene Expression Studies with Implications for Perioperative Cardiovascular Outcomes

Tissue (Species)	Stimulus/Method	Genomic Signature: Number/Types of Genes	Reference
Myocardium (rat)	Ischemia/ $\mu$ A	14 (wound-healing, Ca-handling)	17
Myocardium (human)	CPB/circulatory arrest/ $\mu$ A	58 (inflammation, transcription activators, apoptosis, stress response)-adults 50 (cardioprotective, antiproliferative, antihypertrophic)-neonates	18 19
Myocardium (human)	CPB/cold cardioplegia-induced ischemia/ RNA-seq	Downregulation of 3,724 transcripts (90%), including humoral immune response and complement pathway genes; upregulation of 374 transcripts (9.1%), including hemoglobin genes	20
Myocardium (rat)	IPC vs. APC/ $\mu$ A	566 differentially regulated/56 jointly regulated (cell defense)	21
Myocardium (rat)	APC vs. APostC/ $\mu$ A	Opposing genomic profiles, 8 gene clusters, <2% jointly regulated genes	22
Myocardium (human)	APC, OPCAB, postoperative LV function/ $\mu$ A	319 upregulated and 281 downregulated gene sets in response to OPCAB; deregulation of fatty acid oxidation, DNA-damage signaling and G-CSF survival (perioperative) and PGC-1 $\alpha$ (constitutive) pathways predict improved LV function in sevoflurane treated patients	23
PBMC (human)	APC, sevoflurane/ $\mu$ A	Deregulation of late preconditioning, PGC-1 $\alpha$ , fatty acid oxidation, and L-selectin pathways	24
Atrial myocardium (pig)	Pacing-induced AF/ $\mu$ A+P	81 (MCL-2 ventricular/atrial isoform shift)	25
Atrial myocardium (human)	AF/ $\mu$ A	1,434 (ventricular-like genomic signature)	26
PBMC (human)	Cardiac surgery, PoAF/ $\mu$ A	1,302 genes uniquely deregulated in PoAF/401 upregulated (oxidative stress), 902 downregulated	27
PBMC (human)	Cardiac surgery, POCD/ $\mu$ A	1,201 genes uniquely deregulated in POCD/531 upregulated, 670 downregulated (inflammation, antigen presentation, cell adhesion, and apoptosis)	28
PBMC (human)	Heart transplant/ $\mu$ A	30 (profile correlated with biopsy-proven rejection; persistent immune activation in response to treatment)	29
PBMC (human)	Heart transplant/RT-PCR	11 (AlloMap, AlloMap score)	30
Myocardium (human)	Heart transplant/P	2 (increased $\alpha$ B-crystallin and tropomyosin serum levels)	31
PBMC, plasma (human)	TAAA/ $\mu$ A+P	138 genes and 7 plasma proteins predicted MODS	16
PBMC (human)	Obstructive CAD in non-diabetic patients/RT-PCR	23-gene expression signature	32
Ventricular myocardium (human)	End-stage cardiomyopathy on LVAD/ $\mu$ A	Combined signature of 28 microRNAs and 29 mRNAs had superior performance to classify status and predict recovery	33

AF, atrial fibrillation; APC, anesthetic preconditioning, APostC, anesthetic postconditioning; CPB, cardiopulmonary bypass; CAD, coronary artery disease; G-CSF, granulocyte colony stimulating factor; IPC, ischemic preconditioning; LV, left ventricle;  $\mu$ A, microarray; MCL-2, myosin light chain 2; MODS, multiple organ dysfunction syndrome; OPCAB, off-pump coronary artery bypass; P, proteomics; PBMC, peripheral blood mononuclear cells; PGC-1 $\alpha$ , peroxisome proliferators-activated receptor  $\gamma$  cofactor-1 $\alpha$ ; PoAF, postoperative atrial fibrillation; POCD, postoperative cognitive decline; RT-PCR, real time polymerase chain reaction; TAAA, thoracoabdominal aortic aneurysm repair; LVAD, left ventricular assist device.

In addition to their applications for risk prediction, dynamic genomic markers can improve mechanistic understanding of perioperative stress, by evaluating and cataloguing organ-specific responses to surgical injury and severe systemic stimuli such as cardiopulmonary bypass (CPB), ischemia-reperfusion, and endotoxemia, which can be subsequently used to identify and validate novel targets for organ protective strategies. We illustrate such applications with several examples from the perioperative period. Using an integrated approach of transcriptomic and proteomic analyses of peripheral blood, the molecular response signatures to cardiac surgery with and without CPB have been characterized,<sup>34</sup> offering novel insights into the concepts of contact activation and compartmentalization of inflammatory responses to

major surgery. Although CPB has been traditionally thought to be a robust trigger of systemic inflammation, similar systemic levels of key inflammatory mediators were in fact seen following off-pump cardiac surgery, but with a delayed onset. Rather than being the primary source of serum cytokines as previously believed, peripheral blood leukocytes only assume a primed phenotype upon contact with the extracorporeal circuit which facilitate their trapping and subsequent tissue-associated inflammatory response. Similar whole blood transcriptomic analyses in cardiac surgical patients have identified convergent regulatory mechanisms triggered by ischemia-reperfusion (e.g., HIF-1 $\alpha$ ), priming of leukocytes by exposure to CPB (e.g., TLR4, TLR6), and downstream signaling of pro- and anti-inflammatory genes (pentraxin 3, resistin), which were previously thought to be distinct.<sup>35</sup> Yet other studies have identified genomic differences in circulating blood leukocytes between patients developing postoperative neurocognitive decline<sup>28</sup> or new-onset postoperative atrial fibrillation (AF).<sup>27</sup> Using circulating blood cells as a sentinel or reporter tissue is complemented by a large number of reports describing gene expression changes directly in myocardial tissue in response to acute ischemia, such as alterations in immediate-early genes (*c-fos*, *junB*), genes coding for calcium-handling proteins (calsequestrin, phospholamban), extracellular matrix, and cytoskeletal proteins in ischemic myocardium,<sup>17</sup> as well as upregulation of transcripts involved in cytoprotection (heat shock proteins), resistance to apoptosis, and cell growth in areas of stunned myocardium.<sup>36</sup> Moreover, cardiac gene expression profiling after CPB and cardioplegic arrest has identified age-related upregulation of inflammatory and transcription activators, apoptosis, and stress genes.<sup>18,19</sup> Conversely, next-generation RNA sequencing of human ventricular myocardium during cold cardioplegia-induced ischemia identified significant downregulation of immune inflammatory and complement genes, and interesting targets in transcription factors regulating reactive oxygen species production, apoptosis, and inflammatory response.<sup>20</sup> Whole-genome expression analysis has also been utilized to study molecular changes associated with myocardial preconditioning. The main functional categories of genes identified as potentially involved in cardioprotective pathways include a host of transcription factors, heat shock proteins, antioxidant genes (heme-oxygenase, glutathione peroxidase), and growth factors, but different gene programs were found to be activated in ischemic versus anesthetic preconditioning, resulting in two distinct molecular cardioprotective phenotypes.<sup>21</sup> More recently, a transcriptional response pattern consistent with late preconditioning has been reported in peripheral blood leukocytes following sevoflurane administration in healthy volunteers, characterized by reduced expression of L-selectin as well as downregulation of genes involved in fatty

acid oxidation and the PGC1 $\alpha$  (peroxisome activated receptor gamma coactivator 1 $\alpha$ ) pathway,<sup>24</sup> which mirrors changes observed in the myocardium from patients undergoing off-pump coronary artery bypass grafting (CABG) (Table 6-2).<sup>23</sup> Deregulation of these conserved survival pathways thus appears to generalize across tissues, making them important targets for cardioprotection, but further studies are needed to correlate perioperative gene expression response patterns in end organs such as the myocardium to those in readily available surrogate tissues such as peripheral blood leukocytes.

A limitation of gene expression studies evaluating RNA abundance like those described earlier is that changes in the *transcriptome* (the complete collection of transcribed elements of the genome) is not fully representative of the *proteome* (the complement of proteins encoded by the genome), since many transcripts are not targeted for translation, as evidenced by the concept of gene silencing by RNA interference. Alternative splicing, a wide variety of posttranslational modifications, and protein–protein interactions responsible for biologic function, would therefore remain undetected by gene expression profiling (Fig. 6-4). This has led to the emergence of *proteomics*, a field seeking to study the sequence, abundance, modification, localization, and function of proteins in a biologic system at a given time and in response to a disease state, trauma, stress, or therapeutic intervention.<sup>37</sup> Thus, proteomics offers a more global and integrated view of biology, complementing other functional genomic approaches. Several preclinical proteomic studies relevant to perioperative medicine have characterized the temporal changes in brain protein expression in response to various inhaled anesthetics,<sup>38,39</sup> or following cardiac surgery with hypothermic circulatory arrest.<sup>40</sup> This may focus further studies aimed to identify new anesthetic binding sites, and the development of neuroprotective strategies. The natural cardioprotective adaptations invoked by mammalian hibernators to cope with ischemia-reperfusion injury have been recently characterized using comparative proteomic approaches, and involve extensive metabolic remodeling with increased expression of fatty acid metabolic proteins and reduced levels of toxic lipid metabolites, offering insights into novel strategies for metabolic optimization as a transformative approach for perioperative organ protection.<sup>41</sup> Furthermore, detailed knowledge of the plasma proteome has profound implications in perioperative transfusion medicine,<sup>42</sup> in particular, related to peptide and protein changes that occur during storage of blood products.

Innate and adaptive immune host responses to surgery play key roles in the pathogenesis of perioperative organ injury and dysfunction, prompting the use of comprehensive immune monitoring via *flow cytometry* (exact quantification of surface marker expression on blood immune cells) and cytokine determination for outcome prediction. Monocytic HLA-DR surface

expression and plasma IL-10 were the best predictors of infection risk after cardiac surgery,<sup>43</sup> whereas surface expression of CD99 and CD47 (markers of neutrophil migratory responses) predict acute kidney injury and, when combined with the EuroSCORE, improve prediction of postoperative intensive care unit (ICU) length of stay after cardiac surgery.<sup>44</sup>

Emerging *metabolomic* tools have created the opportunity to establish metabolic signatures of tissue injury. In a population of patients undergoing alcohol septal ablation for hypertrophic obstructive cardiomyopathy, a human model of planned myocardial infarction, targeted mass spectrometry-based metabolite profiling identified changes in circulating levels of metabolites participating in pyrimidine metabolism, the TCA cycle, and the pentose phosphate pathway as early as 10 minutes after myocardial infarction (MI) in an initial derivation group and were validated in a second, independent group. Coronary sinus sampling distinguished cardiac-derived from peripheral metabolic changes. To assess generalizability, the planned MI-derived metabolic signature (consisting of aconitic acid, hypoxanthine, trimethylamine N-oxide, and threonine) differentiated with high accuracy patients with spontaneous MI.<sup>45</sup> We applied a similar approach to cardiac surgical patients undergoing planned global myocardial ischemia/reperfusion, and identified clear differences in metabolic fuel uptake based on the pre-existing ventricular state (left ventricular dysfunction, coronary artery disease, or neither) as well as altered metabolic signatures predictive of postoperative hemodynamic course and perioperative myocardial infarction.<sup>46</sup> Although simultaneous assessment of coronary sinus effluent in addition to the peripheral blood improves cardiac specificity of the observed signatures, direct measurements of metabolites in myocardial tissue allows marked enrichment and easier detection of potential biomarkers compared to plasma, as well as an assessment of how metabolic substrates are utilized in the tissue of interest. Such studies are possible in cardiac surgical patients where atrial tissues are routinely removed; for example, one study using high-resolution <sup>1</sup>H-NMR spectroscopy identified alterations in myocardial ketone metabolism associated with persistent atrial fibrillation (AF), and the ratio of glycolytic to lipid metabolism end-products correlated positively with time of onset of postoperative AF.<sup>47</sup>

### ***Epigenetics: The Link between Environment and Genes***

In response to outside stimuli, the genome can undergo potentially heritable alterations that can substantially affect gene expression and regulation without altering the DNA sequence—hence termed epigenetic. Whereas DNA is the blueprint, epigenetic information provides the instruction for using that blueprint. The epigenetic code—consisting of DNA-based modifications (e.g.,

DNA methylation), posttranslational modifications of histone proteins (e.g., acetylation), and a growing array of noncoding RNAs (e.g., micro RNA)—is responsive to the environment, differs between cell types, and is susceptible to change, thus representing an excellent target to impact health outcomes. Evidence from animal and human studies suggests that epigenetic mechanisms can explain susceptibility to acute and chronic pain, making them potential therapeutic targets. Specific epigenetic mechanisms relevant to perioperative analgesia involve the developmental expression of opioid receptors and opioid-induced hyperalgesia. In general, opiates tend to increase global DNA methylation levels, whereas local anesthetics conversely have a demethylating effect. This local anesthetic effect may have potential in the development of chronic pain and perioperative cancer medicine.<sup>7</sup> Furthermore, important pathophysiologic processes relevant to the perioperative period like stress-induced proinflammatory responses are regulated by epigenetic factors such as histone acetylation. Again, lidocaine has been shown to both demethylate DNA and have strong anti-inflammatory properties, but a direct epigenetic link has not yet been investigated. Finally, the ability of noncoding RNAs to mediate important organ protective phenomena like anesthetic preconditioning, have recently been reported.<sup>6,48</sup>

Next we review the common genomic strategies used to study disease and drug responses.

## *Overview of Genetic Epidemiology and Functional Genomic Methodology*

Most ongoing research on complex disorders focuses on identifying genetic variants that modify susceptibility to given conditions or drug responses. Often the design of such studies is complicated by the presence of multiple risk factors, gene–environment interactions and a lack of even rough estimates of the number of genes underlying such complex traits. Genetic association studies examine the frequency of specific genetic or epigenetic variants in a population-based sample of unrelated diseased individuals and appropriately matched unaffected controls. The nature of most complex diseases in general, and perioperative adverse outcomes in particular (surgical patients are typically elderly), makes the study of extended multigenerational family pedigrees impractical (with few exceptions, e.g., malignant hyperthermia), due to the lack of availability of pedigree information and/or DNA samples. Even a detailed family history, the first tool in the genomic toolbox, is seldom available for most categories of adverse perioperative events. Feasibility without requiring family-based sample collections, and the increased statistical power to uncover small clinical effects of multiple genes constitute the main advantages of the genetic association approach over

traditional linkage analysis methodology.

Two broad strategies have been employed to identify complex trait loci through association analysis. The *candidate gene* approach is motivated by what is known about the trait biologically, with genes selected because of *a priori* hypotheses about their potential etiologic role in disease based on current understanding of the disease pathophysiology,<sup>49</sup> and can be characterized as a hypothesis-testing approach, but is intrinsically biased. Until recently however, most significant results were gathered from candidate gene association studies. As it will be presented in more detail later, this includes most published reports on specific genotypes associated with a variety of organ-specific perioperative adverse outcomes, including myocardial infarction,<sup>50,51</sup> neurocognitive dysfunction,<sup>52-54</sup> renal compromise,<sup>55-57</sup> vein graft restenosis,<sup>58,59</sup> postoperative thrombosis,<sup>60</sup> vascular reactivity,<sup>61</sup> severe sepsis,<sup>62,63</sup> transplant rejection,<sup>64</sup> and death (for reviews, see references 1 and 4).

The second strategy is the *genome-wide scan*, in which thousands of markers uniformly distributed throughout the genome or epigenome are used to locate regions that may harbor genes or regulatory regions influencing phenotypic variability. Examples include genome-wide association studies (GWAS) or epigenome-wide association studies (EWAS), as well as next-generation sequencing (NGS) technologies involving whole-exome sequencing (all the protein-coding genes in a genome) or whole-genome sequencing. These are unbiased approaches, in the sense that no prior assumptions are being made about the biologic processes involved and no weight is given to known genes, thus allowing the detection of previously unknown trait loci. Within the past decade, an explosion of adequately powered and successfully replicated GWAS have identified very significant genetic contributors to risk for common polygenic diseases like CAD,<sup>65-67</sup> MI,<sup>68</sup> diabetes (type I and II),<sup>69,70</sup> AF,<sup>71</sup> obesity, blood pressure,<sup>72</sup> asthma, common cancers, rheumatoid arthritis, Crohn disease, and others. More recently, the GWAS methodology has also been extended to study key perioperative adverse outcomes like MI,<sup>73</sup> AF,<sup>74</sup> ventricular dysfunction,<sup>75</sup> and acute kidney injury.<sup>76</sup> Although the ability to predict disease remains limited, the newly discovered genetic associations have provided insight into unsuspected mechanisms for disease, many of them located in known drug targets.<sup>77</sup> These studies were facilitated by the completion of several key extensions of the Human Genome Project—the International HapMap Project (a high-resolution map of human genetic variation and haplotypes),<sup>78</sup> the 1,000 Genomes Project (an initial catalog of human genetic variation across ethnically diverse populations),<sup>79</sup> and the Encyclopedia of DNA Elements (ENCODE, a map of functional elements in the human genome, their tissue distribution, and their roles in affecting gene function and regulation),<sup>80</sup>—coupled with advances in high-throughput

genotyping technologies. At the time of this publication, the NHGRI-EBI GWAS Catalog ([www.ebi.ac.uk/gwas](http://www.ebi.ac.uk/gwas)) included 2,193 publications and 16,976 associations, with the list growing every day.<sup>81</sup> Several important themes have emerged from GWAS. First, most SNPs associated with common diseases collectively explain only a small proportion of the observed contribution of heredity to the risk of disease (e.g., 6% for type-2 diabetes), or other complex traits (e.g., 2% for body mass index and 5% for height). This “*missing heritability*” problem is in part explained by the underlying rationale for GWAS—the “Common Disease-Common Variant” hypothesis—postulating that common diseases may arise secondary to cumulative effects of common variants. Most genes however lack a common functional coding variant with a detectable functional effect, yet they typically contain several rare variants. A counter-hypothesis has emerged stating that there are additional novel genes harboring such low frequency variants (possibly with larger effects) that may be the primary drivers of common disease. Currently these variants are poorly detected by genotyping microarrays, but with the advent of next-generation sequencing technologies the potential exists to revolutionize complex traits genetics by identifying and typing rare variants and thus rendering virtually every gene susceptible for genetic analysis. Nevertheless, GWAS results also underscored that small genetic effect sizes do not necessarily translate into limited therapeutic effectiveness of intervening in the respective biologic pathways. Case in point, although the risk variant in HMG CoA reductase was associated in GWAS with only 2.3 mg/dL variability in LDL cholesterol,<sup>82</sup> up to 60% reductions in LDL levels can be achieved by intervening in the LDL metabolic pathway. Secondly, more than two-thirds of the variants identified so far are located either in intergenic regions or in genes of unknown function. This, among other findings, has challenged the very concept of “gene” as the traditional unit of heredity. Discovery of the diverse and ubiquitous roles of new classes of RNA (including *microRNAs* and *short interfering RNAs*) led to an emerging picture of gene regulation as interdependent layers of control consisting of interactions of DNA with regulatory proteins and RNA (Fig. 6-4).<sup>83</sup> Furthermore, as discussed earlier, on top of the DNA sequence lays another (*epigenetic*) code, that influences when and what genes should be transcribed or silenced. The epigenome is laid down during prenatal and postnatal development, and is heritable through cell divisions.

One of the main weaknesses of the genetic association approach is that, unless the marker of interest “travels” (i.e., is in *linkage disequilibrium*) with a functional variant, or the marker allele is the actual functional (causal) variant, the power to detect and map complex trait loci will be reduced. Newer (“next-generation”) approaches based on direct *whole-genome sequencing* depart from the concept of linkage by attempting to directly

identify causal alleles.<sup>84</sup> One particular application of genome-scale sequencing is *whole-exome sequencing*. The *exome*, defined as the protein coding portion of the genome, is comprised in humans of approximately 30 megabases (1%) split amongst approximately 200,000 exons. Aside from the ability to identify rare variants and the obvious substantial cost reduction (~20-fold), this approach has the advantage of focusing on nonsynonymous variants in coding genes for which there are well-established methods of functional validation and interpretation of biologic effects, thus enabling their implication as causal variants. However, it completely misses noncoding and structural variation in the genome. Early results suggest that whole-exome sequencing is an effective approach to identify causal mutations for monogenic disorders but also to distinguish signal (causal rare variants) from noise (background rate of rare mutations) for complex traits. Successful studies so far (e.g., early-onset MI) sequenced individuals informed by the following key observations: the younger the age when developing MI, the greater the heritability; selecting extremes of the phenotype distribution (e.g., young with MI versus old without MI as a “hyper-normal” control group) is likely to improve power; and that genetic discovery may be enhanced by studying multiple ethnicities. These studies have demanded the development of novel statistical methods to associate rare variants with the phenotype. One such promising solution for overcoming the statistical challenges revolving around sequencing low frequency variants is to combine all nonsynonymous SNPs (by gene or biologic pathway) into a single statistical test. The first integrated analysis of a complete human genome in a clinical context, in a patient with a family history of vascular disease and early sudden death has been reported in the *Lancet* in 2010.<sup>85</sup> The analysis revealed increased genetic risk for CAD, MI, type 2 diabetes, and some cancers, as well as rare variants in three genes clinically associated with sudden cardiac death. Furthermore, the patient had variants associated with clopidogrel resistance, a positive response to lipid-lowering therapies, and a low initial dosing requirement for warfarin, suggesting that routine whole-genome sequencing can yield clinically relevant information for individual patients. Several additional advantages of next-generation technologies involve sequencing of multiple genomes per person, such as matched tumor and blood DNA samples from 20 common types of cancer in the Cancer Genome Atlas, which enable development of targeted therapeutics based on a detailed molecular understanding of pathogenesis. Equally important for medical progress is the sequencing of genomes of the billions of microorganisms that dwell within us as part of the Human Microbiome Project.

Other known limitations of genetic association studies include potential false positive findings resulting from population stratification (i.e., admixture of different ethnic or genetic backgrounds in the case and control groups),

and multiple comparison issues when large numbers of genes or variants are being assessed.<sup>86</sup> Replication of findings across different populations or related phenotypes remains the most reliable method of validating a true relationship between genetic polymorphisms and disease, but poor reproducibility in subsequent studies has been one of the main criticisms of the candidate gene association approach.<sup>87</sup> Therefore, it is particularly important to follow initial association analysis results with functional analyses using *in silico*, *in vitro*, and *in vivo* experiments aimed at identifying the causal genetic variants, causal epigenetics, and affected biologic pathways.

Translation of genomic findings to the clinic ultimately revolves around either new disease mechanisms (better disease definition or disease stratification) or new therapeutic strategies (new targets, drug repurposing, or drug response stratification). A particular focus of recent efforts to translate genome sequence information into clinical-decision making revolves around the “actionability” of specific genetic variants, and the level of evidence required to establish whether a variant is actionable. In the context of incidental findings or in an asymptomatic individual, *clinical actionability* represents the degree to which an intervention exists that can mitigate harm before a clinical diagnosis is made. Related terms are *clinical validity*, the accuracy and reliability of a variant in identifying or predicting an event with biologic or medical significance in an asymptomatic individual, and *clinical utility*, the usefulness of information in clinical-decision making and improving health outcomes.<sup>88</sup> The National Institutes of Health has created the Clinical Genome Resource (ClinGen) to serve as an authoritative public portal defining the clinical relevance of genomic variants for use in precision medicine ([www.clinicalgenome.org](http://www.clinicalgenome.org)).<sup>89</sup> Several applications to perioperative medicine are presented in the following sections.

## Genomics and Perioperative Risk Profiling

More than 40 million patients undergo surgery annually in the United States at a cost of \$450 billion. Each year approximately 1 million patients sustain medical complications after surgery, resulting in costs of \$25 billion annually. The proportion of the US population above 65 years of age is estimated to double in the next two decades, leading to a 25% increase in the number of surgeries, a 50% increase in surgery-related costs, and a 100% increase in complications from surgery. Although many preoperative predictors have been identified and are constantly being refined, risk stratification based on clinical, procedural, and biologic markers explains only a small part of the variability in the incidence of perioperative complications. As mentioned earlier, it is becoming increasingly recognized that perioperative morbidity arises as a direct result of the environmental stress of

surgery occurring on a landscape of susceptibility that is determined by an individual's clinical and genetic characteristics, and may even occur in otherwise healthy individuals. Such adverse outcomes will develop only in patients whose combined burden of genetic and environmental risk factors exceeds a certain threshold, which may vary with age. Identification of such genetic contributions not only to disease causation and susceptibility but also to the *response* to disease and drug therapy, and incorporation of genetic risk information in clinical decision-making, may lead to improved health outcomes and reduced costs. For instance, understanding the role of genetic variation in proinflammatory and prothrombotic pathways, the main pathophysiologic mechanisms responsible for perioperative complications, may contribute to the development of target-specific therapies, thereby limiting the incidence of adverse events in high-risk patients. To increase clinical relevance for the practicing perioperative physician, we summarize next existing evidence by specific outcome while highlighting candidate genes in relevant mechanistic pathways (Tables 6-3 through 6-5).

## Predictive Biomarkers for Perioperative Adverse Cardiac Events

### Perioperative Myocardial Infarction and Ventricular Dysfunction

Patients with underlying cardiovascular disease can be at increased risk for perioperative cardiac complications. Over the last few decades several multifactorial risk indices have been developed and validated for both noncardiac (e.g., Lee's Revised Cardiac Risk Index) and cardiac surgical patients (e.g., Hannan scores), with the specific aim of stratifying risk for perioperative adverse events. However, these multifactorial risk indices have only limited predictive value for identifying patients at the highest risk of postoperative MI (PMI).<sup>143</sup> In this context, it has been proposed that genomic approaches could aid in refining an individual's risk profile. The incidence of PMI following cardiovascular surgery remains between 7% and 19%,<sup>144,145</sup> despite advances in surgical, cardioprotective, and anesthetic techniques, and is consistently associated with reduced short- and long-term survival in these patients. The pathophysiology of PMI after cardiac surgery involves systemic and local inflammation, "vulnerable" blood, and neuroendocrine stress.<sup>1</sup> In noncardiac surgery, PMI occurs as a result of two distinct mechanisms: (1) coronary plaque rupture and subsequent thrombosis triggered by a number of perioperative stressors including catecholamine surges, proinflammatory, and prothrombotic states; and (2) myocardial oxygen supply–demand imbalance.<sup>146</sup> Interindividual genetic variability in these mechanistic pathways is extensive, which may combine in any given patient to modulate overall susceptibility to perioperative stress and ultimately the magnitude of myocardial injury. Nevertheless, until recently, only a few studies have explored the role of genetic factors in the development of PMI,<sup>58,116,120</sup>

mainly conducted in patients undergoing CABG surgery (Table 6-3).

### ***Inflammation biomarkers and perioperative adverse cardiac events.***

Although the role of inflammation in cardiovascular disease biology has long been established, we are just beginning to understand the relationship between genetically controlled variability in inflammatory responses to surgery and PMI pathogenesis. Several studies reported independent predictive value for incident PMI after cardiac surgery with CPB of polymorphisms in proinflammatory genes interleukin-6 (*IL6*), intercellular adhesion molecule-1 (*ICAM1*), and E-selectin (*SELE*),<sup>50</sup> or a combined haplotype in the mannose-binding lectin gene (*MBL2* LYQA secretor haplotype), an important recognition molecule in the complement pathway.<sup>51</sup> Similarly, genetic variants in *IL6* and *TNFA* have also been described in association with increased incidence of postoperative cardiovascular complications including PMI after lung surgery for cancer.<sup>90</sup> Several polymorphisms in key proinflammatory genes have been associated with

robust increases in perioperative inflammatory responses in patients undergoing cardiac surgery with CPB. These include the promoter SNPs in *IL6* (-572G>C and -174G>C),<sup>147</sup> also shown to prolong the hospital length of stay<sup>148</sup>; the apolipoprotein E genotype (the  $\epsilon 4$  allele)<sup>149</sup>; SNPs in the tumor necrosis factor genes (*TNFA*-308G>A and -863 C>A, *LTA*+250G>A),<sup>150,151</sup> further associated with postoperative left ventricular dysfunction<sup>93</sup>; and a functional SNP in the macrophage migration inhibitory factor (MIF).<sup>152</sup> Conversely, a genetic variant is modulating the release of the anti-inflammatory cytokine interleukin-10 (*IL10*-1082G>A) in response to CPB, with high levels of IL10 surprisingly being associated with postoperative cardiovascular dysfunction.<sup>94</sup> In patients undergoing elective surgical revascularization for peripheral vascular disease, several SNPs in *IL6* (-174 G>C, nt565 G>A) and *IL10* (-1082 G>A, -819 C>T, -592 C>A, and the ATA haplotype) were associated with endothelial dysfunction and an increased risk of a composite endpoint of acute postoperative cardiovascular events.<sup>123</sup>

CRP is the prototypical acute-phase reactant and the most extensively studied inflammatory marker in clinical studies, and high sensitivity CRP (hs-CRP) has emerged as a robust predictor of cardiovascular risk at all stages, from healthy subjects to patients with acute coronary syndromes and acute decompensated heart failure.<sup>153</sup> Whether CRP is merely a marker or also a mediator of inflammatory processes is yet unclear, but several lines of evidence support the latter theory. In perioperative medicine, elevated preoperative CRP levels have been associated with increased short- and long-term morbidity and mortality in patients undergoing primary elective CABG (cutoff >3 mg/L)<sup>154</sup> as well as in higher-acuity CABG patients (cutoff >10 mg/L).<sup>155</sup> Interestingly, in a retrospective analysis of patients with elevated baseline hs-CRP levels undergoing off-pump CABG surgery, preoperative statin therapy was associated with reduced postoperative myocardial injury and need for dialysis.<sup>156</sup> In elective major noncardiac surgery patients, preoperative CRP levels (cutoff >3.4 mg/L) independently predicted perioperative major cardiovascular events (composite of MI, pulmonary edema, cardiovascular death) and significantly improved the predictive power of RCRI in receiver operating characteristic analysis.<sup>157</sup> In addition to the already established heritability of elevated baseline plasma CRP levels, recent reports indicate that the acute-phase rise in postoperative plasma CRP levels is also genetically determined. The *CRP*1059G>C polymorphism was associated with lower peak postoperative serum CRP following both elective CABG with CPB,<sup>158</sup> as well as esophagectomy for thoracic esophageal cancer.<sup>159</sup> Furthermore, *CRP*-717 C>T polymorphism was associated with stress hyperglycemia in patients undergoing esophagectomy for cancer, leading to increased postoperative infectious complications and ICU length of stay.<sup>160</sup>

**Hemostatic biomarkers and perioperative adverse cardiac events.** The host response to surgery is also characterized by alterations in the coagulation system, manifested as increased fibrinogen concentration, platelet adhesiveness, and plasminogen activator inhibitor-1 (PAI-1) production. These changes can be more pronounced after cardiac surgery, where the complex and multifactorial effects of hypothermia, hemodilution, and CPB-induced activation of coagulation, fibrinolytic, and inflammatory pathways are combined. Dysfunction of the coagulation system following cardiac surgery may manifest on a continuum ranging from increased thrombotic complications such as coronary graft thrombosis, PMI, stroke, pulmonary embolism at one end of the spectrum, to excessive bleeding as the other extreme. The balance between normal hemostasis, bleeding, and thrombosis is markedly influenced by the rate of thrombin formation and platelet activation, with genetic variability known to modulate each of these mechanistic pathways, suggesting significant heritability of the prothrombotic state (see [Table 6-5](#) for an overview of genetic variants associated with postoperative bleeding). Several genotypes in hemostatic genes have been associated with increased risk of coronary graft thrombosis and myocardial injury following CABG. A genetic variant in the promoter of the *PAI-1* gene, consisting of an insertion (5G)/deletion (4G) polymorphism, has been associated with changes in the plasma levels of PAI-1. Since PAI-1 is an important negative regulator of fibrinolytic activity, its polymorphism has been associated with increased risk of early graft thrombosis after CABG, and in a meta-analysis, with increased incidence of MI. Functional genetic variants regulating platelet activation have also been associated with adverse postoperative outcomes. These include a polymorphism in the platelet glycoprotein IIIa gene (*ITGB3*), resulting in increased platelet aggregation (PI polymorphism), associated with increased perioperative myocardial injury, risk of thrombotic coronary graft occlusion, MI, and 1-year mortality, as well as a variant in the protease-activated receptor-4 (*PAR4*) gene associated with PMI after CABG. Advanced heart failure patients requiring ventricular mechanical support represent a unique population that might benefit from a thorough preoperative risk profiling, given that implantation of ventricular assist devices can unmask previously undiagnosed thrombophilia. In the setting of noncardiac surgery, two polymorphisms in platelet glycoprotein receptors (*ITGB3* and *GPI BA*) have been shown to be independent risk predictors of PMI in patients undergoing major vascular surgery, and resulted in improved discrimination of an ischemia risk assessment tool when added to historic and procedural risk factors. Finally, a point mutation in coagulation factor V (1691G>A) resulting in resistance to activated protein C (factor V Leiden), was also associated with various postoperative thrombotic complications following noncardiac surgery. Conversely, in patients

undergoing cardiac surgery, factor V Leiden was associated with significant reductions in postoperative blood loss and overall risk of transfusion. Nevertheless, in a prospective study of CABG patients with routine 3-month postoperative angiographic follow-up, carriers of factor V Leiden had a higher incidence of graft occlusion.

***Natriuretic peptides and perioperative adverse cardiac events.*** Circulating B-type natriuretic peptide (BNP) is a powerful biomarker of cardiovascular outcomes in many circumstances. Produced mainly in the ventricular myocardium, BNP is formed by cleavage of its prohormone by the enzyme corin into the biologically active C-terminal fragment (BNP), and an inactive N-terminal fragment (NT-proBNP). Known stimuli of BNP activation are myocardial mechanical stretch (from volume or pressure overload), acute ischemic injury, and a variety of other proinflammatory and neurohormonal stimuli inducing myocardial stress. Although secreted in 1:1 ratio, circulating levels of BNP and NT-proBNP differ considerably due to different clearance characteristics. A large number of studies have reported consistent associations of baseline plasma BNP or NT-proBNP levels with a variety of postoperative short- and long-term morbidity and mortality end points, independent of the traditional risk factors. For noncardiac surgery, these have been summarized in two meta-analyses that overall indicate an approximately 20-fold increase in risk of adverse perioperative cardiovascular outcomes. Similarly, for cardiac surgery patients, preoperative BNP was a strong independent predictor of inhospital postoperative ventricular dysfunction, hospital length of stay, and 5-year mortality following primary CABG, performing better than peak postoperative BNP. Perioperative plasma corin concentrations decrease in patients undergoing CABG surgery, and larger relative decreases are associated with risk of long-term heart failure hospitalization and death. The current guidelines for preoperative cardiac risk assessment in noncardiac surgery list BNP and NT-proBNP measurements as class IIa/level B indications. However, despite the large number of studies conducted in both cardiac and noncardiac surgery, precise cut-off levels for BNP still need to be determined and adjusted for age, gender, and renal function. Similarly, no BNP-based goal-directed therapies have been reported in the perioperative period, although a role for BNP assays in monitoring aortic valve disease for optimal timing of surgery has been proposed. Furthermore, a recent study by Fox et al. identified genetic variation in natriuretic peptide precursor genes (*NPPA/NPPB*) to be independently associated with decreased risk of postoperative ventricular dysfunction following primary CABG, whereas variants in natriuretic peptide receptor *NPR3* were associated with an increased risk (Table 6-3), offering additional clues into the molecular mechanisms underlying postoperative ventricular dysfunction.

**Genetic variation in vascular reactivity and perioperative adverse cardiac events.** The perioperative period is characterized by robust activation of the sympathetic nervous system, which plays an important role in the pathophysiology of PMI. Thus, patients with CAD who carry specific polymorphisms in adrenergic receptor (AR) genes can be at high risk for catecholamine toxicity and cardiovascular complications. Several functionally important SNPs modulating the AR pathways have been described. One of them is the Arg389Gly polymorphism in  $\beta_1$ -AR gene (*ADRB1*), an SNP associated with increased risk of composite cardiovascular morbidity at 1 year after noncardiac surgery under spinal anesthesia. Of note, perioperative  $\beta$ -blockade had no effect. These findings prompted the investigators to suggest that stratification on AR genotype in future trials may help identify patients likely to benefit from perioperative  $\beta$ -blocker (BB) therapy. Significantly increased vascular responsiveness to  $\alpha$ -adrenergic stimulation (phenylephrine) has been observed in carriers of the endothelial nitric oxide synthase (*NOS3*) 894>T polymorphism, and angiotensin-converting enzyme (*ACE*) I/D polymorphism undergoing cardiac surgery with CPB. Conversely, certain patients, especially those undergoing CPB for cardiac surgery, exhibit a form of vasodilatory shock known as vasoplegic syndrome, with a reported incidence of 8% to 20%. Although the precise mechanisms remain unclear, vasoplegic syndrome and vasopressor requirements have been associated with a common polymorphism in the dimethylarginine dimethyl-aminohydrolase II (*DDAH II*) gene, an important regulator of nitric oxide synthase activity, whereas a functional SNP in angiotensin II type 1 receptor-associated protein (*AGTRAP*), the negative regulator of angiotensin II receptor type 1, is associated with decreased postoperative blood pressure following CABG as well as increased mortality in septic shock. Regulation of pulmonary vascular tone is also subject to genetic regulation, and pediatric patients carrying the Glu298Asp polymorphism in *NOS3* are more likely to develop acute postoperative pulmonary hypertension following intracardiac repair of congenital cardiac disease with CPB. Significant alterations in postoperative endothelial function are observed following on-pump cardiac surgery, and are associated with pronounced changes in biomarkers of endothelial origin like soluble P- and E-selectin, tetranectin, von Willebrand factor, and ACE activity. Moreover, plasma concentrations of IL1 $\beta$ , soluble TREM-1, endocan, and cell-free DNA are early predictive biomarkers of sterile-SIRS after cardiovascular surgery. In addition to variability in perioperative vascular tone, a genetic susceptibility to disturbed fluid handling following cardiac surgery has also been identified, with a common polymorphism in uromodulin (*UMOD*) gene as well as a genetic risk score comprising 14 SNPs related to inflammatory and hemodynamic pathways associated with risk of postoperative fluid overload. Differences in perioperative vascular reactivity in relation to

genetic variants of the  $\beta_2$ -AR (*ADRB2*) have similarly been noted in patients undergoing noncardiac surgery. A common functional *ADRB2* SNP (Glu27) was associated with increased blood pressure responses to endotracheal intubation, whereas the incidence and severity of maternal hypotension and response to treatment in obstetric patients following spinal anesthesia for cesarean delivery was affected by *ADRB2* genotype (Gly16 and/or Glu27 led to lower vasopressor use for the treatment of hypotension).

**Genome-wide association studies and perioperative myocardial adverse events.** A common SNP at the 9p21 locus has been identified in several replicated GWAS analyses to be associated with a wide array of vascular phenotypes in ambulatory populations, including CAD, MI, carotid atherosclerosis, abdominal aortic aneurysms, and intracranial aneurysms. Two studies have validated the association of polymorphisms at the 9p21 locus with both perioperative myocardial injury and all-cause mortality after primary CABG. The mechanism of action of this SNP in the development of PMI and mortality is not completely understood, but involves altered regulation of cell proliferation, senescence, and apoptosis. It seems that cardiac surgery with CPB may trigger the effects of the 9p21 gene variant leading to accumulation of senescent cells or cells that show evidence of necrotic death with cellular edema and lysis.

More recently, polymorphisms in the pregnancy-associated plasma protein A2 (*PAPPA2*), histone deacetylase-4 (*HDAC4*), and SEC24 family, member D (*SEC24D*, a member of the cytoplasmic coat protein complex II) and two intergenic regions were identified as part of a GWAS in patients undergoing CABG to be associated with postoperative MI. These novel findings implicate regulation of insulin-like growth factor bioavailability and repair processes (*PAPPA2*), myocardial cell cycle progression, differentiation and apoptosis, with potential use in predicting individual patient responsiveness to HDAC inhibition (*HDAC4*), and endoplasmic reticulum trapping of misfolded proteins under conditions of endoplasmic reticulum stress such as ischemia and oxidative injury (*SEC24D*). Although these observations are intriguing, future follow-up studies will be needed to translate these initial findings into biologic insights that could lead to predictive and therapeutic advances in perioperative care.

## **Perioperative Atrial Fibrillation**

Perioperative atrial fibrillation (PoAF) remains a significant clinical problem after cardiac and noncardiac thoracic procedures. With an incidence of 27% to 40%, PoAF is associated with increased morbidity, hospital length of stay, rehospitalization, health-care costs, and reduced survival. This has prompted several investigators to develop comprehensive indices for PoAF risk

prediction based on demographic, clinical, electrocardiographic, and procedural risk factors. Nevertheless, the predictive accuracy of these risk indices remains limited, suggesting that genetic variation may play a significant role in the occurrence of PoAF. Heritable forms of AF have been described in the ambulatory nonsurgical population, and it appears both monogenic forms like “lone” AF as well as polygenic predisposition to more common acquired forms like PoAF do exist. A GWAS found two polymorphisms on chromosome 4q25 to be significantly associated with AF, findings replicated in other patient groups from Sweden, the United States, and Hong Kong. Subsequently, this locus was also associated with new onset PoAF after cardiac surgery with CPB (CABG with or without concurrent valve surgery). The mechanism of action of this genetic locus is unknown, but it lies close to several genes involved in the development of pulmonary myocardium, or the sleeve of cardiomyocytes extending from the left atrium into the initial portion of the pulmonary veins. Clinical studies have demonstrated that ectopic foci of electric activity arising from within the pulmonary veins and posterior left atrium play a substantial role in initiating and maintaining AF.

Other candidate susceptibility genes for PoAF include those determining the duration of action potential (voltage-gated ion channels, ion transporters), responses to extracellular factors (adrenergic and other hormone receptors, heat shock proteins), remodeling processes, and magnitude of inflammatory and oxidative stress. It has been described that inflammation, reflected by elevated baseline CRP or IL6 levels and exaggerated postoperative leukocytosis, predicts the occurrence of PoAF. A link between inflammation and the development of PoAF is also supported by evidence that postoperative administration of nonsteroidal anti-inflammatory drugs may reduce the incidence of PoAF. Several studies implicated a functional SNP in the *IL6* promoter (-174G>C) to be associated with higher perioperative plasma IL-6 levels and adverse outcomes after CABG, including PoAF. Activation of innate immune responses has also recently been suggested by results from the first GWAS of PoAF following CABG, which identified a variant in lymphocyte antigen 96 (*LY96*) to be associated with decreased incidence of new-onset PoAF after adjustment for clinical and procedural risk factors. In noncardiac surgery, polymorphisms in *IL6* and *TNFA* genes have been shown to be associated with an increased risk of postoperative morbidity, including new-onset arrhythmias. There is however a contradictory lack of association between CRP levels (strongly regulated by IL-6) and PoAF in women undergoing cardiac surgery, which may reflect gender-related differences. On the other hand, both pre- and postoperative PAI-1 levels were independently associated with development of PoAF following cardiac surgery.

Polymorphisms in adrenergic pathway genes have also been implicated in susceptibility to develop new-onset PoAF after CABG. A functional variant in the  $\beta_1$ -AR gene (*ADRB1* Arg389Gly) was associated with PoAF, with effects modulated by BB therapy, being stronger among patients without BB prophylaxis compared to those receiving BBs. Furthermore, in patients undergoing CABG, polymorphisms in G protein-coupled kinase 5 (*GRK5*) were associated with PoAF despite perioperative BB therapy. *GRK5* is expressed in the normal human heart, and regulates cardiac inotropic and chronotropic actions of catecholamines by physiologically modulating  $\beta$ -AR activity through receptor phosphorylation,  $\beta$ -arrestin recruitment, uncoupling from G proteins, and  $\beta$ -AR desensitization. Although the mechanism of action is incompletely understood, functional variants in *GRK5* modify the  $\beta_1$ -adrenergic receptor signaling pathway similar to partial receptor antagonism by BBs, thus altering their effectiveness. In summary, these polymorphisms may provide new insights into new-onset PoAF pathogenesis and differential responses to BB therapy, which can inform development of personalized perioperative treatment strategies for this common complication.

Investigations in the transcriptional responses to AF in human atrial appendage myocardium collected at the time of cardiac surgery or in preclinical models (Table 6-2) have identified a ventricular-like genomic signature in fibrillating atria, with increased ratios of ventricular to atrial isoforms, suggesting dedifferentiation. It remains unclear whether this “ventricularization” of atrial gene expression reflects cause or effect of AF, but likely represents an adaptive energy-saving process to the high metabolic demand of fibrillating atrial myocardium, akin to chronic hibernation. Because atrial tissue gene expression profiling may help to determine how differentially expressed genes in the human atrium before CPB are related to subsequent biologic pathway activation patterns, and whether specific expression profiles are associated with an increased risk for PoAF or altered response to BB therapy after CABG surgery, we recently reported an expression quantitative trait locus (eQTL) analysis of PoAF. We found significant upregulation of *VOPPI* gene (vesicular overexpressed in cancer-prosurvival protein 1) in patients with PoAF, which was associated with transactivating variants in G-protein coupled kinase 5 (*GRK5*), suggesting potential pathophysiologic roles of *VOPPI* in PoAF despite perioperative BB therapy. Patients who exhibit PoAF after cardiac surgery also display a differential genomic response to CPB in their peripheral blood leukocytes, characterized by upregulation of oxidative stress genes correlated with a significant increase in oxidant stress both systemically (as measured by total peroxide levels) as well as at the myocardial level (as measured in the right atrium). Finally, one study used high-resolution H-NMR spectroscopy to conduct combined metabolomic and proteomic analyses of atrial tissue

samples obtained at the time of cardiac surgery identified alterations in myocardial ketone metabolism associated with persistent AF, and the ratio of glycolytic end products to end products of lipid metabolism correlated positively with time of onset of PoAF.<sup>47</sup>

### **Genetic Variants and Postoperative Event-free Survival**

Large randomized clinical trials examining the benefits of CABG surgery and percutaneous coronary interventions relative to medical therapy and/or to one another have refined our knowledge of early and long-term survival after CABG. Although these studies have helped define subgroups of patients who benefit from surgical revascularization, they also revealed substantial variability in long-term survival after CABG, altered by important demographic and environmental risk factors. Increasing evidence suggests that the *ACE* gene indel polymorphism may influence post-CABG complications, with carriers of the *D* allele having higher mortality and restenosis rates after CABG surgery compared with the *I* allele.<sup>116</sup> As discussed earlier, a prothrombotic amino acid alteration in the  $\beta_3$ -integrin chain of the glycoprotein IIb/IIIa platelet receptor (the  $PIA^2$  polymorphism) is associated with an increased risk for major adverse cardiac events (composite of MI, coronary bypass graft occlusion, or death) following CABG surgery (Table 6-3).<sup>117</sup> And variation at the chromosome 9p21 locus described earlier was associated with 5-year all-cause mortality following CABG, and improved the predictive ability of the EuroSCORE.<sup>96</sup> We found preliminary evidence for association of two functional SNPs modulating  $\beta_2$ -AR activity (Arg16Gly and Gln27Glu) with incidence of death or major adverse cardiac events following cardiac surgery,<sup>119</sup> and further identified a functional polymorphism in thrombomodulin gene (*THBD* Ala455Val) associated with increased 5-year mortality after CABG independent of EuroSCORE.<sup>122</sup>

### **Genetic Susceptibility to Adverse Perioperative Neurologic Outcomes**

Despite advances in surgical and anesthetic techniques, significant neurologic morbidity continues to occur following cardiac surgery,<sup>52</sup> ranging in severity from coma and focal stroke (incidence 1% to 3%) to more subtle cognitive deficits (incidence up to 69%), with a substantial impact on the risk of perioperative death, quality of life, and resource utilization. Variability in the reported incidence of both early and late neurologic deficits remains poorly explained by procedural risk factors, suggesting that environmental (operative) and genetic factors may interact to determine disease onset,

progression, and recovery. The pathophysiology of perioperative neurologic injury is thought to involve complex interactions between primary pathways associated with atherosclerosis and thrombosis, and secondary response pathways like inflammation, vascular reactivity, and direct cellular injury. Many functional genetic variants have been reported in each of these mechanistic pathways involved in modulating the magnitude and the response to neurologic injury, which may have implications in chronic as well as acute perioperative neurocognitive outcomes. For example, the interaction of minor alleles of the CRP (1846 C > T) and IL-6 promoter SNP -174G > C significantly increases the risk of acute stroke after cardiac surgery. Similarly, P-selectin and CRP genes both modulate the susceptibility to postoperative cognitive decline (POCD) following cardiac surgery. Specifically, the loss-of-function minor alleles of *CRP* 1059G > C and *SELP* 1087G > A are independently associated with a *reduction* in the observed incidence of POCD after adjustment for known clinical and demographic covariates (Table 6-4).

Our group has demonstrated a significant association between the apolipoprotein E (*APOE*) E4 genotype and adverse cerebral outcomes in cardiac surgery patients.<sup>129,182</sup> This is consistent with the role of the *APOE* genotype in recovery from acute brain injury, such as intracranial hemorrhage,<sup>183</sup> closed head injury,<sup>184</sup> and stroke,<sup>185</sup> as well as experimental models of cerebral ischemia-reperfusion injury<sup>186</sup>; two subsequent studies in CABG patients, however, have not replicated these initial findings. Furthermore, the incidence of postoperative delirium following major noncardiac surgery in the elderly<sup>133</sup> and in critically ill patients<sup>134</sup> is increased in carriers of the *APOE* ε4 allele. Unlike adult cardiac surgery patients, infants possessing the *APOE* ε2 allele are at increased risk for developing adverse neurodevelopmental sequelae following cardiac surgery<sup>130,131</sup>. The mechanisms by which the *APOE* genotypes might influence neurologic outcomes have yet to be determined, but do not seem to be related to alterations in global cerebral blood flow or oxygen metabolism during CPB<sup>187</sup>; however, genotypic effects in modulating the inflammatory response,<sup>149</sup> extent of aortic atheroma burden,<sup>188</sup> and risk for premature coronary atherosclerosis<sup>189</sup> may play a role.

Consistent with the observed role of platelet activation in the pathophysiology of adverse neurologic sequelae, genetic variants in surface platelet membrane glycoproteins, important mediators of platelet adhesion and platelet-platelet interactions, increase the susceptibility to prothrombotic events. Among these, the P1A<sup>2</sup> polymorphism in glycoprotein IIb/IIIa has been related to various adverse thrombotic outcomes, including acute coronary thrombosis<sup>190</sup> and atherothrombotic stroke.<sup>191</sup> We found the P1A<sup>2</sup> allele to be associated with more severe neurocognitive decline after CPB,<sup>53</sup> which could represent exacerbation of platelet-dependent thrombotic processes associated

with plaque embolism.

Cardiac surgical patients who develop POCD demonstrate inherently different genetic responses to CPB from those without POCD, as evidenced by acute deregulation of gene expression pathways involving inflammation, antigen presentation, and cellular adhesion in peripheral blood leukocytes.<sup>28</sup> These findings corroborate with proteomic changes, in which patients with POCD similarly have significantly higher serologic inflammatory indices compared with those patients without POCD,<sup>192,193</sup> and adds to the increasing level of evidence that CPB does not cause an indiscriminate variation in gene expression, but rather distinct patterns in specific pathways that are highly associated with the development of postoperative complications such as POCD. The implications for perioperative medicine include identifying populations at risk who might benefit not only from an improved informed consent, stratification, and resource allocation, but also from targeted anti-inflammatory strategies.

In noncardiac surgery, a study conducted in patients undergoing carotid endarterectomy concluded that preoperative plasma levels of fibrinogen and high-sensitivity CRP (hsCRP) were independently associated with new periprocedural cerebral ischemic lesions caused by microembolic events, as determined by MRI diffusion-weighted imaging.<sup>194</sup>

### **Genetic Susceptibility to Adverse Perioperative Kidney Outcomes**

Acute kidney injury (AKI) is a common, serious complication of cardiac surgery; about 8% to 15% of patients develop moderate renal injury (>1.0 mg/dL peak creatinine rise), and up to 5% of them develop renal failure requiring dialysis.<sup>195</sup> AKI is independently associated with inhospital mortality rates, exceeding 60% in patients requiring dialysis.<sup>195</sup> Several studies have demonstrated that inheritance of genetic polymorphisms in the APOE gene ( $\epsilon 4$  allele)<sup>57</sup> and in the promoter region of the *IL6* gene (-174 C allele)<sup>178</sup> are associated with AKI following CABG surgery (Table 6-5). We have reported that major differences in peak postoperative serum creatinine rise after CABG are predicted by carrying combinations of polymorphisms that interestingly differ by race: the angiotensinogen (*AGT*) 842 T>C and *IL6* -572G>C variants in Caucasians, and the endothelial nitric oxide synthase (*NOS3*) 894G>T and *ACE* I/D in African Americans are associated with more than 50% reduction in postoperative glomerular filtration rate.<sup>55</sup> A recent GWAS of cardiac surgery-associated AKI identified two novel susceptibility loci, one located in the Bardet-Biedl syndrome 9 (*BBS9*) gene, potentially implicating abnormalities in the primary renal cilia function in the pathogenesis of AKI.<sup>76</sup> Further identification of genotypes predictive of adverse perioperative renal outcomes may facilitate individually tailored

therapy, risk stratify the patients for interventional trials targeting the gene product itself, and aid in medical-decision making (e.g., selecting medical over surgical management).

### **Genetic Variants and Risk for Postoperative Lung Injury**

Prolonged mechanical ventilation (inability to extubate patient by 24 hours postoperatively) is a significant complication following cardiac surgery, occurring in 5.6% and 10.5% of patients undergoing first and repeat CABG surgery, respectively.<sup>196</sup> Several pulmonary and nonpulmonary causes have been identified, and scoring systems based on preoperative and procedural risk factors have been proposed and validated. Recently, genetic variants in the renin–angiotensin pathway and in proinflammatory cytokine genes have been associated with respiratory complications post-CPB. The *D* allele of a common functional I/D polymorphism in the *ACE* gene, accounting for 47% of variance in circulating ACE levels,<sup>197</sup> is associated with prolonged mechanical ventilation following CABG,<sup>198</sup> and with susceptibility to and prognosis of acute respiratory distress syndrome (ARDS).<sup>199</sup> Furthermore, a hyposecretor haplotype in the neighboring genes tumor necrosis factor alpha (*TNFA*) and lymphotoxin alpha (*LTA*) on chromosome 6 (*TNFA-308G/LTA+250G* haplotype)<sup>200</sup> and a functional polymorphism modulating postoperative interleukin 6 levels (*IL6-174G>C*)<sup>178</sup> are independently associated with higher risk of prolonged mechanical ventilation post-CABG. The association is more dramatic in patients undergoing conventional CABG than in those undergoing off-pump CABG (OPCAB), suggesting that in high-risk patients identified by preoperative genetic screening OPCAB may be the optimal surgical procedure. In children, plasma gelsolin and sRAGE have been reported to improve prediction of CPB-induced acute lung injury.<sup>201,202</sup>

A next crucial step in understanding the complexity of adverse perioperative outcomes is to assess the contribution of variations in many genes simultaneously and their interaction with traditional risk factors to the longitudinal prediction of outcomes in individual patients. The use of such outcome predictive models incorporating genetic information may help stratify mortality and morbidity in surgical patients, improve prognostication, direct medical decision-making both intraoperatively and during postoperative follow-up, and even suggest novel targets for therapeutic intervention in the perioperative period.

### **Pharmacogenomics and Anesthesia**

Interindividual variability in response to drug therapy, both in terms of efficacy and safety, is a rule by which anesthesiologists live. In fact, much of

the art of anesthesiology is the astute clinician being prepared to deal with outliers. The term *pharmacogenomics* is used to describe how inherited variations in genes modulating drug actions are related to interindividual variability in drug response. Such variability in drug action may be *pharmacokinetic* or *pharmacodynamic* (Fig. 6-5). Pharmacokinetic variability refers to variability in a drug's absorption, distribution, metabolism, and excretion that mediates its efficacy and/or toxicity. The molecules involved in these processes include drug-metabolizing enzymes (such as members of the cytochrome P450, or CYP, superfamily), and drug transport molecules that mediate drug uptake into, and efflux from, intracellular sites. Pharmacodynamic variability refers to variable drug effects despite equivalent drug delivery to molecular sites of action. This may reflect variability in the function of the molecular target of the drug, or in the pathophysiologic context in which the drug interacts with its receptor-target (e.g., affinity, coupling, expression).<sup>203</sup> Thus, pharmacogenomics investigates complex, polygenically determined phenotypes of drug efficacy or toxicity, with the goal of identifying novel therapeutic targets and customizing drug therapy.

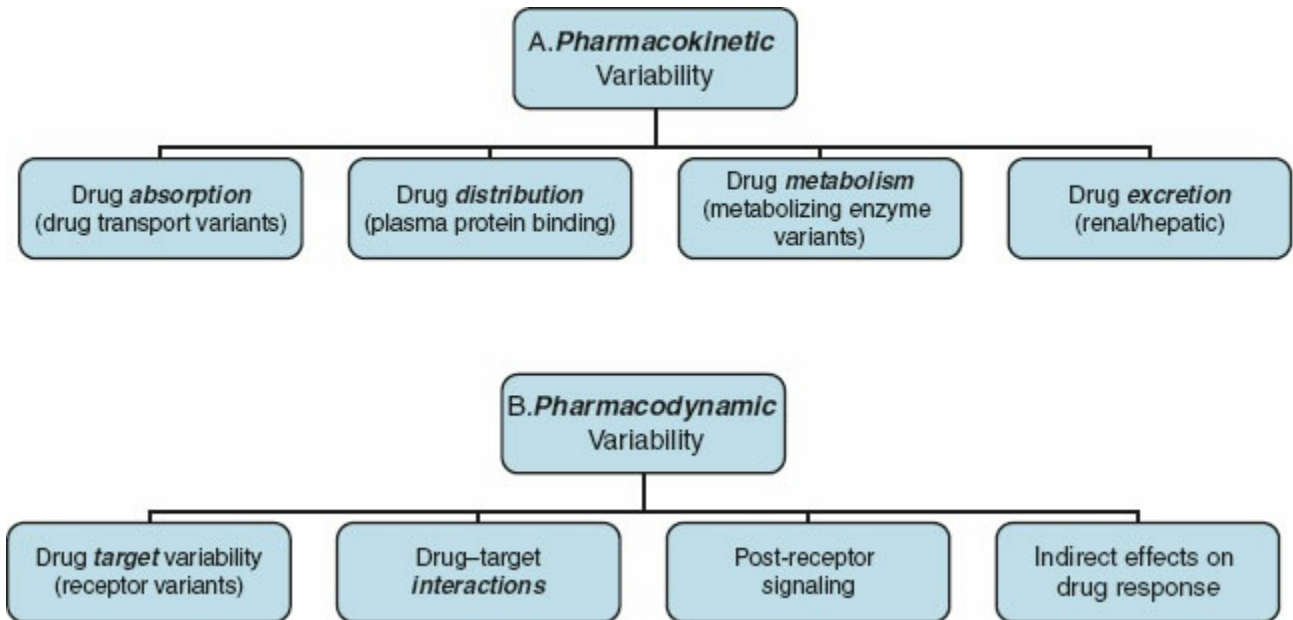

Historically, characterization of the genetic basis for plasma pseudocholinesterase deficiency in 1956 was of fundamental importance to anesthesia and the further development and understanding of genetically determined differences in drug response.<sup>204</sup> Pharmacogenetic testing is currently not recommended in the population at large, but only as an explanation for an adverse event.<sup>205</sup> Moreover, research to refine the genetic underpinnings of malignant hyperthermia, a rare autosomal dominant genetic disease of skeletal muscle calcium metabolism triggered by administration of general anesthesia with volatile anesthetic agents or succinylcholine in susceptible individuals, revealed that MH susceptibility results from a complex interaction between multiple genes and environment.<sup>206</sup> Although direct DNA testing in the general population for susceptibility to MH is currently not recommended, testing individuals with a positive family history has the potential to greatly reduce mortality and morbidity.<sup>205</sup>

### **Genetic Variability in Response to Anesthetic Agents**

Anesthetic potency, defined by the minimum alveolar concentration (MAC) of an inhaled anesthetic that abolishes purposeful movement in response to a noxious stimulus, varies among individuals, with a coefficient of variation (the ratio of standard deviation to the mean) of approximately 10%.<sup>207</sup> This observed variability may be explained by interindividual differences in multiple genes that underlie responsiveness to anesthetics, by environmental or physiologic factors (brain temperature, age), or by

measurement errors. With growing public concern over intraoperative awareness, understanding the mechanisms responsible for this variability may facilitate implementation of patient-specific preventative strategies. Evidence of a genetic basis for increased anesthetic requirements is beginning to emerge, suggested for instance by variability in the immobilizing dose of sevoflurane (as much as 24%) in populations with different ethnic (and thus genetic) backgrounds.<sup>208</sup>

**Figure 6-5** Pharmacogenomic determinants of individual drug response operate by pharmacokinetic and pharmacodynamic mechanisms. **A:** Genetic variants in *drug transporters* (e.g., ATP-binding cassette sub-family B member 1 or *ABCB1* gene) and *drug metabolizing enzymes* (e.g., cytochrome P450 2D6 or *CYP2D6* gene, *CYP2C9* gene, N-acetyltransferase or *NAT2* gene, plasma cholinesterase or *BCHE* gene) are responsible for *pharmacokinetic* variability in drug response. **B:** Polymorphisms in *drug targets* (e.g.,  $\beta_1$  and  $\beta_2$ -adrenergic receptor *ADRB1*, *ADRB2* genes; angiotensin-I converting enzyme *ACE* gene), *postreceptor signaling molecules* (e.g., guanine nucleotide binding protein  $\beta_3$  or *GNB3* gene), or *molecules indirectly affecting drug response* (e.g., various ion channel genes involved in drug-induced arrhythmias) are sources of *pharmacodynamic* variability.

Based on combined pharmacologic and genetic in vivo studies to date, several receptors are unlikely to be direct mediators of MAC, including the GABA<sub>A</sub> (despite their compelling role in IV anesthetic-induced immobility), 5-HT<sub>3</sub>, AMPA, kainate, acetylcholine and  $\alpha_2$ -ARs, and potassium channels.<sup>209</sup> Glycine, NMDA receptors, and sodium channels remain likely candidates.<sup>210</sup> These conclusions, however, do not apply to other anesthetic end points, such as hypnosis, amnesia, and analgesia. Several preclinical proteomic analyses have identified in a more unbiased way a group of potential anesthetic targets for halothane,<sup>37</sup> desflurane,<sup>38</sup> and sevoflurane,<sup>39</sup> which should provide the

basis for more focused studies of anesthetic binding sites. Such “omic” approaches have the potential to evolve into preoperative screening profiles useful in guiding individualized therapeutic decisions, such as prevention of anesthetic awareness in patients with a genetic predisposition to increased anesthetic requirements.

### **Genetic Variability in Pain Response**

Similar to the observed variability in anesthetic potency, the response to painful stimuli and analgesic manipulations varies among individuals. Increasing evidence suggests that pain behavior in response to noxious stimuli and its modulation by the central nervous system in response to drug administration or environmental stress, as well as the development of persistent pain conditions through pain amplification, are strongly influenced by genetic factors.<sup>211–213</sup> Results from studies in twins<sup>214</sup> and inbred mouse strains<sup>215</sup> indicate a moderate heritability for chronic pain syndromes and nociceptive sensitivity, which appears to be mediated by multiple genes. Various strains of knockout mice lacking target genes like neurotrophins and their receptors (e.g., nerve growth factor), peripheral mediators of nociception and hyperalgesia (e.g. substance P), opioid and nonopioid transmitters and their receptors, and intracellular signaling molecules have significantly contributed to the understanding of pain processing mechanisms.<sup>216</sup> A locus responsible for 28% of phenotypic variance in magnitude of systemic morphine analgesia in mouse has been mapped to chromosome 10, in or near the *OPRM* ( $\mu$ -opioid receptor) gene. The  $\mu$ -opioid receptor is also subject to pharmacodynamic variability; polymorphisms in the promoter region of the *OPRM* gene modulating interleukin4-mediated gene expression have been correlated with morphine antinociception. The much quoted *OPRM* 188 A>G polymorphism is associated with decreased responses to morphine-6-glucuronide, resulting in altered analgesic requirements, but also reduced incidence of postoperative nausea and vomiting, and reduced risks of toxicity in renal failure patients. Conversely, variants of the melanocortin 1 receptor (*MC1R*) gene, which produce a red hair-fair skin phenotype, are associated with increased analgesic responses to  $\kappa$ -opioid agonists in women but not men, providing evidence for a gene-by-gender interaction in regulating analgesic response (for a review, see Somogyi et al.<sup>217</sup>). Very recent reports suggest that peripherally located  $\beta_2$ -ARs (*ADRB2*) also contribute to basal pain sensitivity and the development of chronic pain states, as well as opioid-induced hyperalgesia.<sup>213</sup> Functionally important haplotypes in the *ADRB2*<sup>212</sup> and catechol-O-methyltransferase<sup>212</sup> (*COMT*)<sup>218</sup> genes are associated with enhanced pain sensitivity in humans.

In addition to the genetic control of peripheral nociceptive pathways,

considerable evidence exists for genetic variability in the descending central pain modulatory pathways, further explaining the interindividual variability in analgesic responsiveness. One good example relevant to analgesic efficacy is cytochrome P450D6 (*CYP2D6*), a member of the superfamily of microsomal enzymes that catalyze phase I drug metabolism, and responsible for the metabolism of a large number of therapeutic compounds. The relationship between the *CYP2D6* genotype and the enzyme metabolic rate has been extensively characterized, with at least twelve known mutations leading to a tetramodal distribution of *CYP2D6* activity: ultrarapid metabolizers (5% to 7% of the population), extensive metabolizers (60%), intermediate metabolizers (25%), and poor metabolizers (10%). Currently, pharmacogenomic screening tests predict *CYP2D6* phenotype with more than 95% reliability. The consequences of inheriting an allele that compromises *CYP2D6* function include the inability to metabolize codeine (a prodrug) to morphine by O-demethylation, leading to lack of analgesia but increased side effects from the parent drug (e.g., fatigue) in poor metabolizers.<sup>205,211</sup>

4

### **Genetic Variability in Response to Other Drugs Used Perioperatively**

A wide variety of drugs used in the perioperative period display significant pharmacokinetic or pharmacodynamic variability that is genetically modulated (Table 6-6). Although such genetic variation in drug metabolizing enzymes or drug targets usually result in unusually variable drug response, genetic markers associated with rare but life-threatening side effects have also been described. Of note, the most commonly cited categories of drugs involved in adverse drug reactions include cardiovascular, antibiotic, psychiatric, and analgesic medications, and interestingly, each category has a known genetic basis for increased risk of adverse reactions.

There are more than 30 families of drug-metabolizing enzymes in humans, most with genetic polymorphisms shown to influence enzymatic activity. Of special importance to the anesthesiologist is the *CYP2D6*, one of the most intensively studied and best understood examples of pharmacogenetic variation, involved in the metabolism of several drugs including analgesics (codeine, dextromethorphan), BBs, antiarrhythmics (flecainide, propafenone, quinidine), and diltiazem. *CYP2D6* is also involved in the biotransformation of ondansetron, and its genetic variation resulting in the so-called ultrarapid metabolizing phenotype has been associated with increased incidence of ondansetron failure for the prevention of postoperative vomiting but not nausea,<sup>219</sup> which was even more pronounced if tropisetron was used as an antiemetic treatment.<sup>220</sup> Joint assessment of genotype-dependent *CYP2D6* and *CYP3A4* activities revealed that ondansetron metabolism is enantioselective,

and doubling the ondansetron dose is ineffective in patients with high CYP2D6/3A4 activity.<sup>221</sup>

Another important pharmacogenetic variation has been described in cytochrome P450C9 (*CYP2C9*), involved in metabolizing anticoagulants (warfarin), anticonvulsants (phenytoin), antidiabetic agents (glipizide, tolbutamide), and nonsteroidal anti-inflammatory drugs (celecoxib, ibuprofen), among others. Three known *CYP2C9* variant alleles result in different enzyme activities (extensive, intermediate, and slow metabolizer phenotypes), and have clinical implications in the increased risk of life-threatening bleeding complications in slow metabolizers during standard warfarin therapy. This illustrates the concept of “high-risk pharmacokinetics,” which applies to drugs with low therapeutic ratios eliminated by a single pathway (in this case *CYP2C9*-mediated oxidation); genetic variation in that pathway may lead to large changes in drug clearance, concentrations, and effects.<sup>203</sup> Dose adjustments based on the pharmacogenetic phenotype have been proposed for drugs metabolized via both *CYP2D6* and *CYP2C9* pathways,<sup>205</sup> and a commercially available, FDA-approved test (*CYP450* AmpliChip, Roche Molecular Diagnostics) allows clinicians for the first time to test patients for a wide spectrum of genetic variation in drug metabolizing enzymes. The strongest evidence to date for use of pharmacogenomic testing is to aid in the determination of warfarin dosage by using genotypes in the *CYP2C9* and vitamin K epoxide reductase complex 1 (*VKORC1*) genes, with four FDA-approved tests now commercially available. Furthermore, *CYP2C9* genotypes and age could be used in patients on chronic warfarin therapy awaiting elective surgery to inform the time required to discontinue the drug preoperatively (rather than uniformly applying the 5-day recommended guidelines) and thus potentially avoiding the costs associated with surgical delays.<sup>222</sup>

**Table 6-6** Examples of Genetic Polymorphisms Involved In Variable Responses to Drugs Used in the Perioperative Period

Drug Class	Gene Name (Gene Symbol)	Effect of Polymorphism
<b>Pharmacokinetic Variability</b>		
β-blockers	Cytochrome P450 2D6 ( <i>CYP2D6</i> )	Enhanced drug effect
Codeine, dextromethorphan	<i>CYP2D6</i>	Decreased drug effect
Ca-channel blockers	Cytochrome P450 3A4 ( <i>CYP3A4</i> )	Uncertain
Alfentanil	<i>CYP3A4</i>	Enhanced drug response
Angiotensin-II receptor type 1 blockers	Cytochrome P450 2C9 ( <i>CYP2C9</i> )	Enhanced blood pressure response
Warfarin	<i>CYP2C9</i>	Enhanced anticoagulant effect, risk of bleeding
Phenytoin	<i>CYP2C9</i>	Enhanced drug effect
ACE-inhibitors	Angiotensin-I converting enzyme ( <i>ACE</i> )	Blood pressure response
Procainamide	N-acetyltransferase 2 ( <i>NAT2</i> )	Enhanced drug effect
Succinylcholine	Butyrylcholinesterase ( <i>BCHE</i> )	Enhanced drug effect
Digoxin	P-glycoprotein ( <i>ABCB1, MDR1</i> )	Increased bioavailability
<b>Pharmacodynamic Variability</b>		
β-blockers	β <sub>1</sub> and β <sub>2</sub> adrenergic receptors ( <i>ADRB1, ADRB2</i> )	Blood pressure and heart rate response, airway responsiveness to β <sub>2</sub> -agonists
QT-prolonging drugs (antiarrhythmics, cisapride, erythromycin, etc.)	Sodium and potassium ion channels ( <i>SCN5 A, KCNH2, KCNE2, KCNQ1</i> )	Long QT-syndrome, risk of torsade de pointes
Aspirin, glycoprotein IIb/IIIa inhibitors	Glycoprotein IIIa subunit of platelet glycoprotein IIb/IIIa ( <i>ITGB3</i> )	Variability in antiplatelet effects
Phenylephrine	Endothelial nitric oxide synthase ( <i>NOS3</i> )	Blood pressure response

Genetic variation in drug targets (receptors) can have profound effect on drug efficacy, and over 25 examples have already been identified. For example, functional polymorphisms in the β<sub>2</sub>-AR (Arg16Gly, Gln27Glu) influence the bronchodilator and vascular responses to β-agonists, and β<sub>1</sub>-AR variants (Arg389Gly) modulate responses to BBs and may impact postoperative cardiovascular adverse events.<sup>115,170</sup> An excellent recent review by Nagele<sup>223</sup> provides a strong rationale for using pharmacogenomic variation in BB metabolism (*CYP2D6*) and receptor signaling pathways (both *ADRB1*, *ADRB2*, and downstream genes) to determine the effectiveness and safety of perioperative β-blockade for prevention of perioperative MI, particularly given the conflicting results raised by the POISE trial.<sup>224</sup> Finally, clinically important genetic polymorphisms with indirect effects on drug response have been described. These include variants in candidate genes like sodium (*SCN5 A*) and potassium ion channels (*KCNH2, KCNE2, KCNQ1*), which alter susceptibility to drug-induced long-QT syndrome and ventricular arrhythmias (torsade de pointes) associated with the use of drugs like erythromycin, terfenadine, disopyramide, sotalol, cisapride, or quinidine. Carriers of such susceptibility alleles have no manifest QT-interval prolongation or family history of sudden death until QT-prolonging drug challenge is superimposed.<sup>203</sup> Predisposition to QT-interval prolongation (considered a surrogate for risk of life-threatening ventricular arrhythmias) has been responsible for more drug withdrawals from the market than any other category of adverse event in recent times, so understanding genetic

predisposing factors constitutes one of the highest priorities of current pharmacogenomic efforts.

Pharmacogenomics is emerging as an additional modifying component to anesthesia along with age, gender, co-morbidities, and medication usage. Specific testing and treatment guidelines allowing clinicians to appropriately modify drug utilization (e.g., adjust dose or change drug) already exist for a few compounds,<sup>205</sup> and will likely be expanded to all relevant therapeutic compounds (Fig. 6-2), together with identification of novel therapeutic targets. 5

## Conclusions and Future Directions

The Human Genome Project has revolutionized all aspects of medicine, allowing us to assess the impact of genetic variability on disease taxonomy, characterization, and outcome, and individual responses to various drugs and injuries. Mechanistically, information gleaned through genomic approaches is already unraveling longstanding mysteries behind general anesthetic action and adverse responses to drugs used perioperatively. To take full advantage of the unique opportunities offered by the genomic revolution and begin implementing precision medicine concepts, the cycle of innovation in perioperative medicine must shift to a new framework which includes comprehensive and standardized definitions of the phenotypes of interest (including short- and long-term adverse outcomes such as organ injury/dysfunction, adverse drug responses, transition to chronic pain) by developing and refining EMR-driven phenotyping algorithms,<sup>225</sup> followed by identification of the underlying genes, characterization of the mechanism from DNA to phenotype, and rigorous development and validation of actionable companion diagnostics implemented at the point-of-care using EMR-integrated clinical decision support tools (Fig. 6-2).<sup>226</sup> For the anesthesiologist, this may soon translate into prospective risk assessment incorporating genetic profiling of markers important in thrombotic, inflammatory, vascular, and neurologic responses to perioperative stress, with implications ranging from individualized additional preoperative testing and physiologic optimization, to choice of perioperative monitoring strategies and critical care resource utilization. Furthermore, genetic profiling of drug metabolizing enzymes, carrier proteins, and receptors, using currently available high-throughput molecular technologies, will enable personalized choice of drugs and dosage regimens tailored to suit a patient's pharmacogenetic profile. At that point, perioperative physicians will have far more robust information to use in designing the most appropriate and safest anesthetic plan for a given patient.

Although one of the aims of the Human Genome Project is to improve

therapy through genome-based prediction, the birth of personal genomics opens up a Pandora's box of ethical issues, including privacy and the risk for discrimination against individuals who are genetically predisposed for a medical disorder. Such discrimination may include barriers to obtaining health, life, or long-term care insurance, or obtaining employment. Thus, extensive efforts are made to protect patients participating in genetic research from prejudice, discrimination, or uses of genetic information that will adversely affect them. To address the concerns of both biomedical research and health communities, the U.S. Senate has approved in 2003 the Genetic Information and Nondiscrimination Act, which provides the strong safeguards required to protect the public participating in human genome research. Another ethical concern is the transferability of genetic tests across ethnic groups, particularly in the prediction of adverse drug responses. It is known that most polymorphisms associated with variability in drug response show significant differences in allele frequencies among populations and racial groups. Furthermore, the patterns of linkage disequilibrium are markedly different between ethnic groups, which may lead to spurious findings when markers, instead of causal variants, are used in diagnostic tests extrapolated across populations. In exploring racial disparities in health and disease outcomes, considerable debate has focused on whether race and ethnic identity are primarily social or biologic constructs, and the contribution of genetic variability in explaining observed differences in the rates of disease between racial groups. With the goal of personalized medicine being the prediction of risk and treatment of disease on the basis of an individual's genetic profile, some have argued that biologic consideration of race will become obsolete. However, in this discovery phase of the postgenome era, continuing to incorporate racial information in genetic studies should improve our understanding of the architecture of the human genome, and its implications for novel strategies aiming at identifying variants protecting against, or conferring susceptibility to, common diseases and modulating drug effects.<sup>227</sup>

# 7 Experimental Design and Statistics

**NATHAN LEON PACE**

## **Introduction**

### **Foundations**

- Data Structure
- Descriptive Statistics
- Central Location
- Spread or Variability
- Types of Research Design

### **Experimental Medicine: Management of Bias**

- Sampling
- Experimental Constraints
- Control Groups
- Random Allocation of Treatment Groups
- Blinding

### **Experimental Medicine: Statistical Analysis**

- Hypothesis Formulation
- Logic of Proof
- Sample Size Calculations
- Inferential Statistics
- The Fickle  $P$  Value
- The Bayesian Alternative

### **Experimental Medicine: Statistical Tests**

- Interval Data
- Binary Variables
- Linear Regression
- Epidemiology
- Multivariable Linear Regression
- Univariable and Multivariable Logistic Regression
- Propensity Score Matching and Analysis
- Systematic Reviews and Meta-analyses
- Big Data

### **Conclusions**

- Interpretation of Results
- Statistical Resources
- Statistics and Anesthesia

## KEY POINTS

- 1 Statistics and mathematics are the language of scientific medicine.
- 2 Good research planning includes a clear biologic hypothesis, the specification of outcome variables, the choice of anticipated statistical methods, and sample size planning.
- 3 To minimize the risk of bias in clinical research of interventions, the crucial elements of good research design include concurrent control groups; random allocation of subjects to treatment groups; concealment of random allocation; blinding of treatment assignment to patients, caregivers, and outcome assessors; and full reporting of outcomes for all study patients.
- 4 Visual presentation of data by graphs, descriptive statistics (e.g., mean, standard deviation), and inferential statistics (e.g., *t* test, confidence interval) are all essential methods for the presentation of research results.
- 5 Bayesian statistical methods report research results as a function of both observed data and historical (prior) knowledge; the more common Frequentist statistical methods report research results only as a function of observed data.
- 6 Multivariable logistic regression and propensity score matching are statistical techniques for identifying associations between risk factors and outcomes in nonrandomized studies.
- 7 Systematic review and meta-analysis summarize the results of individual studies and permit more powerful inferences for the comparison of interventions.
- 8 Anesthesia data does not yet have the Volume, Velocity, and Variety characteristics of Big Data.
- 9 Resources and guidance for experimental design and statistical methods include policy statements, textbooks, journal articles, and public domain software.

## Introduction

If a physician is to be a practitioner of scientific medicine, he or she must read the language of science to be able to independently assess and interpret the scientific report. Without exception, the language of the medical report is increasingly statistical. Readers of the anesthesia literature, whether in a community hospital or a university environment, cannot and should not totally depend on the editors of journals to banish all errors of statistical analysis and interpretation. In addition, there are regularly questions about simple statistics in examinations required for anesthesiologists. Finally,

certain statistical methods have everyday applications in clinical medicine. This chapter briefly scans some elements of experimental design and statistical analysis.

## Foundations

Statistics is a method for working with *sets* of numbers. Statistics involves the description of number sets, the comparison of number sets with theoretical models, comparison between number sets, and comparison of recently acquired number sets with those from the past. A typical scientific hypothesis asks which of two methods (treatments),  $X$  and  $Y$ , is better. Statistical methods are necessary because there are sources of variation in any data set, including random biologic variation and measurement error. These errors in the data cause difficulties in avoiding bias and in being precise. Bias keeps the true value from being known and fosters incorrect decisions; precision deals with the problem of the data scatter and with quantifying the uncertainty about the value in the population from which a sample is drawn. These statistical methods are relatively independent of the particular field of study.

## Data Structure

Data collected in an experiment include the defining characteristics of the experiment and the values of events or attributes that vary over time or conditions. The former are called *explanatory variables* and the latter are called *response variables*. Variables such as gender, age, and doses of accompanying drugs reflect the variability of the experimental subjects. Explanatory variables, it is hoped, explain the systematic variations in the response variables. In a sense, the response variables depend on the explanatory variables.

Response variables are also called *dependent variables*. Response variables reflect the primary properties of experimental interest in the subjects. Research in anesthesiology is particularly likely to have repeated measurement variables; that is, a particular measurement recorded more than once for each individual. Some variables can be both explanatory and response; these are called *intermediate response variables*. Suppose an experiment is conducted comparing electrocardiography and myocardial responses between five doses of an opioid. One might analyze how ST segments depended on the dose of opioids; here, maximum ST segment depression is a response variable. Maximum ST segment depression might also be used as an explanatory variable to address the subtler question of the extent to which the effect of an opioid dose on postoperative myocardial infarction can be accounted for by ST segment changes.

The mathematical characteristics of the possible values of a variable fit into five classifications (Table 7-1). Properly assigning a variable to the correct data type is essential for choosing the correct statistical technique. For *interval variables*, there is equal distance between successive intervals; the difference between 15 and 10 is the same as the difference between 25 and 20. *Discrete interval data* can have only integer values; for example, number of living children. *Continuous interval data* are measured on a continuum and can be a decimal fraction; for example, blood pressure can be described as accurately as desired (e.g., 136, 136.1, or 136.14 mmHg). The same statistical techniques are used for discrete and continuous data.

**Table 7-1** Data Types

Data Type	Definition	Examples
<b><i>Interval</i></b>		
Discrete	Data measured with an integer only scale	Parity, number of teeth
Continuous	Data measured with a constant scale interval	Blood pressure, temperature
<b><i>Categorical</i></b>		
Dichotomous	Binary data	Mortality, gender
Nominal	Qualitative data that cannot be ordered or ranked	Eye color, drug category
Ordinal	Data ordered, ranked, or measured without a constant scale interval	ASA physical status score, pain score

Putting observations into two or more discrete categories derives *categorical variables*; for statistical analysis, numeric values are assigned as labels to the categories. *Dichotomous data* allow only two possible values; for example, male versus female. *Ordinal data* have three or more categories that can logically be ranked or ordered; however, the ranking or ordering of the variable indicates only relative and not absolute differences between values; there is not necessarily the same difference between American Society of Anesthesiologists Physical Status score I and II as there is between III and IV. Although ordinal data are often treated as interval data in choosing a statistical technique, such analysis may be suspect; alternative techniques for ordinal data are available. *Nominal variables* are placed into categories that have no logical ordering. The eye colors blue, hazel, and brown might be assigned the numbers 1, 2, and 3, but it is nonsense to say that blue is lower than hazel is lower than brown.

## Descriptive Statistics

Although the results of a particular experiment might be presented by repeatedly showing the entire set of numbers, there are concise ways of summarizing the information content of the data set into a few numbers. These numbers are called *sample* or *summary statistics*; summary statistics are calculated using the numbers of the sample. By convention, the symbols of summary statistics are roman letters. The two summary statistics most frequently used for interval variables are the *central location* and the *variability*, but there are other summary statistics. Other data types have analogous summary statistics. Although the first purpose of descriptive statistics is to describe the sample of numbers obtained, there is also the desire to use the summary statistics from the sample to characterize the population from which the sample was obtained. The population also has measures of central location and variability called the *parameters* of the population; Greek letters denote population parameters. Usually, the population parameters cannot be directly calculated because data from all population members cannot be obtained. The beauty of properly chosen summary statistics is that they are the best possible estimators of the population parameters.

These sampling statistics can be used in conjunction with a probability density function to provide additional descriptions of the sample and its population. Also commonly described as a probability distribution, a probability density function is an algebraic equation,  $f(x)$ , which gives a theoretical percentage distribution of  $x$ . Each value of  $x$  has a probability of occurrence given by  $f(x)$ . The most important probability distribution is the *normal* or *Gaussian function*  $f(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right]$ . There are two parameters (population mean and population variance) in the equation of the normal function that are denoted  $\mu$  and  $\sigma^2$ . Often called the *normal equation*, it can be plotted and produces the familiar bell-shaped curve. Why are the mathematical properties of this curve so important to biostatistics? First, it has been empirically noted that when a biologic variable is sampled repeatedly, the pattern of the numbers plotted as a histogram resembles the normal curve; thus, most biologic data are said to follow or to obey a normal distribution. Second, if it is reasonable to assume that a sample is from a normal population, the mathematical properties of the normal equation can be used with the sampling statistic estimators of the population parameters to describe the sample and the population. Third, a mathematical theorem (the central limit theorem) allows the use of the assumption of normality for certain purposes, even if the population is not normally distributed.

## Central Location

The three most common summary statistics of central location for interval variables are the arithmetic *mean*, the *median*, and the *mode*. The mean is merely the average of the numbers in the data set. Being a summary statistic of the sample, the arithmetic mean is denoted by the Roman letter  $\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$  where  $i$  is the index of summation and  $n$  is the count of objects in the sample. If all values in the population could be obtained, then the population mean  $\mu$  could be calculated similarly. Because all values of the population cannot be obtained, the sample mean is used. (Statisticians describe the sample mean as the unbiased, consistent, minimum variance, sufficient estimator of the population mean. Thus, the sample mean  $\bar{x}$  is the estimator of the population mean  $\mu$ .)

The median is the middlemost number or the number that divides the sample into two equal parts—first, ranking the sample values from lowest to highest and then counting up halfway to obtain the median. The concept of ranking is used in nonparametric statistics. A virtue of the median is that it is hardly affected by a few extremely high or low values. The mode is the most popular number of a sample; that is, the number that occurs most frequently. A sample may have ties for the most common value and be bi- or polymodal; these modes may be widely separated or adjacent. The raw data should be inspected for this unusual appearance. The mode is always mentioned in discussions of descriptive statistics, but it is rarely used in statistical practice.

## Spread or Variability

Any set of interval data has variability unless all the numbers are identical. The range of ages from lowest to highest expresses the largest difference. This spread, diversity, and variability can also be expressed in a concise manner. Variability is specified by calculating the *deviation* or *deviate* of each individual  $x_i$  from the center (mean) of all the  $x_i$ 's. The *sum of the squared deviates* is always positive unless all set values are identical. This sum is then divided by the number of individual measurements. The result is the *average squared deviation*; the average squared deviation is ubiquitous in statistics.

The concept of describing the spread of a set of numbers by calculating the average distance from each number to the center of the numbers applies to both a sample and a population; this average squared distance is called the *variance*. The population variance is a parameter and is represented by  $\sigma^2$ . As with the population mean, the population variance is not usually known and cannot be calculated. Just as the sample mean is used in place of the population mean, the sample variance is used in place of the population

variance. The sample variance is  $VAR = SD^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{(n-1)}$ .

Statistical theory demonstrates that if the divisor in the formula for  $SD^2$  is  $(n - 1)$  rather than  $n$ , the sample variance is an unbiased estimator of the population variance. Although the variance is used extensively in statistical calculations, the units of variance are squared units of the original observations. The square root of the variance has the same units as the original observations; the square roots of the sample and population variances are called the *sample (SD)* and *population ( $\sigma$ ) standard deviations*.

It was previously mentioned that most biologic observations appear to come from populations with normal distributions. By accepting this assumption of a normal distribution, further meaning can be given to the sample summary statistics (mean and SD) that have been calculated. This involves the use of the expression  $\bar{x} \pm k \times SD$  where  $k = 1, 2, 3$ , and so forth. If the population from which the sample is taken is unimodal and roughly symmetric, then the bounds for 1, 2, and 3 encompasses roughly 68%, 95%, and 99% of the sample and population members.

## Types of Research Design

Ultimately, research design consists of choosing what subjects to study, what experimental conditions and constraints to enforce, and which observations to collect at what intervals. A few key features in this research design largely determine the strength of scientific inference on the collected data. These key features allow the classification of research reports (Table 7-2). This classification reveals the variety of experimental approaches and indicates strengths and weaknesses of the same design applied to many research problems.

The first distinction is between *longitudinal* and *cross-sectional* studies. The former is the study of changes over time, whereas the latter describes a phenomenon at a certain point in time. For example, reporting the frequency with which certain drugs are used during anesthesia is a cross-sectional study, whereas investigating the hemodynamic effects of different drugs during anesthesia is a longitudinal one.

Longitudinal studies are next classified by the method with which the research subjects are selected. These methods for choosing research subjects can be either *prospective* or *retrospective*; these two approaches are also known as *cohort* (prospective) or *case-control* (retrospective). A prospective study assembles groups of subjects by some input characteristic that is thought to change an output characteristic; a typical input characteristic would be the opioid drug administered during anesthesia; for example, remifentanil or fentanyl. A retrospective study gathers subjects by an output characteristic; an

output characteristic is the status of the subject after an event; for example, the occurrence of a myocardial infarction. A prospective (cohort) study would be one in which a group of patients undergoing neurologic surgery was divided in two groups, given two different opioids (remifentanil or fentanyl), and followed for the development of a perioperative myocardial infarction. In a retrospective (case-control) study, patients who suffered a perioperative myocardial infarction would be identified from hospital records; a group of subjects of similar age, gender, and disease who did not suffer a perioperative myocardial infarction also would be chosen, and the two groups would then be compared for the relative use of the two opioids (remifentanil or fentanyl). Retrospective studies are a primary tool of epidemiology. A case-control study can often identify an association between an input and output characteristic, but the causal link or relationship between the two is more difficult to specify.

**Table 7-2** Classification of Clinical Research Reports

I. Longitudinal studies
A. Prospective (cohort) studies
1. Studies of deliberate intervention
a. Concurrent controls
b. Historical controls
2. Observational studies
B. Retrospective (case-control) studies
II. Cross-sectional studies

 Prospective studies are further divided into those in which the investigator performs a deliberate intervention and those in which the investigator merely observes. In a study of *deliberate intervention*, the investigator would choose several anesthetic maintenance techniques and compare the incidence of postoperative nausea and vomiting. If it were performed as an *observational study*, the investigator would observe a group of patients receiving anesthetics chosen at the discretion of each patient's anesthesiologist and compare the risk of postoperative nausea and vomiting among the anesthetics used. Obviously, in this example of an observational study, there has been an intervention; an anesthetic has been given. The crucial distinction is whether the investigator controlled the intervention. An observational study may reveal differences among treatment groups, but whether such differences are the consequence of the treatments or of other differences among the patients receiving the treatments will remain obscure. The comparison of cohorts with interventions not assigned under experimental control is a prominent technique of epidemiology.

Studies of deliberate intervention are further subdivided into those with concurrent controls and those with historical controls. Concurrent controls are

either a simultaneous parallel control group or a self-control study; historical controls include previous studies and literature reports. A *randomized controlled trial* (RCT) is thus a longitudinal, prospective study of deliberate intervention with concurrent controls.

Although most of this discussion about experimental design has focused on human experimentation, the same principles apply and should be followed in animal experimentation. The randomized, controlled clinical trial is the most potent scientific tool for evaluating medical treatment; randomization into treatment groups is relied on to equally weigh the subjects of the treatment groups for baseline attributes that might predispose or protect the subjects from the outcome of interest.

## Experimental Medicine: Management of Bias

Case reports engender interest, suspicion, doubt, wonder, and perhaps the desire to experiment; however, the case report is not sufficient evidence to advance scientific medicine. The experimenter attempts to constrain and control, as much as possible, the environment in which he or she collects numbers to test a hypothesis. The elements of experimental design are intended to prevent and minimize the possibility of bias, that is, a deviation of results or inferences from the truth.

### Sampling

Two words of great importance to statisticians are *population* and *sample*. In statistical language, each has a specialized meaning. Instead of referring only to the count of individuals in a geographic or political region, population refers to any target group of things (animate or inanimate) in which there is interest. For anesthesia researchers, a typical target population might be mothers in the first stage of labor or head-trauma victims undergoing craniotomy. A target population could also be cell cultures or hospital bills. A sample is a subset of the target population. Samples are taken because of the impossibility of observing the entire population; it is generally not affordable, convenient, or practical to examine more than a relatively small fraction of the population. Nevertheless, the researcher wishes to generalize from the results of the small sample group to the entire population.

Although the subjects of a population are alike in at least one way, these population members are generally quite diverse in other ways. Because the researcher can work only with a subset of the population, he or she hopes that the sample of subjects in the experiment is representative of the population's diversity. Head-injury patients can have open or closed wounds, a variety of coexisting diseases, and normal or increased intracranial pressure. These

subgroups within a population are called *strata*. Often the researcher wishes to increase the sameness or homogeneity of the target population by further restricting it to just a few strata; perhaps only closed and not open head injuries will be included. Restricting the target population to eliminate too much diversity must be balanced against the desire to have the results be applicable to the broadest possible population of patients.

The best hope for a representative sample of the population would be realized if every subject in the population had the same chance of being observed; this is called *random sampling*. If there were several strata of importance, random sampling from each stratum would be appropriate. Unfortunately, in most clinical anesthesia studies researchers are limited to using those patients who happen to show up at their hospitals; this is called *convenience sampling*. Convenience sampling is also subject to the nuances of the surgical schedule, the goodwill of the referring physician and attending surgeon, and the willingness of the patient to cooperate. At best, the convenience sample is representative of patients at that institution, with no assurance that these patients are similar to those elsewhere. Convenience sampling is also the rule in studying new anesthetic drugs; such studies are typically performed on healthy, young volunteers.

### **Experimental Constraints**

The researcher must define the conditions to which the sample members will be exposed. Particularly in clinical research, one must decide whether these conditions should be rigidly standardized or whether the experimental circumstances should be adjusted or individualized to the patient. In anesthetic drug research, should a fixed dose be given to all members of the sample or should the dose be adjusted to produce an effect or to achieve a specific end point? Standardizing the treatment groups by fixed doses simplifies the research work. There are risks to this standardization, however: (1) a fixed dose may produce excessive numbers of side effects in some patients, (2) a fixed dose may be therapeutically insufficient in others, and (3) a treatment standardized for an experimental protocol may be so artificial that it has no broad clinical relevance, even if demonstrated to be superior. The researcher should carefully choose and report the adjustment/individualization of experimental treatments.

### **Control Groups**

Even if a researcher is studying just one experimental group, the results of the experiment are usually not interpreted solely in terms of that one group but are also contrasted and compared with other experimental groups. Examining

the effects of a new drug on blood pressure during anesthetic induction is important, but what is more important is comparing those results with the effects of one or more standard drugs commonly used in the same situation. Where can the researcher obtain these comparative data? There are several possibilities: (1) each patient could receive the standard drug under identical experimental circumstances at another time, (2) another group of patients receiving the standard drug could be studied simultaneously, (3) a group of patients could have been studied previously with the standard drug under similar circumstances, and (4) literature reports of the effects of the drug under related but not necessarily identical circumstances could be used. Under the first two possibilities, the control group is contemporaneous—either a *self-control* (crossover) or *parallel control* group. The second two possibilities are examples of the use of *historical controls*.

Because historical controls already exist, they are convenient and seemingly cheap to use. Unfortunately, the history of medicine is littered with the “debris” of therapies enthusiastically accepted on the basis of comparison with past experience. A classic example is operative ligation of the internal mammary artery for the treatment of angina pectoris—a procedure now known to be of no value. Proposed as a method to improve coronary artery blood flow, the lack of benefit was demonstrated in a trial where some patients had the procedure and some had a sham procedure; both groups showed benefit.<sup>1</sup> There is now firm empirical evidence that studies using historical controls usually show a favorable outcome for a new therapy, whereas studies with concurrent controls, that is, parallel control group or self-control, less often reveal a benefit.<sup>2</sup> Nothing seems to increase the enthusiasm for a new treatment as much as the omission of a concurrent control group. If the outcome with an old treatment is not studied simultaneously with the outcome of a new treatment, one cannot know if any differences in results are a consequence of the two treatments, or of unsuspected and unknowable differences between the patients, or of other changes over time in the general medical environment. One possible exception would be in studying a disease that is uniformly fatal (100% mortality) over a very short time.

### **Random Allocation of Treatment Groups**

Having accepted the necessity of an experiment with a control group, the question arises as to the method by which each subject should be assigned to the predetermined experimental groups. Should it depend on the whim of the investigator, the day of the week, the preference of a referring physician, the wish of the patient, the assignment of the previous subject, the availability of a study drug, a hospital chart number, or some other arbitrary criterion? All

such methods have been used and are still used, but all can ruin the purity and usefulness of the experiment. It is important to remember the purpose of sampling: By exposing a small number of subjects from the target population to the various experimental conditions, one hopes to make conclusions about the entire population. Thus, the experimental groups should be as similar as possible to each other in reflecting the target population; if the groups are **3** different, selection bias is introduced into the experiment. Although randomly allocating subjects of a sample to one or another of the experimental groups requires additional work, this principle prevents selection bias by the researcher, minimizes (but cannot always prevent) the possibility that important differences exist among the experimental groups, and disarms the critics' complaints about research methods. Random allocation is most commonly accomplished by the use of computer-generated random numbers. Even with a random allocation process, selection bias can occur if research personnel are allowed knowledge of the group assignment of the next patient to be recruited for a study. Failure to conceal random allocation leads to biases in the results of clinical studies.<sup>3,4</sup>

## Blinding

*Blinding* refers to the masking from the view of patient and experimenters the experimental group to which the subject has been or will be assigned. In clinical trials, the necessity for blinding starts even before a patient is enrolled in the research study; this is called the *concealment of random allocation*. There is good evidence that, if the process of random allocation is accessible to view, the referring physicians, the research team members, or both are tempted to manipulate the entrance of specific patients into the study to influence their assignment to a specific treatment group<sup>5</sup>; they do so having formed a personal opinion about the relative merits of the treatment groups and desiring to get the “best” for someone they favor. This creates bias in the experimental groups.

Each subject should remain, if possible, ignorant of the assigned treatment group after entrance into the research protocol. The patient's expectation of improvement, a placebo effect, is a real and useful part of clinical care. But when studying a new treatment, one must ensure that the fame or infamy of the treatments does not induce a bias in outcome by changing patient expectations. A researcher's knowledge of the treatment assignment can bias his or her ability to administer the research protocol and to observe and record data faithfully; this is true for clinical, animal, and in vitro research. If the treatment group is known, those who observe data cannot trust themselves to record the data impartially and dispassionately. The appellations *single-blind* and *double-blind* to describe blinding are commonly

used in research reports, but often applied inconsistently; the researcher should carefully plan and report exactly who is blinded.

## Experimental Medicine: Statistical Analysis

### Hypothesis Formulation

The researcher starts work with some intuitive feel for the phenomenon to be studied. Whether stated explicitly or not, this is the *biologic hypothesis*; it is a statement of experimental expectations to be accomplished by the use of experimental tools, instruments, or methods accessible to the research team. An example would be the hope that isoflurane would produce less myocardial ischemia than fentanyl; the experimental method might be the electrocardiography determination of ST segment changes. The biologic hypothesis of the researcher becomes a *statistical hypothesis* during research planning. The researcher measures quantities that can vary—variables such as heart rate or temperature or ST segment change—in samples from populations of interest. In a statistical hypothesis, statements are made about the relationship among parameters of one or more populations. (To restate, a *parameter* is a number describing a variable of a population; Greek letters are used to denote parameters.) The typical statistical hypothesis can be established in a somewhat rote fashion for every research project, regardless of the methods, materials, or goals. The most frequently used method of setting up the algebraic formulation of the statistical hypothesis is to create two mutually exclusive statements about some parameters of the study population (Table 7-3); estimates for the values for these parameters are acquired by sampling data. In the hypothetical example comparing isoflurane and fentanyl,  $\phi_1$  and  $\phi_2$  would represent the ST segment changes with isoflurane and with fentanyl. The *null hypothesis* is the hypothesis of no difference of ST segment changes between isoflurane and fentanyl. The *alternative hypothesis* is usually nondirectional, that is, either  $\phi_1$  is less than  $\phi_2$  or  $\phi_1$  is more than  $\phi_2$ ; this is known as a *two-tail alternative hypothesis*. This is a more conservative alternative hypothesis than assuming that the inequality can only be either less than or greater than.

**Table 7-3** Algebraic Statement of Statistical Hypotheses

$H_0: \phi_1 = \phi_2$ (null hypothesis)
$H_a: \phi_1 \neq \phi_2$ (alternative hypothesis)
$\phi_1$ = Parameter estimated from sample of first population
$\phi_2$ = Parameter estimated from sample of second population

## Logic of Proof

One particular decision strategy is used most commonly to choose between the null and alternative hypothesis. The approach is to assume that the null hypothesis is true even though the goal of the experiment is to show that there is a difference. One examines the consequences of this assumption by examining the actual sample values obtained for the variable(s) of interest. This is done by calculating what is called a *sample test statistic*; sample test statistics are calculated from the sample numbers. Associated with a sample test statistic is a *probability*. One also chooses the *level of significance*; the level of significance is the probability level considered too low to warrant support of the null hypothesis being tested. If sample values are sufficiently unlikely to have occurred by chance (i.e., the probability of the sample test statistic is less than the chosen level of significance), the null hypothesis is rejected; otherwise, the null hypothesis is not rejected.

Because the statistics deal with probabilities, not certainties, there is a chance that the decision concerning the null hypothesis is erroneous. These errors are best displayed in table form (Table 7-4); condition 1 and condition 2 could be different drugs, two doses of the same drug, or different patient groups. Of the four possible outcomes, two decisions are clearly undesirable. The error of wrongly rejecting the null hypothesis (false-positive) is called the *type I* or  $\alpha$ -error. The experimenter should choose a probability value for  $\alpha$  before collecting data; the experimenter decides how cautious to be against falsely claiming a difference. The most common choice for the value of  $\alpha$  is 0.05. What are the consequences of choosing an  $\alpha$  of 0.05? Assuming that there is, in fact, no difference between the two conditions and that the experiment is to be repeated 20 times, then during one of these experimental replications (5% of 20), a mistaken conclusion that there is a difference would be made. The probability of a type I error depends on the chosen level of significance and the existence or nonexistence of a difference between the two experimental conditions. The smaller the chosen  $\alpha$ , the smaller will be the risk of a type I error.

The error of failing to reject a false null hypothesis (false-negative) is called a *type II* or  $\beta$ -error. (The power of a test is  $1 - \beta$ .) The probability of a type II error depends on four factors. Unfortunately, the smaller the  $\alpha$ , the greater the chance of a false-negative conclusion; this fact keeps the experimenter from automatically choosing a very small  $\alpha$ . Second, the more variability there is in the populations being compared, the greater the chance of a type II error. This is analogous to listening to a noisy radio broadcast; the more static there is, the harder it will be to discriminate between words. Next, increasing the number of subjects will lower the probability of a type II error. The fourth and most important factor is the magnitude of the difference

between the two experimental conditions. The probability of a type II error goes from very high, when there is only a small difference, to extremely low, when the two conditions produce large differences in population parameters.

### Sample Size Calculations

Formerly, researchers typically ignored the latter error in experimental design. The practical importance of worrying about type II errors reached the consciousness of the medical research community several decades ago. Some controlled clinical trials that claimed to find no advantage of new therapies compared with standard therapies lacked sufficient statistical power to discriminate between the experimental groups and would have missed an important therapeutic improvement. As an example, the formula for calculating the size of each sample in a study comparing the means of two populations is:  $n = 2 \left[ \frac{(z_\alpha - z_\beta) \sigma}{\mu_1 - \mu_2} \right]^2$ . The  $z$  values are taken from the normal probability distribution and represent assumptions about the prespecified  $\alpha$  and  $\beta$ ; the sigma ( $\sigma$ ) is the assumed common SD; the mu's ( $\mu$ ) are the assumed population values. There are four options for decreasing type II error (increasing statistical power): (1) raise  $\alpha$ , (2) reduce population variability, (3) make the sample bigger, and (4) make the difference between the conditions greater. Under most circumstances, only the sample size can be varied. Sample size planning has become an important part of research design for controlled clinical trials. Some published research still fails the test of adequate sample size planning.

**Table 7-4** Errors in Hypothesis Testing: The Two-Way Truth Table

		Reality (population parameters)	
		Conditions 1 and 2 Equivalent	Conditions 1 and 2 Not Equivalent
Conclusion from sample (sample statistics)	Conditions 1 and 2 equivalent <sup>a</sup>	Correct conclusion	False-negative type II error ( $\beta$ -error)
	Conditions 1 and 2 not equivalent <sup>b</sup>	False-positive type I error ( $\alpha$ -error)	Correct conclusion

<sup>a</sup>Do not reject the null hypothesis: condition 1 = condition 2.

<sup>b</sup>Reject the null hypothesis: condition 1  $\neq$  condition 2.

### Inferential Statistics

The testing of hypotheses or *significance testing* has been the main focus of **4** inferential statistics. Hypothesis testing allows the experimenter to use data from the sample to make inferences about the population. Statisticians have created formulas that use the values of the samples to calculate test statistics. Statisticians have also explored the properties of

various theoretical probability distributions. Depending on the assumptions about how data are collected, the appropriate probability distribution is chosen as the source of critical values to accept or reject the null hypothesis. If the value of the test statistic calculated from the sample(s) is greater than the critical value, the null hypothesis is rejected. The critical value is chosen from the appropriate probability distribution after the magnitude of the type I error is specified.

There are parameters within the equation that generate any particular probability distribution; for the normal probability distribution, the parameters are  $\mu$  and  $\sigma^2$ . For the normal distribution, each set of values for  $\mu$  and  $\sigma^2$  will generate a different shape for the bell-like normal curve. All probability distributions contain one or more parameters and can be plotted as curves; these parameters may be discrete (integer only) or continuous. Each value or combination of values for these parameters will create a different curve for the probability distribution being used. Thus, each probability distribution is actually a family of probability curves. Some additional parameters of theoretical probability distributions have been given the special name *degrees of freedom* and are represented by Latin letters such as *m*, *n*, and *s*.

Associated with the formula for computing a test statistic is a rule for assigning integer values to the one or more parameters called degrees of freedom. The number of degrees of freedom and the value for each degree of freedom depend on (1) the number of subjects, (2) the number of experimental groups, (3) the specifics of the statistical hypothesis, and (4) the type of statistical test. The correct curve of the probability distribution from which to obtain a critical value for comparison with the value of the test statistic is obtained with the values of one or more degrees of freedom.

To accept or reject the null hypothesis, the following steps are performed: (1) confirm that experimental data conform to the assumptions of the intended statistical test; (2) choose a significance level ( $\alpha$ ); (3) calculate the test statistic; (4) determine the degree(s) of freedom; (5) find the critical value for the chosen  $\alpha$  and the degree(s) of freedom from the appropriate probability distribution; (6) if the test statistic exceeds the critical value, reject the null hypothesis; (7) if the test statistic does not exceed the critical value, do not reject the null hypothesis.

### **The Fickle P Value**

There is an extremely common misapprehension about the meaning of the *P* value in the typical null hypothesis/alternative hypothesis testing.<sup>6,7</sup> If a statistical test is declared to be significant at  $P = 0.05$ , most physicians will state that there is 95% certainty that the null hypothesis is incorrect.<sup>6</sup> As

Goodman<sup>6</sup> stated: “This is an understandable but categorically wrong interpretation because the P value is calculated on the assumption that the null hypothesis is true. It cannot, therefore, be a direct measure of the probability that the null hypothesis is false.” The odds that the desired outcome, the alternative hypothesis, is true will depend not just on the data of the experiment, but also on how plausible was that hypothesis before conducting the research. This interaction of hypothesis plausibility and statistical results can be displayed graphically (Fig. 7-1).<sup>8,9</sup> A long shot, implausible hypothesis (19-to-1 odds against) stills remains implausible (11% chance of a real effect) if the P value of the experiment is 0.05.

**Figure 7-1** Probable cause. A P value measures whether an observed result can be attributed to chance. But it cannot answer a researcher’s real question: What are the odds that a hypothesis is correct? Those odds depend on how strong the result was and, most importantly, on how plausible the hypothesis is in the first place. (Reprinted with permission from Nuzzo R. Statistical errors. P values, the ‘gold standard’ of statistical validity, are not as reliable as many scientists assume. *Nature*. 2014;506:150–152. ### The Bayesian Alternative

Be it an RCT or an observational study report, the results and claims of medical research are not and should not be considered in isolation from prior knowledge. Yet the most commonly used methods of statistical inference used in medical research (see supra) explicitly uses only the newly obtained data. This is the Frequentist approach or inference, so called because the precise

definition of probability values depends on assumptions about hypothetical repeated replication of data collection. The new information of a study is a function only of the data.

**5** A competing approach is called Bayesian inference that explicitly reports the new information of a study as a function of both observed data and historical (prior) knowledge. Both Frequentist and Bayesian inferences make statements about parameters. But Bayesian methods involve the multiplication of the prior knowledge represented as a probability distribution of the parameter(s) times the likelihood of the observed data; the product is the new (posterior) probability distribution of the parameter.<sup>10,11</sup> Bayesian methods have been proposed to resolve the conundrum that some highly cited clinical research whose evidence is interpreted by a Frequentist  $P$  value is later contradicted or found to be excessively optimistic in the magnitude of effect.<sup>12–15</sup> Among reasons for the slower adoption of Bayesian methods are concerns about the subjectivity in defining the prior probability distribution and the considerably greater computational difficulty in performing an analysis.

## Experimental Medicine: Statistical Tests

### *Interval Data*

Parametric statistics are the usual choice in the analysis of interval data, both discrete and continuous. The purpose of such analysis is to test the hypothesis of a difference between population means. The population means are unknown and are estimated by the sample means. A typical example would be the comparison of the mean heart rates of patients receiving and not receiving atropine. Parametric test statistics have been developed by using the properties of the normal probability distribution and two related probability distributions, the  $t$  and the  $F$  distributions. In using such parametric methods, the assumption is made that the sample or samples is/are drawn from population(s) with a normal distribution. The parametric test statistics that have been created for interval data all have the form of a ratio. In general terms, the numerator of this ratio is the variability of the means of the samples; the denominator of this ratio is the variability among all the members of the samples. These variabilities are similar to the variances developed for descriptive statistics. The test statistic is thus a ratio of variabilities or variances. All parametric test statistics are used in the same fashion; if the test statistic ratio becomes large, the null hypothesis of no difference is rejected. The critical values against which to compare the test statistic are taken from tables of the three relevant probability distributions (normal,  $t$ , or  $F$ ). In hypothesis testing at least one of the population means is

unknown, but the population variance(s) may or may not be known. Parametric statistics can be divided into two groups according to whether or not the population variances are known. If the population variance is known, the test statistic used is called the  $z$  score; critical values are obtained from the normal distribution. In most biomedical applications, the population variance is rarely known and the  $z$  score is little used.

## Confidence Intervals

The other major areas of statistical inference are the estimation of parameters with associated *confidence intervals* (CIs). In statistics, a CI is an interval estimate of a population parameter. A CI describes how likely it is that the population parameter is estimated by any particular sample statistic such as the mean. (The technical definition of the CI of the mean is more rigorous. A 95% CI implies that if the experiment were done over and over again, 95 of each 100 CIs would be expected to contain the true value of the mean.) CIs are a range of the following form: summary statistic  $\pm$  (confidence factor)  $\times$  (precision factor).

The *precision factor* is derived from the sample itself, whereas the *confidence factor* is taken from a probability distribution and also depends on the specified confidence level chosen. For a sample of interval data taken from a normally distributed population for which CIs are to be chosen for  $\bar{x}$  the precision factor is called the *standard error of the mean* and is obtained by dividing SD by the square root of the sample size or  $SE = \frac{SD}{\sqrt{n}} = \sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 / n(n-1)}$ .

The confidence factors are the same as those used for the dispersion or spread of the sample and are obtained from the normal distribution. The CIs for confidence factors 1, 2, and 3 have roughly a 68%, 95%, and 99% chance of containing the population mean. Strictly speaking, when the SD must be estimated from sample values, the confidence factors should be taken from the *t distribution*, another probability distribution. These coefficients will be larger than those used previously. This is usually ignored if the sample size is reasonable; for example,  $n$  is greater than 25. Even when the sample size is only 5 or greater, the use of the coefficients 1, 2, and 3 is simple and sufficiently accurate for quick mental calculations of CIs on parameter estimates.

Almost all research reports include the use of SE, regardless of the probability distribution of the populations sampled. This use is a consequence of the *central limit theorem*, one of the most remarkable theorems in all of mathematics. The central limit theorem states that the SE can always be used, if the sample size is sufficiently large, to specify CIs around the sample mean. These CIs are calculated as previously described. This is true even if the population distribution is so different from normal that SD cannot be used to

characterize the dispersion of the population members. Only rough guidelines can be given for the necessary sample size; for interval data, 25 and above is large enough and 4 and below is too small.

Although the SE is often discussed along with other descriptive statistics, it is really an inferential statistic. SE and SD are usually mentioned together because of their similarities of computation, but there is often confusion about their use in research reports in the form “mean  $\pm$  number.” Some confusion results from the failure of the author to specify whether the number after the  $\pm$  sign is one or the other. The choice is actually simple. When describing the spread, scatter, or dispersion of the sample, use SD; when describing the precision with which the population mean is known, use SE.

## **t Test**

An important advance in statistical inference came early in the twentieth century with the creation of *Student's t test statistic* and the *t distribution*, which allowed the testing of hypotheses when the population variance is not known. The most common use of Student's *t* test is to compare the mean values of two populations. There are two types of *t* test. If each subject has two measurements taken, for example, one before ( $x_i$ ) and one after ( $y_i$ ) a drug, then a one sample or *paired t test* procedure is used; each control measurement taken before drug administration is paired with a measurement in the same patient after drug administration. Of course, this is a self-control experiment. This pairing of measurements in the same patient reduces variability and increases statistical power. The difference  $d_i = x_i - y_i$  of each pair of values is calculated and the average  $\bar{d}$  is calculated. In the formula for Student's *t* statistic, the numerator is  $\bar{d}$  whereas the denominator is the SE of  $\bar{d}$  denoted  $(SE_{\bar{d}})$  so the test statistic is  $t = \frac{\bar{d}}{SE_{\bar{d}}}$ .

All *t* statistics are created in this way; the numerator is the difference of two means, whereas the denominator is the SE of the two means. If the difference between the two means is large compared with their variability, then the null hypothesis of no difference is rejected. The critical values for the *t* statistic are taken from the *t* probability distribution. The *t* distribution is symmetric and bell-shaped but more spread out than the normal distribution. The *t* distribution has a single integer parameter; for a paired *t* test, the value of this single degree of freedom is the sample size minus one. There can be some confusion about the use of the letter *t*. It refers both to the value of the test statistic calculated by the formula and to the critical value from the theoretical probability distribution. The critical *t* value is determined by looking in a *t* table after a significance level is chosen and the degree of freedom is computed.

More commonly, measurements are taken on two separate groups of

subjects. For example, one group receives blood pressure treatment with sample values  $x_i$ , whereas no treatment is given to a control group with sample values  $y_i$ . The number of subjects in each group might or might not be identical; regardless of this, in no sense is an individual measurement in the first group matched or paired with a specific measurement in the second group. An *unpaired* or *two-sample t test* is used to compare the means of the two groups. The numerator of the  $t$  statistic is  $\bar{x} - \bar{y}$ . The denominator is a weighted average of the SDs of each sample so that the test statistic  $t$  is

$$t = \frac{\bar{x} - \bar{y}}{\sqrt{\left(\frac{1}{n_x} + \frac{1}{n_y}\right) \left(\frac{(n_x - 1)s_x^2 + (n_y - 1)s_y^2}{n_x + n_y - 2}\right)}}$$

The degree of freedom for an unpaired  $t$  test is calculated as the sum of the subjects of the two groups minus two. As with the paired  $t$  test, if the  $t$  ratio becomes large, the null hypothesis is rejected.

The results of a comparison of samples from two populations should be complete. In addition to displaying the individual mean values of  $\bar{x}$  and  $\bar{y}$  with their CIs and the results of the  $t$  test, the mean difference,  $\bar{x} - \bar{y}$ , is also included with its associated CI. This difference of means is the effect size, a quantitative measure of the magnitude of effect. The reporting of the effect size facilitates the interpretation of the clinical importance, as opposed to the statistical significance of a research result.

## Analysis of Variance

Experiments in anesthesia, whether they are with humans or with animals, may not be limited to one or two groups of data for each variable. It is very common to follow a variable longitudinally; heart rate, for example, might be measured five times before and during anesthetic induction. These are also called *repeated measurement experiments*; the experimenter will wish to compare changes between the initial heart rate measurement and those obtained during induction. The experimental design might also include several groups receiving different induction drugs; for example, comparing heart rate across groups immediately after laryngoscopy. Researchers have mistakenly handled these analysis problems with just the  $t$  test. If heart rate is collected five times, these collection times could be labeled  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$ . Then  $A$  could be compared with  $B$ ,  $C$ ,  $D$ , and  $E$ ;  $B$  could be compared with  $C$ ,  $D$ , and  $E$ ; and so forth. The total of possible pairings is ten; thus, ten paired  $t$  tests could be calculated for all the possible pairings of  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$ . A similar approach can be used for comparing more than two groups for unpaired data.

The use of  $t$  tests in this fashion is inappropriate. In testing a statistical hypothesis, the experimenter sets the level of type I error; this is usually chosen to be 0.05. When using many  $t$  tests, as in the example given earlier,

the chosen error rate for performing all these  $t$  tests is much higher than 0.05, even though the type I error is set at 0.05 for each individual comparison. In fact, the type I error rate for all  $t$  tests simultaneously; that is, the chance of finding at least one of the multiple  $t$  test statistics significant merely by chance is given by the formula  $\alpha = 1 - 0.95^k$ . If 13  $t$  tests are performed ( $k = 13$ ), the real error rate is 49%. Applying  $t$  tests over and over again to all the possible pairings of a variable will misleadingly identify statistical significance when in fact there is none.

The most versatile approach for handling comparisons of means between more than two groups or between several measurements in the same group is called *analysis of variance* and is frequently cited by the acronym ANOVA. Analysis of variance consists of rules for creating test statistics on means when there are more than two groups. These test statistics are called *F ratios*, after Ronald Fisher; the critical values for the  $F$  test statistic are taken from the  $F$  probability distribution that Fisher derived.

Suppose that data for three groups are obtained. What can be said about the mean values of the three target populations? The  $F$  test is actually asking several questions simultaneously: Is group 1 different from group 2; is group 2 different from group 3; and is group 1 different from group 3? As with the  $t$  test, the  $F$  test statistic is a ratio; in general terms, the numerator expresses the variability of the mean values of the three groups, whereas the denominator expresses the average variability or difference of each sample value from the mean of all sample values. The formulas to create the test statistic are computationally elegant but are rather hard to appreciate intuitively. The  $F$  statistic has two degrees of freedom, denoted  $m$  and  $n$ ; the value of  $m$  is a function of the number of experimental groups; the value for  $n$  is a function of the number of subjects in all experimental groups. The analysis of multigroup data is not necessarily finished after the ANOVAs are calculated. If the null hypothesis is rejected and it is accepted that there are differences among the groups tested, how can it be decided where the differences are? A variety of techniques are available to make what are called *multiple comparisons* after the ANOVA test is performed.

## **Robustness and Nonparametric Tests**

Most statistical tests depend on certain assumptions about the nature of the distribution of values in the underlying populations from which experimental samples are taken. For the parametric statistics, that is,  $t$  tests and analysis of variance, it is assumed that the populations follow the normal distribution. However, for some data, experience or historical reasons suggests that these assumptions of a normal distribution do not hold; some examples include proportions, percentages, and response times. What should the experimenter

do if he or she fears that the data are not normally distributed?

The experimenter might choose to ignore the problem of nonnormal data and inhomogeneity of variance, hoping that everything will work out. Such insouciance is actually a very practical and reasonable approach to the problem. Parametric statistics are called *robust* statistics; they stand up to much adversity. To a statistician, robustness implies that the magnitude of type I errors is not seriously affected by ill-conditioned data. Parametric statistics are sufficiently robust that the accuracy of decisions reached by means of  $t$  tests and analysis of variance remains very credible, even for moderately severe departures from the assumptions.

Another possibility would be to use statistics that do not require any assumptions about probability distributions of the populations. Such statistics are known as *nonparametric tests*; they can be used whenever there is very serious concern about the shape of the data. Nonparametric statistics are also the tests of choice for ordinal data. The basic concept behind nonparametric statistics is the ability to rank or order the observations; nonparametric tests are also called *order statistics*.

Most nonparametric statistics still require the use of theoretical probability distributions; the critical values that must be exceeded by the test statistic are taken from the binomial, normal, and chi-square distributions, depending on the nonparametric test being used. The *nonparametric sign test*, *Mann–Whitney rank sum test*, and *Kruskal–Wallis one-way analysis of variance* are analogous to the paired  $t$  test, unpaired  $t$  test, and one-way analysis of variance, respectively. The currently available nonparametric tests are not used more commonly because they do not adapt well to complex statistical models and because they are less able than parametric tests to distinguish between the null and alternative hypotheses if the data are, in fact, normally distributed. There are general guidelines that relate the variable type and the experimental design to the choice of statistical test (Table 7-5).

## Binary Variables

### Confidence Intervals on Proportions

*Categorical binary data*, also called *enumeration data*, provide counts of subject responses. Given a sample of subjects of whom some have a certain characteristic (e.g., death, female sex), a ratio of responders to the number of subjects can be easily calculated as  $p = x/n$ ; this ratio or rate can be expressed as a decimal fraction or as a percentage. It should be clear that this is a measure of central location of binary data. In the population from which the sample is taken, the ratio of responders to total subjects is a population parameter, denoted  $\pi$ . (This is not related to the geometry constant  $\pi =$

3.14159....) The sample proportion  $p$  is the estimator ( $\hat{\pi}$ ) of the population proportion  $\pi$ . As with other data types,  $\pi$  is usually not known, but must be estimated from the sample. The sample ratio  $p$  is the best estimate of  $\pi$ .

Because the population is not generally known, the experimenter usually wishes to estimate  $\pi$  by the sample ratio  $p$  and to specify with what precision  $\pi$  is known. If the sample is sufficiently large ( $n \times p \geq 5$ ;  $n \times (1 - p) \geq 5$ ), advantage is taken of the central limit theorem to derive an SE analogous to that derived for interval data:  $SE = \sqrt{\frac{p \times (1 - p)}{n}}$ . This sample SE is exactly analogous to the sample SE of the mean for interval data, except that it is an SE of the proportion. Just as a 95% CI of the mean was calculated, so may a CI on the proportion may be obtained. Larger samples will make the CI more precise.

If nothing goes wrong, is everything all right? This question was proposed by Henley and Lippman-Hand<sup>16</sup> to discuss the interpretations of zero numerators using the 3 over  $n$  rule. Consider an observational study that reports no morbidity in 167 patients receiving a new intravenous anesthetic. Is there really no risk? Although the best estimate of the population parameter  $\pi$  is 0/167 or 0%, an upper bound on the 95% CI is relevant to consider how high the rate of adverse events might be. As the probability of binary data is provided by the *binomial probability distribution function*, this upper bound may be derived from  $1 - (0.05)^{1/n}$  where  $n$  is the denominator; for  $n$  is greater than 30, this is well approximated by  $3/n = 3/167 \approx 1.8\%$ .

The zero numerator example can be used to illustrate a difference between a Bayesian and Frequentist approach. If there is no prior information (Bayes-Laplace  $\beta$ -*probability distribution function*), the upper bound is  $3/(n + 1) = 3/168 \approx 1.8\%$ ; the Bayesian equivalent of a CI is called a Credible Interval (CI).<sup>17</sup> As the sample size increases,  $3/n$  and  $3/(n + 1)$  becomes closer and closer. By contrast, when there is prior information Bayesian inference will provide a more informative CI than a Frequentist approach. Suppose a prior study with the same new anesthetic had found 15 morbid events in 10,000 (0.15%) patients. Then with the new data the estimate of the population rate of morbidity is 0.12% (upper bound 95% CI = 0.36%).<sup>17</sup> Using prior information and the new data of 0 events in 167 patients, the population rate estimate has been reduced from 0.15% to 0.12% and the upper bound of the 95% CI is much lower (0.36% vs. 1.8%) than by Frequentist estimation.

## Hypothesis Testing

In the experiment negating the value of mammary artery ligation, five of eight patients (62.5%) having ligation showed benefit, and five of nine patients (55.6%) having sham surgery also had benefit.<sup>1</sup> Is this difference real? This experiment sampled patients from two populations—those having

the real procedure and those having the sham procedure. A variety of statistical techniques allow a comparison of the success rate. These include *Fisher's exact test* and (*Pearson's chi-square test*). The chi-square test offers the advantage of being computationally simpler; it can also analyze contingency tables with more than two rows and two columns; however, certain assumptions of sample size and response rate are not achieved by this experiment. Fisher's exact test fails to reject the null hypothesis for this data.

**Table 7-5** When to Use What

Variable Type	One-sample Tests	Two-sample Tests	Multiple-sample Tests
Dichotomous or nominal	Binomial distribution	Chi-square test, Fisher's exact test	Chi-square test
Ordinal	Chi-square test	Chi-square test, nonparametric tests	Chi-square test, nonparametric tests
Continuous or discrete	z distribution or t distribution	Unpaired t test, paired t test, nonparametric tests	Analysis of variance, nonparametric analysis of variance

The results of such experiments are often presented as a rate/risk ratio (RR), an effect size. (Other effect sizes for comparison of two populations with binary outcomes are the odds ratio [OR], the risk difference, and the number needed to treat.) The rate of improvement for the experimental group ( $5/8 = 62.5\%$ ) is divided by the rate of improvement for the control group ( $5/9 = 55.6\%$ ). An RR of 1.00 (100%) fails to show a difference of benefit or harm between the two groups. In this example the RR is 1.125. Thus, the experimental group had a 12.5% greater chance of improvement compared with the control group. A CI can be calculated for the RR; in this example it is (0.40, 3.13), thus widely spread to either side of the RR of no difference. (If such an experiment were performed now, the sample size would be much larger to have adequate statistical power.)

## Linear Regression

Often a goal of an experiment is to find relationships between two variables so that in new patients the prediction of the value of one characteristic may be made by knowledge of another characteristic. The most commonly used technique for this purpose is linear regression analysis. Experiments for this purpose collect data pairs  $(x_i, y_i)$ ; these data pairs may be captured in either clinical trials or observational studies. The  $y$  variable is called the dependent or response variable, and the  $x$  variable is denoted the independent or explanatory variable. These data should be displayed in a scatter plot; in the simplest type, a straight line (linear relationship) is assumed between two variables; the  $y$  variable is considered a function of the  $x$  variable. This is expressed as the linear regression equation  $y = a + bx$ ; the parameters of the

regression equation are  $a$  and  $b$ . (Strictly defined,  $a$  and  $b$  are estimators of the population parameters alpha [ $\alpha$ ] and beta [ $\beta$ ].) The parameter  $b$  is the slope of the straight line relating  $x$  and  $y$ ; for each 1 unit change in  $x$ , there are  $b$  unit changes in  $y$ . The parameter  $a$  is the intercept (value of  $y$  when  $x$  equals 0). Estimates of the parameters are obtained from a least squares method that sets the slope  $b$  value to minimize the sum of the vertical distances from the data pairs to the regression

$$\text{line: } b = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2}; a = \bar{y} - b\bar{x}. \text{ The parameter of}$$

greatest interest in regression is usually the slope, especially whether the slope is nonzero; a zero valued slope implies that  $x$  and  $y$  are not linearly related. With the additional assumption of bivariate normality (both  $x$  and  $y$  normally distributed), a  $t$  test statistic is used to check the statistical significance of the slope.

The same  $(x_i, y_i)$  data pairs are usually subjected to correlation analysis. The correlation coefficient  $r$  is a measure of the linear covariation of  $x$  and  $y$ ;  $r$  ranges from  $-1$  to  $1$ . There is no linear correlation between  $x$  and  $y$  if  $r$  is zero valued. It is estimated by

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}}. \text{ The test of the statistical significance of } r \text{ is}$$

equivalent to the test for the significance of the regression slope  $b$ . The squared value of  $r$ , known as the coefficient of determination ( $r^2$ ) varies between 0 and 1 and is sometime expressed as a percentage. The coefficient of determination has a very useful interpretation: the fraction of the variation of  $y$  explained by the variation of  $x$ .

As a hypothetical example, suppose that age and a plasma biomarker of physical maturity are collected in 11 children. The  $(x_i, y_i)$  values recorded are (10, 8.04), (8, 6.95), (13, 7.58), (9, 8.81), (11, 8.33), (14, 9.96), (6, 7.24), (4, 4.26), (12, 10.84), (7, 4.82), and (5, 5.68). Neither an inspection of these values nor of the summary statistics ( $\bar{x} = 9.00$ ,  $\bar{y} = 7.50$ ) permit the reader to detect any relationship. The calculation of the coefficient of determination ( $r^2 = 0.67$ ) does allow the inference that 67% of the variation in the biomarker is explained by the variation in age.

A researcher or reader should not be satisfied to see only the statistical results of regression and correlation. The statistician Anscombe<sup>18</sup> created four hypothetical data sets to illustrate the importance of visual inspection of data. Each data set has 11 paired  $(x_i, y_i)$  observations (Fig. 7-2). The hypothetical example (listed earlier) is displayed in the upper left 

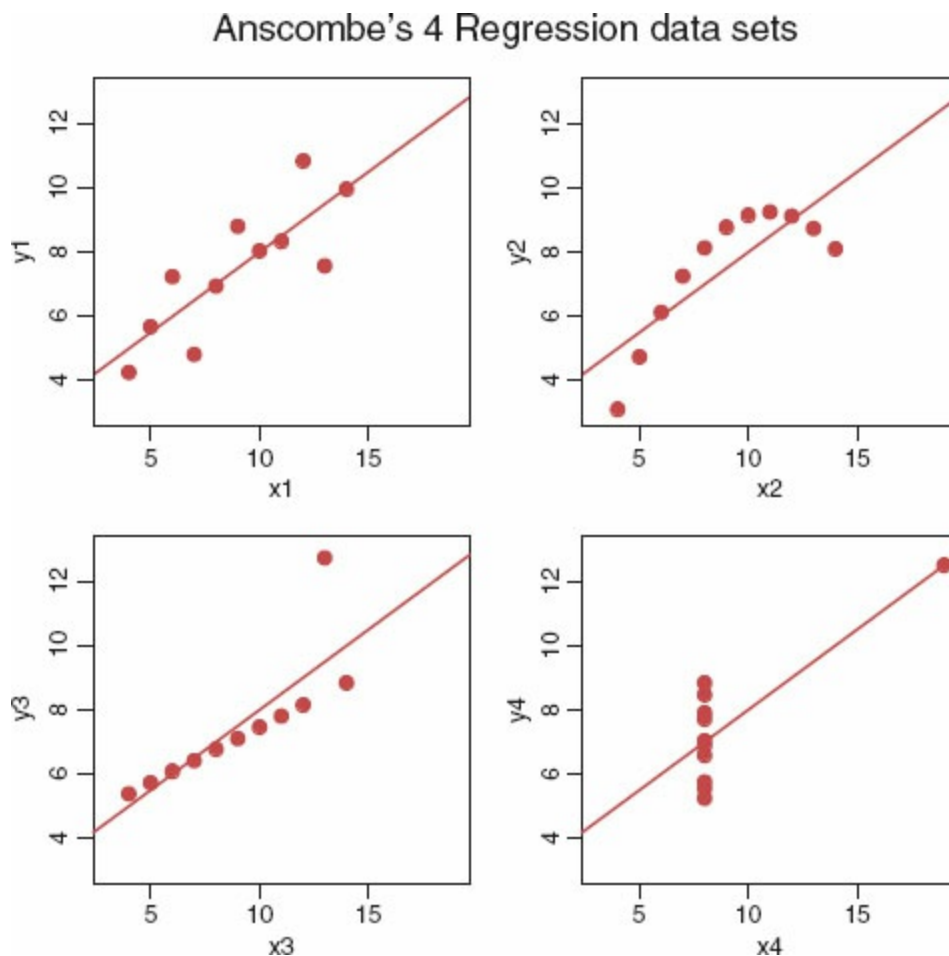

quadrant; a linear relationship is displayed. For the data in the upper right quadrant, the relationship between  $x$  and  $y$  is curvilinear (quadratic). For the lower right quadrant, there is no relationship between  $x$  and  $y$ ; with one exception all data pairs have the same  $x$  value. For the lower left quadrant, there is a near perfect correlation between  $x$  and  $y$  except for one data pair with a much higher  $y$  value. Nevertheless, all summary statistics, regression, and correlation values of the four data sets including means, SDs, slopes, intercepts, standard errors of regression parameters, statistical significance of regression parameters, and correlation coefficients are equal. There are clearly four different patterns that can only be detected by visual inspection. Even this simplest form of regression and correlation analysis is based on the strong assumption of an underlying linear relationship between  $x$  and  $y$ ; failure of that assumption leads to erroneous statistical inference. Using just the summary, regression, and correlation statistics, the four data sets would have been thought to have very similar/identical underlying relationships.

## *Epidemiology*

*Epidemiology* is the study of the patterns, causes, and effects of health and disease conditions. Epidemiology is based on observations collected systematically, but without the interventions (anesthetic drugs and techniques) being allocated to patients under experimental control. Major areas of epidemiologic study relevant to anesthesia care are nonrandomized studies (NRSs) of the effectiveness of anesthetic drugs and techniques on outcomes following anesthesia and surgery, the properties of diagnostic tests for the identification of perioperative complications, the determination of risk factors for outcomes, and the estimation of risk prognosis models for individual predication. Systematic reviews (SRs) and meta-analysis (MA) also come under the banner of epidemiology as does the advent of “Big Data.”

A fundamental axiom of epidemiology is “Association does not necessarily imply causation.” In 1965, the epidemiologist Bradford Hill suggested guidelines for assessing evidence of causation when presented with an observed association between the environment and disease. Fifty years later Ioannidis<sup>19</sup> revisited these criteria, assessed which of these had worked, and identified two: Consistency and Experiment. Of the former, Hill<sup>20</sup> offered this question: “Has it (an association) been repeatedly observed by different persons, in different places, circumstances, and times?” But nothing can replace Experiment. Ioannidis<sup>13</sup> reported: “Among the most highly cited papers in the biomedical literature, five out of six observational studies have been ‘refuted’ by subsequent randomized trials...” Be it an RCT or an observational study report, the results and claims of medical research are not and should not be considered in isolation from prior knowledge. The precision

with which the  $P$  value is calculated by statistical software by itself should not replace a consideration of all evidence.

**Figure 7-2** Four scatter plots from the Anscombe data sets. For each data set,  $n = 11$ ,  $\bar{x} = 9.00$ ,  $SD_x = 3.31$ ,  $\bar{y} = 7.50$ ,  $SD_y = 2.03$ ,  $y = 3.00 + 0.50x$ ,  $SE_a = 1.12$ ,  $SE_b = 0.12$ ,  $r^2 = 0.67$ , and so forth. All statistics are equal up to the fourth decimal place.

### Multivariable Linear Regression

Regression methods can be extended to data sets in which one response variable is linearly related to many explanatory variables. This regression includes methods for choosing which of the explanatory variables have a statistically significant (i.e., nonzero) regression slope. Multivariable linear regression is the creation of a model relating some continuous response such as heart rate to  $k$  explanatory variables; these are also called covariates. This regression starts with data from  $n$  patients of the form  $(y_i, x_{i,1}, x_{i,2}, \dots, x_{i,k})$ , where the subscript  $i$  denotes the  $i$ th patient,  $y_i$  is the response in the  $i$ th patient,  $x_i$  is the value of a covariate in the  $i$ th patient, and the second subscript of  $x_i$  denotes the  $1$  to  $k$  covariates. The linear model equation for the  $i$ th individual is:

$$\mu_i = \beta_0 + \beta_1 x_{i,1} + \beta_2 x_{i,2} + \dots + \beta_k x_{i,k} = \sum_{j=1}^k \beta_j x_{i,j}. \text{ The } \beta_j\text{s are the unknown coefficients}$$

(parameters) of the model that will be estimated from the observed data. For the  $i$ th individual, the expected value of the model,  $\mu_i$ , is the linear sum of each covariate value multiplied by its coefficient. The difference between the observed ( $y_i$ ) and expected value ( $\mu_i$ ) reflects biologic variability, measurement error, and so forth.

## Univariable and Multivariable Logistic Regression

If the response variable is binary (alive/dead, complication/no complication), linear regression has been extended. Thus, the typical sigmoidally shaped regression of a binary outcome (e.g., movement) versus anesthetic dose. There are multiple methods for regression of binary outcomes, the most common being logistic regression. The most commonly used format of the logistic method is the multivariable logistic regression model. The response variable  $y_i$  denotes the value of the binary outcome in the  $i$ th individual and is generally coded as 0 or 1, representing the absence or presence of an event (e.g., day-of-surgery mortality). Letting  $\pi$  represent the probability that the response variable has value 1, then the logit transformation, *log of the odds ratio* =  $\ln\left(\frac{\pi}{1-\pi}\right)$ , allows  $\pi$  to be expressed as the linear combination of the

covariates: 
$$\ln\left(\frac{\pi_i}{1-\pi_i}\right) = \beta_0 + \beta_1 x_{i,1} + \beta_2 x_{i,2} + \dots + \beta_k x_{i,k} = \sum_{j=1}^k \beta_j x_{i,j}$$
. The logit transformation is the link function relating the sum of the covariates to the probability of the binary outcome.

Multivariable regression is used to control for confounding. Confounding occurs when the apparent association between a covariate and an outcome is affected by the relationship of a third variable to the covariate and to the outcome; the third variable is a confounder. As contrasted to sequentially regressing each covariate against the response variable, this is done by simultaneously fitting all explanatory variables simultaneously.<sup>21</sup> For example, in exploring the relationship between tobacco and myocardial infarction, male sex, poverty, and sedentary lifestyle could be confounders because they are associated with both smoking and coronary heart disease.

Each year thousands of reports are published in the medical literature using stepwise, multivariable logistic regression on observational data to identify “independent” predictors for various clinical outcomes.<sup>22</sup> In the anesthesia literature PONV has been a very common topic for such statistical modeling.<sup>23–26</sup> Stepwise, multivariable logistic regression is an automatic procedure where there are a large number of potential explanatory variables and no underlying theory on which to base the selection of prediction model risk factors.<sup>27</sup> Once these prediction models have been created, there is a framework for assessing their performance.<sup>28–30</sup> Great skepticism should be

shown for most of these prognostic models, especially those concerning mortality, as they usually have not been validated, have modest accuracy, and do not have documented clinical utility.<sup>31,32</sup>

## *Propensity Score Matching and Analysis*

Another approach for providing estimation of treatment-effect in NRSs is the methodology of propensity score matching.<sup>33</sup> This use of NRS data is intended to investigate the effect of treatment  $X$  on a specified dichotomous outcome  $Y$ ; the good outcome can be denoted  $Y^+$ , for example, survival, with  $Y^-$  being the opposite. It is usually the case that one or more baseline prognostic covariates (confounders  $C_1, C_2, \dots, C_k$ ) may be imbalanced between the patients that did ( $X^+$ ) and did not ( $X^-$ ) receive the treatment of interest. The favorable outcome, conditional on receiving treatment  $X^+$ , is denoted  $Y^+|X^+$  with  $Y^+|X^-$  being a favorable outcome in those not receiving the treatment. Any difference between interventions on the outcome  $Y$  may be a consequence of the confounders influencing both the treatment and the outcome; a failure to observe a difference in outcome may also be a consequence of confounding. As an example, pulmonary artery catheterization (PAC) in the care of the critically ill was adopted about 40 years ago and widely disseminated without rigorous evaluation. The enthusiasm of intensivists for such monitoring even forced the cessation of an RCT comparing care with and without PACs because of the unwillingness of physicians to allow patient participation in the study.<sup>34</sup> Using data of 5,735 critically ill patients, Connors et al.<sup>35</sup> reported lower 6-month survival in the 2,184 patients with PACs ( $Y^+|X^+ = 46.3\%$  vs.  $Y^+|X^- = 53.7\%$ ), but far more  $X^+$  patients had multiorgan system failure (MOSF: 57% vs. 35%) at the time of PAC placement; there were other imbalances of initial covariates. Was the higher mortality attributable to the use of PACs or to a greater severity of illness? Using propensity matching, Connors created a pair of subsets (1,008 patients vs. 1,008 patients) with similar proportions of prognostic factors in both groups (e.g., MOSF: 34%); 6-month survival was still lower ( $Y^+|X^+ = 46.0\%$  vs.  $Y^+|X^- = 51.2\%$ ).

Propensity score matching is a statistical technique within the general concept of matching. If only one prognostic factor was important, for example, sex, then a pair of matched subsets could be created easily by repeatedly and randomly placing one man and one woman into each subset—matching the groups just by sex. However, there is usually a great deal of baseline information about patients observed in an NRS; Connors et al.<sup>35</sup> had details for about 40+ baseline covariates. In addition, it is often not evident which baseline characteristics are predictive of outcome. Creating matched groups by simple matching is not generally possible using more than a very

few covariates.

The propensity score is defined as a subject's probability of receiving a specific treatment conditional on the many baseline covariates. The propensity score is usually estimated by multivariable logistic regression. In contrast to the attempt to create a parsimonious model with a few independent predictors of outcome by logistic regression modeling of NRS data, all available covariates are left in the model for a propensity score whether or not they are statistically significant. These covariates must be restricted to those that are known prior to the intervention. In the study by Connors, the presence/absence of MOSF on hospital admission should be included in propensity score; MOSF developing a week later should not.

For each patient in the data set, the  $z$  score obtained from the sum of each covariate times its regression coefficient is calculated:

$$z = \beta_0 + \beta_1 C_{i,1} + \beta_2 C_{i,2} + \dots + \beta_k C_{i,k} = \sum_{j=1}^k \beta_j C_{i,j}.$$

Taking the antilogit of the  $z$  score ( $p = \frac{1}{1 + e^{-z}}$ ) yields the probability that a patient with those covariate values received the intervention. Of course, it is in fact known whether or not a patient received the intervention. Propensity matched subsets of patients are created by randomly choosing and matching one patient receiving the intervention to one patient not receiving the intervention with the same probability from the  $z$  score; usually the propensity probabilities (scores) are matched to the third or greater decimal place. The success of propensity score matching in balancing many covariates was well displayed in an observational comparison of epidural anesthesia for intermediate-to-high risk noncardiac surgery by Wijeyesundera et al.<sup>36</sup> As graphed by Gayat et al.<sup>37</sup> (Fig. 7-3), 45 baseline characteristics of two matched subsets of about 44,000 patients each became extremely well balanced. In the original data set, an arterial line was used in 59% versus 33%; after balancing, an arterial line was used in 48% for both. The total of patients in the two matched subsets will always be less than the total count of patients in the NRS data set; some patients cannot be matched. Simple paired statistics are used to compare the outcomes of the two subsets.

Propensity score methods are being used in NRSs to reduce the effect of selection bias in estimating causal treatment effects. Besides propensity score matching, the effect of selection bias can also be reduced by using propensity scores for stratification, regression adjustment, and weighting. It is now routine to see NRS using propensity analysis in the intensive care and anesthesia literature—most commonly using matching.<sup>37</sup> A propensity score matching analysis should include: (1) details of propensity score building; (2) matching method; and (3) demonstration of covariate balancing by tabular or graphical display.<sup>37</sup> The propensity score can reduce bias due to observed covariates.

But propensity score methods cannot replace the RCT because randomization minimizes covariate imbalance between treatment groups for observed, unobserved, and unobservable covariates. In 2007, Murphy et al.<sup>38</sup> reported outcomes following cardiac surgery using a database of operations on about 8,700 patients; propensity scores estimated from preoperative risk factors and intraoperative events were used to adjust all statistical comparisons for this potential confounding. Mortality, morbidity, and cost of care was increased in patients receiving blood. In 2015 Murphy et al.<sup>39</sup> reported the 2,000-patient TITRe2 trial with the hypothesis that a restrictive threshold for red-cell transfusion would reduce postoperative morbidity. There was no difference by transfusion strategy in the primary, composite outcome (serious infections or ischemic events); indeed, mortality was higher (4.2% vs. 2.6%) at 3 months in the restrictive-threshold group. Contrasting RCTs and NRS, the authors concluded: “The difference is probably due to the fact that observational analyses are confounded by prognostic factors that influence the decision to transfuse red cells.” Even a well-conducted propensity adjusted analysis cannot remove confounding for unobserved or unobservable covariates.

**Figure 7-3** Graphical representation of 45 baseline covariates before and after propensity score matching using data from Wijeyesundera et al.<sup>36</sup> The standardized difference for each covariate is the average difference between groups divided by the average standard deviation of the two groups. The standardized difference increases directly with increasing imbalance between groups. With propensity score matching, the standardized difference is close to zero for all covariates. (Reprinted from Gayat E, Pirracchio R, Resche-Rigon M, et al. Propensity scores in intensive care and anaesthesiology literature: a systematic review. *Intensive Care Med.* 36;2010;1997.<sup>37</sup> With kind permission from Springer Science+Business Media.)

### Systematic Reviews and Meta-analyses

**7** It is over 25 years since the first systematic review (SR) with an accompanying meta-analysis (MA) was published in an anesthesia journal<sup>40</sup> and reports using these research methods are now commonplace in anesthesia journals.<sup>41-44</sup> The focused question of an SR of interventions can be

subsumed by the acronym PICO: P, Population; I, Intervention; C, Comparison; and O, Outcome. The structured title of an SR usually contains most of the PICO elements.

Data are obtained from controlled trials (usually randomized) already in the medical literature rather than from newly conducted clinical trials; the basic unit of analysis of this observational research is the published study. A structured protocol is followed that includes in part: (1) choice of study inclusion/exclusion criteria; (2) explicitly defined literature searching; (3) abstraction of data from included studies; (4) appraisal of risk bias within each study; (5) systematic pooling of data; and (6) discussion of inferences. This structured protocol is intended to minimize bias. Even RCTs may have sources of bias such as (1) selection bias: systematic differences between the patients receiving each intervention; (2) performance bias: systematic differences in care being given to study patients other than the preplanned interventions being evaluated; (3) attrition bias: systematic differences in the withdrawal of patients from each of the two intervention groups; and (4) detection bias: systematic differences in the ascertainment and recording of outcomes. The main focus of bias detection in the trials incorporated into an SR is (1) the randomization process, (2) the concealment of random allocation, (3) the use of blinding, and (4) the reporting/analysis of dropouts.

Binary outcomes (yes/no, alive/dead, presence/absence) within a study are usually compared by the RR or OR effect size; for continuous variables, the effect size is the mean difference. If there is sufficient clinical similarity among the included studies, a summary value of the overall effect size of the intervention versus comparison treatments is estimated by MA. MA is a set of statistical techniques for combining results from different studies. The results of an MA are usually present in a figure called a *Forest plot* (Fig. 7-4). The far left column identifies the included studies; the center left columns display the observed data. The center right columns lists the RRs with 95% CIs for the individual studies and the summary statistics. The horizontal lines and diamond shapes in the figures of the far right column are graphical representations of individual study relative risk and summary relative risk, respectively. There are also descriptive and inferential statistics concerning the statistical heterogeneity of the MA and the significance of the summary statistics. Methods for MA continue to be refined. For example, the assessment of statistical power of MAs has prompted new statistical approaches to maintain the Type I error rate with MA updating.<sup>45</sup> Also, it has been noted that the initial estimates of benefit in an SR are generally inflated when compared to the effect size estimated when the SR is later updated.<sup>46</sup>

An examination of [Figure 7-4](#) shows that 11 of 15 individual comparisons had wide, nonsignificant CIs that touch or cross the RR of identity (RR = 1). However, the overall consistency of effect is easily seen with lidocaine being

“favored” in only one study. The RR calculated from all studies was 7.31 with a 95% CI [4.16, 12.86]. The power of summary statistics to combine evidence is clear. About every seventh patient (92/637) who had a lidocaine spinal block had Transient Neurologic Syndrome (TNS); this risk of TNS was about seven times higher compared to other local anesthetics.<sup>47</sup>

The production of SRs comes from several sources. Many come from the individual initiative of researchers who publish their results as stand-alone reports in the journals of medicine and anesthesia. The American Society of Anesthesiologists has developed a process for the creation of practice parameters that includes among other things a variant form of SRs. A prominent proponent of SRs is the Cochrane Collaboration: an international network of more than 30,000 volunteers from over 100 countries that have published over 6,500 SRs online in The Cochrane Library.<sup>a</sup> An important distinction between Cochrane and non-Cochrane SRs is an obligation by the authors to maintain and update Cochrane SRs periodically as new research reports become available; an SR is provisional, an update with new evidence always being possible. The Cochrane Collaboration has extensive documentation, tutorials, and software available electronically explaining the techniques of SRs and MA.<sup>48</sup> There are more than 50 collaborative review groups within the Cochrane Collaboration that provide the editorial control and supervision of SRs; one of these is responsible for reviews of interventions in anesthesia, and critical and emergency care.<sup>49</sup>

## Big Data

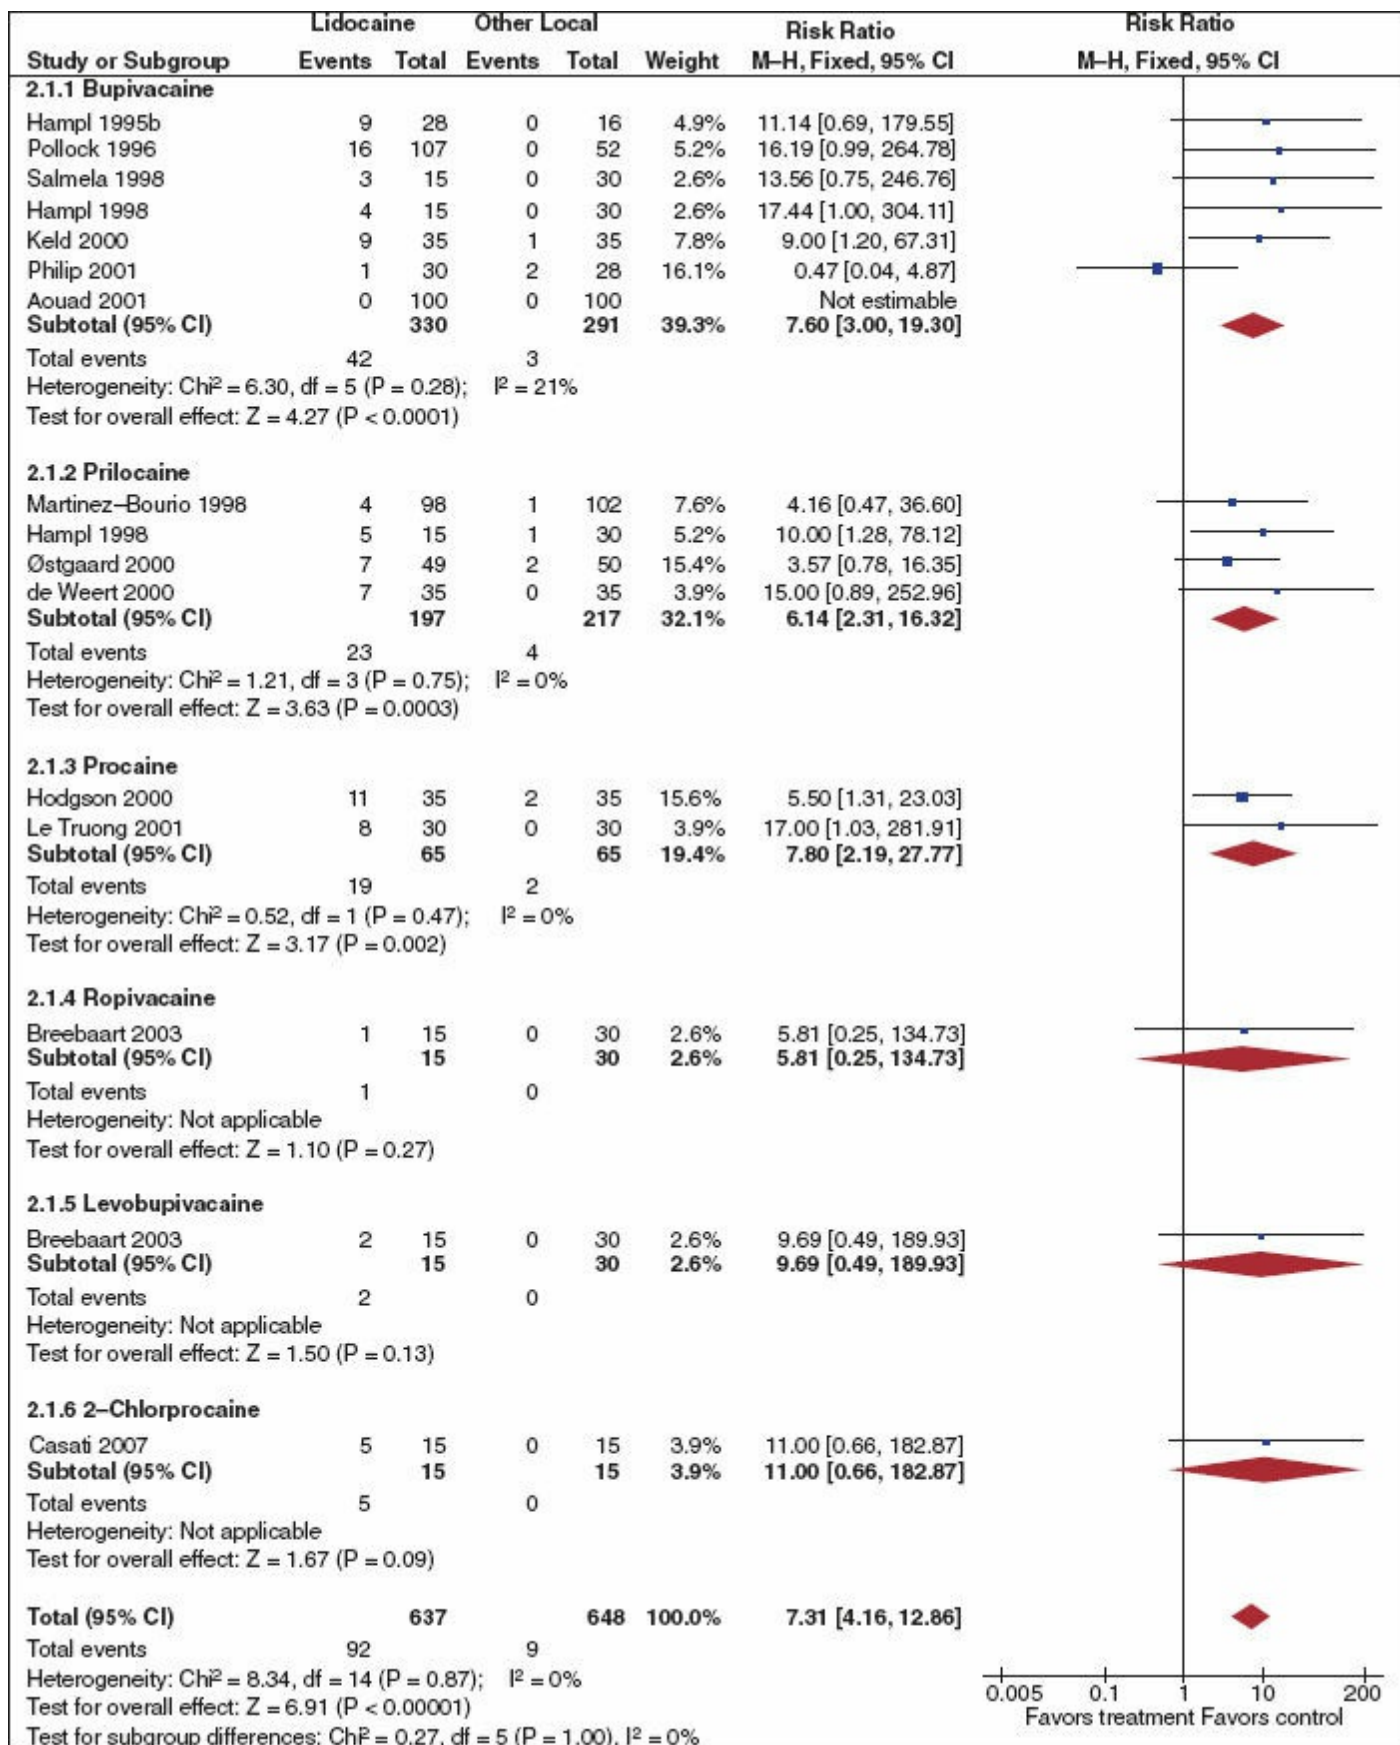

Big data has the attributes of the three “V”s (Volume, Velocity, and Variety). How big is Big Data? The volume usually cited is billions of records 8 produced at a velocity of millions each day encompassing many variable types. The computer storage of Big Data requires a new nomenclature beyond gigabyte (GB) and terabyte: petabyte =  $10^6$  GBs; exabyte =  $10^9$  GBs; and even higher. Big Data is now a formal activity at the National Institutes of Health, the Big Data to Knowledge (BD2 K) Initiative.<sup>50</sup> The mission statement of BD2 K includes: “To conduct research and develop the methods, software, and tools needed to analyze biomedical Big Data.”<sup>b</sup>

Big Data can be also defined to include studies that required new approaches to the collection, management, and analysis of data beyond those commonly used or available; historically, two epidemiology reports in anesthesia published 50 or more years ago can claim inclusion within Big Data. The first was a 5-year (1948–1952) study of all postoperative deaths following about 600,000 anesthetics at 10 academic medical centers distributed across the United States.<sup>51</sup> The other was the National Halothane Study, which reported the rate of deaths and fatal hepatic necrosis during four

years (1959–1962) following about 850,000 anesthetics at 34 hospitals.<sup>52</sup> Both studies required a scaling up of resources for data collection and management and both included new statistical methods.

Besides the Big Data of genomics and medical images, what else does Big Data promise? Messages posted to social media and inquiries on web search engines tally in the millions each day. The logs of this activity have been called the digital exhaust of our age. Is there usable health content therein? Authors from the search engine company Google reported that by tallying search topics, for example, “Cold/flu remedy” or “Influenza complication,” this social media data predicted accurately flu trends across several years of flu epidemics; these predictions mirrored official health statistics of the rise and fall of infections.<sup>53</sup> It was proposed that by harnessing the collective intelligence of millions of users, even faster surveillance of disease activity was possible. A more skeptical reexamination of these social media models found them not sufficient to replace timely local and national surveillance of health trends.<sup>54</sup>

Whither Big Data in anesthesia?<sup>55–57</sup> There is much use of institutional and governmental administrative and billing databases in epidemiology reports of anesthesia. And there are now several national repositories of perioperative data including the National Clinical Outcomes Registry (NACOR), the Multicenter Perioperative Outcomes Group (MPOG), the National Surgery Quality Program (NSQIP), and the Society of Thoracic Surgeons National Database.<sup>56</sup> Although all have millions of patient records, only MPOG routinely captures all physiologic monitoring data at 5-minute or more frequent intervals. Even with this perioperative data, no repository or administrative database meets the definition of Big Data. The routine digitation of waveforms (e.g., electrocardiogram) at high resolution with storage in a national repository would quickly create Big Data.<sup>58</sup> The use of prospective genotyping of patients prior to anesthesia and surgery would also create Big Data.<sup>56,59</sup> Until then, anesthesia does not fit under Big Data.

**Figure 7-4** A Forest plot illustrates the relative strength of treatment effect across multiple studies. The point estimate for each study is represented by a square with 95% CIs represented by horizontal lines. In a Forest plot of RRs or ORs, the x-axis of the graph is on a logarithmic scale so that CIs are symmetrical about the point estimate. The vertical line of no effect is at 1. The area of each square is proportional to the weight of that study in the summary RR. The summary RRs are diamonds whose lateral

points indicate the 95% CI of the summary value. Reprinted by permission and is published within a Cochrane Review in the Cochrane Database of Systematic Reviews 2009, Issue 2. Cochrane Reviews are regularly updated as new evidence emerges and in response to comments and criticisms, and the Cochrane Database of Systematic Reviews should be consulted for the most recent version of the Review. (Reprinted with permission from Zaric D, Pace NL. Transient neurologic symptoms [TNS] following spinal anaesthesia with lidocaine versus other local anaesthetics. Cochrane Database of Systematic Reviews 2009, Issue 2. Art. No.: CD003006. DOI: <http://dx.doi.org/10.1002/14651858.CD003006.pub3>. Copyright John Wiley & Sons.)<sup>47</sup>

## Conclusions

### *Interpretation of Results*

Scientific studies do not end with the statistical test.<sup>60</sup> The experimenter must submit an opinion as to the generalizability of his or her work to the rest of the world. Even if there is a statistically significant difference, the experimenter must decide if this difference is medically or physiologically important. Statistical significance does not always equate with biologic relevance. The questions an experimenter should ask about the interpretation of results are highly dependent on the specifics of the experiment. First, even small, clinically unimportant differences between groups can be detected if the sample size is sufficiently large. On the other hand, if the sample size is small, one must always worry that identified or unidentified confounding variables may explain any difference; as the sample size decreases, randomization is less successful in assuring homogenous groups. Second, if the experimental groups are given three or more doses of a drug, do the results suggest a steadily increasing or decreasing dose–response relationship? Suppose the observed effect for an intermediate dose is either much higher or much lower than that for both the highest and lowest dose; a dose–response relationship may exist, but some skepticism about the experimental methods is warranted. Third, for clinical studies comparing different drugs, devices, and operations on patient outcome, are the patients, clinical care, and studied therapies sufficiently similar to those provided at other locations to be of interest to a wide group of practitioners? This is the distinction between *efficacy*—does it work under the best (research) circumstances—and *effectiveness*—does it work under the typical circumstances of routine clinical care?

Finally, in comparing alternative therapies, the confidence that a claim for a superior therapy is true depends on the study design. The strength of the evidence concerning efficacy will be least for an anecdotal case report; next in importance will be a retrospective study, then a prospective series of patients

compared with historical controls, and finally a randomized, controlled clinical trial. The greatest strength for a therapeutic claim is a series of randomized, controlled clinical trials confirming the same hypothesis.

## Statistical Resources

Accompanying the exponential growth of medical information has been the creation of a wealth of biostatistical knowledge. The increased emphasis on evidence-based medicine creates a great need for educating future and current physicians in quantitative reasoning, probability, and statistics. Detailed expositions of specific and recommended topics within these domains are available.<sup>61</sup> Textbooks oriented toward medical statistics and with expositions of basic, intermediate, and advanced statistics abound.<sup>62–67</sup> There are journals of biomedical statistics, including *Epidemiology*, *Research Synthesis Methods*, *Systematic Reviews*, *Statistics in Medicine*, and *Statistical Methods in Medical Research*, whose audiences are both statisticians and biomedical researchers. Some medical journals, for example, the *British Medical Journal*, regularly publish expositions of both basic and newer advanced statistical methods. Extensive Internet resources including free online courses of data analysis methods, electronic textbooks of basic statistical methods, online statistical calculators, standard data sets, and reviews of statistical software can be easily found. High performance statistical software is freely available from **9** the R Foundation for Statistical Computing, Vienna, Austria.<sup>c</sup>

There is a continuing expansion in the resources giving guidance in methodology. Much of the improvement has been driven by epidemiologists and statisticians associated with the Cochrane Collaboration. Standards for the reporting of the clinical trials and observational studies and for the SR and MA techniques include: (1) the 2010 CONSORT (Consolidated Standards of Reporting Trials) statement<sup>68,69</sup>; (2) the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement<sup>70,71</sup>; (3) the PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) statement<sup>72,73</sup>; and (4) the MOOSE (Meta-analysis of Observational Studies in Epidemiology) statement.<sup>74</sup> There is a centralized resource for obtaining these and other guidelines at the Equator-Network.<sup>d</sup>

## Statistics and Anesthesia

Reports in journals of anesthesia now include many newer methods that have not been mentioned in this chapter. To mention just three: (1) studies of the pharmacokinetics and pharmacokinetics of a drug or a combination of drugs typically use linear mixed effects or generalized linear mixed effects models, (2) techniques of survival analysis are applied to hospital discharge times or

postoperative morbidity/mortality outcomes, and (3) methods of interim analysis or sequential trial design are used in RCTs to stop futile or dangerous treatments.

Academic anesthesia needs more workers to immerse themselves in these statistical fundamentals. Having done so, these statistically knowledgeable academic anesthesiologists will be prepared to improve their own research projects, to assist their colleagues in research, to efficiently seek consultation from the professional statistician, to strengthen the editorial review of journal articles, and to expound to the clinical reader the whys and wherefores of statistics. The clinical reader also needs to expend his or her own effort to acquire some basic statistical skills. Journals are increasingly difficult to understand without some basic statistical understanding. Finally, understanding principles of experimental design and statistical inference can prevent premature acceptances of new therapies from faulty studies.

## Summary

Areas for Future Research

## KEY POINTS

- 1 The most crucial component of infection prevention is frequent and effective hand hygiene. Wearing gloves does not reduce the need for hand hygiene.
- 2 The ideal hand hygiene agent kills a broad spectrum of microbes, has antimicrobial activity that persists for at least 6 hours after application, is simple to use, and has few side effects. Antibiotic prophylaxis has become standard for surgeries in which there is more than a minimum risk of infection. The most commonly used antibiotic for surgical prophylaxis is cefazolin, a first-generation cephalosporin, as the potential pathogens for most surgeries are gram-positive cocci from the skin.
- 3 The exact timing for the administration of the antibiotic depends on the pharmacology and half-life of the drug, but should generally be 0 to 60 minutes before incision. Anesthesiologists should work in consultation

with surgeons to use guidelines determined by the local infection control committee to take initiative for administering prophylactic antibiotics because they have access to the patient during the 60 minutes prior to incision and can optimize timing of administration. The standard teaching that oxygen delivery depends more on hemoglobin-bound oxygen (oxygen content) than on arterial PO<sub>2</sub> may be true of working muscle, but it is not true of wound healing.

- 4 Although oxygen consumption is relatively low in wounds, it is consumed by processes that require oxygen at a high concentration. Delivery of oxygen to wounds depends on arterial PO<sub>2</sub> rather than hemoglobin-bound oxygen (oxygen content). High oxygen tensions (>100 mmHg) can be reached in wounds but only if perfusion is normal and arterial PO<sub>2</sub> is high. Peripheral vasoconstriction, which results from central sympathetic control of subcutaneous vascular tone, is probably the most frequent and clinically the most important impediment to wound oxygenation and wound healing. All vasoconstrictive stimuli must be corrected simultaneously to allow optimal healing. Modifiable risks for wound infections include smoking, malnutrition, obesity, hyperglycemia, hypercholesterolemia, and hypertension. These should be assessed and corrected when possible prior to surgery.
- 5 Prevention or correction of hypothermia has been shown to decrease wound infections and increase collagen deposition in patients undergoing major abdominal surgery. Maintenance of a high room temperature or active warming before, during, and after the operation is significantly more effective than other methods of warming, such as application of warmed blankets, circulating water blankets placed on the surface of the operating table, and humidification of the breathing circuit.
- 6 Optimizing the volume of perioperative fluid administration to minimize morbidity and mortality remains a significant and controversial challenge. Current best recommendations for volume management include replacing fluid losses based on standard recommendations for the type of surgery, replacement of blood loss, and replacement of other ongoing fluid losses (e.g., high urine output due to diuretic or dye administration, hyperglycemia, or thermoregulatory vasoconstriction).
- 7 Administration of supplemental oxygen via face mask or nasal cannulae increases safety in patients receiving systemic opioids. As a side benefit, it may also improve wound healing. Pain control also appears important since it favorably influences both pulmonary function and vascular tone.
- 8 In patients with moderate to high risk of surgical site infection, anesthesiologists have the opportunity to enhance wound healing and reduce the incidence of wound infections by simple, inexpensive, and readily available means.

## Introduction

Despite major advances in the management of patients undergoing surgery—including aseptic technique, prophylactic antibiotics, and advances in surgical approaches such as laparoscopic surgery—surgical wound infection and wound failure remain common complications of surgery (Fig. 8-1).<sup>1</sup> The Centers for Disease Control and Prevention (CDC) estimates that 18 million operative procedures were performed in acute care hospitals in the United States in 2010 and there were approximately 157,500 surgical site infections (SSIs) in 2011 (Table 8-1).<sup>2</sup> Wound complications are associated with prolonged hospitalization, increased resource consumption, and even increased mortality. A growing body of literature supports the concept that patient factors are a major determinant of wound outcome following surgery. Comorbidities such as diabetes and cardiac disease clearly contribute, and a patient's genetic make-up may also contribute.<sup>3</sup> Environmental stressors and the individual response to stress are also important. In particular, wounds are exquisitely sensitive to hypoxia, which is both common and preventable. Perioperative management can be adapted to promote postoperative wound healing and resistance to infection. Along with aseptic technique and prophylactic antibiotics, maintaining perfusion and oxygenation of the wound is paramount. This chapter discusses how knowledge of the principles of infection control and the biology and physiology of wound repair and resistance to infection can improve outcomes.

**Figure 8-1** Thomas et al. reviewed the records of 15,000 nonpsychiatric patients discharged from a representative sample of Utah and Colorado hospitals in 1992 for adverse events. There were 17,912 adverse events identified, or  $2.9 \pm 0.2\%$  of hospitalizations. Of these, almost half (45%) were related to operative care. The graph shows the distribution of adverse events within the subcategory of operative care (7,716 operative adverse events). About 20% were infection related and about 15% were wound related. SSI, surgical site infection; HCAI, health-care–associated infection; DVT, deep venous thrombosis; MI, myocardial infarction; PE, pulmonary embolus; CHF,

congestive heart failure; CVA, cerebrovascular accident. (Data from Thomas EJ, Studdert DM, Burstin HR, et al. Incidence and types of adverse events and negligent care in Utah and Colorado. *Med Care*. 2000;38:261–271.)

## Infection Control

### 1 Hand Hygiene

Perhaps the most crucial component of infection prevention is frequent and effective hand hygiene. In 1847, Ignaz Semmelweis made the observation that women who delivered their babies in the First Clinic at the General Hospital of Vienna, staffed by medical students and physicians, had a mortality rate of 5% to 15%, largely the result of puerperal infections; this was substantially higher than the 2% rate of women who delivered at Clinic 2, which was staffed by midwife students and midwives.<sup>4</sup> Students and physicians at Clinic 1 usually started the day performing autopsies (including on patients who died of puerperal fever) and then moved on to the clinic, where they performed examinations on women in labor. Semmelweis made the connection, and although germ theory was some years off, he insisted that physicians and medical students wash their hands in a chlorinated solution when leaving the pathology laboratory. This reduced the rate of puerperal fever to the same rate as at Clinic 2. Soon, Semmelweis identified cases of transmission from an infected to an uninfected patient, and instituted the use of chlorinated solution hand washing between cases as well. He also demonstrated that the chlorinated solution was more effective than soap and water. Unfortunately, his innovation was not widely adopted, resulting from a combination of his delay in publishing his results, the reluctance of his colleagues to accept that they might be responsible for transmitting disease, and his lack of tact in trying to convince health-care workers to adopt his measures. Despite our current knowledge of germ theory, hand hygiene remains an inexplicably neglected component of infection control: Studies consistently demonstrate about a 40% rate of adherence (range, 5% to 81%) to hand hygiene guidelines,<sup>4</sup> and compliance by anesthesiologists in the operating room (OR) is notably lower.<sup>5</sup>

Bacteria are resident in the skin and can never be completely eliminated.<sup>6</sup> Resident flora are embedded in the deeper folds of the skin and are more resistant to removal, but are also infrequently pathogenic. Coagulase-negative Staphylococci and diphtheroids are the most common. Transient flora colonize the superficial layers of the skin and thus are easier to remove with hand hygiene. Transient flora are also the source of most health-care-associated infections, as health-care worker skin can become contaminated from patient contact or contact with contaminated surfaces. Contamination from surfaces is

most commonly with organisms such as Staphylococci and Enterococci, which are resistant to drying. Even “clean” activities such as taking a patient’s pulse or applying monitors can lead to hand contamination: 100 to 1,000 colony-forming units of *Klebsiella* species were measured on nurses’ hands following such activities in one study.<sup>7</sup> No studies have related hand contamination to actual transmission of infection to patients; however, numerous studies, starting with those of Semmelweis, have demonstrated a reduction in health-care–associated infections following institution of hand hygiene or improved adherence to hand hygiene.<sup>6</sup>

A number of products are available for hand hygiene. The ideal agent kills a broad spectrum of microbes, has antimicrobial activity that persists for at least 6 hours after application, is simple to use, and has few side effects. The most commonly used and efficacious agents are reviewed here.

Plain (not antiseptic) soap and water are generally the least effective at reducing hand contamination.<sup>8</sup> Although obvious dirt is removed by the detergent effect of soap and the mechanical action of washing, bacterial load is not greatly reduced. Further, soap and water hand hygiene is associated with high rates of skin irritation and drying, both of which are risk factors for an increased bacterial load. Soap and water are, however, the most effective at removing spores, and therefore should be used when contamination with *Clostridium difficile* or *Bacillus anthracis* is a concern.<sup>6</sup>

Alcohol-based rinses, gels, and foams denature proteins, and this confers their antimicrobial activity.<sup>6</sup> Ethanol is most commonly used because it has more antiviral activity than isopropanol. Antiseptics containing 60% to 95% ethanol with a water base are germicidal and effective against gram-positive and gram-negative bacteria, lipophilic viruses such as herpes simplex, human immunodeficiency, influenza, respiratory syncytial, and vaccinia viruses, and hepatitis B and C viruses. They have little persistent activity, although regrowth of bacteria does occur slowly after use of alcohol-based products. Combination with low doses of other agents such as chlorhexidine, quaternary ammonium compounds, or triclosan can confer persistent activity. Efficacy depends on volume applied (3 mL is superior to 1 mL) and duration of contact (ideally, 30 seconds).

**Table 8-1** Criteria for Defining a Surgical Site Infection (SSI)

**Superficial Incisional SSI**

- Infection occurs within 30 days after the operation  
and
- Infection involves only skin or subcutaneous tissue of the incision  
and
- At least one of the following:
  1. Purulent drainage, with or without laboratory confirmation, from the superficial incision
  2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
  3. At least one of the following signs or symptoms of infection: Pain or tenderness, localized swelling, redness, or heat and superficial incision is deliberately opened by the surgeon, *unless* the incision is culture-negative
  4. Diagnosis of superficial incisional SSI by the surgeon or attending physician
- Do *not* report the following conditions as superficial incisional SSI:
  1. Stitch abscess (minimal inflammation and discharge confined to the points of suture penetration)
  2. Infection of an episiotomy or newborn circumcision site
  3. Infected burn wound
  4. Incisional SSI that extends into the facial and muscle layers (see "Deep Incisional SSI")

Note: Specific criteria are used for identifying infected episiotomy and circumcision sites and burn wounds

**Deep Incisional SSI**

- Infection occurs within 30 days after the operation if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operation  
and
- Infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision  
and
- At least one of the following:
  1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site
  2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms: Fever (>38°C), localized pain, or tenderness, unless site is culture-negative
  3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination
  4. Diagnosis of a deep incisional SSI by a surgeon or attending physician

Notes:

1. Report infection that involves both superficial and deep incision sites as deep incisional SSI
2. Report an organ/space SSI that drains through the incision as a deep incisional SSI

**Organ/Space SSI**

- Infection occurs within 30 days after the operation if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operation  
and
- Infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation  
and
- At least one of the following:
  1. Purulent drainage from a drain that is placed through a stab wound into the organ/space
  2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
  3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
  4. Diagnosis of an organ/space SSI by a surgeon or attending physician

From Mangram AJ, Horan TC, Pearson ML, et al. Guideline for Prevention of Surgical Site Infection, 1999. Centers for Disease Control and Prevention (CDC) Hospital Infection Control Practices Advisory Committee. *Am J Infect Control*. 1999;27:97-132, with permission.

Chlorhexidine is a cationic bisbiguanide that disrupts cytoplasmic membranes, resulting in precipitation of cellular contents.<sup>6</sup> It is germicidal against gram-positive bacteria and lipophilic viruses, with somewhat less activity against gram-negative bacteria and fungi, and minimal against tubercle bacilli. It has substantial persistence on the skin. The CDC has identified chlorhexidine as the topical agent of choice. It may cause severe corneal damage after direct contact with the eye, ototoxicity after direct contact with the inner or middle ear, and neurotoxicity after direct contact with the brain or meninges. There are reports of bacteria that have acquired reduced susceptibility to chlorhexidine, but these are of questionable clinical

pertinence since the concentrations at which resistance was found were substantially lower than that of commercially available products. Recent reports have identified immunoglobulin E-mediated allergic reactions to chlorhexidine.<sup>9</sup> Cases are likely underreported because of the difficulty identifying the source of anaphylactic reactions perioperatively. Chlorhexidine is present in a wide range of medical and community-based products, including wipes, impregnated central venous catheters, toothpaste, mouthwash, contact lens cleanser, and food preservatives. Therefore, potentially sensitizing exposures are common.

**Table 8-2** Indications for Hand Hygiene

When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with either a nonantimicrobial soap and water or an antimicrobial soap and water.  
If hands are not visibly soiled, use an alcohol-based hand rub for routinely decontaminating hands. Alternatively, wash hands with an antimicrobial soap and water.  
Decontaminate hands before having direct contact with patients.  
Decontaminate hands before donning sterile gloves when inserting a central intravascular catheter.  
Decontaminate hands before inserting indwelling urinary catheters, peripheral vascular catheters, or other invasive devices that do not require a surgical procedure.  
Decontaminate hands after contact with a patient's intact skin (e.g., applying monitors, moving patient).  
Decontaminate hands after contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled.  
Decontaminate hands if moving from a contaminated-body site (e.g., mouth during tracheal intubation) to a clean-body site (e.g., adjusting gas flow, turning on ventilator, starting IV) during patient care.  
Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient. Take care to reduce contamination of the anesthesia machine (e.g., after tracheal intubation) as well!  
Decontaminate hands after removing gloves.  
Before eating and after using a restroom, wash hands with a nonantimicrobial soap and water or with an antimicrobial soap and water.  
Antimicrobial-impregnated wipes (i.e., towelettes) may be considered as an alternative to washing hands with nonantimicrobial soap and water. Because they are not as effective as alcohol-based hand rubs or washing hands with an antimicrobial soap and water for reducing bacterial counts on the hands of HCWs, they are not a substitute for using an alcohol-based hand rub or antimicrobial soap.

IV, intravenous (tube); HCW, health-care worker.

Modified from Boyce JM, Pittet D. Guideline for hand hygiene in health-care settings. Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HIPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. *Am J Infect Control*. 2002;30(8):S1.

Iodine and iodophors (iodine with a polymer carrier) penetrate the cell wall and impair protein synthesis and cell membrane function.<sup>6</sup> They are bactericidal against gram-positive, gram-negative, and some spore-forming bacteria including clostridia and *Bacillus* species, although inactive against spores. They also have activity against mycobacteria, viruses, and fungi. Their persistence is generally fairly poor. They cause more contact dermatitis than other commonly used agents, and allergies to this class of topical agent are common. Iodophors generally cause fewer side effects than iodine agents.

The choice of an antiseptic depends on the expected pathogens, acceptability by health-care workers, and cost. In general, antiseptics cost about \$1 per patient day, far less than the cost of health-care-associated infections. In nine studies that examined the effect of improved hand hygiene adherence on health-care-associated infections, the majority demonstrated that as hand hygiene practices improved, infection rates decreased.<sup>6</sup>

Barriers to hand hygiene include skin irritation and fear of skin irritation, inaccessibility, time, and health-care worker acceptance (largely related to the other factors mentioned). Although alcohol-based agents have long been believed to cause more skin irritation, several recent trials have demonstrated less skin irritation and better acceptance with emollient-containing, alcohol-based hand rubs compared with either antimicrobial or nonantimicrobial soaps. The use of appropriate (glove-compatible) lotions twice a day also reduces skin irritation—as well as leading to a 50% increase in hand hygiene frequency in one study.<sup>6</sup> Alcohol-based gels and foams are also generally more accessible than antiseptic soap and water, as the dispenser may be pocket-sized or placed conveniently near sites of patient care. It has been estimated that alcohol-based gels and foams require only about 25% of the time of going to a sink to wash one's hands. However, soap and water should be used to remove particulate matter including blood and other body fluids or after five to ten applications of alcohol-based agent.

Adherence to hand hygiene guidelines (Tables 8-2 to 8-4) generally decreases as the frequency of indicated hand washing increases, as the workload increases, and as staffing decreases. CDC guidelines for health-care providers traditionally focused on hand hygiene prior to entering and after leaving a patient room. More recently, the World Health Organization has developed a campaign highlighting the “5 Moments” of hand hygiene (Fig. 8-2). The campaign emphasizes the need to perform hand hygiene after each contact with a patient or their immediate environment.<sup>10</sup>

**Table 8-3** Hand Hygiene Technique

When decontaminating hands with an alcohol-based hand rub, apply the recommended volume of product to the palm of one hand and rub hands together, covering all surfaces of hands and fingers, until hands are dry.

When washing hands with soap and water, wet hands first with water, apply an amount of the product recommended by the manufacturer to hands, and rub hands together vigorously for at least 15 seconds, covering all surfaces of the hands and fingers. Rinse hands with water and dry thoroughly with a disposable towel. Use towel to turn off the faucet. Avoid using hot water because repeated exposure to hot water may increase the risk of dermatitis.

Liquid, bar, leaflet, or powdered forms of plain soap are acceptable when washing hands with a nonantimicrobial soap and water. When bar soap is used, soap racks that facilitate drainage and small bars of soap should be used.

Modified from Boyce JM, Pittet D. Guideline for hand hygiene in health-care settings. Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HIPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. *Am J Infect Control*. 2002;30(8):S1.

## Table 8-4 Skin Care

Provide health-care workers with hand lotions or creams to minimize the occurrence of irritant contact dermatitis associated with hand antisepsis or hand washing. Solicit information from manufacturers regarding any effects that hand lotions, creams, or alcohol-based hand antiseptics may have on the persistent effects of antimicrobial soaps being used in the institution, as well as on glove integrity. Select a combination of products that minimizes these effects.

Modified from Boyce JM, Pittet D. Guideline for hand hygiene in health-care settings. Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HIPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. *Am J Infect Control*. 2002;30(8):51.

In an intensive care unit (ICU), hand hygiene for nurses is generally indicated about 20 times per hour, as compared with lower acuity units, where this number decreases to eight times per hour.<sup>6</sup> In the operating room (OR), frequent patient contact by the anesthesiologist requires frequent hand hygiene, probably at about the level of nurses in the ICU, while accessibility is often quite limited. Sinks are available only outside the OR. Therefore, alcohol-based agents should be available within hand's reach of the anesthesia machine. Loftus et al.<sup>11</sup> studied bacterial contamination of the anesthesia work area (adjustable pressure limiting valve complex and agent flowmeter) and cross-contamination of the sterile anesthesia stopcock during 61 first cases in their OR. They found an average increase in bacterial contamination of the work area of 115 colonies per surface area sampled during cases (95% confidence interval: 62–169;  $p < 0.001$ ). Transmission of bacteria from the work area to the sterile stopcock in the patients' intravenous tubing occurred in 32% of cases, including transmission of methicillin-resistant *Staphylococcus aureus* (MRSA) in two cases and vancomycin-resistant *Enterococcus* in one case. A high level of contamination of the work area ( $>100$  colonies per surface area sampled) increased the risk of stopcock contamination 4.7-fold (95% confidence interval: 1.42–15.42;  $p = 0.011$ ).

In a follow-up study, Koff et al.<sup>5</sup> demonstrated that increased hand hygiene episodes (7 to 9 per hour compared to  $<0.5$  per hour during the control period) triggered by an alarm and encouraged by education decreased work area contamination, decreased stopcock contamination from 32% to 8%, and decreased health-care-associated infections significantly. Opportunities were not measured and hand hygiene episodes were not necessarily coordinated with one of the 5 Moments. Thus, transmission of bacterial contamination by the anesthesia provider appears to be common, a potential source of nosocomial infections, and largely preventable.<sup>11</sup> More recent studies by the same group demonstrate anesthesia provider hands as a source of cross-contamination between patients.<sup>12</sup> Frequent hand hygiene by anesthesia providers has a direct and positive impact on patient outcomes.

Wearing gloves does not reduce the need for hand hygiene. Although gloves provide protection, bacterial flora from patients may be cultured from up to 30% of health-care workers who wear gloves during patient contact.<sup>6</sup> Therefore, hand hygiene should be practiced both before putting on gloves and immediately after removal. Moreover, gloves should be removed or changed immediately after each procedure, including vascular access, intubation, and neuraxial anesthesia, because gloves become contaminated by patient contact just as hands do. Balancing hand hygiene with close attention to the patient during critical portions of the case (e.g., securing the airway) can be challenging. Double gloving and providing a convenient location for contaminated equipment have been suggested as effective approaches.<sup>13,14</sup>

Artificial and long fingernails, as well as chipped fingernail polish, are associated with higher concentrations of bacteria on the hands of health-care workers. Artificial nails have been identified as a source in several hospital-associated outbreaks of infection with gram-negative bacilli and yeast, and CDC guidelines discourage wearing of artificial nails by health-care workers in high-risk settings; many hospitals have banned wearing of artificial nails by any employee who has direct patient contact.<sup>6</sup> It may also be appropriate to counsel patients scheduled for surgery that artificial nails may increase their risk of infection, although this has not been investigated. Large quantities of bacteria are typically trapped under the fingernails, and 2002 CDC guidelines recommend that health-care workers keep their nail tips trimmed to less than  $\frac{1}{4}$  inch.<sup>6</sup>

Bacteria may be cultured at higher concentrations from the skin beneath a ring. On the other hand, wearing a ring does not increase overall bacterial levels measured on the hands of health-care workers. Therefore, it remains unclear whether transmission of infection could be reduced by prohibiting health-care workers from wearing rings.<sup>6</sup>

## **Antisepsis**

Masks have long been advocated as preventing SSI and are used almost universally in ORs in the US. Tunevall<sup>15</sup> studied the rate of wound infections in 3,088 patients over 115 weeks. In alternating weeks, OR personnel either wore masks or did not (personnel with active respiratory infections continued to wear masks). There was no difference in the rate of surgical wound infections (4.7% vs. 3.5%, respectively) in the two groups, nor in bacterial species cultured from the wounds. Friberg et al.<sup>16</sup> demonstrated comparable air and surface contamination during sham surgery in a horizontal laminar airflow unit whether OR personnel wore a nonsterile hood and mask or a sterilized helmet aspirator system. However, when the head cover but not the mask was omitted, contamination increased three- to fivefold. These data

suggest that wearing a head cover is useful for preventing SSI, while wearing a mask is not. Nonetheless, the study by Tunevall is a small one, and most hospitals continue to require a mask in the OR while surgical instruments are open. Moreover, the mask does serve the purpose of protecting the health-care provider, particularly when combined with eye protection, and thus should most likely be used during tracheal intubation, emergence from anesthesia, and at other times when exposure to body fluids is likely.

Although the preponderance of postoperative surgical infections is caused by flora that are endogenous to the patient, environmental and airborne contaminants may also play a causative role. An important, but frequently overlooked, consideration is the role that traffic patterns into an OR can play in patient exposure to airborne organisms. A recent Israeli study of risk factors for surgical infection after total knee replacement demonstrated a trend toward increased infection rates with increased number of orthopedic surgeons or anesthesiologists present in the OR.<sup>17</sup> This study reconfirmed a prior study showing a trend toward increased incidence of SSI as the number of people in the operating suite increases.<sup>18</sup> However, it has been noted in one audit that physicians and nurses did little to limit the number of people through ORs during procedures.<sup>19</sup> Current recommended practices are that traffic patterns should limit the flow of people through an OR that is in use, and that no more people than necessary should be in an OR during a procedure.<sup>20</sup> The anesthesiologist is clearly in a position to play a leadership role in controlling human traffic through the OR.

**Figure 8-2** World Health Organization schematic of the 5 Moments for Hand Hygiene.

Mermel et al.<sup>21</sup> demonstrated in 1991 that central venous lines placed by

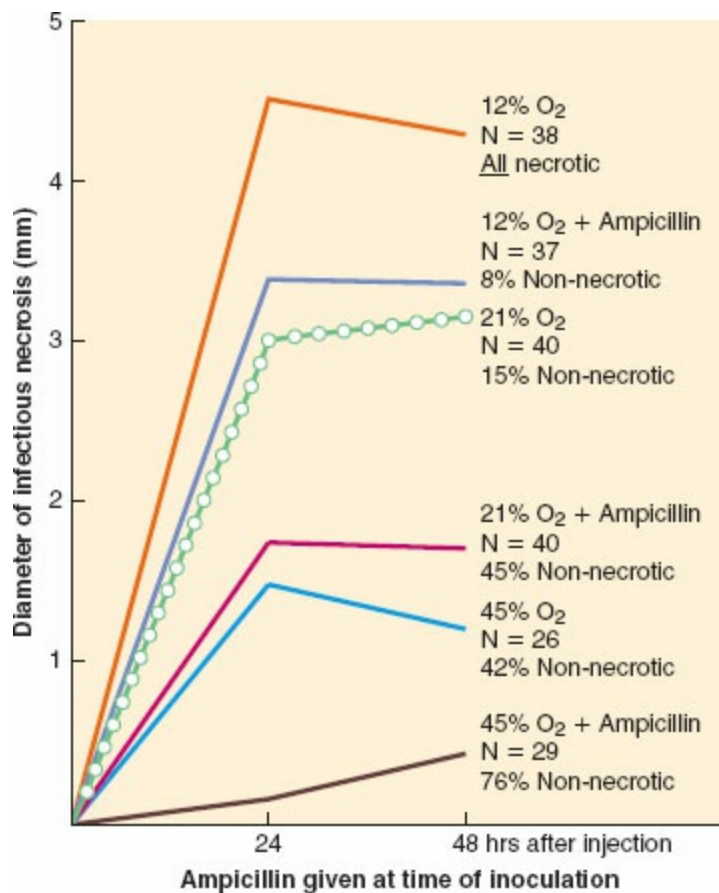

the anesthesiologist in the OR became infected more often (relative risk [RR], 2.1;  $p = 0.03$ ) than those placed by surgeons or other providers, whether in or out of the OR. Contributing factors appeared to be site of placement and the stringency of aseptic technique. Infection risk is significantly higher with femoral (HR 3.5) or jugular (HR 2.1) site selection as compared to subclavian placement; however, subclavian placement does have a higher associated rate of pneumothorax.<sup>22</sup> Chlorhexidine–alcohol skin preparation results in a lower rate of central venous catheter–associated bloodstream infection than povidone-iodine with alcohol and should be used preferentially.<sup>23</sup> Raad et al.<sup>24</sup> demonstrated that use of a maximal sterile barrier technique versus sterile gloves and small sterile drapes led to a significant reduction in central venous catheter-related infection from 7.2% to 2.2% ( $p = 0.03$ ). Therefore, gowning and gloving, careful aseptic technique, and use of a wide sterile field should be routine.<sup>25</sup> Use of ultrasound guidance for placement is not associated with an increased infection rate, and therefore is recommended since it decreases mechanical complications during placement.<sup>26</sup> In anesthetized patients, the central line is ideally placed before the surgical site is draped in order to avoid contamination of the wire on the underside of the surgical drape.

Epidural abscess formation is an extremely rare but potentially catastrophic complication of neuraxial anesthesia and epidural catheter placement. Therefore, careful attention to aseptic technique and infection control is required. The most important consideration is to prevent contamination of the needle and catheter. Thus, hand washing, skin preparation, draping, and maintenance of a sterile field should be carefully observed. Gowning and wearing a mask likely play a smaller role, but are reasonable given the devastating consequences of infection. Finally, epidurals should probably be avoided in patients known or suspected to have bacteremia or deferred until after appropriate antibiotics are administered.

### *Antibiotic Prophylaxis*

After antibiotics came into widespread use in the 1940s and 1950s, there was much debate over the possibility that antibiotic prophylaxis might prevent SSI. In 1957, Miles et al.<sup>27</sup> used a guinea pig model for proof of the principle that administration of an antibiotic prior to contamination (incision) could reduce the risk of SSI. When appropriate antibiotics were given within 2 hours before or after intradermal injection of bacteria, they were effective in preventing invasive infection and necrosis. When given outside this window, they were not effective. This gave rise to the concept of a “decisive period” in which antibiotics will be effective, which remains a guiding principle of antibiotic prophylaxis. Miles et al. also demonstrated that injection of

epinephrine intradermally prior to administration of antibiotics led to antibiotic failure, as demonstrated by an increased wound infection rate. This demonstrated the crucial role of local perfusion in delivering antibiotics to the site. Knighton et al.,<sup>28</sup> using the same model, demonstrated that increased inspired oxygen was equally as effective as antibiotics in preventing infection, and that the two effects were additive (Fig. 8-3). Knighton et al.<sup>29</sup> also delayed the administration of oxygen for up to 6 hours after inoculation and demonstrated no reduction in effect. Thus, the decisive period for oxygen is considerably longer than that for antibiotics.

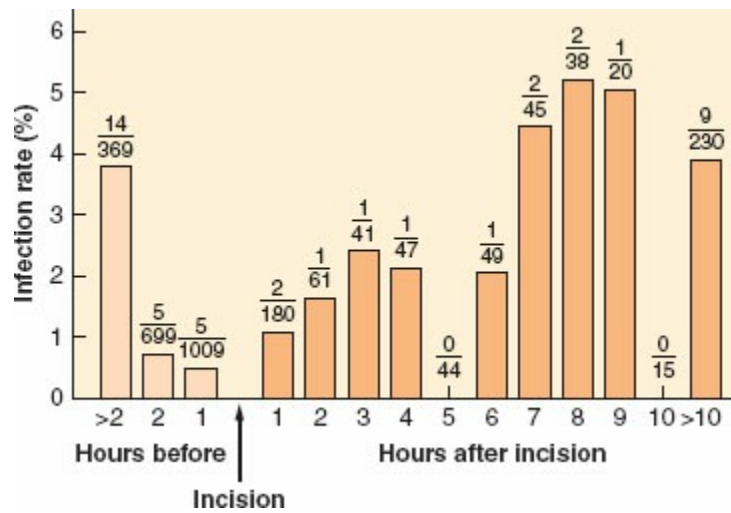

**Figure 8-3** The effect of oxygen and/or antibiotics on lesion diameter after intradermal injection of bacteria into guinea pigs. Note that at every level, oxygen adds to the effect of antibiotics and that increasing oxygen in the breathing mixture from 12% to 20% or from 20% to 45% exerts an effect comparable to that of appropriately timed antibiotics. (Reprinted with permission from Rabkin J, Hunt TK. Infection and oxygen. In: Davis J, Hunt TK, eds. *Problem Wounds: The Role of Oxygen*. New York: Elsevier; 1988:1.)

Two surgeons at Washington University in St. Louis, Harvey Bernard and William Cole,<sup>30</sup> reported on the first controlled clinical trial of the efficacy of antibiotic prophylaxis in 1964 and demonstrated a benefit in abdominal operations. Thereafter, numerous clinical trials were performed with somewhat variable results. Eventually these served to define the timing and population in which prophylactic antibiotics work. By the 1970s, antibiotic

prophylaxis for high-risk surgery—meaning clean-contaminated and contaminated cases—was becoming well accepted and widely used, although some skeptics remained. In 1992, Classen et al.<sup>31</sup> published their prospective series including 2,847 patients undergoing clean or clean-contaminated surgical procedures at LDS Hospital in Salt Lake City, UT (Fig. 8-4). They demonstrated that the decisive period for SSI in humans undergoing surgery was essentially the same as for experimental infections in guinea pigs. That is, they found the lowest infection rate when antibiotics were given within 2 hours before or after incision, and a rapid increase in SSI rate when they were given outside that range. The best results, though only by a small margin and not statistically significant, were within 0 and 60 minutes of surgery, and this subsequently became the clinical standard.

Antibiotic prophylaxis has now become standard for surgeries in which there is more than a minimum risk of infection. Although not every surgery and situation has been studied, a strong rationale for the approach to prophylactic antibiotics has emerged. Ideally, the antimicrobial of choice for prophylaxis should prevent SSI, prevent SSI-related morbidity and mortality, be cost-effective, avoid adverse effects, and have no adverse consequences on the microbial flora of the patient or of the hospital.<sup>32</sup> The agent for antibiotic prophylaxis must cover the most likely spectrum of bacteria presented in the surgical field. The most common surgical-site pathogens in clean procedures are skin flora, including *Staphylococcus aureus* and coagulase-negative staphylococci (e.g., *Staphylococcus epidermidis*). In clean-contaminated procedures, the most common pathogens include gram-negative rods, and enterococci in addition to skin flora. Data from the National Nosocomial Infections Surveillance (NNIS) system for 2006 to 2007 indicate that the proportion of SSI caused by *S. aureus* has increased to 30%, with about half caused by MRSA. Infections caused by MRSA are associated with higher mortality rates, prolonged hospital stays, and higher hospital costs than infections caused by other agents. Nevertheless, it is not recommended that vancomycin be used as a routine agent for surgical antimicrobial prophylaxis.<sup>32</sup>

**Figure 8-4** The figure demonstrates rates of surgical wound infection corresponding to the temporal relation between antibiotic administration and the start of surgery. The number of infections and the number of patients for each hourly interval appear as the numerator and denominator, respectively, of the fraction for that interval. The trend toward higher rates of infection for each hour that antibiotic administration was delayed after the surgical incision was significant (z score = 2.00;  $p < 0.05$  by the Wilcoxon test). (Adapted from Classen DC, Evans RS, Pestotnik KS, et al. The timing of prophylactic administration of antibiotics and the risk of surgical-wound infection. *N Engl J Med.* 1992;326;281.)

Several groups separately developed guidelines for use of surgical prophylactic antibiotics, culminating in recommendations published in 2004 by the National Surgical Infection Prevention Project and updated in 2013.<sup>32</sup> These guidelines emphasize timing and choice of appropriate agents; a number of agents are recommended as appropriate for each procedure, allowing for choices to be guided by local sensitivity patterns and providing for alternate agents in the case of drug sensitivity or allergy. (See [Table 8-5](#) for general recommendations.) The most commonly used antibiotic for surgical prophylaxis is cefazolin, a first-generation cephalosporin, because it is the most widely studied agent, with proven efficacy, safety, and desirable duration of action, and its spectrum of activity covers the organisms commonly encountered in surgery.<sup>32,33</sup>

By definition, prophylactic antibiotics are given pre- or intraoperatively. The exact timing for the administration of the antibiotic depends on the **3** pharmacology and half-life of the drug. It has been suggested that administration of prophylactic antibiotics is ideal within 30 minutes to 1 hour of incision.<sup>33,34</sup> Drugs given by bolus administration (e.g., cefazolin) achieve adequate tissue concentration rapidly, so that giving these drugs within 0 and 30 minutes of incisions appears equally efficacious. Giving the antibiotics too early (so that the incision is more than 60 minutes after the dose) is a recurrent issue at many hospitals, especially in cases that require complex patient positioning. Giving the antibiotics closer to the incision time prevents

this problem. Providing timely prophylactic antibiotics is relatively uncomplicated for antibiotics that can be given as a bolus dose (e.g., cephalosporins) or as an infusion over a few minutes (e.g., clindamycin) and thus provide tissue levels within minutes. For drugs like vancomycin that require infusion over an hour or more, coordination of administration is more complex. In general, it is considered acceptable if the infusion is started within 120 minutes before incision. Vancomycin is usually given in the context of known or suspected MRSA colonization; giving a dose of cefazolin in addition within an hour of incision is a way to ensure adequate antibiotic levels at the time of incision while providing coverage for MRSA with the vancomycin. When a tourniquet is used, the infusion must be complete prior to inflation of the tourniquet. An appropriate dose based on body weight and volume of distribution should be given. Depending on the half-life, antibiotics should be repeated during long operations or operations with large blood loss.<sup>32</sup> For example, cefazolin is normally dosed every 8 hours but the dose should be repeated every 4 hours intraoperatively.<sup>32</sup> Finally, prophylactic antibiotics should be discontinued by 24 hours following surgery if postoperative dosing is selected at all. Prolonging the course of prophylactic antibiotics does not reduce the risk of infection but does increase the risk of adverse consequences of antibiotic administration,<sup>32</sup> including resistance, *C. difficile* infection, and sensitization.

**Table 8-5** General Recommendations for Antibiotic Prophylaxis

- Antibiotic prophylaxis choice, dose, and timing should be determined by a hospital committee based on national guidelines,<sup>32</sup> local patterns of antibiotic sensitivity, and other considerations.
- Always confirm the antibiotic selection with surgeons at the time-out or earlier.
  - The surgeon may wish to delay antibiotics until after culture.
  - Antibiotics may not be indicated (e.g., low-risk, elective procedures such as laparoscopic cholecystectomy or breast biopsy where implants will not be used).
  - Make sure to record the reason for not giving antibiotics on the record.
- $\beta$ -Lactam allergies.
  - Penicillin allergy is almost never a contraindication to cefazolin or other cephalosporin administration. A *documented* history of anaphylaxis or other serious reaction (angioedema, hives, bronchospasm, Stevens–Johnson syndrome or toxic epidermal necrolysis) is the exception. Determine the severity of a patient’s  $\beta$ -lactam allergy prior to choosing an alternative antimicrobial.
  - Lack of understanding of a true allergic reaction can lead to choosing an antimicrobial with reduced efficacy, increased cost, and greater risk of side effects.
- Ideally an antibiotic infusion should be completed before incision, but CMS guidelines consider starting the infusion before incision adequate. When possible, for drugs requiring slow (>30 min) infusion, the infusion should be initiated preoperatively.
- When a tourniquet is used, the dose should be completed at least 5 minutes before the tourniquet is inflated.
- Dosing schedules are more frequent than for therapeutic use to maintain wound tissue levels throughout surgery and ongoing contamination. Renal insufficiency may delay redosing, although initial dose is usually not affected.
- Additional intraoperative doses should be given when there is significant blood loss (~ half to one blood volume). Use the recommended second dose for this purpose.
- When *therapeutic* antibiotics are given preoperatively for an infection or presumed infection (e.g., acute appendicitis), prophylactic antibiotics are not required. Each situation should be examined individually: In some cases, coverage of skin flora may be appropriate prior to skin incision, but often continuation of the therapeutic antibiotics is all that is required.

Used with permission from University of Utah Health Care.

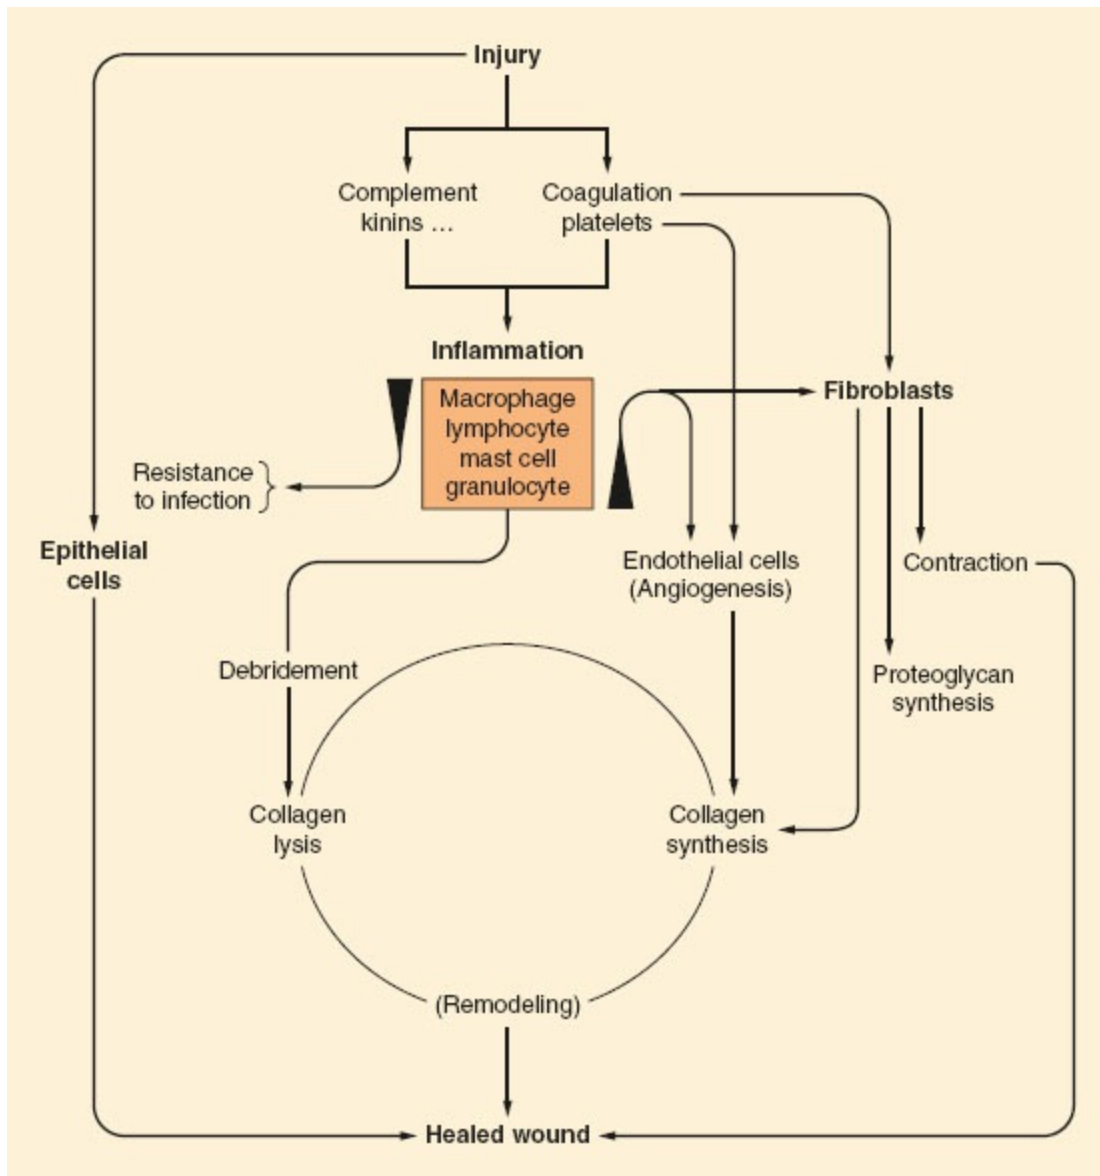

Because they have access to the patient during the 60 minutes prior to incision and can optimize timing of administration, anesthesiologists should work in consultation with the surgeon to use guidelines determined by the

local infection control committee to take initiative for administering prophylactic antibiotics. In this way, anesthesiologists can make a major contribution to preventing SSI. The Centers for Medicare and Medicaid Services has identified timely and appropriate antibiotic prophylaxis administration as a cornerstone of SSI prevention. Physician and hospital reimbursements are increasingly tied to such performance measures, meaning anesthesiologists also have an economic interest in ensuring adherence to guidelines.

## Mechanisms of Wound Repair

Wound healing is a complex process, requiring a coordinated repair response including inflammation, matrix production, angiogenesis, epithelialization, and remodeling (Fig. 8-5). Many factors may impair wound healing. Systemic factors such as medical comorbidities, nutrition,<sup>35</sup> sympathetic nervous system activation,<sup>36</sup> and age<sup>37-39</sup> have a substantial effect on the repair process. Local environmental factors in and around the wound including bacterial load,<sup>40</sup> degree of inflammation, moisture content,<sup>41</sup> oxygen tension,<sup>42</sup> and vascular perfusion<sup>43</sup> also have a profound effect on healing. Although all of these factors are important, perhaps the most critical element is oxygen supply to the wound. Wound hypoxia impairs each of the components of healing.<sup>44</sup>

**Figure 8-5** Schematic of the processes of wound healing. (Reprinted with permission from Hunt T. *Fundamentals of Wound Management in Surgery, Wound Healing: Disorders of Repair*. South Plainfield, NJ: Chirugecom, Inc., 1976.)

Although the role of oxygen is usually thought of in terms of aerobic respiration and energy production via oxidative phosphorylation, in wound healing oxygen is required as a cofactor for enzymatic processes and for cell-signaling mechanisms. Oxygen is a rate-limiting component in leukocyte-mediated bacterial killing and collagen formation because specific enzymes require oxygen at a partial pressure of at least 40 mmHg.<sup>45,46</sup> The mechanisms by which the other processes are oxygen-dependent are less clear, but these processes also require oxygen at a concentration much above that required for cellular respiration.<sup>47-49</sup>

### **The Initial Response to Injury**

A surgical incision disrupts the skin barrier, creating an acute wound, and an

effective initial response to injury depends on the ability to clean out foreign material and to resist infection. This response initiates a sequence of events that starts with any source of injury that disrupts homeostasis in the local environment and eventually leads to healing.

Wound healing is described in four overlapping phases: hemostasis, inflammation, proliferation, and remodeling.<sup>50</sup> Each phase is composed of complex interactions between host cells, contaminants, cytokines, and other chemical mediators that, when functioning properly, lead to repair of injury. These processes are highly conserved across species,<sup>51</sup> indicating the critical importance of the inflammatory response that directs the process of cellular/tissue repair. When any component of healing is disturbed and interrupts the orderly progression of repair, wound failure may result.<sup>50</sup>

Injury damages the local circulation and causes platelets to aggregate and release a variety of substances, including chemoattractants and growth factors.<sup>50</sup> The initial result is coagulation, which prevents exsanguination but also widens the area that is no longer perfused. Platelet degranulation releases platelet-derived growth factor, transforming growth factor beta (TGF- $\beta$ ), epidermal growth factor, and insulin-like growth factor-1 (IGF-1), which conjointly initiate the inflammatory process.<sup>50</sup> Bradykinin, complement, and histamine released by mast cells cause vasodilation and increased vascular permeability. Polymorphonuclear leukocytes arrive at the wound almost immediately and are followed by macrophages at 24 to 48 hours. These inflammatory cells activate in response to endothelial integrins, selectins, cell adhesion molecules, cadherins, fibrin, lactate, hypoxia, foreign bodies, infectious agents, and growth factors.<sup>50</sup> In turn, macrophages and lymphocytes produce more lactate<sup>52</sup> and growth factors, including IGF-1, leukocyte growth factor, interleukins (ILs) 1 and 2, TGF- $\beta$ , and vascular endothelial growth factor (VEGF).<sup>53</sup> This early inflammatory phase is characterized by erythema and edema of the wound edges.

Activated neutrophils and macrophages also release proteases, including neutrophil elastase, neutrophil collagenase, matrix metalloproteinase, and macrophage metalloelastase.<sup>50</sup> These proteases degrade damaged extracellular matrix components to allow their replacement. Proteases also degrade the basement membrane of capillaries to enable inflammatory cells to migrate into the wound.

In wounds, local blood supply is compromised at the same time that metabolic demand is increased. As a result, the wound environment becomes hypoxic and acidotic with high lactate levels.<sup>54,55</sup> This represents the sum of three effects: (1) decreased oxygen supply due to vascular damage and coagulation, (2) increased metabolic demand due to the heightened cellular response (anaerobic glycolysis), and (3) aerobic glycolysis by inflammatory cells.<sup>56,57</sup> Leukocytes contain few mitochondria and therefore acquire energy

from glucose, primarily by production of lactate and even in the presence of adequate oxygen supply.<sup>56</sup> In activated neutrophils, the respiratory burst, in which oxygen and glucose are converted to superoxide, hydrogen ion, and lactate, accounts for up to 98% of oxygen consumption; in the setting of injury, this activity increases by up to 50-fold over baseline.<sup>58</sup>

Local hypoxia is a normal and inevitable result of tissue injury.<sup>59,60</sup> Hypoxia acts as a stimulus to repair,<sup>61</sup> but also leads to poor healing<sup>42</sup> and increased susceptibility to infection.<sup>62,63</sup> Numerous experimental models<sup>27,62,64,65</sup> as well as human clinical experience<sup>63,66</sup> have led to the conclusion that wound healing is delayed in hypoxic wounds. The partial pressure of oxygen in dermal wounds is heterogeneous, ranging from 0 to 10 mmHg in the central (“dead space”) portion of the wound, to 80 to 100 mmHg (near arterial) adjacent to perfused arterioles and capillaries (Fig. 8-6).<sup>60</sup> The PO<sub>2</sub> of a given area depends on diffusion of oxygen from perfused capillaries, and thus wound PO<sub>2</sub> depends on capillary density, arterial PO<sub>2</sub>, and the metabolic activity of the cells, with some contribution from shifts in the oxyhemoglobin dissociation curve associated with wound pH and temperature.

### **Resistance to Infection**

After a disruption of the normal skin barrier, successful wound healing requires the ability to clear foreign material and resist infection. Neutrophils provide nonspecific immunity and prevent infection. Leukocytes migrate in tissue toward the site of injury via chemotaxis, defined as locomotion oriented along a chemical gradient.<sup>50</sup> Chemical gradients can be produced both exogenously and endogenously. Exogenous gradients result from bacterial products present in contaminated tissues. Endogenous mediators include components of the complement system (C5a), products of lipoxygenase pathway (leukotriene B<sub>4</sub>), and cytokines (IL-1, 8), along with lactate.<sup>67,68</sup> Together, these chemical mediators help to organize and control leukocyte invasion, bacterial killing, necrotic tissue removal, and the initiation of angiogenesis and matrix production. In the absence of infection, neutrophils disappear by about 48 hours. Nonspecific phagocytosis and intracellular killing are the major immune pathways activated in wounds.<sup>69</sup>

Neutrophils are the primary cells responsible for nonspecific immunity, and their function depends on a high partial pressure of oxygen.<sup>46,70</sup> This is because reactive oxygen species are the major component of the bactericidal defense against wound pathogens.<sup>69</sup> Phagocytosis of the pathogen activates the phagosomal oxidase (also known as the primary oxidase or nicotinamide adenine dinucleotide phosphate-oxidase [NADPH]-linked oxygenase), present in the phagocytic membrane, which uses oxygen as the substrate to catalyze

the formation of superoxide. Superoxide itself is bactericidal, but more importantly it initiates a series of cascades that produce other oxidants within the phagosome that increase bacterial-killing capacity (Fig. 8-7). For example, in the presence of superoxide dismutase, superoxide is reduced to hydrogen peroxide ( $H_2O_2$ ).  $H_2O_2$  combines with chloride and in the presence of myeloperoxidase forms the bactericidal hypochlorous acid, more commonly recognized as the active ingredient in bleach.<sup>71</sup> Since intraphagosomal oxidant production depends on conversion of oxygen to superoxide, the process is exquisitely sensitive to the partial pressure of oxygen in the tissue. The  $K_m$  (half-maximal velocity) for the phagosomal oxidase using oxygen as a substrate is 40 to 80 mmHg.<sup>46</sup> This means that resistance to infection is critically impaired by wound hypoxia and becomes more efficient as  $PO_2$  increases even to very high levels (500 to 1,000 mmHg).<sup>46</sup> Such levels do not occur naturally in tissue, but can be achieved by the administration of hyperbaric oxygen.<sup>72-74</sup> This is one mechanism for the proposed benefit of hyperbaric oxygen therapy as an adjunctive treatment for necrotizing infections and chronic refractory osteomyelitis.<sup>75</sup>

**Figure 8-6** The varying oxygen tension in the wound module. Cross-section of the wound module in a rabbit ear chamber is in left upper corner of figure.  $PO_2$ , depicted graphically above the cross-section (*orange line*), is highest next to the vessels, with a gradient down to zero at the wound edge. Note also the lactate gradient (*green line*), high in the dead space and lower (but still above plasma) toward the vasculature. Hydrogen peroxide ( $H_2O_2$ ) is present at fairly high concentrations (*blue line*) and is also a major stimulus to wound repair.<sup>67</sup> Growth factors such as VEGF are produced by inflammatory cells in the hypoxic, high lactate, high hydrogen peroxide “signaling zone” and then diffuse to the “response zone” where they act on fibroblasts and endothelial

cells to promote healing. VEGF, vascular endothelial growth factor. (Modified from Silver IE. The physiology of wound healing. In: Hunt TK, Dunphy JE, eds. *Fundamentals of Wound Management*. New York: Appleton-Century-Crofts, 1980:30.)

Oxidants produced by inflammatory cells have a dual role in wound repair. Not only are they central to resistance to infection, but they also play a major role in initiating and directing the healing process. Oxidants, and in particular hydrogen peroxide produced via the respiratory burst, increase neovascularization and collagen deposition in vitro and in vivo.<sup>67</sup>

## **Proliferation**

The proliferative phase normally begins approximately 4 days after injury, concurrent with a waning of the inflammatory phase. It consists of granulation tissue formation and epithelialization. Granulation involves neovascularization and synthesis of collagen and connective tissue proteins.

## **Neovascularization**

New blood vessels must replace the injured microcirculation. Neovascularization in wounds proceeds both by angiogenesis and vasculogenesis. Angiogenesis is the phenomenon of new vessel growth via budding from existing vessels. In the setting of wounds, new vessels grow from mature vessels, usually intact postcapillary venules in the undamaged tissue immediately adjacent to the site of injury. Normally, the oxygen tension in adjacent tissue is sufficient to support this process. The new vessel growth extends and enters into the damaged areas that are typically high in lactate and have a low partial pressure of oxygen. Mature extracellular matrix is required for ingrowth of mature vessels.<sup>76</sup>

In vasculogenesis, bone marrow-derived endothelial precursor cells (EPCs) populate the tissue and differentiate and grow into new vessel tubules. In wounds, these tubules appear in the damaged area before any direct anastomosis with pre-existing vessels are made. These tubules must connect with existing vasculature to establish an intact blood supply in the wound. Angiogenesis has long been held to be the primary mechanism for new blood vessel growth in granulation tissue. Recent research, however, has demonstrated that as many as 15% to 20% of new blood vessels in wounds are derived from hematopoietic stem cells.<sup>76-78</sup>

**Figure 8-7** Schematic of superoxide and other oxidant production within the phagosome. NADPH, nicotinamide adenine dinucleotide phosphate-oxidase; NADP, nicotinamide adenine dinucleotide phosphate; SOD, superoxide dismutase; MP, myeloperoxidase. (Reprinted with permission from Hunt TK, Hopf HW. Wound healing and wound infection. What surgeons and anesthesiologists can do. *Surg Clin North Am.* 1997;77[3]:587–606.)

Angiogenesis and vasculogenesis both occur in response to similar stimuli, consisting of some combination of redox stress, hypoxia, and lactate. However, the specific mechanisms by which they proceed appear to differ somewhat. Angiogenesis involves the movement of endothelial cells in response to three waves of growth factors. The first wave of growth factors comes with the release by platelets of platelet-derived growth factor, TGF- $\beta$ , IGF-1, and others during the inflammatory phase. The second wave comes from fibroblast growth factor released from normal binding sites on connective tissue molecules. The third and dominant wave comes from VEGF, delivered largely by macrophages stimulated by fibrinopeptides, hypoxia, and lactate.<sup>79</sup> Although it is usually present, hypoxia is not required for granulation because of constitutive (aerobic) lactate production by inflammatory cells and fibroblasts. Too little lactate leads to inadequate granulation, while levels in excess of about 15 mM—usually associated with inflammation or infection—delay granulation.<sup>80</sup> The capillary endothelial response to angiogenic agents requires oxygen so that angiogenesis progresses in proportion to blood perfusion and arterial PO<sub>2</sub>.<sup>81</sup>

Vasculogenesis occurs in response to similar stressors as angiogenesis. EPCs are mobilized from the bone marrow into the circulation via a nitric oxide-mediated mechanism. Tissue hypoxia induces release of VEGF-A, which activates bone marrow stromal nitric oxide synthase. Increased bone marrow nitric oxide leads to release of EPCs into the circulation. These circulating EPCs home to the wound via tissue-hypoxia-induced upregulation of stromal cell-derived factor 1 $\alpha$ . Within the wound, EPCs undergo differentiation and

participate in the formation of new blood vessels.<sup>77</sup>

## **Collagen and Extracellular Matrix Deposition**

New blood vessels grow into the matrix that is produced by fibroblasts. Although fibroblasts replicate and migrate mainly in response to growth factors and chemoattractants, production of mature collagen requires oxygen.<sup>45</sup> Lactate, hypoxia, and some growth factors induce collagen mRNA synthesis and procollagen production. Posttranslational modification by prolyl and lysyl hydroxylases is required to allow collagen peptides to aggregate into triple helices. Collagen can only be exported from the cell when it is in this triple helical structure. The helical configuration is also primarily responsible for tissue strength. The activity of the hydroxylases is critically dependent on vitamin C and tissue oxygen tension, with a  $K_m$  for oxygen of about 25 mmHg.<sup>45,82</sup> Wound strength, which results from collagen deposition, is therefore highly vulnerable to wound hypoxia.<sup>42</sup>

Neovascularization and extracellular matrix (primarily collagen) production are closely linked. Fibroblasts cannot produce mature collagen in the absence of mature blood vessels that deliver oxygen to the site. New blood vessels cannot mature without a strong collagen matrix. Mice kept in a hypoxic environment of 13% inspired oxygen develop some new blood vessels in a test wound with the addition of exogenous VEGF or lactate, but these vessels are immature with little surrounding matrix and demonstrate frequent areas of hemorrhage.<sup>47</sup>

## **Epithelialization**

Epithelialization is characterized by replication and migration of epithelial cells across the skin edges in response to growth factors. Cell migration may begin from any site that contains living keratinocytes, including remnants of hair follicles, sebaceous glands, islands of living epidermis, or the normal wound edge. In acute wounds that are primarily closed, epithelialization is normally completed in 1 to 3 days. In open wounds healing by secondary intention, epithelialization is the final phase of healing and cannot progress until the wound bed is fully granulated. Like immunity and granulation, epithelialization depends on growth factors and oxygen. Silver<sup>83</sup> and Medawar<sup>49</sup> demonstrated in vivo that the rate of epithelialization depends on local oxygen. Topical oxygen applied in a manner that does not dry out epithelial cells has been advocated as a method to increase the rate of epithelialization.<sup>84</sup> Ngo et al.<sup>85</sup> demonstrated oxygen-dependent differentiation and cell growth in human keratinocyte culture. In contrast, O'Toole et al.<sup>86</sup> demonstrated that hypoxia increases epithelial migration in vitro. This may be explained, at least in part, by the dependence of

epithelialization on the presence of a bed of healthy granulation tissue, which is known to be oxygen-dependent.

### *Maturation and Remodeling*

The final phase of wound repair is maturation, which involves ongoing remodeling of the granulation tissue and increasing wound tensile strength. As the matrix becomes denser with thicker, stronger collagen fibrils, it becomes stiffer and less compliant. Fibroblasts are capable of adapting to changing mechanical stress and loading. Fibroblasts migrate throughout the matrix to help mold the wound to new stresses. Matrix metalloproteinases and other proteases help with fibroblast migration and continued matrix remodeling in response to mechanical stress. Some fibroblasts differentiate into myofibroblasts under the influence of TGF- $\beta$ , resulting in contractile cells. As the myofibroblasts contract, the collagenous matrix cross-links in the shortened position. This helps to strengthen the matrix and minimize scar size. Contraction is inhibited by the use of high doses of corticosteroids.<sup>87</sup> Even steroids given several days after injury have this effect. In those wounds where contraction is detrimental, this effect can be used for benefit. Although there is little definitive evidence, one dose of dexamethasone intraoperatively to prevent postoperative nausea and vomiting does not appear to impair healing.

Net collagen synthesis continues for at least 6 weeks and up to 6 months after wounding. Over time, the initial collagen threads are reabsorbed and deposited along stress lines, conferring greater tensile strength. Collagen found in granulation tissue is biochemically different from collagen of uninjured skin, and a scar never achieves the tensile strength of uninjured skin. Hydroxylation and glycosylation of lysine residues in granulation tissue collagen lead to thinner collagen fibers. At 1 week, a wound closed by primary intention has only reached 3% of the tensile strength of normal skin. By 3 weeks it is at 30%, and it only reaches its maximum tensile strength of 80% after 3 to 6 months.

Some wounds heal to excess. Hypertrophic scar and keloid are common forms of abnormal scar due to abnormal responses to healing. Hypertrophic scarring may be thought of as “exuberant” scarring within the boundaries of the wound. The inflammatory process that allows wound healing remains excessively active, resulting in stiff, rubbery, nonmobile scar tissue. Hypertrophic scars are most commonly seen following burns and in incisions over areas of tension and are thought to correlate with the length of time required to close the wound and opposing tension forces present in the wound, although other factors are also believed to play a role and are being actively explored. Keloids are scars that outgrow the boundaries of the initial

scar, and are most typically seen following skin incisions. Keloid formation is most likely due to a genetic predisposition, although exogenous inflammatory factors may also play a role.

## Wound Perfusion and Oxygenation

Complications of wounds include failure to heal, infection, and excessive scarring or contracture. Rapid repair has the least potential for infection and excess scarring. The perioperative physician's goals, therefore, are to avoid contamination, ensure rapid tissue synthesis, and optimize the immune response. All surgical procedures lead to some degree of contamination that must be controlled by local host defenses. The initial hours after contamination represent a decisive period during which inadequate local defenses may allow an infection to become established.

Normally, wounds on the extremities and trunk heal more slowly than those on the face. The major difference in these wounds is the degree of tissue perfusion and thus the wound tissue oxygen tension. As a rule, repair proceeds most rapidly and immunity is strongest when wound oxygen levels are high, and this is only achieved by maintaining perfusion of injured tissue.<sup>88</sup> Ischemic or hypoxic tissue, on the other hand, is highly susceptible to infection and heals poorly, if at all.<sup>66</sup> Wound tissue oxygenation is complex and depends on the interaction of blood perfusion, arterial oxygen tension, hemoglobin dissociation conditions, carrying capacity, mass transfer resistances, and local oxygen consumption. Wound oxygen delivery depends on vascular anatomy, the degree of vasoconstriction, and arterial  $PO_2$ .

The standard teaching that oxygen delivery depends more on hemoglobin-bound oxygen (oxygen content) than on arterial  $PO_2$  may be true of working muscle, but it is not true of wound healing. In muscle, intercapillary distances are small and oxygen consumption is high. In contrast, intercapillary distances are large and oxygen consumption is relatively low in subcutaneous tissue.<sup>48</sup> In wounds, where the microvasculature is damaged, diffusion distances are substantially increased. Peripheral vasoconstriction further increases diffusion distance.<sup>60</sup> The driving force of diffusion is partial pressure. Hence, a high  $PO_2$  is needed to force oxygen into injured and healing tissues, particularly in subcutaneous tissue, fascia, tendon, and bone, the tissues most at risk for poor healing.

**4** Although oxygen consumption is relatively low in wounds, it is consumed by processes that require oxygen at a high concentration. Inflammatory cells use little oxygen for respiration, producing energy largely via the hexose monophosphate shunt.<sup>46</sup> Most of the oxygen consumed in wounds is used for oxidant production (bacterial killing), with a significant contribution as well for collagen synthesis, angiogenesis, and

epithelialization. The rate constants ( $K_m$ ) for oxygen for these components of repair all fall within the physiologic range of 25 to 100 mmHg.<sup>45,46,49,70,89</sup>

Because of the high rate constants for oxygen substrate for the components of repair, the rate at which repair proceeds varies according to tissue  $PO_2$  from zero to at least 250 mmHg. In vitro fibroblast replication is optimal at a  $PO_2$  of about 40 to 60 mmHg. Neutrophils lose their ability to kill bacteria in vitro below a  $PO_2$  of about 40 mmHg.<sup>90,91</sup> These in vitro observations are clinically relevant. "Normal" subcutaneous  $PO_2$ , measured in test wounds in uninjured, euthermic, euvoletic volunteers breathing room air, is  $65 \pm 7$  mmHg.<sup>92</sup> Thus, any reduction in wound  $PO_2$  may impair immunity and repair. In surgical patients, the rate of wound infections is inversely proportional<sup>63</sup> and collagen deposition is directly proportional<sup>42</sup> to postoperative subcutaneous wound tissue oxygen tension.

High oxygen tensions ( $> 100$  mmHg) can be reached in wounds but only if perfusion is rapid and arterial  $PO_2$  is high.<sup>42,88</sup> This is because subcutaneous tissue serves a reservoir function, so there is normally flow in excess of nutritional needs and wound cells consume relatively little oxygen, about 0.7/100 mL of blood flow at a normal perfusion rate.<sup>48,93</sup> When arterial oxygen tension ( $PaO_2$ ) is high, this small volume can be carried by plasma alone. Contrary to popular belief, therefore, oxygen-carrying capacity, that is, hemoglobin concentration, is not particularly important to wound healing, provided that perfusion is normal.<sup>94,95</sup> Wound  $PO_2$  and collagen synthesis remain normal in individuals who have hematocrit levels as low as 15% to 18% provided they can appropriately increase cardiac output, and vasoconstriction is prevented.<sup>95,96</sup>

Peripheral vasoconstriction, which results from central sympathetic control of subcutaneous vascular tone, is probably the most frequent and clinically the most important impediment to wound oxygenation. Subcutaneous tissue is both a reservoir to maintain central volume and a major site of thermoregulation. There is little local regulation of blood flow, except by local heating.<sup>97</sup> Therefore, subcutaneous tissue is particularly vulnerable to vasoconstriction. Sympathetically induced peripheral vasoconstriction is stimulated by cold, pain, fear, and blood volume deficit,<sup>98,99</sup> and by various pharmacologic agents including nicotine,<sup>92</sup>  $\beta$ -adrenergic antagonists, and  $\alpha_1$ -agonists, all commonly present in the perioperative environment. Use of low doses of vasopressor agents to correct anesthesia (vasodilation)-induced hypotension, however, does not generally impair wound perfusion or free-flap survival.<sup>100</sup> Perioperative hypothermia is common and results from anesthetic drugs, exposure to cold, and redistribution of body heat from the core to the periphery.<sup>101</sup> Blood loss and increases in insensible losses increase fluid requirements in the perioperative period, thereby leaving the patient vulnerable to inadequate fluid

replacement. Thus, vasomotor tone is, to a large degree, under the perioperative physician's control.<sup>98,99</sup>

Prevention or correction of hypothermia<sup>102</sup> and blood volume deficits<sup>103</sup> have been shown to decrease wound infections and increase collagen deposition in patients undergoing major abdominal surgery. Preoperative systemic (forced air warmer) or local (warming bandage) warming have also been shown to decrease wound infections, even in clean, low-risk surgeries such as breast surgery and inguinal hernia repair.<sup>104</sup> Subcutaneous tissue oxygen tension is significantly higher in patients with good pain control than in those with poor pain control after arthroscopic knee surgery.<sup>105</sup> Stress also causes wound hypoxia and significantly impairs wound healing and resistance to infection.<sup>106,107</sup> These effects are clearly mediated, in large part, by changes in the partial pressure of oxygen in the injured tissue.

A number of groups have evaluated whether increasing inspired oxygen during surgery can reduce SSI by increasing wound oxygen levels. Most found benefit. Greif et al.<sup>108</sup> demonstrated in a randomized, controlled, double-blind trial including 500 patients that in warm, volume-replete patients with good pain control undergoing major colon surgery, administration of 80% versus 30% oxygen intraoperatively and for the first 2 hours after surgery significantly reduced the wound infection rate by 50%. Wound oxygen levels were significantly higher (almost double) intraoperatively and in the postanesthesia care unit (PACU) in the 80% oxygen group. Belda et al.<sup>109</sup> replicated these results (significant 40% reduction in SSI) in a randomized, controlled, double-blind trial in 300 colon surgery patients randomized to 80% versus 30% oxygen intraoperatively and during the first 6 hours after surgery. Surgical and anesthetic management were standardized and intended to support optimal perfusion. Myles et al.<sup>110</sup> demonstrated a significant reduction in major postoperative complications, as well as specifically wound infections in 2,050 major surgery patients randomized to 80% oxygen in 20% nitrogen versus 30% oxygen in 70% nitrous oxide intraoperatively. Bickel et al.<sup>111</sup> demonstrated a significant reduction in SSI (5.6% vs. 13.5%;  $p = 0.04$ ) in patients undergoing open appendectomy ( $n = 210$ ) who received 80% oxygen intraoperatively and high flow oxygen for 2 hours after surgery versus those who received 30% oxygen intraoperatively. Schietroma et al.<sup>112</sup> demonstrated in patients undergoing major rectal cancer surgery ( $n = 72$ ) that the risk of anastomotic leak was 46% lower in the 80% inspired oxygen group (RR, 0.63; 95% confidence interval, 0.42–0.98) versus the 30% group. In a retrospective case–control study of patients undergoing spine surgery,<sup>113</sup> intraoperative administered fraction of inspired oxygen of less than 50% was the strongest predictor of SSI (OR, 12; 94% CI, 4.5–33;  $P < 0.001$ ).

Pryor et al.<sup>114</sup> demonstrated a doubling of SSI in patients randomized to

80% versus 35% oxygen intraoperatively ( $n = 165$ ). There were a number of methodologic flaws in the study, but, more importantly, the two groups of patients were not equivalent, which likely explained the increase in infections seen in the 80% oxygen group. Meyhoff et al.<sup>115</sup> found no difference in SSI rate (20.1% vs. 19.1%,  $p = \text{NS}$ ) as a function of oxygen administration in 1,400 patients undergoing colon and gynecologic surgery. A major difference in design from the studies that demonstrated benefit was the use of a highly restricted volume replacement regimen. The stated aim was that patients were to gain no more than 1 kg by the second day after operation. Without data on wound oxygen (which was not measured), it is difficult to determine the reason for the difference in outcome compared to the Greif, Belda, and Myles studies, but wound vasoconstriction and a resulting lack of increase in wound oxygen tension is a strong possibility.

Although the preponderance of evidence indicates that use of high-inspired oxygen intraoperatively and providing supplemental oxygen postoperatively in *well-perfused* patients undergoing major abdominal surgery will reduce the risk of wound infection, there remains controversy about the benefits of high-inspired oxygen. One factor in the hesitation to adopt high-inspired oxygen is concern about potential side effects or toxicity of 80% oxygen. Two of the above studies examined this question in detail and found no difference in pulmonary complications or atelectasis.<sup>115,116</sup> A randomized controlled trial in patients at low risk for SSI ( $n = 100$ ) found no difference in postoperative oxygen requirement in patients randomized to 30% oxygen intraoperatively versus those randomized to more than 90%.<sup>117</sup> A recent Cochrane analysis of studies of high perioperative inspired oxygen<sup>118</sup> found no significant effect on mortality, although the authors point out that the sample size is not sufficient to rule out the possibility of harm. Thus, high-inspired oxygen appears to be a low-risk approach to enhancing host defenses and reducing SSI.

Perfusion and oxygen also play a key role in the effectiveness of antibiotic prophylaxis. Delivery of antibiotics depends on perfusion. Parenteral antibiotics given so that high levels are present in the blood at the time of wounding clearly diminish but do not eliminate wound infections.<sup>31</sup> In about one-third of all wound infections, the bacteria cultured from the wound are sensitive to the prophylactic antibiotic given to the patient, even when the antibiotics were given according to standard procedure.<sup>31</sup> The vulnerable third of patients appear to be the hypoxic and vasoconstricted group. When antibiotics are present in the wound at the time of injury, they are trapped in the fibrin clot at the wound site where they may have efficacy against contaminating organisms. Antibiotics diffuse poorly into the fibrin clot; however, so that later administration, whether more than 2 hours after injury or in response to wound infection, will have little effect. On the other hand, oxygen diffuses easily through the fibrin clots and is effective even 6 hours

after contamination.<sup>29</sup>

Bactericidal antibodies currently in use employ oxygen to kill organisms in much the same way as phagocytes. Kohanski<sup>119</sup> has demonstrated that quinolones,  $\beta$ -lactams, and aminoglycosides kill *S. aureus* and *Escherichia coli* by stimulating hydroxyl radical production from oxygen, even though all have different mechanisms for entering bacteria. Suller and Lloyd<sup>120</sup> observed a logarithmic reduction in bacterial cell counts in 10 to 15 hours in aerobic conditions compared with more than 60 hours to achieve the same result in an anaerobic environment for four facultative anaerobic staphylococcal strains exposed to vancomycin in air-equilibrated versus hypoxic conditions. Thus, maintaining conditions that optimize wound oxygen will also optimize the effectiveness of many commonly used antibiotics.

## Patient Management

A recent meta-analysis of 16 randomized controlled trials, quasiexperimental studies, and cohort studies<sup>121</sup> demonstrated that the use of “bundles” of evidence-based care in patients undergoing colorectal surgery significantly reduced the risk of SSI. Unfortunately, as the authors note, there is currently “no consensus as to what comprises the optimal colorectal surgical care bundle.” Standardization of care is likely responsible for some of the benefit. Further study is required to identify individual best practices. In the meantime, the following are approaches that anesthesiologists can take with the aim of improving wound healing and resistance to infection in their patients.

### Preoperative Preparation

Given knowledge of the physiology of wound healing, what are the best strategies for an anesthesiologist to pursue to ensure optimal healing? SSI result from a multitude of factors that include the health of the patient, the type of surgery, the number and type of organisms contaminating the surgical site, and surgical technique. To the degree they are predictable, interventions can be targeted at those patients most at risk (Table 8-6).

The CDC, in the Study of the Effect of Nosocomial Infection Control (SENIC),<sup>122</sup> developed a remarkably useful and simple predictive tool based on a score of 0 or 1 for each of the following four patient factors: an abdominal operation, an operation that lasts 2 hours or more, a surgical site that is contaminated or infected, and a patient who will have three or more diagnoses at discharge, exclusive of wound infection. The risk of infection with a score of 0 is 1%, with a score of 1 is 3.6%, with a score of 2 is 9%, with a score of 3 is 17%, and with a score of 4 is 27%. These percentages may

seem high, but this index was constructed on 3% of the American surgical patients from 1975–1976 and 1983, and the overall results are consistent with numerous other studies. More recent risk analyses by the same group, based on simpler predictors (e.g., American Society of Anesthesiologists Physical Status Classification) have yielded less sensitivity, but about the same overall infection rate.<sup>123</sup>

Modifiable or potentially modifiable risks include smoking, malnutrition, obesity, diabetes and hyperglycemia, steroid use, anemia, hypercholesterolemia, and hypertension. These should be assessed and corrected when possible prior to surgery. The decision to delay surgery must take into account both the urgency of the surgery and the severity of the risk.

**Table 8-6** Preoperative Checklist

Assess and optimize cardiopulmonary function. Correct hypertension.  
Treat vasoconstriction: Attend to blood volume, thermoregulatory vasoconstriction, pain, and anxiety.  
Assess recent nutrition and treat as appropriate.  
Treat existing infection. Among other actions, clean and treat skin infections.  
Assess wound risk by SENIC score in order to decide on the extent to which prophylactic measures should be taken.  
Start vitamin A or anabolic steroids in patients taking prednisone.  
Improve or maintain blood sugar control.

From Hunt TK, Hopf HW. Wound healing and wound infection. What surgeons and anesthesiologists can do. *Surg Clin North Am.* 1997;77:587, with permission.

Stress also predisposes to poor wound healing. Adverse psychosocial circumstances at the time of surgery may put patients at risk for poor wound healing. Kiecolt-Glaser et al.<sup>124</sup> studied the impact of hostile marital interactions on the healing of experimental blister wounds. High-hostile couples produced more proinflammatory cytokines and healed more slowly than low-hostile couples. Using a tape-stripping model, Muizzuddin et al.<sup>125</sup> investigated the effect of marital dissolution on skin barrier recovery and found that high stress was associated with slower recovery. Bosch et al.<sup>126</sup> studied the healing of a circular wound on the oral hard palate in subjects who varied in depression and/or dysphoria. High-dysphoric individuals had higher wound sizes from day 2 onward and depressive symptoms predicted slower wound healing. Collectively, these studies point to links between psychosocial distress, dysregulation at the system level, and impaired capacity for wound healing. It seems likely that stress-reduction techniques will reduce wound complications, and well-designed clinical trials are needed in this area.

## **Intraoperative Management**

Careful surgical technique is fundamental to optimal wound healing (Table 8-7). Delicate handling of the tissue, adequate hemostasis, and surgeon experience lead to healthier wounds. Incisions should be planned with regard to blood supply, particularly when operating near or in old incisions. Mechanical retractors should be released from time to time to allow perfusion to the wound edges. Judicious antibiotic irrigation of contaminated areas may be effective. Because dried wounds lose perfusion, wounds should be kept moist, especially during long operations. Not all wounds can be anatomically closed. Edema, obesity, the possibility of unacceptable respiratory compromise, or the need to debride grossly contaminated or necrotic soft tissues can all interfere with closure of the wound.

As the operation proceeds, new wounds are made and contamination continues. All anesthetic agents tend to cause hypothermia—first, by causing vasodilation, which redistributes heat from core to periphery in previously vasoconstricted patients, and second, by increasing heat loss and decreasing heat production.<sup>101</sup> Vasoconstriction is uncommon intraoperatively, as the threshold for thermoregulatory vasoconstriction is decreased, but is often severe in the immediate postoperative period when anesthesia is discontinued and the thermoregulatory threshold returns to normal in the face of core hypothermia. The onset of pain with emergence from anesthesia adds to this vasoconstriction because of the associated catecholamine release.<sup>105</sup> Rapid rewarming using a forced air warmer for hypothermic patients in the post-anesthesia care unit (PACU) does appear to be effective,<sup>127</sup> although prevention of hypothermia is clearly the goal.<sup>102</sup> Maintenance of a high room temperature or active warming before, during, and after the operation is significantly more effective than other methods of warming such as application of warm blankets, circulating water blankets placed on the operating table surface, and humidification of the breathing circuit.<sup>128</sup>

**Table 8-7** Intraoperative Management

Appropriate prophylactic antibiotics should be given at the start of any procedure in which infection is highly probable and/or has potentially disastrous consequences. Maintain antibiotic levels during long operations.  
Keep patients warm.  
Observe gentle surgical technique with minimal use of ties and cautery.  
Keep wounds moist.  
Antibiotic irrigation in contaminated cases.  
Elevate PaO<sub>2</sub>.  
Delayed closure for heavily contaminated wounds.  
Use appropriate sutures (and skin tapes).  
Use appropriate dressings.

From Hunt TK, Hopf HW. Wound healing and wound infection. What surgeons and anesthesiologists can do. *Surg Clin North Am.* 1997;77:587, with permission.

Forced air warming was the first practical means of keeping patients warm intraoperatively. More recently, a number of other effective approaches have been introduced, including resistive warming, negative pressure warming, and thin, adhesive circulating water pads that are applied directly to the skin.<sup>129</sup>

## Volume Management

Intravascular volume management during surgery has implications for tissue perfusion and, therefore, wound healing. Numerous factors, including patient comorbidities, medications such as diuretics, fever, preoperative volume state, surgical procedure, blood and insensible losses, and surgical stress all influence fluid requirements during surgery. It is widely agreed that the goal of intraoperative fluid management is to ensure sufficient intravascular volume to maintain perfusion and maximize oxygen delivery to the tissues, while avoiding the ill effects of hypervolemia, namely interstitial edema; what is difficult to determine is how to achieve that goal. Patient monitoring, fluid choice, and fluid administration strategy are topics of much debate, with a poorly standardized and often contradictory literature. For a comprehensive review of fluid management, see [Chapter 16: Fluids, Electrolytes and Acid-Base Physiology](#).

Estimating preoperative volume status can be challenging, as there are many factors to consider. Preoperative fluid state may be reduced by fasting, mechanical bowel preparation, or medication use. Pre-existing medical conditions such as systolic and diastolic heart failure may cause hypervolemia and physiology that is exquisitely sensitive to fluid overload. While hemodialysis reliably induces hypovolemia, patients with end-stage renal disease are also susceptible to fluid overload, and intraoperative fluid replacement is complex. Patient history and physical examination, for more straightforward patients, and other tools such as preoperative echocardiography, for complex patients, can give the anesthesiologist an idea of presurgical patient's general volume status.

There are known serious complications of both hyper- and hypovolemia, particularly in the perioperative period. The major complications of hypovolemia, aside from hemodynamic instability, include decreased oxygenation of surgical wounds (which predisposes to wound infection),<sup>42,63,88,130–132</sup> decreased collagen formation,<sup>42,103</sup> impaired wound healing, and increased wound breakdown. The major complications associated with hypervolemia include pulmonary edema, congestive heart failure, edema of gut with prolonged ileus, and possibly an increase in cardiac arrhythmias.<sup>133</sup> Inappropriately high fluid administration may result in elevated atrial natriuretic peptide, inducing endothelial glycocalyx

dysfunction, with resultant vascular permeability and extravascular fluid shifts.<sup>134</sup>

Recent studies suggest patients benefit from ingestion of high-carbohydrate, clear liquids 2 to 3 hours prior to surgery in order to achieve a euvolemic state at the start of surgery. In addition to providing hydration, there is evidence that this is a safe practice with the additional benefits of increased patient satisfaction<sup>135</sup> and decreased postoperative insulin resistance.<sup>136</sup>

Intraoperative assessment of fluid status is necessary for optimization of intravascular volume. Estimates of blood loss, third-space fluid losses, and maintenance requirements are notoriously inaccurate and may lead to either over- or underreplacement if used as guides. Surgical stress can result in increased intravenous fluid requirements. The increased fluid requirement may be partly due to substances like IL-6, TNF, substance-P, and bradykinin, which are released in response to, and in proportion to, surgical stress.<sup>137</sup> These inflammatory mediators cause both vasodilation and an increase in vascular permeability.<sup>138</sup> However, the concept of third spacing as a cause of functional intravascular fluid depletion has been challenged.<sup>139</sup>

**6** Optimizing the volume of perioperative fluid administration to minimize morbidity and mortality remains a significant and controversial challenge. Currently, most practitioners rely on clinical acumen, vital signs such as heart rate and blood pressure, and urine output to manage perioperative fluids. Surgical patients can be markedly hypovolemic without a change in any one of these variables because of the compensatory action of peripheral vasoconstriction.<sup>42,88,132</sup> Unfortunately, this shunts blood away from skin, increases wound hypoxemia, and increases the risk of surgical wound infection. Static monitors such as heart rate, blood pressure, urine output, central venous pressure,<sup>42,63,103,140</sup> and pulmonary artery catheters have been shown to be limited. More dynamic monitors such as stroke volume assessment, pulse pressure variation, and systolic pressure variation can be predictive of fluid responsiveness<sup>141</sup>; however, these have limitations, including the requirements of a regular R to R interval, closed chest, and adequate tidal volumes. Echocardiography, including assessment of stroke volume and other indices for preload, afterload, and contractility, can be a helpful intraoperative guide,<sup>142</sup> but large-scale clinical trials are needed to validate its use as a dynamic modality for monitoring. Additional limitations include lack of available hardware and expertise.

Intraoperative fluid optimization strategies have ranged from liberal, to restrictive (also known as zero-balance), to goal-directed (SV optimization). There is evidence that increased volume may be beneficial for skin perfusion. Arkilic et al.<sup>130</sup> randomized 56 patients to liberal (16 to 18 mL/kg/hr) or conservative (8 mL/kg/hr) intraoperative fluid therapy and measured tissue

perfusion and oxygen tension as a surrogate for wound healing. The liberal fluid regimen was associated with significantly greater intraoperative subcutaneous oxygen tension as measured by a tissue oxygen sensor. The study was too small to evaluate the effect on wound complications. Kabon et al.<sup>143</sup> performed a randomized, controlled trial to compare standard (8 mL/kg/hr) versus high (16 to 18 mL/kg/hr) volume administration in 253 patients undergoing elective colon resection. They found a trend toward reduced wound infections in the group that received high volume (8.5% vs. 11.3%), which would be a clinically significant reduction. Unfortunately, the study was terminated early, so it had inadequate power. Patients at high risk for heart failure or with end-stage renal disease were excluded, so the study also has limited generalizability. On the other side, there is concern that liberal fluid administration may be excessive and may be detrimental to patients. In a systematic review, Holte et al.<sup>138</sup> found benefit in avoiding excessive fluid administration in major surgery.

The discussion of “liberal” and “restricted” fluids requires consideration of whether colloids or crystalloids are preferable for intraoperative fluid administration. Synthetic colloids have been associated with coagulopathy when large volumes are delivered, which appears to be in large part mediated by dilution of coagulation factors.<sup>144</sup> Crystalloids, on the other hand, may cause a hypercoagulable state.<sup>143</sup> The intravascular half-life of colloids, either albumin or synthetic colloids, is much longer than that of crystalloids, allowing the total volume of fluid administered to be reduced by including colloids in surgical fluid resuscitation.<sup>144</sup> Edema formation may also be decreased. A number of studies<sup>133,144–147</sup> purport to evaluate intraoperative or postoperative fluid administration in terms of restrictive versus traditional fluid management. Virtually all have compared colloid (“restrictive” group) with crystalloid (“traditional” group) administration. Thus, the “restricted” volume group likely received a larger amount of effective intravascular volume than the traditional or “liberal” group. In general, these studies have demonstrated improved outcomes (reduction in SSI, earlier return of bowel function) for the colloid group. The mechanism for the benefit is unclear, however, as on the basis of effective intravascular volume delivered, the crystalloid groups might actually have been less well volume replaced than the colloid groups.

What is clear is that fluid overload to the point of interstitial edema is not beneficial for most organ function, including kidneys, liver, lungs, and heart. Interstitial edema can result in poor wound healing and infection due to decreased oxygen diffusion distance. Finding the balance between appropriate volume supplementation for adequate perfusion and avoiding tissue edema is the challenge. One of the difficulties in interpreting the literature on volume management is the lack of standardization of definitions such as “liberal” and

“restricted,” the amount and combinations of fluid used for replacement, and the lack of standardization of targets and outcomes. At this time, an individualized plan based on preoperative and intraoperative volume assessment, and appropriate monitoring, depending on the complexity of comorbidities and the surgical procedure, is required to attempt to find this balance for every patient. Goal-directed therapy, using stroke volume variation or echocardiography, holds promise, but much work remains to be done to define and implement reliable standards.

Current best recommendations include replacing fluid losses based on standard recommendations (Table 8-8) for the type of surgery, replacement of blood loss, and replacement of other ongoing fluid losses (e.g., high urine output due to diuretic or dye administration, hyperglycemia, or thermoregulatory vasoconstriction). Maintenance of normothermia is also critical to optimal volume management. Warm patients are unlikely to develop pulmonary edema with a high rate of fluid administration because they have excess capacitance due to vasodilation. Cold patients, on the other hand, are highly susceptible to pulmonary edema even after relatively small fluid boluses. Thermoregulatory vasoconstriction increases afterload, causing increased cardiac work. Moreover, administered fluid cannot open up constricted vessels until the hypothermic stimulus is removed; thus, there is virtually no excess capacitance in the system.

Pain control should be addressed intraoperatively so that patients do not have severe pain on emergence. Achieving the goal is more important than the technique used to do so. Although regional anesthesia and analgesia may provide superior pain relief, the effects of specific analgesic regimens on wound outcome have not yet adequately been studied.

**Table 8-8** Standard Volume Management Guidelines for Surgical Patients

Fluid requirement = deficit + maintenance (baseline plus replacement) + estimated blood loss and other sensible fluid losses
Deficit = maintenance (1.5 mL/kg/hr) × hours NPO
Adjust for fever, high NG output, bowel preparation, and other sources of ongoing preoperative increased fluid loss
Use goal-directed therapy as available
Replace EBL 3:1 with crystalloid, 1:1 with colloid
<b>Maintenance requirements for different surgeries:</b>
Superficial surgical trauma: 1–2 mL/kg/hr
Peripheral surgery
Minimal surgical trauma: 3–4 mL/kg/hr
Head and neck, hernia, knee surgery
Moderate surgical trauma: 5–6 mL/kg/hr
Major surgery without exposed abdominal contents
Severe surgical trauma: 8–10 mL/kg/hr
Major abdominal, especially with exposed abdominal contents

NPO, nothing by mouth; NG, nasogastric; EBL, estimated blood loss.

## Postoperative Management

Wounds are most vulnerable in the first few hours after surgery (Table 8-9). Although antibiotics lose their effectiveness after the first hours, oxygen-mediated natural wound immunity lasts longer.<sup>29</sup> Even a short period of vasoconstriction during the first day is sufficient to reduce oxygen supply and increase infection risk.<sup>63</sup> Correction and prevention of vasoconstriction in the first 24 to 48 hours after surgery will have significant beneficial effects.<sup>63</sup> Given the large number of diabetic patients who undergo surgery, along with the fact that the stress response frequently induces hyperglycemia intraoperatively even in nondiabetic patients, guidelines for controlling blood sugar in perioperative patients are critical to prevention of SSI. Unfortunately, balancing a narrow therapeutic window between hypoglycemia and hyperglycemia is a complex issue in blood sugar control. Clinical trials have provided conflicting results. A 2001 randomized controlled trial demonstrated a 25% reduction in risk of septicemia in critically ill surgical patients whose blood glucose levels were more tightly controlled than a comparison group.<sup>148</sup> On the other hand, in 2007 Gandhi et al.<sup>149</sup> found no difference in SSI in 400 cardiac surgery patients comparing a target blood sugar of 80 to 100 versus less than 200 mg/dL. The NICE-SUGAR study in 6,104 ICU patients demonstrated excess mortality in the tight control (81 to 108 mg/dL) versus standard (<180 mg/dL) group.<sup>150</sup> The current recommendation is to keep glucose close to normal (e.g., 100 to 180 or 200 mg/dL).<sup>151</sup>

**Table 8-9** Postoperative Management

Keep patient warm.  
Provide analgesia to keep patient comfortable, if not pain free. Patient report and the ability to move freely are the best signs of adequate pain relief.  
Only one more dose of antibiotic unless an infection is present or contamination continues.  
Keep up with third-space losses. Remember that fever increases fluid losses.  
Assess perfusion and react to abnormalities.  
Avoid diuresis until pain is gone and patient is warm.  
Assess losses (including thermal losses) if wound is open.  
Assess need for parenteral or enteral nutrition and respond.  
Continue to control hypertension and hyperglycemia.

From Hunt TK, Hopf HW. Wound healing and wound infection. What surgeons and anesthesiologists can do. *Surg Clin North Am.* 1997;77:587, with permission.

All vasoconstrictive stimuli must be corrected simultaneously to allow optimal healing. Volume is the last to be corrected because vasoconstriction for other reasons induces diuresis and renders the patient relatively hypovolemic (peripherally, not centrally). These measures are particularly important in any patients at high risk for wound complications for other

reasons (e.g., malnutrition, steroid use, diabetes), or when vasoconstrictive drugs such as  $\beta$ -blockers and  $\alpha$ -agonists are required for other reasons.

Local perfusion is not assured until patients have a normal blood volume, are warm and pain free, and are receiving no vasoconstrictive drugs; that is, until the sympathetic nervous system is inactivated. Warming should continue until patients are thoroughly awake and active and can maintain their own thermal balance. After major operations, warming may be useful for many hours or even days. The goal is to achieve warmth at the skin; wound vasoconstriction due to cold surroundings often coexists with core hyperthermia. Moderate hyperthermia is not, itself, a problem. When extensive wounds are left open, warmth should be continued, and heat losses due to evaporation should be prevented to avoid vasoconstriction and to minimize caloric losses.

Assessing perfusion, especially in the PACU, is critical. Unfortunately, urine output is a poor, often misleading guide to peripheral perfusion.<sup>131</sup> Markedly low output may indicate decreased renal perfusion, but normal or even high urine output has little correlation to wound or tissue PO<sub>2</sub>. Many factors commonly present in the perioperative period, including hyperglycemia, dye administration, thermoregulatory vasoconstriction, adrenal insufficiency, and various drugs, may cause inappropriate diuresis in the face of mild hypovolemia.

Physical examination of the patient is a better guide to hypovolemia and vasoconstriction. Assess vasoconstriction by a capillary return time of more than 2 to 3 seconds at the forehead and more than 5 seconds over the patella. Eye turgor is another good measure of volume status. Finally, patients can usually distinguish thirst from a dry mouth. Skin should be warm and dry.

After major abdominal surgery, third-space losses continue for about 12 to 24 hours, so that increased fluid requirements continue. In general, for large abdominal cases, 2 to 3 mL/kg/hr of IV fluids is sufficient for the first 12 to 24 postoperative hours. After that period, the IV rate should be decreased below calculated maintenance levels because edema fluid begins to be mobilized, thus increasing circulating intravascular volume.

When excessive tissue fluids have accumulated, diuresis should be undertaken gently so that transcapillary refill can maintain blood volume. This applies to patients who need renal dialysis as well. The average dialysis patient vasoconstricts sufficiently to lower tissue PO<sub>2</sub> by 30% or more during dialysis and needs about 24 hours to return vasomotor tone and wound and tissue PO<sub>2</sub> to normal.<sup>152</sup> Fluid losses from the vascular system are not necessarily replaced from the tissues as rapidly as they are sustained. Tissue edema may be the price paid for adequate intravascular volume. Edema increases intracapillary distance, so that there may be a delicate balance between excessive edema and peripheral vasoconstriction (which worsens the

hypoxia caused by edema).

Vasoconstrictive drugs should be avoided. The most common and most avoidable is nicotine in the form of cigarettes.  $\beta$ -Blockers should be used only when clearly medically indicated. Both are known to reduce wound and tissue PO<sub>2</sub>. Clonidine is an alternative drug for heart rate control<sup>153,154</sup> that also induces vasodilation and may increase wound PO<sub>2</sub>.<sup>155</sup> High-dose  $\alpha$ -adrenergic agonists or other vasopressors may cause harm by decreasing tissue PO<sub>2</sub>, but lower doses have little or no effect on wound/tissue PO<sub>2</sub>.<sup>100</sup> It is important to remember that decreasing cardiac output may also reduce wound perfusion. Thus, a balance must be maintained between minimizing use of vasopressors and maintaining adequate cardiac output.

Maintenance of tissue PO<sub>2</sub> requires attention to pulmonary function **7** postoperatively. Administration of supplemental oxygen via face mask or nasal cannulae increases safety in patients receiving systemic opioids<sup>156</sup> and one study demonstrated a reduction in SSI after lower extremity revascularization.<sup>157</sup> Pain control also appears important since it favorably influences both pulmonary function and vascular tone. This is particularly true in patients at high risk for pulmonary complications postoperatively, such as morbidly obese patients and those with pulmonary disease.<sup>158</sup> Epidural analgesia may be the route of choice in these patients. It has several advantages over parenterally administered opioids in that it generally achieves lower pain scores with less sedation. Nonetheless, opioid-induced pruritus is more common with epidural administration, and in some patients may be severe enough to counteract the benefits of pain control.

Patient-controlled analgesia is also quite effective at achieving low pain scores. It also has the benefit of giving control to the patient, leading to patient satisfaction as high as with epidural analgesia in many cases.<sup>159</sup> Nurse-administered, as-needed doses of IV or intramuscular opioids should be avoided as inadequate pain control often exceeds 50% using this approach.<sup>160</sup> The key to pain control is recognition of the need for analgesia and attention to the patient's complaints of pain. Opioid requirements vary enormously and are not always predictable, but even tolerant patients (IV drug abusers or those with cancer pain) can be given adequate pain relief with sufficient attention. Multimodal analgesia appears to be a valuable approach, reducing pain while minimizing respiratory depression.

## Summary

**8** In patients with moderate to high risk of SSI, anesthesiologists have the opportunity to enhance wound healing and reduce the incidence of wound infections by simple, inexpensive, and readily available means. Intraoperatively, appropriate antibiotic use, prevention of vasoconstriction

through volume and warming, and maintenance of a high PaO<sub>2</sub> (300 to 500 mmHg) are key. Postoperatively, the focus should remain on prevention of vasoconstriction through pain relief, warming, and adequate volume administration in the PACU. The addition of measures to reduce and prevent the stress response is likely to be effective as well, although further study is required.

### Areas for Future Research

- Does universal adherence to the “5 Moments for Hand Hygiene” improve outcomes?
- Is delay of antibiotics for culture justified?
- Psychological preparation and intervention can modulate the stress response. Will this reduce wound complications?
- Do nonsteroidal anti-inflammatory agents increase risk of wound complications?
- Does dexamethasone for postoperative nausea and vomiting prophylaxis increase the risk of wound complications?
- Do epidurals reduce the risk of SSI? Are they cost-effective (vs. time and risk)?
- How much fluid is required? Does goal-directed fluid therapy improve outcomes?
- Who should get a high FiO<sub>2</sub>? Is there potential toxicity?
- Does postoperative oxygen reduce wound complications? How long should patients receive supplemental oxygen postoperatively?

Evaluation of Patients with Allergic Reactions

Agents Implicated in Allergic Reactions

## Summary

## KEY POINTS

- 1 Anesthesiologists routinely administer multiple agents in the perioperative period including drugs (antibiotics, anesthetic agents, neuromuscular blocking agents [NMBAs]), polypeptides (i.e., protamine), and blood products, or patients are exposed to environmental antigens (i.e., latex) all of which can produce an allergic reaction.
- 2 Cytokines are inflammatory cell activators that are synthesized to act as secondary messengers and activate endothelial cells and white cells.
- 3 Antibodies are specific proteins called immunoglobulins that can recognize and bind to a specific antigens, and usually IgE or IgG is

- implicated.
- 4 Immune competence during surgery can be affected by direct and hormonal effects of anesthetic drugs, by immunologic effects of other drugs used, by the surgery, by coincident infection, and by transfused blood products.
  - 5 Most of the allergic reactions evoked by intravenous drugs occur within 5 minutes of administration. In the anesthetized patient, the most common life-threatening manifestation of an allergic reaction is circulatory collapse, reflecting vasodilation with resulting decreased venous return.
  - 6 Many diverse molecules administered during the perioperative period release histamine in a dose-dependent, nonimmunologic fashion.
  - 7 A plan for treating anaphylactic reactions must be established before the event. Airway maintenance, 100% oxygen administration, intravascular volume expansion, and epinephrine are essential to treat the hypotension and hypoxia that result from vasodilation, increased capillary permeability, and bronchospasm. Vasopressin and additional diagnostic monitoring should be considered for refractory shock.
  - 8 After an anaphylactic reaction, it is important to attempt to identify the causative agent to prevent readministration.
  - 9 Health-care workers and children with spina bifida, urogenital abnormalities, or certain food allergies have been recognized as people at increased risk for anaphylaxis to latex.
  - 10 NMBAs have several unique molecular features that make them potential antigens.

## Introduction

Allergic reactions represent an important cause of perioperative complications. Anesthesiologists routinely administer multiple drugs and blood products and manage patients during their perioperative medical care where they are exposed to multiple agents including drugs (i.e., antibiotics, anesthetic agents, neuromuscular blocking agents [NMBAs]), polypeptides (protamine), blood products, and environmental antigens (i.e., latex). Anesthesiologists must be able to rapidly recognize and treat anaphylaxis, the most life-threatening form of an allergic reaction.<sup>1</sup>

The allergic response represents just one aspect of the pathologic response that the immune system evolved to recognize foreign substances. As part of normal host surveillance mechanisms, a series of cellular and humoral elements oversees foreign surfaces of cell surfaces and molecular structures called *antigens* to provide host defense. These foreign substances (antigens) consist of molecular arrangements found on cells, bacteria, viruses, proteins,

or complex macromolecules.<sup>2,3</sup> Immunologic mechanisms (1) involve antigen interaction with antibodies or specific effector cells; (2) are reproducible; and (3) are specific and adaptive, distinguishing foreign substances and amplifying reactivity through a series of inflammatory cells and proteins. The immune system serves to protect the body against external microorganisms and toxins, as well as internal threats from neoplastic cells; however, it can respond inappropriately to cause hypersensitive (allergic) reactions. Life-threatening allergic reactions to drugs and other foreign substances observed perioperatively may represent different expressions of the immune response.<sup>2,3</sup>

## Basic Immunologic Principles

The immune system protects the body from invasion by organisms by recognizing and removing foreign substances called *antigens* that are molecular structures, usually proteins and/or carbohydrates. The body also has mechanisms to tolerate similar molecular configurations of the host (self-tolerance); however, problems arise when the immune system is dysfunctional as in cases of autoimmunity that can give rise to serious diseases including rheumatoid arthritis and lupus. The immune response includes both cell-mediated immunity and humoral immunity. Cell-mediated immunity involves immune cells directed at elimination or destruction of pathogens or cells. Humoral immunity comprises different antibodies and proteins, such as complement, that can directly or in concert with cellular immunity orchestrate cell injury and destruction. The purpose is to provide host defense mechanisms.

**2** As part of humoral immune responses, protein mediators called cytokines and chemokines are released initially by inflammatory responses to bring other immune cells to the site of the injury or infection, cause further inflammatory responses and fever, and increase capillary permeability to allow other immune cells to migrate and translocate to the site of injury. This inflammatory response also causes hemostatic activation and produces pain, erythema, and edema locally and potentially systemically depending on the extent of the injury. Cytokines have an extensive spectrum of inflammatory effects, an issue studied extensively in sepsis.<sup>4</sup> The immune response can be variable in onset from immediate in anaphylaxis to days, and can remember antigens for many years, especially following immunization.

Although this is a simplified review of the immune system, it is important to consider individual aspects of the immune response and their importance.

### Antigens

As mentioned, molecules stimulating an immune response (antibody production or lymphocyte stimulation) are called *antigens*.<sup>5,6</sup> Only a few drugs used by anesthesiologists, such as polypeptides (protamine) and other large macromolecules (dextrans), are complete antigens (Table 9-1). Most commonly used drugs are simple organic compounds of low molecular weight (around 1,000 Da). For most drugs that are small molecules, to become immunogenic they must bind two circulating proteins or tissues to result in an antigen (haptent–macromolecular complex). Small molecular weight substances such as drugs or drug metabolites that bind to host proteins or cell membranes to sensitize patients are called *haptens*. Haptens are not antigenic by themselves. Often, a reactive drug metabolite (i.e., penicilloyl derivative of penicillin) is believed to bind with macromolecules to become antigens. Certain molecular structures in bacteria or fungi are immediately recognized as foreign by multiple aspects of the immune system.

**Table 9-1** Agents Administered during Anesthesia That Act as Antigens

Haptens	Macromolecules
Penicillin and its derivatives	Aprotinin
Anesthetic drugs	Blood products
	Chymopapain
	Colloid volume expanders
	Neuromuscular blocking agents
	Protamine
	Latex

### **Thymus-derived (T-cell) and Bursa-derived (B-cell) Lymphocytes**

The thymus of the fetus differentiates immature lymphocytes into thymus-derived cells (T cells). T cells have receptors that are activated by binding with foreign antigens and secrete mediators that regulate the immune response. The subpopulations of T cells that exist in humans include helper, suppressor, cytotoxic, and killer cells.<sup>5,6</sup> The two types of regulatory T cells are helper cells (OKT4) and suppressor cells (OKT8). Helper cells are important for key effector cell responses, whereas suppressor cells inhibit immune function. Infection of helper T cells with a retrovirus, the human immunodeficiency virus, produces a specific increase in the number of suppressor cells. Cytotoxic T cells destroy mycobacteria, fungi, and viruses. Other lymphocytes, called natural killer cells, do not need specific antigen stimulation to set up their role. Both the cytotoxic T cells and natural killer cells take part in defense against tumor cells and in transplant rejection. T cells produce mediators that influence the response of other cell types involved in the recognition and destruction of foreign substances.<sup>5,6</sup>

B cells represent a specific lymphocyte cell line that can differentiate into specific plasma cells that synthesize antibodies, a step controlled by both helper and suppressor T-cell lymphocytes. B cells are also called bursa-derived cells because in birds, the bursa of Fabricius is important in producing cells responsible for antibody synthesis.

## Antibodies

Antibodies are specific proteins called *immunoglobulins* (Igs) that can recognize and bind to a specific antigen. The basic structure of the antibody molecule is illustrated in [Figure 9-1](#). Each antibody has at least two heavy chains and two light chains that are bound together by disulfide bonds. The Fab fragment has the ability to bind antigen, and the Fc, or crystallizable, fragment is responsible for the unique biologic properties of the different classes of Igs (cell binding and complement activation). Antibodies function as specific receptor molecules for immune cells and proteins. When antigen binds covalently to the Fab fragments, the antibody undergoes conformational changes to activate the Fc receptor. The results of antigen–antibody binding depend on the cell type, which causes a specific type of activation (i.e., lymphocyte proliferation and differentiation into antibody-secreting cells, mast cell degranulation, and complement activation). Multiple therapeutic agents are based on Fab fragments that bind irreversibly to a specific molecular configuration or drug and include such agents as abciximab (a platelet inhibitor that binds the IIb/IIIa receptor) and idarucizumab (that binds to dabigatran to reverse its anticoagulant effect).

**Figure 9-1** Basic structural configuration of the antibody molecule representing human immunoglobulin G (IgG). Immunoglobulins are composed of two heavy chains and two light chains bound by disulfide linkages (represented by *crossbars*). Papain cleaves the molecule into two Fab fragments and one Fc fragment. Antigen binding occurs on the Fab fragments, whereas the Fc segment is responsible for membrane binding or

complement activation. (Reprinted with permission from: Levy JH. *Anaphylactic Reactions in Anesthesia and Intensive Care*. 2nd ed. Boston, MA: Butterworth-Heinemann; 1992.)

**Table 9-2** Biologic Characteristics of Immunoglobulins

	IgG	IgM	IgA	IgE	IgD

Modified with permission from: Levy JH. *Anaphylactic Reactions in Anesthesia and Intensive Care*. 2nd ed. Boston, MA: Butterworth-Heinemann; 1992.

Five major classes of antibodies occur in humans: IgG, IgA, IgM, IgD, and IgE. The heavy chain determines the structure and function of each molecule. The basic properties of each antibody are listed in [Table 9-2](#).

## Effector Cells and Proteins of the Immune Response

### Cells

Monocytes, neutrophils (polymorphonuclear leukocytes [PMNs]), and eosinophils represent important effector cells that migrate into areas of inflammation in response to specific chemotactic factors, including lymphokines, cytokines, and complement-derived mediators. The deposition of antibody or complement fragments on the surface of foreign cells is called *opsonization*, a process that promotes killing foreign cells by effector cells. In addition, lymphokines and cytokines produce chemotaxis of other inflammatory cells in a manner described in the following sections.<sup>5,6</sup> Activation of this cellular process is orchestrated by multiple mechanisms, as best recently reviewed.<sup>7</sup>

### Monocytes and Macrophages

Macrophages regulate immune responses by processing and presenting antigens to effect inflammatory, tumoricidal, and microbicidal functions. Macrophages arise from circulating monocytes or may be confined to specific organs such as the lung. They are recruited and activated in response to microorganisms or tissue injury. Macrophages ingest antigens before they

interact with receptors on the lymphocyte surface to regulate their action. Macrophages synthesize mediators to facilitate both B-lymphocyte and T-lymphocyte responses.

### *Polymorphonuclear Leukocytes (Neutrophils)*

The first cells to appear in acute inflammatory reaction are neutrophils that contain acid hydrolases, neutral proteases, and lysosomes. Once activated, they produce hydroxyl radicals, superoxide, and hydrogen peroxide, which aid in microbial killing.

### *Eosinophils*

The exact function of the eosinophil in host defense is unclear; however, inflammatory cells recruit eosinophils to collect at sites of parasitic infections, tumors, and allergic reactions.

### *Basophils*

Basophils comprise 0.5% to 1% of circulating granulocytes in the blood. On the surface of basophils are IgE receptors, which function similarly to those on mast cells.

### *Mast Cells*

Mast cells are important cells for immediate hypersensitivity responses. They are tissue fixed and located in the perivascular spaces of the skin, lung, and intestine. On the surface of mast cells are IgE receptors, which bind to specific antigens. Once activated, these cells release physiologically active mediators important to immediate hypersensitivity responses (see IgE-mediated Pathophysiology section under Anaphylactic Reactions). Mast cells can be activated by a series of both immune and nonimmune stimuli.

## **Proteins**

### *Cytokines/Interleukins*

Cytokines are inflammatory cell activators that are synthesized by macrophages to act as secondary messengers and activate endothelial cells and white cells.<sup>8</sup> Interleukin-1 and tumor necrosis factor are examples of cytokines considered to be important mediators of the biologic responses to infection and other inflammatory reactions. Liberation of interleukin-1 and tumor necrosis factor produces fever, neuropeptide release, endothelial cell activation, increased adhesion molecule expression, neutrophil priming, hypotension, myocardial suppression, and a catabolic state.<sup>8</sup> The term *interleukin* was coined for a group of cytokines that promotes communication

between and among (“inter”) leukocytes (“leukin”). Interleukins are a group of different regulatory proteins that act to control many aspects of the immune and inflammatory responses. The interleukins are polypeptides synthesized in response to cellular activation; they produce their inflammatory effects by activating specific receptors on inflammatory cells and vasculature. T-cell lymphocytes influence the activity of other immunologic and nonimmunologic cells by producing an array of interleukins that they secrete. Different interleukins of this class have been isolated and characterized; they function as short-range or intracellular soluble mediators of the immune and inflammatory responses. The interleukin family of cytokines has been rapidly growing in number because of advances in gene cloning.

### *Complement*

The primary humoral response to antigen and antibody binding is activation of the complement system.<sup>9,10</sup> The complement system consists of around 20 different proteins that bind to activated antibodies, other complement proteins, and cell membranes. The complement system is an important effector system of inflammation. Complement activation can be initiated by IgG or IgM binding to antigen, by plasmin through the classic pathway, by endotoxin, or by drugs through the alternate (properdin) pathway (Fig. 9-2). Specific fragments released during complement activation include C3a, C4a, and C5a, which have important humoral and chemotactic properties (see Non-IgE-mediated Reactions section). The major function of the complement system is to recognize bacteria both directly and indirectly by attracting phagocytes (chemotaxis), as well as the increased adhesion of phagocytes to antigens (opsonization), and cell lysis by activation of the complete cascade.<sup>9,10</sup>

A series of inhibitors regulates activation to ensure regulation of the complement system. Hereditary (autosomal dominant) or acquired (associated with lymphoma, lymphosarcoma, chronic lymphatic leukemia, and macroglobulinemia) angioedema is an example of a deficiency in an inhibitor of the C1 complement system (C1 esterase deficiency). This syndrome is characterized by recurrent increased vascular permeability of specific subcutaneous and serosal tissues (angioedema), which produces laryngeal obstruction and respiratory and cardiovascular abnormalities after tissue trauma and surgery, or even without any obvious precipitating factor.<sup>11</sup> One of the important pathologic manifestations of complement activation is acute pulmonary vasoconstriction associated with protamine administration.<sup>1</sup>

**Figure 9-2** Diagram of complement activation. Complement system can be activated by either the classic pathway (IgG, IgM–antigen interaction) or the alternate pathway (endotoxin, drug interaction). Small peptide fragments of C3 and C5 called anaphylatoxins (C3a, C5a) that are released during activation are potent vasoactive mediators. Formation of the complete complement cascade produces a membrane attack unit that lyses cell walls and membranes. An inhibitor of the complement cascade, the C1 esterase inhibitor, ensures the complement system is turned off most of the time.

### Effects of Anesthesia on Immune Function

Anesthesia and surgery depress nonspecific host resistance mechanisms, including lymphocyte activation and phagocytosis.<sup>12</sup> Immune competence during surgery can be affected by direct and hormonal effects of anesthetic drugs, by immunologic effects of other drugs used, by the surgery, by coincident infections, and by transfused blood products. Blood represents a complex of humoral and cellular elements that may alter immunomodulation to various antigens. Although multiple studies demonstrate in vitro changes of immune function, no studies have ever proved their importance.<sup>12</sup> Besides, such changes are likely of minor importance compared with the hormonal aspects of stress responses.

### Hypersensitivity Responses (Allergy)

Gell and Coombs first described a scheme for classifying immune responses to understand specific diseases mediated by immunologic processes. The immune pathway functions as a protective mechanism, but can also react inappropriately to produce a hypersensitivity or allergic response. They defined four basic types of hypersensitivity, types I to IV. It is useful first to review all four mechanisms to understand the different immune reactions that occur in humans.

#### Type I Reactions

Type I reactions are anaphylactic or immediate-type hypersensitivity reactions (Fig. 9-3). Physiologically active mediators are released from mast cells and

basophils after antigen binding to IgE antibodies on the membranes of these cells. Type I hypersensitivity reactions include anaphylaxis, extrinsic asthma, and allergic rhinitis.

## Type II Reactions

Type II reactions are also known as antibody-dependent cell-mediated cytotoxic hypersensitivity or cytotoxic reactions (antibody-dependent cell-mediated cytotoxic) (Fig. 9-4). These reactions are mediated by either IgG or IgM antibodies directed against antigens on the surface of foreign cells. These antigens may be either integral cell membrane components (A or B blood group antigens in ABO incompatibility reactions) or haptens that absorb to the surface of a cell, stimulating the production of anti-hapten antibodies (autoimmune hemolytic anemia). The cell damage in type II reactions is produced by (1) direct cell lysis after complete complement cascade activation, (2) increased phagocytosis by macrophages, or (3) killer T-cell lymphocytes producing antibody-dependent cell-mediated cytotoxic effects. Examples of type II reactions in humans are ABO-incompatible transfusion reactions, drug-induced immune hemolytic anemia, and heparin-induced thrombocytopenia.

**Figure 9-3** Type I immediate hypersensitivity reactions (anaphylaxis) involve IgE antibodies binding to mast cells or basophils by way of their Fc receptors. On encountering immunospecific antigens, the IgE becomes cross-linked, inducing degranulation, intracellular activation, and release of mediators. This reaction is independent of complement.

**Figure 9-4** Type II or cytotoxic reactions. Antibody of an IgG or IgM class is directed against antigens on an individual's own cells (target cells). The antigens may be integral membrane components or foreign molecules that have been absorbed. This may lead to complement activation, including cell lysis (*upper figure*) or cytotoxic action by killer T-cell lymphocytes (*lower figure*).

### **Type III Reactions (Immune Complex Reactions)**

Type III reactions result from circulating soluble antigens and antibodies that bind to form insoluble complexes that deposit in the microvasculature (Fig. 9-5). Complement is activated, and neutrophils are localized to the site of complement deposition to produce tissue damage. Type III reactions include classic serum sickness observed after snake antisera or antithymocyte globulin, and immune complex vascular injury, and may occur through mechanisms of protamine-mediated pulmonary vasoconstriction.<sup>1</sup>

### **Type IV Reactions (Delayed Hypersensitivity Reactions)**

Type IV reactions result from the interactions of sensitized lymphocytes with specific antigens (Fig. 9-6). Delayed hypersensitivity reactions are mainly mononuclear, manifest in 18 to 24 hours, peak at 40 to 80 hours, and disappear in 72 to 96 hours. Antigen-lymphocyte binding produces lymphokine synthesis, lymphocyte proliferation, and generation of cytotoxic T cells, attracting macrophages and other inflammatory cells. Cytotoxic T cells are produced specifically to kill target cells that bear antigens identical with those that triggered the reaction. This form of immunity is important in tissue rejection, graft-versus-host reactions, contact dermatitis (e.g., poison ivy), and tuberculin immunity.

**Figure 9-5** Type III immune complex reactions. Antibodies of an IgG or IgM type bind to the antigen in the soluble base and are subsequently deposited in the microvasculature. Complement is activated, resulting in chemotaxis and activation of polymorphonuclear leukocytes at the site of antigen–antibody complexes and subsequent tissue injury.

### Intraoperative Allergic Reactions

Understanding perioperative anaphylaxis is important because of the potential for morbidity and mortality.<sup>13</sup> However, most estimates of the incidence are based on retrospective data, which may account for variability in the incidence. The risk of perioperative anaphylaxis is reported as between 1:3,500 and 1:20,000, with a mortality rate of 4% and an additional 2% surviving with severe brain damage.<sup>13,14</sup> More than 90% of the allergic reactions evoked by intravenous drugs occur within 5 minutes of administration. In the anesthetized patient, the most common life-threatening manifestation of an allergic reaction is circulatory collapse, reflecting vasodilation with resulting decreased venous return (Table 9-3). The only manifestation of an allergic reaction may be refractory hypotension. Portier and Richet first used the word *anaphylaxis* (from *ana*, “against,” and *prophylaxis*, “protection”) to describe the profound shock and resulting death that sometimes occurred in dogs immediately after a second challenge with a foreign antigen.<sup>15</sup> When life-threatening allergic reactions mediated by antibodies occur, they are defined as anaphylactic. Although the term *anaphylactoid* has been used in the past to describe nonimmunologic reactions, this term is now rarely used.

5

**Figure 9-6** Type IV immune complex reactions (delayed hypersensitivity or cell-mediated immunity). Antigen binds to sensitized T-cell lymphocytes to release lymphokines after a second contact with the same antigen. This reaction is independent of circulating antibody or complement activation. Lymphokines induce inflammatory reactions and activate, as well as attract, macrophages and other mononuclear cells to produce delayed tissue injury.

**Table 9-3** Recognition of Anaphylaxis during Regional and General Anesthesia

Systems	Symptoms	Signs
Respiratory	Dyspnea Chest discomfort	Coughing Wheezing Sneezing Laryngeal edema Decreased pulmonary compliance Fulminant pulmonary edema Acute respiratory failure
Cardiovascular	Dizziness Malaise Retrosternal oppression	Disorientation Diaphoresis Loss of consciousness Hypotension Tachycardia Dysrhythmias Decreased systemic vascular resistance Cardiac arrest Pulmonary hypertension
Cutaneous	Itching Burning Tingling	Urticaria (hives) Flushing Periorbital edema Perioral edema

## Anaphylactic Reactions

### IgE-mediated Pathophysiology

Antigen binding to IgE antibodies initiates anaphylaxis (Fig. 9-7). Prior exposure to the antigen or to a substance of similar structure is needed to produce sensitization, although an allergic history may be unknown to the patient. On reexposure, binding of the antigen to bridge two immunospecific IgE antibodies found on the surfaces of mast cells and basophils releases

stored mediators, including histamine, tryptase, and chemotactic factors.<sup>13,16,17</sup> Arachidonic acid metabolites (leukotrienes and prostaglandins), kinins, and cytokines are subsequently synthesized and released in response to cellular activation.<sup>18</sup> The released mediators produce a symptom complex of bronchospasm and upper airway edema in the respiratory system, vasodilation and increased capillary permeability in the cardiovascular system, and urticaria in the cutaneous system. Different mediators are released from mast cells and basophils after activation.

### **Chemical Mediators of Anaphylaxis**

Histamine stimulates H<sub>1</sub>, H<sub>2</sub>, and H<sub>3</sub> receptors. H<sub>1</sub> receptor activation releases endothelium-derived relaxing factor (nitric oxide) from vascular endothelium, increases capillary permeability, and contracts airway and vascular smooth muscle.<sup>16,19</sup> H<sub>2</sub> receptor activation causes gastric secretion, inhibits mast cell activation, and contributes to vasodilation. When injected into skin, histamine produces the classic wheal (increased capillary permeability producing tissue edema) and flare (cutaneous vasodilation) response in humans.<sup>20,21</sup> Histamine undergoes rapid metabolism in humans by the enzymes histamine *N*-methyltransferase and diamine oxidase found in endothelial cells.

### **Peptide Mediators of Anaphylaxis**

Factors are released from mast cells and basophils that cause granulocyte migration (chemotaxis) and collection at the site of the inflammatory stimulus.<sup>17,18</sup> Eosinophilic chemotactic factor of anaphylaxis (ECF-A) is a small molecular weight peptide chemotactic for eosinophils.<sup>22</sup> Although the exact role of ECF-A or the eosinophil in acute allergic response is unclear, eosinophils release enzymes that can inactivate histamine and leukotrienes.<sup>18</sup> In addition, a neutrophilic chemotactic factor is released that causes chemotaxis and activation.<sup>18,23</sup> Neutrophil activation may be responsible for recurrent manifestations of anaphylaxis.

**Figure 9-7** During anaphylaxis (type I immediate hypersensitivity reaction), (1) antigen enters a patient during anesthesia through a parenteral route. (2) It bridges two IgE antibodies on the surface of mast cells or basophils. In a calcium-dependent and energy-dependent process, cells release various substances—histamine, eosinophilic chemotactic factor of anaphylaxis, leukotrienes, prostaglandins, and kinins. (3) These released mediators produce the characteristic effects in the pulmonary, cardiovascular, and cutaneous systems. The most severe and life-threatening effects of the vasoactive mediators occur in the respiratory and cardiovascular systems. (Reprinted with permission from: Levy JH. *Identification and Treatment of Anaphylaxis: Mechanisms of Action and Strategies for Treatment Under General Anesthesia*. Chicago, IL: Smith Laboratories; 1983.)

### Arachidonic Acid Metabolites

Leukotrienes and prostaglandins are both synthesized after mast cell activation from arachidonic acid metabolism of phospholipid cell membranes through either lipoxygenase or cyclooxygenase pathways.<sup>22</sup> The classic slow-reacting substance of anaphylaxis is a combination of leukotrienes C<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub>. Leukotrienes produce bronchoconstriction (more intense than that produced by histamine), increased capillary permeability, vasodilation, coronary vasoconstriction, and myocardial depression.<sup>24</sup> Prostaglandins are potent mast cell mediators that produce vasodilation, bronchospasm, pulmonary hypertension, and increased capillary permeability. Prostaglandin D<sub>2</sub>, the major metabolite of mast cells, produces bronchospasm and vasodilation. Elevated plasma levels of thromboxane B<sub>2</sub> (the metabolite of thromboxane A<sub>2</sub>), also a prostaglandin synthesized by mast cells as well as by PMNs, have been demonstrated after protamine reactions associated with pulmonary hypertension.

### Kinins

Small peptides called *kinins* are synthesized in mast cells and basophils to produce vasodilation, increased capillary permeability, and bronchoconstriction. Kinins can stimulate vascular endothelium to release vasoactive factors, including prostacyclin, and endothelial-derived relaxing factors such as nitric oxide.

### Platelet-Activating Factor

Platelet-activating factor (PAF), an unstored lipid synthesized in activated human mast cells, is a potent biologic material. PAF aggregates and activates human platelets, and perhaps leukocytes, to release inflammatory products. PAF levels were significantly higher in patients with anaphylaxis than controls and were correlated with the severity of anaphylaxis.<sup>23</sup>

### Recognition of Anaphylaxis

The onset and severity of the reaction relate to the mediator’s specific end-organ effects. Antigenic challenge in a sensitized individual usually produces immediate clinical manifestations of anaphylaxis, but the onset may be delayed 2 to 20 minutes.<sup>24-27</sup> The reaction may include some or all of the symptoms and signs listed in [Table 9-3](#). Individuals vary in their manifestations and course of anaphylaxis. A spectrum of reactions exists, ranging from minor clinical changes to the full-blown syndrome leading to death.<sup>24,28</sup> The enigma of anaphylaxis lies in the unpredictability of happening, the severity of the attack, and the lack of a prior allergic history.

### Non-IgE-mediated Reactions

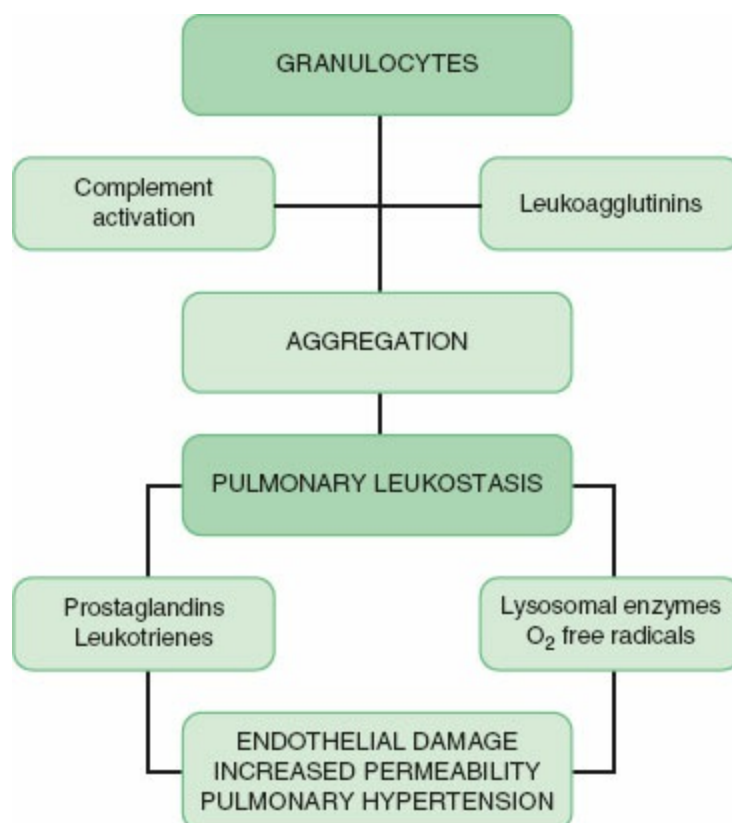

Other immunologic and nonimmunologic mechanisms release many of the mediators previously discussed independent of IgE, creating a clinical syndrome identical with anaphylaxis. Specific pathways important in producing the same clinical manifestations are considered later.

**Table 9-4** Biologic Effects of Anaphylatoxins

Biologic Effects	C3a	C5a
Histamine release	+	+
Smooth muscle contraction	+	+
Increased vascular permeability	+	+
Chemotaxis		+
Leukocyte and platelet aggregation		+
Interleukin release	+	+

## Complement Activation

Complement activation follows both immunologic (antibody mediated; i.e., classic pathway) or nonimmunologic (alternative) pathways to include a series of multimolecular, self-assembling proteins that release biologically active complement fragments of C3 and C5.<sup>9,10</sup> C3a and C5a are called *anaphylatoxins* because they release histamine from mast cells and basophils, contract smooth muscle, increase capillary permeability, and cause interleukin synthesis (Table 9-4). C5a interacts with specific high-affinity receptors on PMNs and platelets, causing leukocyte chemotaxis, aggregation, and activation.<sup>9,10</sup> Aggregated leukocytes embolize to various organs, producing microvascular occlusion and liberation of inflammatory products such as arachidonic acid metabolites, oxygen free radicals, and lysosomal enzymes (Fig. 9-8). Antibodies of the IgG class directed against antigenic determinants or granulocyte surfaces can also produce leukocyte aggregation.<sup>29</sup> These antibodies are called *leukoagglutinins*. Investigators have associated complement activation and PMN aggregation in producing the clinical expression of transfusion reactions, pulmonary vasoconstriction after protamine reactions, adult respiratory distress syndrome, and septic shock.<sup>1</sup>

**Figure 9-8** Sequence of events producing granulocyte aggregation, pulmonary leukostasis, and cardiopulmonary dysfunction. (Reprinted with permission from: Levy JH. *Anaphylactic Reactions in Anesthesia and Intensive Care*. 2nd ed. Boston, MA: Butterworth-Heinemann; 1992.)

Angioedema can also occur from allergic reactions but also from complement deficiency states.<sup>11</sup> Hereditary angioedema (HAE) is an example of the complement deficiency state that can present with life-threatening episodes of airway edema and gastrointestinal edema/diarrhea requiring emergency or urgent interventions. Several variants of HAE exist that occur due to unopposed activation of multiple kinins and mediators including kallikrein and bradykinin causing increased vascular permeability and edema.<sup>11</sup> Older treatment was anabolic steroids and antifibrinolytics. C1 esterase inhibitor (C1-INH) concentrates are licensed in the United States for use in HAE patients, one for prophylaxis (Cinryze, ViroPharma, administered every 3 or 4 days for routine prophylaxis against angioedema attacks in HAE patients) and the other for treating acute abdominal and facial HAE attacks (Berinert P, CSL Behring).<sup>11</sup> The first kinin pathway modulator, ecallantide (Kalbitor, Dyax), is also licensed in the United States for treating HAE attacks.<sup>11</sup>

**Table 9-5** Drugs Capable of Nonimmunologic Histamine Release

Antibiotics (vancomycin, pentamidine)
Basic compounds
Hyperosmotic agents
Muscle relaxants ( <i>d</i> -tubocurarine, metocurine, atracurium, mivacurium, doxacurium)
Opioids (morphine, meperidine, codeine)
Thiobarbiturates

## Nonimmunologic Release of Histamine

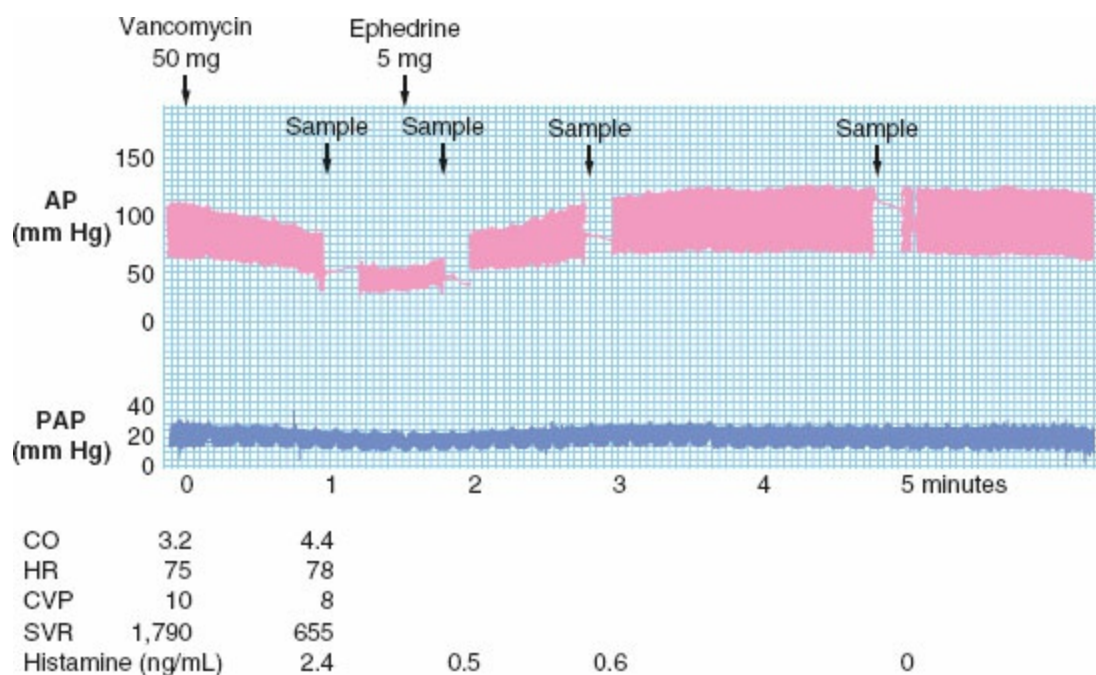

**6** Many diverse molecules administered during the perioperative period release histamine in a dose-dependent, nonimmunologic fashion (Table 9-5 and Fig. 9-9).<sup>1</sup> The mechanisms involved in nonimmunologic histamine release are not well understood, but represent selective mast cell and not basophil activation (Fig. 9-10).<sup>30,31</sup> Human cutaneous mast cells are the only cell population that releases histamine in response to both drugs and endogenous stimuli (neuropeptides). Nonimmunologic histamine release may involve mast cell activation through specific cell-signaling activation (Fig. 9-11). Different molecular structures release histamine in humans, which suggests that different mechanisms are involved. Histamine release is not dependent on the  $\mu$ -receptor because fentanyl and sufentanil, the most potent  $\mu$ -receptor agonists clinically available, do not release histamine in human skin.<sup>32</sup> Although the newer muscle relaxants may be more potent at the neuromuscular junction, drugs that are mast cell degranulators are equally capable of releasing histamine.<sup>33</sup> On an equimolar basis, atracurium is as

potent as *d*-tubocurarine or metocurine in its ability to degranulate mast cells.<sup>33</sup> Newer aminosteroidal agents such as rocuronium and rapacuronium at clinically recommended doses have minimal effects on histamine release.<sup>34,35</sup>

Antihistamine pretreatment before administration of drugs that are known to release histamine in humans does not inhibit histamine release; rather, the antihistamines compete with histamine at the receptor and may attenuate decreases in systemic vascular resistance.<sup>1</sup> However, the effect of any drug on systemic vascular resistance may depend on other factors in addition to histamine release.

### Treatment Plan

A plan for treating anaphylactic reactions must be established before the event. Airway maintenance, 100% oxygen administration, intravascular volume expansion, and epinephrine are essential to treat the hypotension and hypoxemia that result from vasodilation, increased capillary permeability, and bronchospasm.<sup>1</sup> **7** Table 9-6 lists a protocol for managing anaphylaxis during general anesthesia, with representative doses for a 70-kg adult. Therapy must be titrated to cardiopulmonary stability with monitoring.<sup>1</sup> Severe reactions need aggressive therapy and may be protracted, with persistent hypotension, pulmonary hypertension, lower respiratory obstruction, or laryngeal obstruction that may persist 5 to 32 hours despite vigorous therapy. All patients who have experienced an anaphylactic reaction should be admitted to an intensive care unit for 24 hours of monitoring because manifestations may recur after successful treatment.

**Figure 9-9** Example of an anaphylactic reaction after rapid vancomycin administration in a patient. Hypotension is associated with an increased cardiac output and decreased

calculated systemic vascular resistance. Plasma histamine levels 1 minute after vancomycin administration were 2.4 ng/mL and subsequently decreased to zero. The patient was given ephedrine 5 mg, and blood pressure returned to baseline values. AP, arterial pressure; PAP, pulmonary artery pressure; CO, cardiac output; HR, heart rate; CVP, central venous pressure; SVR, systemic vascular resistance. **Figure 9-10** Electron micrograph of human cutaneous mast cell after injection of dynorphin, a  $\kappa$ -opioid agonist. The cell outline is rounded and most of the cytoplasmic granules are swollen, exhibiting varying degrees of decreased electron density and flocculence consistent with ongoing degranulation. The perigranular membranes of the adjacent granules at the periphery of the cell are fused to each other and to the plasma membrane. Original magnification  $\times 72,000$ . (Reprinted with permission from: Casale TB, Bowman S, Kaliner M. Induction of human cutaneous mast cell degranulation by opiates and endogenous opioid peptides: Evidence for opiate and nonopiate receptor participation. *J Allergy Clin Immunol*. 1984;73:778.)

**Figure 9-11** Different mechanisms of mediator release from human cutaneous mast cells stimulated immunologically by anti-IgE and by nonimmunologic stimuli with substance P. Anti-IgE stimulation, like antigen stimulation, initiates the release of histamine, prostaglandin D<sub>2</sub> (PGD<sub>2</sub>), or leukotriene C<sub>4</sub> (LTC<sub>4</sub>) by a mechanism that takes 5 minutes to reach completion and requires the influx of intracellular calcium. Nonimmunologic activation with drugs or substance P releases histamine but not PGD<sub>2</sub> or LTC<sub>4</sub> by a mechanism that is complete within 15 seconds and uses calcium mobilized from intracellular sources. (Adapted from: Caulfield JP, El-Lati S, Thomas G, et al. Dissociated human foreskin mast cells degranulate in response to anti-IgE and substance P. *Lab Invest.* 1990;63:502.)

## Initial Therapy

Although it may not be possible to stop the administration of antigen, limiting antigen administration may prevent further mast cell and basophil activation.

### *Maintain Airway and Administer 100% Oxygen*

Profound ventilation–perfusion abnormalities producing hypoxemia can occur with anaphylactic reactions. Always administer 100% oxygen with ventilatory support as needed. Arterial blood gas values may be useful to follow during

resuscitation.

### *Discontinue All Anesthetic Drugs*

Inhalational anesthetic drugs are not the bronchodilators of choice in treating bronchospasm after anaphylaxis, especially during hypotension. These drugs interfere with the body's compensatory response to cardiovascular collapse, and halothane sensitizes the myocardium to epinephrine.

### *Provide Volume Expansion*

Hypovolemia rapidly follows during anaphylactic shock with up to 40% loss of intravascular fluid into the interstitial space during reactions. Therefore, volume expansion is important with epinephrine in correcting the acute hypotension. Initially, 2 to 4 L of lactated Ringer's solution, or colloid or normal saline, should be administered, keeping in mind that an additional 25 to 50 mL/kg may be necessary if hypotension persists. Refractory hypotension after volume and epinephrine administration requires additional hemodynamic monitoring. The use of transesophageal echocardiography for rapid assessment of intraventricular volume and ventricular function, and to determine other occult causes of acute cardiovascular dysfunction, can be important for accurate assessment of intravascular volume and guidance of rational therapeutic interventions.<sup>1</sup> Fulminant noncardiogenic pulmonary edema with loss of intravascular volume can occur after anaphylaxis. This condition requires intravascular volume repletion with careful hemodynamic monitoring until the capillary defect improves. Colloid volume expansion has not proved to be more effective than crystalloid volume expansion for treating anaphylactic shock.

### *Administer Epinephrine*

Epinephrine is the drug of choice when resuscitating patients during anaphylactic shock.  $\alpha$ -Adrenergic effects vasoconstrict to reverse hypotension;  $\beta_2$ -receptor stimulation bronchodilates and inhibits mediator release by increasing cyclic adenosine monophosphate (cAMP) in mast cells and basophils. The route of epinephrine administration and the dose depend on the patient's condition. Rapid and timely intervention is important when treating anaphylaxis. Furthermore, patients under general anesthesia may have altered sympathoadrenergic responses to acute anaphylactic shock, whereas the patient under spinal or epidural anesthesia may be partially sympathectomized and may need even larger doses of catecholamines.

In hypotensive patients, 5 to 10  $\mu$ g boluses of epinephrine should be administered intravenously and incrementally titrated to restore blood pressure. (This dose of epinephrine can be obtained with 0.05 to 0.1 mL of a

1:10,000 dilution [100 µg/mL] or by mixing 2 mg epinephrine with 250 mL of fluid to yield an 8 µg/mL solution.) Additional volume and incrementally increased doses of epinephrine should be administered until hypotension is corrected. Although infusion is an ideal method of administering epinephrine, it is usually impossible to infuse the drug through peripheral intravenous access lines during acute volume resuscitation. With cardiovascular collapse, full intravenous cardiopulmonary resuscitative doses of epinephrine, 0.1 to 1.0 mg, should be administered and repeated until hemodynamic stability resumes. Patients with laryngeal edema without hypotension should receive subcutaneous epinephrine. Epinephrine should not be administered IV to patients with normal blood pressures.

## Secondary Treatment

### *Antihistamines*

Because H<sub>1</sub> receptors mediate many of the adverse effects of histamine, the intravenous administration of 0.5 to 1 mg/kg of an H<sub>1</sub> antagonist such as diphenhydramine may be useful in treating acute anaphylaxis. Antihistamines do not inhibit anaphylactic reactions or histamine release, but compete with histamine at receptor sites. H<sub>1</sub> antagonists are indicated in all forms of anaphylaxis. The H<sub>1</sub> antagonists available for parenteral administration may have antidopaminergic effects and should be given slowly to prevent precipitous hypotension in potentially hypovolemic patients.<sup>1</sup> The indications for administering an H<sub>2</sub> antagonist once anaphylaxis has occurred remain unclear.

### *Catecholamines*

Epinephrine infusions may be useful in patients with persistent hypotension or bronchospasm after initial resuscitation.<sup>1</sup> Epinephrine infusions should be started at 0.05 to 0.1 µg/kg/min (5 to 10 µg/min) and titrated to correct hypotension. Norepinephrine infusions may be needed in patients with refractory hypotension due to decreased systemic vascular resistance. It may be started at 0.05 to 0.1 µg/kg/min (5 to 10 µg/min) and adjusted to correct hypotension.<sup>1</sup>

### *Bronchodilators*

Inhaled β-adrenergic agents include inhaled albuterol or terbutaline if bronchospasm is a major feature.<sup>36</sup> Inhaled ipratropium may be especially useful for treatment of bronchospasm in patients receiving β-adrenergic blockers.<sup>36</sup> Special adaptors allow administration of bronchodilators through the endotracheal tube.

## *Corticosteroids*

Corticosteroids have anti-inflammatory effects that are mediated by multiple mechanisms, including altering the activation and migration of other inflammatory cells (i.e., PMNs) after an acute reaction. Consider infusing high-dose corticosteroids early in the course of therapy although beneficial effects are delayed at least 4 to 6 hours.<sup>36</sup> Despite their unproven usefulness in treating acute reactions, they are often administered as adjuncts to therapy when refractory bronchospasm or refractory shock occurs after resuscitative therapy. Although the exact corticosteroid dose and preparation are unclear, investigators have recommended 0.25 to 1 g intravenously of hydrocortisone in IgE-mediated reactions. Alternatively, 1 to 2 g of methylprednisolone (30 to 35 mg/kg) intravenously may be useful in reactions believed to be complement mediated, such as catastrophic pulmonary vasoconstriction after protamine transfusion reactions. Administering corticosteroids after an anaphylactic reaction may also be important in attenuating the late-phase reactions reported to occur 12 to 24 hours after anaphylaxis.

## *Bicarbonate*

Acidosis develops rapidly in patients with persistent hypotension. This acidosis reduces the effect of epinephrine on the heart and systemic vasculature. Therefore, with refractory hypotension or acidemia, sodium bicarbonate, 0.5 to 1 mEq/kg, may be given and repeated every 5 minutes or as dictated by arterial blood gas values.

## *Airway Evaluation*

Because profound laryngeal edema can occur, the airway should be evaluated before extubation of the trachea. Persistent facial edema suggests airway edema. The tracheas of these patients should remain intubated until the edema subsides. Developing a significant air leak after endotracheal tube cuff deflation and before extubation of the trachea is useful in assessing airway patency. If there is any question of airway edema, direct laryngoscopy should be performed before the trachea is extubated.

## *Refractory Hypotension*

Vasopressin is an important drug for refractory shock, including vasodilatory shock associated with anaphylaxis. Vasodilatory shock is characterized by hypotension association with a high cardiac output and is thought to be due to the multiple activation of vasodilator mechanisms and the inability of  $\alpha$ -adrenergic mechanisms to compensate. Starting doses to consider are 0.01 units/min as an infusion, although bolus administration is part of Advanced Cardiopulmonary Life Support (ACLS) guidelines.<sup>36</sup> Vasopressin may

attenuate pathologic-induced vasodilation. Further, additional monitoring, including echocardiography should be considered in patients with refractory hypotension to better evaluate cardiac function or hypovolemia.

## Perioperative Management of the Patient with Allergies

Allergic drug reactions account for 6% to 10% of all adverse reactions, and the risk of an allergic drug reaction occurring is approximately 1% to 3% for most drugs, and around 5% of adults in the United States may be allergic to one or more drugs.<sup>37-39</sup> Unfortunately, patients often refer to adverse drug effects as being allergic in nature. For example, opioid administration can produce nausea, vomiting, or even local release of histamine along the vein of administration. Patients will say they are “allergic” to a specific drug when in fact their adverse reaction is independent of allergy. Nearly 15% of adults in the United States believe they are allergic to specific medication(s) and therefore may be denied treatment with an indicated drug. To understand allergic reactions, the spectrum of adverse reactions to drugs needs to be considered.

Predictable adverse drug reactions account for about 80% of adverse drug effects. They are often dose dependent, related to known pharmacologic actions of the drug, and typically occur in normal patients. Most serious, predictable adverse drug reactions are toxic and are directly related to the drug in the body (overdosage) or to an unintentional route of administration (e.g., lidocaine-induced seizures or cardiovascular collapse). Side effects are the most common adverse drug reactions and are undesirable pharmacologic actions of the drugs occurring at usual prescribed dosages. Most anesthetic drugs present multiple side effects that can produce precipitous hypotension. For example, morphine dilates the venous capacitance bed, thereby decreasing preload; releases histamine from cutaneous mast cells, thereby producing arterial and venous dilation; slows the heart rate; and decreases sympathetic tone. However, the net effects of morphine on blood pressure and myocardial function depend on the patient’s blood volume, sympathetic tone, and ventricular function. Hypotension rapidly develops in a volume-depleted trauma patient in pain who is given morphine. Drug interactions also represent important predictable adverse drug reactions. Intravenous fentanyl administration to a patient who has just received intravenous benzodiazepines or other sedative-hypnotic drugs may produce precipitous hypotension that results from decreased sympathetic tone or direct vasodilation from propofol administration.<sup>40</sup> This represents a dose-dependent, predictable adverse drug reaction that is independent of allergy.

Unpredictable adverse drug reactions are usually dose independent and usually not related to the drug’s pharmacologic actions, but are often related

to the immunologic response (allergy) of the individual. On occasion, adverse reactions can be related to genetic differences (i.e., idiosyncratic) in a susceptible individual who has an isolated genetic enzyme deficiency. In most allergic drug reactions, an immunologic mechanism is present or, more often, presumed. Determining whether the causing event involves a reaction between the drug or drug metabolites with drug-specific antibodies or sensitized T lymphocytes is often impractical. Without direct immunologic evidence, which may be helpful in distinguishing an allergic reaction from other adverse reactions, including allergic reactions that occur in only a small percentage of patients receiving the drug, the clinical manifestations do not resemble known pharmacologic actions. In the absence of prior drug exposure, allergic symptoms rarely appear after less than 1 week of continuous treatment. After sensitization, the reaction develops rapidly on re-exposure to the drug. In general, drugs that have been administered without complications for several months or longer are rarely responsible for producing drug allergy. The time span between exposure to the drug and noticed manifestations is often the most vital information in deciding which drugs administered were the cause of a suspected allergic reaction.

Although the reaction may produce a life-threatening response in the cardiopulmonary system (anaphylaxis), various cutaneous manifestations, fever, and pulmonary reactions have been attributed to drug hypersensitivity. Usually, the reaction may be reproduced by small doses of the suspected drug or other agents having similar or cross-reacting chemical structures. On occasion, drug-specific antibodies or lymphocytes have been identified that react with the suspected drug, although the relationship is seldom diagnostically useful in practice. Even when an immune response to a drug is demonstrated, it may not be associated with a clinical allergic reaction. As with adverse drug reactions in general, the reaction usually subsides within several days of discontinuation of the drug.

### *Immunologic Mechanisms of Drug Allergy*

Different immunologic responses to any antigen can occur. Drugs have been associated with all the immunologic mechanisms proposed by Gell and Coombs. Although more than one mechanism may contribute to a particular reaction, any one can occur. Penicillin may produce different reactions in different patients or a spectrum of reactions in the same patient. In one patient, penicillin can produce anaphylaxis (type I reaction), hemolytic anemia (type II reaction), serum sickness (type III reaction), and contact dermatitis (type IV reaction).<sup>5,6</sup> Therefore, any one antigen has the ability to produce a diffuse spectrum of allergic responses in humans. Why some patients have localized rashes or angioedema in response to penicillin whereas

others suffer complete cardiopulmonary collapse is unknown. Most anesthetic drugs and agents administered perioperatively have been reported to produce anaphylactic reactions (Table 9-7).<sup>31,39</sup> Muscle relaxants are the most common drugs responsible for evoking intraoperative allergic reactions. In this regard, there is cross-sensitivity between succinylcholine and the nondepolarizing muscle relaxants. Unexplained intraoperative cardiovascular collapse has been attributed to anaphylaxis triggered by latex (natural rubber).

Life-threatening allergic reactions are potentially thought to occur more likely in patients with a history of allergy, atopy, or asthma, although this concept is also controversial and in part based on older data.<sup>41</sup> Nevertheless, because the incidence is low, the history is not a reliable predictor that an allergic reaction will occur and does not mandate that such patients should be investigated or pretreated or that specific drugs be selected or avoided. Although different mechanisms have been proposed, no one theory has been proved. The drugs and foreign substances listed in Table 9-7 may have both immunologic and nonimmunologic mechanisms for adverse drug reactions in humans.

### *Evaluation of Patients with Allergic Reactions*

Identifying the drug responsible for a suspected allergic reaction still depends on circumstantial evidence suggesting the temporal sequence of drug administration. Conventional in vivo and in vitro methods of diagnosing allergic reactions to most anesthetic drugs are unavailable or not applicable. The most important factor in diagnosis is the awareness of the physician that an untoward event may be related to a drug the patient received. The physician must always be aware of the capacity of any drug to produce an allergic reaction. The history is important when evaluating whether an adverse drug reaction is allergic and whether the drug can be readministered. Although a prior allergic reaction to the drug in question is important, this is rarely the case. Direct challenge of a patient with a test dose of drug is the only way to prove a reaction, but this is potentially dangerous and not recommended. Although the anesthesiologist commonly gives small test doses of anesthetic drugs, these are pharmacologic test doses and have nothing to do with immunologic dosages. The demonstration of drug-specific IgE antibodies is accepted as evidence that the patient may be at risk for anaphylaxis if the drug is administered. Different clinical tests are of historical interest, and few of them are actually available to confirm or diagnose drug allergy, but these are considered in the following section.

**Table 9-7** Agents Implicated in Allergic Reactions during Anesthesia

<b>Anesthetic Agents</b>
Induction agents (cremophor-solubilized drugs, barbiturates, etomidate, propofol)
Local anesthetics (para-aminobenzoic ester agents)
Muscle relaxants (succinylcholine, gallamine, pancuronium, d-tubocurarine, metocurine, atracurium, vecuronium, mivacurium, doxacurium)
Opioids (meperidine, morphine, fentanyl)
<b>Other Agents</b>
Antibiotics (cephalosporins, penicillin, sulfonamides, vancomycin)
Aprotinin
Blood products (whole blood, packed cells, plasma/fresh frozen plasma, platelets, cryoprecipitate, fibrin glue, immunoglobulins)
Bone cement
Chymopapain
Corticosteroids
Cyclosporine
Drug additives (preservatives)
Furosemide
Insulin
Mannitol
Methyl methacrylate
Nonsteroidal anti-inflammatory drugs
Protamine
Radiocontrast dye
Latex (natural rubber)
Streptokinase
Vascular graft material
Vitamin K
Colloid volume expanders (dextrans, protein fractions, albumin, hydroxyethyl starch)

Reprinted with permission from: Levy JH. *Anaphylactic Reactions in Anesthesia and Intensive Care*. 2nd ed. Boston, MA: Butterworth-Heinemann; 1992.

## Testing for Allergy

**8** After an anaphylactic reaction, it is important to identify the causative agent to prevent readministration. When one particular drug has been administered and there is a clear correlation between the time of administration and the occurrence of a reaction, testing may be unnecessary, and general avoidance of the drug should be instituted. However, when patients have simultaneously received multiple drugs (e.g., an opioid, muscle relaxant, hypnotic, and antibiotic), it is often difficult to prove which particular drug caused the reaction. Further, the reaction might have been caused by the vehicle or by one of the preservatives. For patients who want to know which drug was responsible and for patients scheduled for subsequent procedures, some degree of allergy evaluation should be undertaken to evaluate the drug at risk. Unfortunately, few *laboratory* tests exist for anesthetic drugs; therefore, the available allergy tests are discussed.

## *Leukocyte Histamine Release*

Leukocyte histamine is performed by incubating the patient's leukocytes with the offending drug and measuring histamine release as a marker for basophil activation, although false-positive results can occur. This test is not easy to perform, although variations allow the use of whole blood instead of isolated PMNs, and is generally not available nor used.

## *In Vitro Immunologic Testing*

The enzyme-linked immunosorbent assay (ELISA) measures antigen-specific antibodies. The ELISA evaluates immunospecific IgE directed against the antigen in question by adding an anti-IgE coupled to an enzyme such as peroxidase that acts as a chromogen. A colorless substrate is acted on by peroxidase to produce a colored byproduct. The ELISA has been used to prove IgE antibodies to proteins such as protamine, has been developed to screen for other antibodies to diverse agents, and has become the mainstay of immunologic testing. Although antibodies can occur, patients may be asymptomatic. An older test previously used was the radioallergosorbent test (RAST), which used radiolabeled antibodies directed against human IgE and was counted in a scintillation counter, and has been largely replaced by ELISA assays. Major limitations to in vitro immunologic testing too many anesthetic drugs include the commercial availability of the drug prepared as an antigen.

## *Intradermal Testing (Skin Testing)*

Skin testing is the method most often used in patients after anaphylactic reaction to anesthetic drugs after the history has suggested the relevant antigens for testing.<sup>42</sup> Within minutes after antigen introduction, histamine released from cutaneous mast cells causes vasodilation (flare) and localized edema from increased vascular permeability (wheal). Fisher suggested that this is a simple, safe, and useful method of establishing a diagnosis in most cases of anaphylactic reactions occurring in the perioperative period. If the strict protocols established by Fisher are used, intradermal reactions are helpful.<sup>42</sup> Intradermal testing is of no value in reactions to contrast media or colloid volume expanders. Cross-sensitivity between drugs of similar structures can often be evaluated based on skin testing.

## ***Agents Implicated in Allergic Reactions***

Any drug or biologic agent can cause anaphylaxis in a patient. However, the agents most often implicated in the perioperative period include antibiotics, blood products, chlorhexidine, neuromuscular blocking drugs (NMBDs), polypeptides (aprotinin, latex, and protamine), and intravascular volume

expanders. Most of the information about perioperative anaphylaxis is from Australia, Europe, the United Kingdom, and New Zealand, where centers have existed for many years to investigate perioperative anaphylaxis when it occurs.<sup>43–48</sup> In one of the largest reports, perioperative anaphylaxis was evaluated over an 8-year period from 1997 to 2004 in France. Among the 2,516 patients with anaphylaxis, IgE-mediated reactions occurred in 1,816 cases (72.2%). The most common causes for the IgE-mediated events were NMBDs in 58% ( $n = 1067$ ), latex in 19.6% ( $n = 316$ ), and antibiotics in 12.8% ( $n = 236$ ).<sup>49</sup> One of the concerns regarding NMBA allergy is that if patients are allergic to a muscle relaxant, there is a potential for cross-reactivity because of the similarity of the active site, a quaternary ammonium molecule, among the different types of relaxants, and alternatives cannot be chosen without some degree of immunologic testing.

From the United States/North American perspective, only a few reports note either the incidence or agents implicated for perioperative anaphylaxis. Older reports from 1990 noted barbiturates were the most likely causative agent for 38% of IgE-mediated anaphylaxis, an agent that has disappeared from clinical practice in the United States.<sup>50</sup> However, European reports suggest the most frequent agent reported for perioperative IgE-mediated anaphylaxis is NMBAs.<sup>51</sup> A recent report from 2011 in the United States examined a skin test database of 38 patients with perioperative anaphylaxis who were tested to medications implicated in the reactions.<sup>52</sup> The history obtained by an allergist, skin test results, and tryptase measurements were reported.<sup>52</sup> Of note, 40% of the surgical procedures were aborted, and 58% of events resulted in intensive care unit admissions, suggesting the severity of the responses.<sup>52</sup> Of the 38 patients, 18 were considered IgE-mediated reactions by skin testing, 6 were non-IgE-mediated anaphylactic reactions as determined by elevated tryptase levels and negative skin testing, and 14 were probable non-IgE-mediated anaphylactic reactions because tryptase levels were normal or not obtained and skin testing was negative. Of the IgE-mediated anaphylactic reactions, antibiotics were the causative agents in half of the patients while NMBAs were implicated solely as a likely causative agent in only one reaction. The authors noted causative agents could not be determined in the other half of the patients.<sup>52</sup> The authors identified only one true IgE-mediated reaction to an NMBA; however, another patient had positive skin tests to three agents including vecuronium, propofol, and cefazolin, making the diagnosis uncertain. A previous Danish study reported 68 patients, of which 36 underwent complete investigations with in vitro testing and skin testing, and found that only one patient tested positive for NMBAs (4.8%: 1/21), while chlorhexidine accounted for 19.1% of reactions and antibiotics, 14.3%.<sup>53</sup> In the current study chlorhexidine was tested in only 4% of cases and may account for some of the undiagnosed reactions with

elevated tryptase.<sup>52</sup> Because of this information, antibiotics, latex, and NMBAs will be considered in more detail, along with local anesthetic (LA) agents.

## Antibiotics

Most surgical patients receive an antibiotic that includes a cephalosporin or vancomycin for prophylaxis. Despite their widespread use, the incidence of antibiotic allergy and its reported prevalence vary widely, as cutaneous manifestations are often the presenting reaction.<sup>39</sup> As reviewed in a recent article,<sup>1</sup> anaphylaxis to penicillins is low, occurring in an estimated 0.004% to 0.015%, but this widely quoted reference is old and penicillin is rarely used.<sup>54</sup> Further, data on anaphylaxis to cephalosporins is also uncommon, occurring from 0.0001% to 0.1%; however, this number is not zero.<sup>55</sup> Anaphylactic reactions to vancomycin are rare, but as we have demonstrated, it is a potent histamine-releasing agent that can cause severe hypotension and flushing on administration especially with rapid infusion.<sup>30,31</sup>

As reviewed previously, managing the patient with a history of penicillin allergy when the surgeon requests cephalosporin administration is still not clear based on reported data.<sup>1</sup> Older data suggest cross-reactivity to cephalosporins among penicillin-allergic patients is high and suggest choosing another agent, a practice that developed from case reports<sup>56</sup> of anaphylaxis following first-generation cephalosporins together with *in vitro* and skin testing, which showed extensive cross-reactivity between penicillins and first-generation cephalosporins.<sup>1</sup> The clinical relevance of this *in vitro* cross-reactivity was never demonstrated.<sup>56</sup> However, the risk of acute cephalosporin reactions among patients with positive penicillin skin tests is reported to be ~4.4%, compared with 0.6% among patients with negative penicillin skin tests.<sup>56,57</sup> Anaphylactic reactors were selectively omitted from these open studies. Further, an allergic reaction to a cephalosporin may occur independently of prior penicillin sensitization. One authority has concluded that most patients who have a history of penicillin allergy will tolerate cephalosporins, but that indiscriminate administration cannot be recommended, especially for patients who have had serious acute reactions to any  $\beta$ -lactam antibiotic.<sup>39</sup> Penicillin skin testing when available can be useful in identifying the 85% of patients with histories of penicillin allergy who no longer have (or never had) IgE antibodies to major and minor determinants and are therefore at negligible risk of cephalosporin reactions. For the remaining patients who are skin test positive, gradual escalation of the first dose of a cephalosporin under careful observation will further mitigate against uncommon but potentially serious acute reactions.

If a patient has a penicillin allergy history that is consistent with anaphylaxis and penicillin skin testing is unavailable, then cephalosporins

should be used with caution, with graded dose escalation of the first dose. A patient who has experienced an allergic reaction to a specific cephalosporin should probably not receive that cephalosporin again. However, the risk of an acute reaction when a different cephalosporin is administered appears to be low, but systemic evaluations of reaction risks when administering other cephalosporins or  $\beta$ -lactam antibiotics to patients with IgE antibodies to a particular cephalosporin are not available. Unfortunately, patient histories are often unreliable in this circumstance.

## Latex Allergy

For the anesthesiologist, latex represents an environmental agent often implicated as an important cause of perioperative anaphylaxis. Latex is the milky sap derived from the tree *Hevea brasiliensis*, to which multiple agents, including preservatives, accelerators, and antioxidants are added to make the final rubber product. Latex is present in a variety of different products. Latex allergy is an IgE-dependent immediate hypersensitivity reaction to latex proteins. The first case of an allergic reaction because of latex was reported in 1979 and was manifested by contact urticaria. In 1989, the first reports of intraoperative anaphylaxis because of latex were reported.

Health-care workers and children with spina bifida, urogenital abnormalities, or certain food allergies have also been recognized as people at increased risk for anaphylaxis to latex. Brown and colleagues reported a 24% incidence of irritant or contact dermatitis and a 12.5% incidence of latex-specific IgE positivity in anesthesiologists. Of this group, 10% were clinically asymptomatic, although IgE positive.<sup>58</sup> A history of atopy was also a significant risk factor for latex sensitization. Brown and colleagues suggested that these people are in their early stages of sensitization and perhaps, by avoiding latex exposure, their progression to symptomatic disease can be prevented.<sup>58</sup> Patients allergic to bananas, avocados, and kiwis have also been reported to have antibodies that cross-react with latex.<sup>59,60</sup> Multiple attempts are being made to reduce latex exposure to both health-care workers and patients. If latex allergy occurs, then strict avoidance of latex from gloves and other sources needs to be considered, following recommendations as reported by Holzman.<sup>61,62</sup> Although latex was previously a common environmental antigen, ongoing effort by suppliers of hospital equipment has significantly reduced latex exposure in recent years.

More importantly, anesthesiologists must be prepared to treat the life-threatening cardiopulmonary collapse that occurs after anaphylaxis, as previously discussed. The most important preventive therapy is to avoid antigen exposure; although clinicians have used pretreatment with

antihistamine (diphenhydramine and cimetidine) and corticosteroids, there are no data in the literature to suggest that pretreatment prevents anaphylaxis or decreases its severity.<sup>1</sup> Patients in whom latex allergy is suspected should be referred to an allergist for proper evaluation and potential testing for definitive diagnosis. When this is not possible, patients should be treated as if they were latex allergic, and the antigen avoided. Patients with a documented history of latex allergy should wear Medic Alert bracelets.

## Local Anesthetics

Skin testing to local anesthetics (LAs) is considered a direct challenge or provocative dose testing. LA drugs are injected in increasing quantities under controlled circumstances. This testing decides if the person can safely receive amide derivatives (e.g., lidocaine) and can also be used to decide if the person is sensitive to *para*-aminobenzoic ester agents (e.g., procaine, tetracaine). Because the immediate hypersensitivity reactions to LAs are unknown, they are commonly regarded as “pseudo-allergic” or “nonimmune type” anaphylaxis, as immunologically mediated reactions have rarely been observed with positive skin-prick tests.<sup>63</sup> Other ingredients in LA preparations have to be considered as elicitors; for example, preservatives like benzoates or sulfites or latex contaminants in injection bottles. Practical management of patients with a history of LA reaction includes a careful allergy history and skin-prick and intradermal tests. Undiluted LA solutions may elicit false-positive intradermal test reactions. If prick and intradermal tests are negative, the procedure of subcutaneous provocation testing is applied in a placebo-controlled manner. When patients are constantly reacting to placebo, a regimen of “reverse placebo provocation” with injection of an LA (*verum*) is applied while the patient is informed about receiving placebo in order to “rule out psychosomatic involvement.” With this regimen it is possible to eliminate anxiousness and fear, and the patient has proof that he has tolerated the respective LA substance.<sup>63</sup>

However, the diagnostic evaluation of patients with suspected allergy to LAs who have experienced a reaction remains controversial. One of the largest reports of skin testing for LA allergy evaluation is a retrospective chart review of patients following LA skin testing who underwent prick and intradermal skin testing followed by incremental subcutaneous and open subcutaneous challenge.<sup>64</sup> A total of 178 patients underwent 227 LA skin tests of which 220 (97%) were negative, and 214 (97%) had negative challenge or probable non-IgE-mediated events during challenge while three patients with six negative skin tests had a local reaction during the challenge. Only seven skin tests per five patients met the criteria for a positive skin test, and one patient had a skin reaction without systemic effects, three patients had a

negative subcutaneous challenge, and one patient did not undergo a challenge. Overall, 98% of patients receiving LAs after open subcutaneous challenge tolerated the medications. The negative predictive value of the LA skin test was 97% with few positive skin tests. Positive LA skin tests are uncommon and the LA skin tests have an excellent negative predictive value.<sup>64</sup>

## Neuromuscular Blocking Agents

NMBAs have several unique molecular features that make them potential antigens. All NMBAs are functionally divalent and are thus capable of cross-linking cell-surface IgE and causing mediator release from mast cells and basophils without binding or haptening to larger carrier molecules. NMBAs have also been implicated in epidemiologic studies of anesthetic drug-induced anaphylaxis. Epidemiologic data from France suggest that NMBAs are responsible for 62% to 81% of reactions, depending on the time period evaluated. 10

In more recent years, NMBAs, especially steroid-derived agents, have been reported as potential causative agents of anaphylactic reactions during anesthesia. The data associating NMBAs in the most recent reports from France are mainly based on skin testing; however, studies have previously reported that steroidal-derived NMBAs and other molecules produce false-positive skin tests (i.e., weal and flare). One of the major problems is that anaphylaxis to NMBAs is rare in the United States but has been reported more often in Europe. Although suggestions have been made that this is because of underreporting, the severity of anaphylaxis and its sequelae to produce adverse outcomes clearly make this unlikely based on the current medicolegal climate that exists in the United States. One of the only ways to explain this widely divergent perspective is to understand how the diagnosis is made, because the recommended threshold test concentrations have not been defined, resulting in unreliable results.

We have previously reported that steroid-derived agents can induce positive weal and flare responses independent of mast cell degranulation, even at low concentrations, following intradermal injection. This effect is likely because of a direct effect on the cutaneous vasculature that occurs for most NMBAs at concentrations as low as  $10^{-5}$  M, using intradermal skin tests in 30 volunteers. A positive cutaneous reaction without evidence of mast cell degranulation was noted at low concentrations (100  $\mu$ g/mL) of rocuronium in almost all the volunteers. We have used intradermal injections to compare cutaneous effects of anesthetic and other agents.

Other investigators have also reported similar results. Because prick tests are often used for authenticating NMBAs as causative drugs, Dhonneur and

colleagues evaluated 30 volunteers, using prick testing. Each subject received 10 prick tests (50  $\mu$ L) on both forearms.<sup>65</sup> The investigators studied the weal and flare responses to prick tests with rocuronium and vecuronium, using four dilutions (1/1,000, 1/100, 1/10, and 1) and two controls, and measured weal and flare immediately after and at 15 minutes. They noted 50% and 40% of the subjects had a positive skin reaction to undiluted rocuronium and vecuronium, respectively. To avoid false-positive results, they suggested that prick testing with rocuronium and vecuronium should be performed in subjects who have experienced a hypersensitivity reaction during anesthesia, with concentrations below that commonly inducing positive reactions in anesthesia-naive, healthy subjects (i.e., for men in a dilution of 1/10 and for women in a dilution of 1/100).<sup>65</sup> Guidelines for prick testing that are internationally agreed on need to be established. Many of these differences may explain the various incidences of allergy to NMBAs among countries. Concentration–skin response curves to rocuronium and vecuronium have showed that prick tests should be performed with dilution of the commercially available preparation. Female volunteers significantly ( $P < 0.01$ ) reacted to lower vecuronium and rocuronium concentrations more frequently than did males. In female subjects, positive skin reactions were reported with dilutions of 1/100 of both relaxants. In male subjects, positive skin reactions were noted with the undiluted concentration, except for one volunteer who reacted to rocuronium (1/10 dilution).<sup>65</sup>

## Summary

Although the immune system functions to provide host defense, it can respond inappropriately to produce hypersensitivity or allergic reactions. A spectrum of life-threatening allergic reactions to any drug or agent can occur in the perioperative period. The enigma of these reactions lies in their unpredictable nature. Certain patients undergoing high-risk procedures with multiple blood product exposures are also at higher risk. However, a high index of suspicion, prompt recognition, and appropriate and aggressive therapy can help avoid a disastrous outcome.

## KEY POINTS

- 1 The components of the anesthetic state include unconsciousness, amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimulation.
- 2 Minimum alveolar concentration (MAC) remains the most robust measurement and the standard for determining the potency of volatile anesthetics.
- 3 Direct interactions of anesthetic molecules with proteins would not only satisfy the Meyer–Overton rule, but would also provide the simplest explanation for compounds that deviate from this rule.
- 4 Current evidence strongly indicates protein rather than lipid as the molecular target for anesthetic action.
- 5 While current data still support the prevailing view that neuronal excitability is only slightly affected by general anesthetics, this small effect may nevertheless contribute significantly to the clinical actions of volatile anesthetics.
- 6 The synapse is generally thought to be the most likely relevant site of anesthetic action. Existing evidence indicates that even at this one site, anesthetics produce various effects, including presynaptic inhibition of neurotransmitter release, inhibition of excitatory neurotransmission, and enhancement of inhibitory neurotransmission. Furthermore, the effects of anesthetics on synaptic function differ among various anesthetic agents, neurotransmitters, and neuronal preparations.
- 7 Existing evidence suggests that most voltage-dependent calcium channels (VDCCs) are modestly sensitive or insensitive to anesthetics. However, some sodium channel subtypes are inhibited by volatile anesthetics and this effect may be responsible in part for a reduction in neurotransmitter release at some synapses.
- 8 Activation of background  $K^+$  channels could be an important and general mechanism through which volatile and gaseous anesthetics regulate neuronal resting membrane potential and thereby excitability.
- 9 Hyperpolarization-activated cyclic nucleotide-gated channels are a relatively recently discovered channel type inhibited by volatile anesthetics and some intravenous anesthetics at clinical concentrations.
- 10 A large body of evidence shows that clinical concentrations of many anesthetics potentiate GABA-activated currents in the central nervous system. Other members of the ligand-activated ion channel family, including glycine receptors, neuronal nicotinic receptors, and 5-HT<sub>3</sub> receptors, are also affected by clinical concentrations of anesthetics and remain plausible anesthetic targets.
- 11 Genetic experiments in mice provide definitive evidence for roles of

specific GABA<sub>A</sub> receptor channels, two-pore potassium channels, and HCN channels in particular anesthetic behavioral effects. Genetically engineered mice also show that distinct anesthetic targets mediate different anesthetic endpoints and that not all anesthetics have the same targets.

- 12 While anesthetic action to produce immobility occurs largely at the spinal cord, specific molecular targets for amnesia lie in the hippocampus.
- 13 Anesthetic-induced unconsciousness can be viewed as impairment of both arousal and awareness. These actions are mediated by targets distributed across the brainstem, hypothalamus, thalamus, and cerebral cortex.
- 14 Anesthetic ablation of arousal relies on disruption of redundant subcortical systems that regulate sleep and patterns of cortical activity.
- 15 Anesthetics alter the interaction of cortical networks responsible for cognitive functions and may thereby alter awareness by limiting the capacity to both represent and integrate information.

The introduction of general anesthetics into clinical practice over 150 years ago stands as one of the seminal innovations of medicine. This single discovery facilitated the development of modern surgery and spawned the specialty of anesthesiology. Despite the importance of general anesthetics, and despite more than 100 years of active research, the molecular mechanisms responsible for anesthetic action are only partially understood.

Why have mechanisms of anesthesia been so difficult to elucidate? Anesthetics, as a class of drugs, are challenging to study for three major reasons:

1. Anesthesia, by definition, is a change in the responses of an *intact animal* to external stimuli. Making a definitive link between anesthetic effects observed *in vitro* and the anesthetic state observed and defined *in vivo* has proven difficult.
2. No structure–activity relationships are apparent among anesthetics; a wide variety of structurally unrelated compounds, ranging from steroids to elemental xenon, are capable of producing clinical anesthesia. This suggests that there are multiple molecular mechanisms that can produce clinical anesthesia.
3. Anesthetics work at very high concentrations in comparison to drugs, neurotransmitters, and hormones that act at specific receptors. This **1** implies that if anesthetics do act by binding to specific receptor sites, they must bind with very low affinity and probably stay bound to the receptor for very short periods of time. Low-affinity binding is much more difficult to observe and characterize than is high-affinity binding.

Despite these difficulties, molecular and genetic tools are now available that should allow for major insights into anesthetic mechanisms in the next decade. The aim of this chapter is to provide a conceptual framework for the reader to catalog current knowledge and integrate future developments about mechanisms of anesthesia. Five specific questions will be addressed in this chapter:

1. What is anesthesia and how do we measure it?
2. What are the molecular targets of anesthetics?
3. What are the cellular neurophysiologic mechanisms of anesthesia (e.g., effects on synaptic function vs. effects on action potential generation) and what anesthetic effects on ion channels and other neuronal proteins underlie these mechanisms?
4. How are the molecular and cellular effects of anesthetics linked to the behavioral effects of anesthetics observed in vivo?
5. What are the major anatomic sites of anesthetic action in the central nervous system (CNS), and how do anesthetics interfere with their interactions?

## What Is Anesthesia?

General anesthesia can be broadly defined as a drug-induced reversible depression of the CNS resulting in the loss of response to and perception of all external stimuli. Unfortunately, such a broad definition is inadequate for two reasons. First, the definition is not actually broad enough. Anesthesia is not simply a deafferented state; amnesia and unconsciousness are important aspects of the anesthetic state. Second, the definition is too broad, as all general anesthetics do not produce equal depression of all sensory modalities. For example, barbiturates are considered to be anesthetics but produce minimal analgesia. A more practical description of the anesthetic state is a collection of five “component” changes in behavior or perception—unconsciousness, amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimulation.

Regardless of which definition of anesthesia is used, rapid and reversible drug-induced changes in behavior or perception are essential to anesthesia. As such, anesthesia can only be defined and measured in the intact organism. Changes in behavior such as unconsciousness or amnesia can be intuitively understood in higher organisms such as mammals, but become increasingly difficult to define as one descends the phylogenetic tree. Thus, while anesthetics have effects on organisms ranging from worms to man, it is difficult to map with certainty the effects of anesthetics observed in lower organisms to any of our behavioral definitions of anesthesia. This contributes to the difficulty of using simple organisms as models in which to study the

molecular mechanisms of anesthesia. Similarly, any cellular or molecular effects of anesthetics observed in higher organisms can be extremely difficult to link with the constellation of behaviors that constitute the anesthetic state. The absence of a simple and concise definition of anesthesia has clearly been one of the stumbling blocks to elucidating the mechanisms of anesthesia at a molecular and cellular level. Precise definitions for each of the component behaviors of the anesthetic state will be an important tool in dissecting the molecular and cellular mechanisms of each of the clinically important effects of anesthetic agents.

An additional difficulty in defining anesthesia is that our understanding of the mechanisms of consciousness is rather amorphous at present. One cannot easily define anesthesia when the neurobiologic phenomena ablated by anesthesia are not well understood. As discussed later in this chapter, the neural substrates for consciousness are beginning to be unraveled<sup>1,2</sup> and new theories<sup>3,4</sup> have incorporated this new anatomic knowledge leading to identification of surrogate physiologic markers of consciousness.<sup>5</sup> These new insights into mechanisms of consciousness are discussed in the section *Where in the Central Nervous System Do Anesthetics Work?*

Finally, it has long been assumed that anesthesia is a state that is achieved when an anesthetic agent reaches a specific concentration at its effect site in the brain and that if tolerance to the anesthetic develops, increasing concentrations of anesthetic might be required to maintain a constant level of anesthesia during prolonged anesthetic administration. The finding that it takes a higher anesthetic brain concentration to induce anesthesia than to maintain anesthesia (i.e., emergence occurs at a significantly lower concentration than induction) contradicts these assumptions.<sup>6</sup> This phenomenon, referred to as neural inertia, adds a wrinkle to the definition of anesthesia, suggesting that the mechanisms of anesthetic induction and emergence may be different. This suggestion is supported by the recent finding that the sedative component of anesthesia can be reversed by stimulation of specific arousal pathways in the brain, even in the presence of “anesthetic” concentrations of inhalational agents.<sup>7,8</sup>

## How Is Anesthesia Measured?

In order to study the pharmacology of anesthetic action, quantitative measurements of anesthetic potency are absolutely essential. To this end, Quasha et al.<sup>9</sup> have defined the concept of minimum alveolar concentration (MAC). MAC is defined as the alveolar partial pressure of a gas at which 50% of humans do not respond to a surgical incision. In animals, MAC is defined as the alveolar partial pressure of a gas at which 50% of animals do not respond to a noxious stimulus, such as tail clamp,<sup>10</sup> or at which they lose their righting

reflex. The use of MAC as a measure of anesthetic potency has two major advantages. First, it is an extremely reproducible measurement that is remarkably constant over a wide range of species.<sup>9</sup> Second, the use of end-tidal gas concentration provides an index of the “free” concentration of drug required to produce anesthesia since the end-tidal gas concentration is in equilibrium with the free concentration in plasma.

The MAC concept has several important limitations, particularly when trying to relate MAC values to anesthetic potency observed *in vitro*. First, the endpoint in a MAC determination is quantal: A subject is either anesthetized or unanesthetized; it cannot be partially anesthetized. Furthermore, MAC represents the average response of a whole population of subjects rather than the response of a single subject. The quantal nature of the MAC measurement makes it very difficult to compare MAC measurements to concentration–response curves obtained *in vitro*, where the graded response of a single preparation is measured as a function of anesthetic concentration. The second limitation of MAC measurements is that they can only be directly applied to anesthetic gases. Parenteral anesthetics (barbiturates, neurosteroids, propofol) cannot be assigned a MAC value, making it difficult to compare the potency of parenteral and volatile anesthetics. A MAC equivalent for parenteral anesthetics is the free concentration of the drug in plasma required to prevent response to a noxious stimulus in 50% of subjects; this value has been estimated for several parenteral anesthetics.<sup>11</sup> A third limitation of MAC is that it is highly dependent on the anesthetic endpoint used to define it. For example, if loss of response to a verbal command is used as an anesthetic endpoint, the MAC values obtained (MAC<sub>awake</sub>) will be much lower than classic MAC values based on response to a noxious stimulus. Indeed, each behavioral component of the anesthetic state will likely have a different MAC value. Despite its limitations, MAC remains the most robust measurement and the standard for determining the potency of volatile anesthetics.

Because of the limitations of MAC, monitors that measure some correlate of anesthetic depth have been introduced into clinical practice.<sup>12</sup> The most popular of these monitors converts spontaneous electroencephalogram (EEG) waveforms into a single value that correlates with anesthetic depth for some general anesthetics. To date, these monitors have not been shown to be more effective at preventing awareness during anesthesia than simply maintaining an adequate end-tidal anesthetic concentration<sup>13,14</sup> or giving a standard dose of intravenous anesthetic. Nonetheless it is logical to think that different individuals may have different sensitivities to anesthetics and that measuring a surrogate endpoint such as a processed EEG value,<sup>15</sup> an evoked potential,<sup>16</sup> or a functional neuroimaging signal indicative of integrated cortical activity<sup>1</sup> might be a better indicator of anesthetic depth than merely measuring delivered concentration.

# What Is the Chemical Nature of Anesthetic Target Sites?

## The Meyer–Overton Rule

More than 100 years ago, Meyer<sup>17</sup> and Overton<sup>18</sup> independently observed that the potency of gases as anesthetics was strongly correlated with their solubility in olive oil (Fig. 10-1). Since a wide variety of structurally unrelated compounds obey the Meyer–Overton rule, it has been reasoned that all anesthetics are likely to act at the same molecular site. This idea is referred to as the *unitary theory of anesthesia*. It has also been argued that since solubility in a specific solvent strongly correlates with anesthetic potency, the solvent showing the strongest correlation between anesthetic solubility and potency is likely to most closely mimic the chemical and physical properties of the anesthetic target site in the CNS. On the basis of this reasoning, the anesthetic target site was assumed to be hydrophobic in nature. Since olive oil/gas partition coefficients can be determined for gases and volatile liquids, but not for liquid anesthetics, attempts have been made to correlate anesthetic potency with solvent/water partition coefficients. To date, the octanol/water partition coefficient best correlates with anesthetic potency. This correlation holds for a variety of classes of anesthetics and spans a 10,000-fold range of anesthetic potencies.<sup>19</sup> The properties of the solvent octanol suggest that the anesthetic site is likely to be amphipathic, having both polar and nonpolar characteristics.

**Figure 10-1** The Meyer–Overton rule. There is a linear relationship (on a log–log scale) between the oil/gas partition coefficient and the anesthetic potency (minimum alveolar concentration, MAC) of a number of gases. The correlation between lipid solubility and

MAC extends over a 70,000-fold difference in anesthetic potency. (Reproduced with permission from Tanifuji Y, Eger EI, Terrell RC. Some characteristics of an exceptionally potent inhaled anesthetic: thiomethoxyflurane. *Anesth Analg*. 1977;56:387.)

## Exceptions to the Meyer–Overton Rule

Compounds exist that are structurally similar to halogenated anesthetics,<sup>20</sup> barbiturates,<sup>21</sup> and neurosteroids,<sup>22</sup> yet are convulsants rather than anesthetics. On the basis of olive oil/gas partition coefficients of the halogenated convulsant compounds, anesthesia should have been achieved within the range of concentrations studied.<sup>23</sup> Halogenated compounds have also been identified that are neither anesthetic nor convulsant, despite oil/gas partition coefficients that would predict they should be anesthetics.<sup>23</sup> Interestingly, some of these polyhalogenated compounds do produce amnesia in animals<sup>24</sup> and are thus referred to as *nonimmobilizers* rather than as nonanesthetics.

In several homologous series of anesthetics, anesthetic potency increases with increasing chain length until a certain critical chain length is reached. Beyond this critical chain length, compounds are unable to produce anesthesia, even at the highest attainable concentrations. In the series of *n*-alkanols, for example, anesthetic potency increases from methanol through dodecanol; all longer alkanols are unable to produce anesthesia.<sup>25</sup> This phenomenon is referred to as the *cutoff effect*. Cutoff effects have been described for several homologous series of anesthetics including *n*-alkanes, *n*-alkanols, cycloalkanemethanols,<sup>26</sup> and perfluoroalkanes.<sup>27</sup> While the anesthetic potency in each of these homologous series of anesthetics shows a cutoff, a corresponding cutoff in octanol/water or oil/gas partition coefficients has not been demonstrated. Therefore, compounds above the cutoff represent a deviation from the Meyer–Overton rule.

A final deviation from the Meyer–Overton rule is the observation that enantiomers of anesthetics differ in their potency as anesthetics. Enantiomers (mirror-image compounds) are a class of stereoisomers that have identical physical properties, including identical solubility in solvents such as octanol or olive oil. Animal studies of barbiturate anesthetics,<sup>28</sup> ketamine,<sup>29</sup> neurosteroids,<sup>30</sup> etomidate,<sup>31</sup> and isoflurane<sup>32</sup> all show enantioselective differences in anesthetic potency. It is argued that a *major* difference in anesthetic potency between a pair of enantiomers can only be explained by a protein-binding site (see *Protein Theories of Anesthesia*); this appears to be the case for etomidate and the neurosteroids. The exceptions to the Meyer–Overton rule indicate that the properties of a solvent such as octanol describe some, but not all, of the properties of an anesthetic-binding site. Properties such as size and shape must also be important determinants of anesthetic sites

of action.

## ***Lipid versus Protein Targets***

Anesthetics might interact with several possible molecular targets to produce their effects on the *function* of ion channels and other proteins. Anesthetics might dissolve in the *lipid* bilayer, causing physicochemical changes in membrane structure that alter the ability of embedded membrane proteins to undergo conformational changes important for their function. Alternatively, anesthetics could bind directly to *proteins* (either ion channel proteins or modulatory proteins), thus either interfering with binding of a ligand (e.g., a neurotransmitter, a substrate, a second messenger molecule) or altering the ability of the protein to undergo conformational changes important for its function. The following section summarizes the arguments for and against lipid theories and protein theories of anesthesia.

## ***Lipid Theories of Anesthesia***

In its simplest incarnation, the lipid theory of anesthesia postulates that anesthetics dissolve in the lipid bilayers of biologic membranes and produce anesthesia when they reach a critical concentration in the membrane. Consistent with this hypothesis, the membrane/gas partition coefficients of anesthetic gases in pure lipid bilayers correlate strongly with anesthetic potency.<sup>33</sup> Also, consistent with the lipid theories, various membrane perturbations are produced by general anesthetics; however, the magnitude of these changes produced by clinical concentrations of anesthetics are quite small and are thought to be very unlikely to disrupt nervous system function.<sup>34</sup> While some of the more sophisticated lipid theories can account for the cutoff effect and for the ineffectiveness of nonimmobilizers, no lipid theory can plausibly explain all anesthetic pharmacology. Thus, most investigators do not consider lipids as the most likely target of general anesthetics.

## ***Protein Theories of Anesthesia***

The Meyer–Overton rule could also be explained by the direct interaction of anesthetics with hydrophobic sites on proteins. Three types of hydrophobic sites on proteins might interact with anesthetics:

1. Hydrophobic amino acids comprise the core of water-soluble proteins. Anesthetics could bind in hydrophobic pockets that are fortuitously present in the protein core.

2. Hydrophobic amino acids also form the lining of binding sites for hydrophobic ligands. For example, there are hydrophobic pockets in which fatty acids tightly bind on proteins such as albumin and the low-molecular-weight fatty acid-binding proteins. Anesthetics could compete with endogenous ligands for binding to such sites on either water-soluble or membrane proteins.
3. Hydrophobic amino acids are major constituents of the  $\alpha$ -helices, which form the membrane-spanning regions of membrane proteins; hydrophobic amino acid side chains form the protein surface that faces the membrane lipid. Anesthetic molecules could interact with pockets formed between the  $\alpha$ -helices or with the hydrophobic surface of these membrane proteins, disrupting normal lipid-protein interactions and possibly directly affecting protein conformation.

Direct interaction of anesthetic molecules with proteins not only satisfies the Meyer-Overton rule, but would also provide the simplest explanation 3 for compounds that deviate from this rule. Any protein-binding site is likely to be defined by properties such as size and shape in addition to its solvent properties. Limitations in size and shape could reduce the binding affinity of compounds beyond the cutoff, thus explaining their lack of anesthetic effect. Enantioselectivity is also most easily explained by a direct binding of anesthetic molecules to defined sites on proteins; a protein-binding site of defined dimensions could readily distinguish between enantiomers on the basis of their different shapes. Protein-binding sites for anesthetics could also explain the convulsant effects of some polyhalogenated alkanes. Different compounds binding (in slightly different ways) to the same binding pocket can produce different effects on protein conformation and hence on protein function. For example, polyhalogenated alkanes (*nonimmobilizers*) could be inverse agonists, binding at the same protein sites at which halogenated alkane anesthetics are agonists. The evidence for direct interactions between anesthetics and proteins is briefly reviewed in the following section.

### **Evidence for Anesthetic Binding to Proteins**

A breakthrough in protein theories of anesthesia was the demonstration that a purified water-soluble protein, firefly luciferase, could be inhibited by general anesthetics. This provided the important proof of principle that anesthetics could bind to proteins in the absence of membranes. Numerous studies have extensively characterized the anesthetic inhibition of firefly luciferase activity and have shown that inhibition occurs at concentrations very similar to those required to produce clinical anesthesia, is consistent with the Meyer-Overton rule, is competitive with respect to the substrate D-luciferin, and exhibits a cutoff in anesthetic potency for both *n*-alkanes and *n*-alkanols.<sup>35,36</sup> These data

suggest that the luciferin-binding pocket may have physical and chemical characteristics similar to those of a putative anesthetic-binding site in the CNS. To address proteins more relevant to anesthetic effects on the nervous system, numerous studies have employed site-directed mutagenesis of anesthetic-sensitive ion channels to identify amino acid residues that are crucial to anesthetic action. While the residues identified in these studies may contribute to anesthetic-binding sites, they may alternatively be sites that are essential for anesthetic-induced conformational changes in the protein. The literature on site-directed mutagenesis studies to identify putative anesthetic-binding sites on ion channels is extensively reviewed in the section *Anesthetic Actions on Ion Channels*.

More direct approaches to study anesthetic binding to proteins have included NMR spectroscopy and photoaffinity labeling. Early studies using <sup>19</sup>F-NMR spectroscopy demonstrated that isoflurane binds to the fatty acid-binding sites on bovine serum albumin (BSA), and that binding is competitively inhibited by halothane, methoxyflurane, sevoflurane, and octanol.<sup>37,38</sup> Using this BSA model, it was subsequently shown that anesthetic-binding sites could be identified and characterized using photoaffinity labeling with <sup>14</sup>C-labeled halothane.<sup>39,40</sup> Photoaffinity-labeling reagents have subsequently been developed for a variety of anesthetics, including etomidate,<sup>41</sup> propofol,<sup>42,43</sup> barbiturates,<sup>44</sup> and neurosteroids.<sup>45</sup> These photoaffinity-labeling reagents can be used to identify putative anesthetic-binding sites, the functional significance of which can be validated using site-directed mutagenesis.

The most extensive photolabeling studies have used etomidate analogue photolabeling reagents to identify etomidate-binding sites on purified GABA<sub>A</sub> receptors. An initial study used azi-etomidate, a photolabeling reagent that preferentially labels nucleophilic amino acids, to photolabel-purified GABA<sub>A</sub> receptors from bovine brain.<sup>46</sup> This study identified two methionine residues that were sites of attachment for azi-etomidate: One site on the TM1 helix (Met-236) of the  $\alpha_1$  subunit and the other (Met-286) on the TM3 helix of the  $\beta_3$  subunit. These data suggest an etomidate-binding pocket in the transmembrane domain at the interface between the  $\alpha_1$  and  $\beta_3$  subunits. A subsequent study using TDBzl-etomidate, a photolabeling reagent with broader amino acid side chain reactivity, identified additional amino acids that confirmed and further defined this inter-subunit-binding site.<sup>44</sup> The combined results of site-directed mutagenesis studies and photoaffinity-labeling studies identified a specific, functionally relevant binding site for etomidate on GABA<sub>A</sub> receptors, definitively refuting lipid theories of anesthetic action. Photoaffinity-labeling studies with other anesthetic agents including propofol<sup>43,47</sup> and barbiturates<sup>48</sup> have identified binding pockets for anesthetics, which are currently being tested and validated using site-directed

mutagenesis.

Although photoaffinity-labeling techniques can provide extensive information about anesthetic-binding sites on proteins, they cannot reveal the details of the three-dimensional structure of these sites. X-ray diffraction crystallography can provide this kind of three-dimensional detail and has been used to study anesthetic interactions with a small number of proteins. Firefly luciferase has been crystallized in the presence and absence of the anesthetic bromoform, confirming that anesthetics bind in the D-luciferin-binding pocket.<sup>49</sup> Human serum albumin has also been crystallized in the presence of either propofol or halothane, demonstrating binding of both anesthetics to preformed fatty acid-binding pockets. While these data provide insight into the structure of anesthetic-binding sites, x-ray crystallographic studies of anesthetic-binding sites on biologically relevant targets such as ion channels have been hampered by difficulties with crystallizing membrane proteins. Recently, a bacterial homolog of the ligand-gated ion channels, GLIC, has been crystallized and its crystal structure has been solved.<sup>50</sup> GLIC has been shown to be sensitive to clinical concentrations of anesthetics, and furthermore the crystal structure of GLIC complexed with either desflurane or propofol has been solved.<sup>51</sup> These data reveal a preformed binding cavity in the interface between the transmembrane domains of each subunit of the ion channel. The recent description of the high-resolution crystal structure of a GABA<sub>A</sub> receptor<sup>52</sup> should soon make it possible to define the precise dimensions and location of anesthetic-binding pockets on a relevant anesthetic target protein. It is important to recognize that even the x-ray crystal structures of anesthetics bound to target ion channels may not fully elucidate how and where anesthetics act. Ion channels are allosteric proteins that fluctuate between multiple conformations, whereas x-ray structures are static “snapshots” of just one conformation. Anesthetics bind to and stabilize specific conformations of proteins, which may or may not be the same conformation in which the protein is crystallized.

## Summary

Evidence from studies using water-soluble proteins demonstrates that anesthetics can bind to hydrophobic pockets on proteins and that anesthetic-protein interactions can account for the Meyer-Overton rule and deviations from it. Photoaffinity-labeling studies demonstrate that etomidate binds to a pocket in the interface between the  $\alpha_1$  and  $\beta_3$  subunits of the GABA<sub>A</sub> receptor. Mutagenesis of amino acids within this etomidate-binding pocket eliminates the anesthetic effect of etomidate, providing unequivocal evidence that anesthetic action can be mediated by binding to a specific protein site. Studies with propofol and barbiturate analogue photoaffinity-labeling reagents have

also demonstrated putative binding sites on the GABA<sub>A</sub> receptor. Finally, recent x-ray crystallographic studies using the bacterial ion channel GLIC provide the first glimpse of the three-dimensional structure of an anesthetic-binding site on a relevant protein model. While the long-standing controversy between lipid and protein theories of anesthesia may be behind us, numerous unanswered questions remain about the details of anesthetic–protein interactions, including:

4

1. What is the stoichiometry of anesthetic binding to a protein (i.e., do many anesthetic molecules interact with a single protein molecule or only a few)?
2. Do anesthetics compete with endogenous ligands for binding to hydrophobic pockets on protein targets or do they bind to fortuitous cavities in the protein?
3. Do all anesthetics bind to the same pocket on a protein or are there multiple hydrophobic pockets for different anesthetics?
4. How many proteins have hydrophobic pockets in which anesthetics can bind at clinically relevant concentrations?

## How Do Anesthetics Interfere with the Electrophysiologic Function of the Nervous System?

The functional unit of the CNS is the neuron, and ultimately general anesthetics must disrupt the function of neurons mediating behavior, consciousness, and memory. In the simplest terms, anesthetics could accomplish this by altering the intrinsic firing rate of individual neurons, termed neuronal excitability, and/or by altering communication between neurons, generally occurring via synaptic transmission.

### Neuronal Excitability

Neurons transmit information down their axons through action potentials. The propensity of a neuron to generate and propagate action potentials from the cell body to their nerve terminals is called its excitability. Intrinsic neuronal excitability is chiefly determined by three parameters: resting membrane potential, the threshold potential for action-potential generation, and the size/propagation of the action potential. Anesthetics can hyperpolarize (create a more negative resting membrane potential) both spinal motor neurons and cortical neurons,<sup>53,54</sup> and this ability to hyperpolarize neurons correlates with anesthetic potency. In general, the hyperpolarization produced by anesthetics is small in magnitude and is unlikely to alter *propagation* of an action potential down an axon. Small changes in resting potential may, however, inhibit the *initiation* of an action potential generated in response to synaptic excitation or

in a spontaneously firing neuron. Indeed, isoflurane has been shown to hyperpolarize thalamic neurons, leading to an inhibition of tonic firing of action potentials.<sup>55</sup> Anesthetics have not been shown to reliably alter the threshold potential of a neuron for action-potential generation. However, the data are conflicting on whether the size of the action potential, once initiated, is diminished by general anesthetics. A classic article by Larrabee and Posternak<sup>56</sup> demonstrated that concentrations of ether and chloroform that completely block synaptic transmission in mammalian sympathetic ganglia have no effect on presynaptic action-potential amplitude. Similar results have been obtained with fluorinated volatile anesthetics in mammalian brain preparations.<sup>57,58</sup> This dogma that the action potential is relatively resistant to general anesthetics has been challenged by more recent reports that volatile anesthetics at clinical concentrations produce a small but significant reduction in the size of the action potential in mammalian neurons.<sup>59–61</sup> At a large synapse, amenable to direct measurement of the action potential and transmitter release in the same neuron, the slightly smaller action potential was shown to produce a substantial reduction in transmitter release due to the exponential relationship between the two.<sup>60</sup> Thus, while current data still support the prevailing view that neuronal excitability is only slightly affected by general anesthetics, this small effect may nevertheless contribute significantly to the clinical actions of volatile anesthetics.

## *Synaptic Transmission*

Synaptic transmission is widely considered to be the most likely subcellular site of general anesthetic action. Neurotransmission across both excitatory and inhibitory synapses is markedly altered by general anesthetics. General anesthetics inhibit excitatory synaptic transmission in a variety of preparations, including sympathetic ganglia,<sup>56</sup> olfactory cortex,<sup>57</sup> hippocampus,<sup>58</sup> and spinal cord.<sup>62</sup> However, not all excitatory synapses appear to be equally sensitive to anesthetics; indeed, transmission across some hippocampal excitatory synapses is enhanced by inhalational anesthetics.<sup>63</sup> In a similar fashion, general anesthetics both enhance and depress inhibitory synaptic transmission in various preparations. In a classic article in 1975, Nicoll et al.<sup>64</sup> showed that barbiturates enhanced inhibitory synaptic transmission by prolonging the decay of the GABAergic inhibitory postsynaptic current. Enhancement of inhibitory transmission has also been observed with many other general anesthetics including etomidate,<sup>65</sup> propofol,<sup>66</sup> inhalational anesthetics,<sup>67</sup> and neurosteroids.<sup>68</sup> As discussed below, a growing body of genetic experiments in mice demonstrate that the potentiation of GABAergic inhibitory postsynaptic currents is necessary for a significant portion of the behavioral effects of each of these classes of

anesthetics.

## Presynaptic Effects

Neurotransmitter release at glutamatergic synapses has consistently been found to be inhibited by clinical concentrations of volatile anesthetics. For example, a study by Perouansky et al.<sup>69</sup> conducted in mouse hippocampal slices showed that halothane inhibited excitatory postsynaptic potentials elicited by presynaptic electrical stimulation, but not those elicited by direct application of glutamate. This indicates that halothane must be acting to prevent the release of glutamate. MacIver and Roth<sup>63</sup> extended these observations by finding that the inhibition of glutamate release from hippocampal neurons is not due to effects at GABA-ergic synapses that could indirectly decrease transmitter release from glutamatergic neurons. Reduction of glutamate release by intravenous anesthetics has also been demonstrated, but the evidence is more limited and the effects potentially indirect.<sup>70,71</sup>

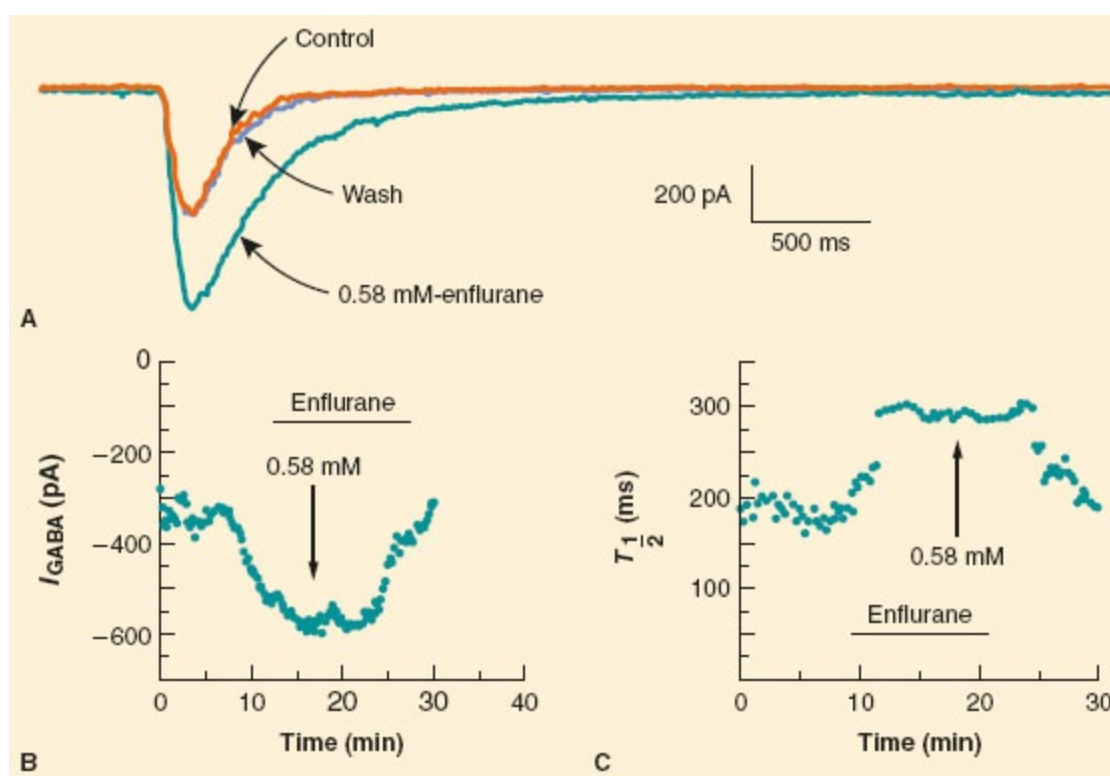

The data for anesthetic effects on inhibitory neurotransmitter release are mixed. Inhibition,<sup>72</sup> stimulation,<sup>73,74</sup> and no effect<sup>75</sup> on GABA release have been reported for both volatile and intravenous anesthetics. In a brain synaptosomal preparation where both GABA and glutamate release could be studied simultaneously, Westphalen and Hemmings<sup>76</sup> found that glutamate and, to a lesser degree, GABA release were inhibited by clinical concentrations of isoflurane. More recently the same group has shown that release from norepinephrine, dopamine, and acetylcholine-containing synaptosomes is also inhibited by isoflurane, although again less potently compared to glutamatergic synaptosomes.<sup>77</sup> The mechanism underlying anesthetic effects on transmitter release has not been established. The mechanism does not appear to involve reduced neurotransmitter synthesis or storage, but rather is a direct effect on neurosecretion. A variety of evidence argues that at some synapses a substantial portion of the anesthetic effect is upstream of the transmitter release machinery,<sup>78</sup> perhaps on presynaptic sodium channels or potassium leak channels (see later discussion). However, genetic data in *Caenorhabditis elegans* show that mutations in the transmitter release machinery strongly influence volatile anesthetic sensitivity.<sup>79,80</sup> Recent evidence in rodent preparations suggests that this mechanism may be conserved in mammals.<sup>81</sup>

## Postsynaptic Effects

At a variety of synapses, anesthetics alter the postsynaptic response to released neurotransmitter. Anesthetic modulation of excitatory neurotransmitter receptor function varies depending on the receptor type, anesthetic agent, and preparation. In a classic study, Richards and Smaje<sup>82</sup>

examined the effects of several anesthetic agents on the response of olfactory cortical neurons to application of glutamate, the major excitatory neurotransmitter in the CNS. They found that while pentobarbital, diethyl ether, methoxyflurane, and alphaxalone depressed the electrical response to glutamate, halothane did not. In contrast, when acetylcholine was applied to the same olfactory cortical preparation, halothane and methoxyflurane stimulated the electrical response, whereas pentobarbital had no effect; only alphaxalone depressed the electrical response to acetylcholine.<sup>82,83</sup>

Anesthetic modulation of neuronal responses to inhibitory neurotransmitters is more consistent. A wide variety of anesthetics, including barbiturates, etomidate, neurosteroids, propofol, and the fluorinated volatile anesthetics, have been shown to potentiate the electrical response to exogenously applied GABA (for reviews, see Refs.<sup>84,85</sup>). For example, [Figure 10-2](#) illustrates the ability of enflurane to increase both the amplitude and the duration of the current elicited by application of GABA to hippocampal neurons.<sup>86</sup>

**Figure 10-2** Enflurane potentiates the ability of GABA ( $\gamma$ -aminobutyric acid) to activate a chloride current in cultured rat hippocampal cells. This potentiation is rapidly reversed by removal of enflurane (wash; **A**). Enflurane increases both the amplitude of the current (**B**) and the time ( $\tau_{1/2}$ ) it takes for the current to decay (**C**). (Reproduced with permission from Jones MV, Brooks PA, Harrison L. Enhancement of  $\gamma$ -aminobutyric acid-activated  $\text{Cl}^-$  currents in cultured rat hippocampal neurones by three volatile anaesthetics. *J Physiol.* 1992;449:289.)

## Summary

Anesthetics alter the two fundamental determinants of neuronal communication, neuronal excitability and synaptic transmission. Anesthetics have powerful and widespread effects on synaptic transmission that would logically contribute to general anesthesia. Thus, the synapse is generally thought to be the more relevant site of anesthetic action. Existing evidence indicates that even at the synapse, anesthetics have diverse actions, including presynaptic inhibition of neurotransmitter release, inhibition of excitatory neurotransmitter effect, and enhancement of inhibitory neurotransmitter effect. Furthermore, the synaptic effects of anesthetics differ among various anesthetic agents, neurotransmitters, and neuronal preparations.

## Anesthetic Actions on Ion Channels

Ion channels are a likely target of anesthetic action. The advent of patch clamp techniques in the early 1980s made it possible to measure directly the currents from single ion channel proteins. Accordingly, during the 1980s and 1990s a major effort was directed at describing the effects of anesthetics on the various kinds of ion channels. The following section summarizes and distills this effort. For the purposes of this discussion, ion channels are cataloged according to the stimuli to which they respond by opening or closing (i.e., their mechanism of gating).

## Anesthetic Effects on Voltage-dependent Ion Channels

A variety of ion channels can sense a change in membrane potential and respond by either opening or closing their pores. These channels include voltage-dependent sodium, potassium, and calcium channels, all of which share significant structural homologies. Voltage-dependent sodium and potassium channels are largely involved in generating and shaping action potentials. The effects of anesthetics on these channels have been extensively studied by Haydon and Urban<sup>87</sup> in the squid giant axon. These studies show that these invertebrate sodium and potassium channels are remarkably insensitive to volatile anesthetics. For example, the halothane concentration required to inhibit 50% of the peak sodium channel current is eight times the halothane concentration required to produce anesthesia. The delayed rectifier potassium channel was even less sensitive, requiring halothane concentrations more than 20 times those required to produce anesthesia. Similar results have been obtained in a mammalian cell line (GH<sub>3</sub> pituitary cells) where both sodium and potassium currents were inhibited by halothane only at concentrations greater than five times those required to produce anesthesia.<sup>88</sup>

However, more recent studies with volatile anesthetics have challenged the notion that voltage-dependent sodium channels are insensitive to anesthetics.<sup>89</sup> Rehberg et al.<sup>90</sup> expressed rat brain IIA sodium channels in a mammalian cell line, and showed that clinically relevant concentrations of a variety of inhalational anesthetics suppressed voltage-elicited sodium currents. Ratnakumari and Hemmings<sup>91</sup> showed that sodium flux mediated by rat brain sodium channels was significantly inhibited by clinical concentrations of halothane. Shiraishi and Harris<sup>92</sup> documented the effects of isoflurane on a variety of sodium channel subtypes and found that several but not all subtypes are sensitive to clinical concentrations. Finally, as previously described, in a rat brainstem neuron, Wu et al.<sup>60</sup> found that a small inhibition of sodium currents by isoflurane resulted in a large inhibition of synaptic activity. Thus, sodium channel activity not only appears to be inhibited by volatile anesthetics, but this inhibition results in a significant reduction in synaptic function, at least at some mammalian synapses. Intravenous anesthetics have also been shown to inhibit sodium channels, but the concentrations for this effect are supraclinical.<sup>93,94</sup>

*Voltage-dependent calcium channels* (VDCCs) couple electrical activity to specific cellular functions. In the nervous system, VDCCs located at presynaptic terminals respond to action potentials by opening. This allows calcium to enter the cell, activating calcium-dependent secretion of neurotransmitter into the synaptic cleft. At least six types of calcium channels (designated L, N, P, Q, R, and T) have been identified on the basis of electrophysiologic properties, and a larger number based on amino acid sequence similarities. N-, P-, Q-, and R-type channels, as well as some of the untitled channels, are preferentially expressed in the nervous system and are thought to play a major role in synaptic transmission. L-type calcium channels, although expressed in brain, have been best studied in their role in excitation—contraction coupling in cardiac, skeletal, and smooth muscle and are thought to be less important in synaptic transmission. The anesthetics' actions on L- and T-type currents have been well characterized,<sup>88,95,96</sup> and some studies have reported effects of anesthetics on N- and P-type currents.<sup>97–99</sup> As a general rule, these studies have shown that volatile anesthetics inhibit VDCCs (50% reduction in current) at concentrations two to five times those required to produce anesthesia in humans, with less than a 20% inhibition of calcium current at clinical concentrations of anesthetics. However, some studies have found VDCCs that are extremely sensitive to anesthetics. Takenoshita and Steinbach<sup>100</sup> reported a T-type calcium current in dorsal root ganglion neurons that was inhibited by subanesthetic concentrations of halothane. Additionally, French-Mullen et al.<sup>101</sup> have reported a VDCC of unspecified type in guinea pig hippocampus that is inhibited by pentobarbital at concentrations identical to those required to

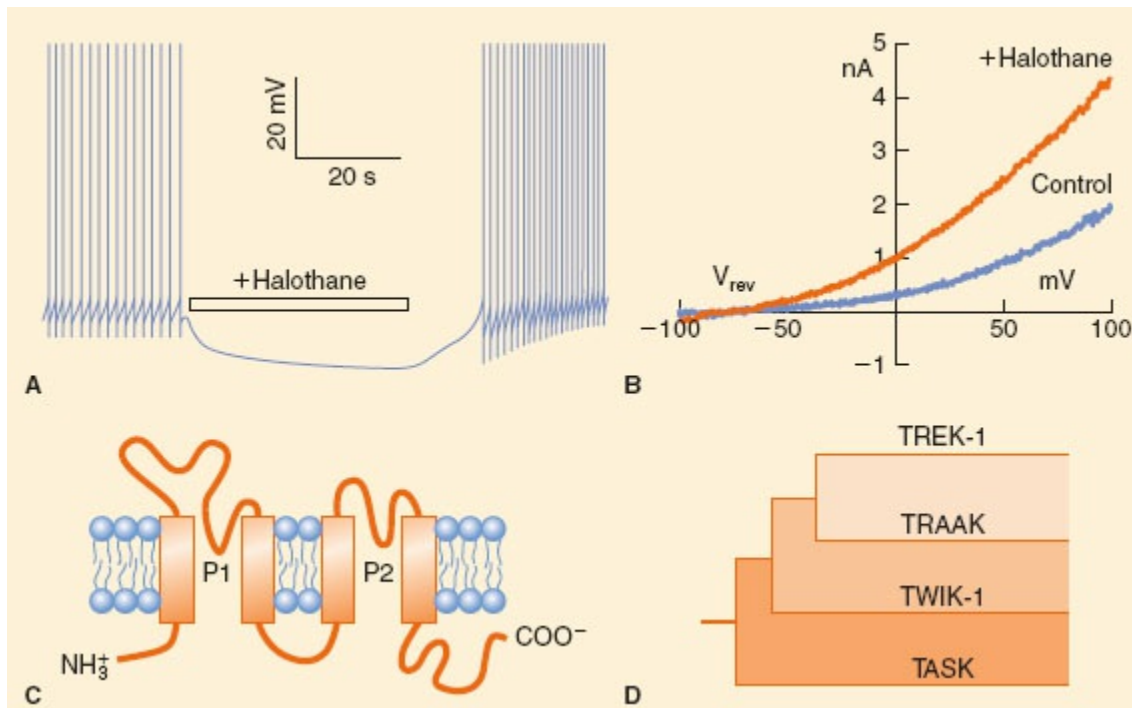

produce anesthesia. Thus, VDCCs could well mediate some actions of general anesthetics, but their general insensitivity makes them unlikely to be major targets.

*Potassium channels* are the most diverse of the ion channel types and include voltage-gated, background, or leak channels that open over a wide range of voltages, including the resting membrane potential of neurons, second messenger and ligand-activated, and so-called inward rectifying channels; some channels fall into more than one category. High concentrations of both volatile anesthetics and intravenous anesthetics are required to significantly affect the function of voltage-gated K<sup>+</sup> channels.<sup>87,102,103</sup> Similarly, classic inward rectifying K<sup>+</sup> channels are relatively insensitive to sevoflurane and barbiturates.<sup>104–106</sup> However, some background K<sup>+</sup> channels are quite sensitive to volatile anesthetics.

*Background or leak K<sup>+</sup> channels* are activated by both volatile and gaseous anesthetics.<sup>107,108</sup> Background or leak channels are so named because they tend to be open at all voltages including the resting membrane potential of neurons, producing a “leak current.” Leak currents can significantly 8 regulate the excitability of neurons in which they are expressed. Anesthetic activation of a leak channel was first observed in a ganglion of the pond snail, *Lymnea stagnalis*.<sup>109</sup> Clinical concentrations of halothane activated this channel called I<sub>K(AN)</sub>, resulting in silencing of the spontaneous bursting of these neurons (Fig. 10-3A). A similar anesthetic-activated background potassium channel was subsequently found by Winegar and Yost<sup>110</sup> in the marine mollusk *Aplysia*. The importance of volatile anesthetic activation of these invertebrate potassium channels has now become apparent with the discovery of a large family of background potassium channels in mammals. These mammalian potassium channels share a unique structure with two pore-forming domains in tandem, plus four transmembrane segments (2P/4TM; Fig. 10-3C,D).<sup>111</sup> Patel et al.<sup>112</sup> have studied the effects of volatile anesthetics on several members of the mammalian 2P/4TM family. They have shown that TREK-1 channels are activated by clinical concentrations of chloroform, diethyl ether, halothane, and isoflurane (Fig. 10-3B). In contrast, closely related TRAAK channels are insensitive to all the volatile anesthetics, and TASK channels are activated by halothane and isoflurane, inhibited by diethyl ether, and unaffected by chloroform. These authors further showed that the C-terminal regions of TASK and TREK-1 contain amino acids essential for anesthetic action. TREK-1 but not TASK was found to be activated by clinical concentrations of the gaseous anesthetics xenon, nitrous oxide, and cyclopropane.<sup>113</sup> Thus, activation of background K<sup>+</sup> channels in mammalian vertebrates could be an important and general mechanism through which inhalational and gaseous anesthetics regulate neuronal resting membrane potential and thereby excitability. Indeed, genetic evidence argues for a role

of these channels in producing anesthesia (see later discussion).

**Figure 10-3** Volatile anesthetics activate background  $K^+$  channels. **A:** Halothane reversibly hyperpolarizes a pacemaker neuron from *Lymnaea stagnalis* (the pond snail) by activating  $I_{Kan}$ . **B:** Halothane (300  $\mu M$ ) activates human recombinant TREK-1 channels expressed in COS cells. The figure shows current–voltage relationships with reversal potential ( $V_{rev}$ ) of  $-88$  mV, indicative of a  $K^+$  channel. **C:** Predicted structure of a typical subunit of the mammalian background  $K^+$  channels. Note the four transmembrane spanning segments (orange rectangles) and the two pore-forming domains (P1 and P2). Some, but not all of these 2P/4TM  $K^+$  channels are activated by volatile anesthetics. **D:** Phylogenetic tree for the 2P/4TM family. (Reproduced with permission from Franks NP, Lieb WR. Background  $K^+$  channels: an important target for anesthetics? *Nat Neurosci.* 1999;2:395.)

*Hyperpolarization-activated cyclic nucleotide-gated channels* (HCN channels) are a relatively recently discovered channel type that is modulated by clinical concentrations of both volatile and some intravenous anesthetics. HCN channels pass a depolarizing current (termed  $I_h$  in the CNS) consisting of a mix of sodium and potassium ions and are activated by membrane hyperpolarization, the voltage dependence of which is shifted to a more depolarized range with the second messenger cyclic AMP.<sup>114</sup> Therefore, cAMP activates HCN channels under most physiologic conditions. HCN channels are composed of homomeric and heteromeric combinations of four subunits—HCN1, 2, 3, 4, all of which are expressed in both brain and heart. HCN channels have been shown to regulate resting membrane potential and rhythmic firing of both the sinoatrial node and spontaneously spiking neurons. Thus, they are important for synchronous oscillations of neuronal

networks.<sup>114</sup>

Volatile anesthetics, propofol, and ketamine have been shown to inhibit HCN-mediated currents in both cell culture and native mouse neurons. The Bayliss group has shown that halothane shifted to more negative membrane potentials the voltage-dependent activation of the  $I_h$  current, and also inhibited its maximal amplitude.<sup>115</sup> Expression of HCN1 and HCN2 homomeric channels in cultured cells showed that halothane altered voltage-dependence of activation of HCN1 channels while reducing the maximal amplitude of HCN2 currents. In isolated spinal motor neurons, halothane reduced the  $I_h$  current, consistent with inhibition of HCN channels. Similar inhibition of HCN1 channels was subsequently observed with clinical concentrations of propofol and ketamine.<sup>116,117</sup> The inhibition of HCN1 by ketamine was stereoselective in the same manner as its stereoselectivity for general anesthesia.<sup>116</sup> Notably in this same study, etomidate was not found to inhibit HCN1 channel activation. Thus, HCN1 channels may be important for the actions of both volatile anesthetics and a subset of intravenous anesthetics. Genetic experiments described below argue that anesthetic inhibition of HCN1 and HCN2 channels may contribute to anesthesia.

## Summary

Existing evidence suggests that most VDCCs are modestly sensitive or insensitive to anesthetics. However, some sodium channel subtypes are inhibited by volatile anesthetics, and this effect may be responsible in part for a reduction in neurotransmitter release at some synapses. Recent evidence suggests that members of the 2P/4TM family of background potassium channels may be important in producing some components of the anesthetic state. Additionally, the HCN family of channels has emerged as a potentially relevant anesthetic target for both volatile and intravenous anesthetics.

## Anesthetic Effects on Ligand-gated Ion Channels

Fast excitatory and inhibitory neurotransmission is mediated by the actions of ligand-gated ion channels. Synaptically released glutamate or GABA diffuse across the synaptic cleft and bind to channel proteins that open as a consequence of neurotransmitter release. The channel proteins that bind GABA (GABA<sub>A</sub> receptors) are members of a superfamily of structurally related ligand-gated ion channel proteins that include nicotinic acetylcholine receptors, glycine receptors, and 5-HT<sub>3</sub> receptors. Based on the structure of the nicotinic acetylcholine receptor, each ligand-gated channel is thought to be composed of five subunits. The glutamate receptors comprise another family, with each receptor thought to be a tetrameric protein composed of

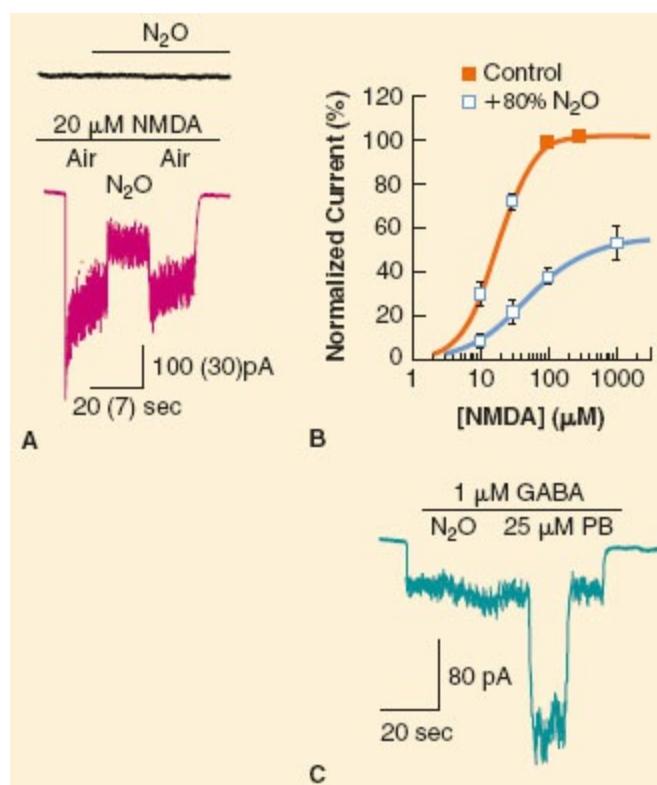

structurally related subunits. These ligand-gated ion channels provide a logical target for anesthetic action because selective effects on these channels could inhibit fast excitatory synaptic transmission and/or facilitate fast inhibitory synaptic transmission. The effects of anesthetic agents on ligand-gated ion channels have been thoroughly cataloged in several reviews.<sup>34,84,118,119</sup> The following section provides a brief summary of this large body of work.

## Glutamate-activated Ion Channels

Glutamate-activated ion channels have been classified, based on selective agonists, into three categories: AMPA receptors, kainate receptors, and NMDA receptors. AMPA and kainate receptors are relatively nonselective monovalent cation channels involved in fast excitatory synaptic transmission, whereas NMDA channels conduct not only Na<sup>+</sup> and K<sup>+</sup>, but also Ca<sup>++</sup>. They are involved in long-term modulation of synaptic responses (long-term potentiation). Studies from the early 1980s in mouse and rat brain preparations showed that AMPA- and kainate-activated currents are insensitive to clinical concentrations of halothane,<sup>120</sup> enflurane,<sup>121</sup> and the neurosteroid allopregnanolone.<sup>122</sup> In contrast, kainate- and AMPA-activated currents were shown to be sensitive to barbiturates. In rat hippocampal neurons, 50 μM pentobarbital (pentobarbital produces anesthesia at approximately 50 μM) inhibited kainate and AMPA responses by 50%.<sup>122</sup> Studies using cloned and expressed glutamate receptor subunits show that submaximal agonist responses of GluR3 (AMPA-type) receptors are inhibited by fluorinated volatile anesthetics, whereas agonist responses of GluR6 (kainate-type) receptors are enhanced.<sup>123</sup> In contrast, both GluR3 and GluR6 receptors are inhibited by pentobarbital. The directionally opposite effects of the volatile anesthetics on different glutamate receptor subtypes may explain the earlier inconclusive effects observed in tissue, where multiple subunit types are expressed. These opposite effects have also been used as a strategy to identify critical sites on the molecules involved in anesthetic effect. By producing GluR3/GluR6 receptor chimeras (receptors made up of various combinations of sections of the GluR3 and GluR6 receptors) and screening for volatile anesthetic effect, specific areas of the protein required for volatile anesthetic potentiation of GluR6 have been identified. Subsequent site-directed mutagenesis studies have identified a specific glycine residue (Gly-819) as critical for volatile anesthetic action on GluR6-containing receptors.<sup>124</sup>

NMDA-activated currents are also sensitive to a subset of anesthetics. Electrophysiologic studies show virtually no effects of clinical concentrations of volatile anesthetics,<sup>120,121</sup> neurosteroids, or barbiturates<sup>122</sup> on NMDA-activated currents. On the other hand, biochemical flux studies have shown

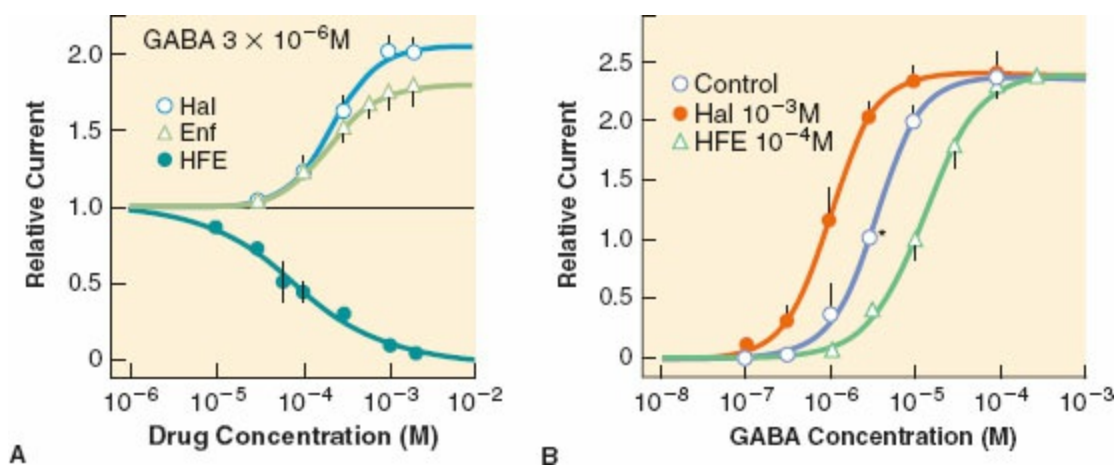

that volatile anesthetics may inhibit NMDA-activated channels. A study in rat brain microvesicles showed that anesthetic concentrations (0.2 to 0.3 mM) of halothane and enflurane inhibited NMDA-activated calcium flux by 50%.<sup>125</sup> Ketamine is a potent and selective inhibitor of NMDA-activated currents. Ketamine stereoselectively inhibits NMDA currents by binding to the phencyclidine site on the NMDA receptor protein.<sup>126–128</sup> The anesthetic effects of ketamine in intact animals show the same stereoselectivity as that observed in vitro,<sup>29</sup> consistent with the hypothesis that the NMDA receptor is a relevant molecular target for the anesthetic actions of ketamine. Two other recent findings suggest that NMDA receptors may also be an important target for nitrous oxide and xenon. These studies show that N<sub>2</sub>O<sup>129,130</sup> and xenon<sup>131</sup> are potent and selective inhibitors of NMDA-activated currents. This is illustrated in Figure 10-4, showing that N<sub>2</sub>O inhibits NMDA-elicited, but not GABA-elicited, currents in hippocampal neurons.

**Figure 10-4** Nitrous oxide inhibits NMDA-elicited, but not GABA-elicited currents in rat hippocampal neurons. **A:** Eighty percent N<sub>2</sub>O has no effect on holding current (upper trace), but inhibits the current elicited by NMDA. **B:** N<sub>2</sub>O causes a rightward and downward shift of the NMDA concentration–response curve, indicating a mixed competitive/noncompetitive antagonism. **C:** Eighty percent N<sub>2</sub>O has little effect on GABA-elicited currents. In contrast, an equipotent anesthetic concentration of pentobarbital markedly enhances the GABA-elicited current. (Reproduced with permission from Jevtovic-Todorovic V, Todorovic SM, Mennerick S, et al. Nitrous oxide (laughing gas) is an NMDA antagonist, neuroprotectant, and neurotoxin. *Nat Med.* 1998;4:460.)

## GABA-activated Ion Channels

GABA is the most important inhibitory neurotransmitter in the mammalian CNS. GABA-activated ion channels (GABA<sub>A</sub> receptors) mediate the postsynaptic response to synaptically released GABA by selectively allowing chloride ions to enter, and thereby hyperpolarize neurons. GABA<sub>A</sub> receptors are pentameric multi-subunit proteins consisting of various combinations of  $\alpha$ ,  $\beta$ ,  $\delta$ , and  $\gamma$  subunits, and there are many subtypes of each of these subunits. The function of GABA<sub>A</sub> receptors is modulated by a wide variety of pharmacologic agents including convulsants, anticonvulsants, sedatives, anxiolytics, and anesthetics.<sup>84</sup> The effects of these various drugs on GABA<sub>A</sub> receptor function varies across brain regions and cell types. The following section briefly reviews the effects of anesthetics on GABA<sub>A</sub> receptor function.

**Figure 10-5** The effects of halothane (Hal), enflurane (Enf), and fluorothyl (HFE) on GABA-activated chloride currents in dissociated rat CNS neurons. **A:** Clinical concentrations of halothane and enflurane potentiate the ability of GABA to elicit a chloride current. The convulsant fluorothyl antagonizes the effects of GABA ( $\gamma$ -aminobutyric acid). **B:** GABA causes a concentration-dependent activation of a chloride current. Halothane shifts the GABA concentration–response curve to the left (increases the apparent affinity of the channel for GABA), whereas fluorothyl shifts the curve to the right (decreases the apparent affinity of the channel for GABA). (Reproduced with permission from Wakamori M, Ikemoto Y, Akaike N. Effects of two volatile anesthetics and a volatile convulsant on the excitatory and inhibitory amino acid responses in dissociated CNS neurons of the rat. *J Neurophysiol.* 1991;66:2014.)

Barbiturates, anesthetic steroids, benzodiazepines, propofol, etomidate, and the volatile anesthetics all modulate GABA<sub>A</sub> receptor function.<sup>86,132–135</sup> These drugs produce three kinds of effects on the electrophysiologic behavior of the GABA<sub>A</sub> receptor channels: potentiation, direct gating, and inhibition. *Potentiation* refers to the ability of anesthetics to increase markedly the current elicited by low concentrations of GABA. Potentiation is illustrated in [Figure 10-5](#), showing the effects of halothane on currents elicited by a range

of GABA concentrations in dissociated cortical neurons. Anesthetic potentiation of GABA<sub>A</sub> currents generally occurs at concentrations of anesthetics within the clinical range. *Direct gating* refers to the ability of anesthetics to activate GABA<sub>A</sub> channels in the absence of GABA. Generally, direct gating of GABA<sub>A</sub> currents occurs at anesthetic concentrations higher than those used clinically, but the concentration–response curves for potentiation and for direct gating can overlap. It is not known whether direct gating of GABA<sub>A</sub> channels is either required for or contributes to the effects of anesthetics on GABA-mediated inhibitory synaptic transmission in vivo. In the case of anesthetic steroids, strong evidence indicates that potentiation, rather than direct gating of GABA<sub>A</sub> currents, is required for producing anesthesia.<sup>30</sup> Anesthetics can also inhibit GABA-activated currents. *Inhibition* refers to the ability of anesthetics to prevent GABA from initiating current flow through GABA<sub>A</sub> channels, and has generally been observed at high concentrations of both GABA and anesthetics.<sup>136,137</sup> Inhibition of GABA<sub>A</sub> channels may help to explain why volatile anesthetics have, in some cases, been observed to inhibit rather than facilitate inhibitory synaptic transmission.<sup>138</sup>

Effects of anesthetics have also been observed on the function of single GABA<sub>A</sub> channels. These studies show that barbiturates,<sup>135</sup> propofol,<sup>133</sup> and volatile anesthetics<sup>139</sup> do not alter the conductance (rate at which ions traverse the open channel) of the channel; instead, they increase the frequency with which the channel opens and/or the average length of time that the channel remains open. Collectively, the whole cell and single channel data are most consistent with the idea that clinical concentrations of anesthetics produce a change in the conformation of GABA<sub>A</sub> receptors that increases the affinity of the receptor for GABA. This is consistent with the ability of anesthetics to increase the duration of inhibitory postsynaptic potentials, since higher affinity binding of GABA would slow the dissociation of GABA from postsynaptic GABA<sub>A</sub> channels. Anesthetics would not be expected to increase the peak amplitude of a GABAergic inhibitory postsynaptic potential, since synaptically released GABA probably reaches very high concentrations in the synapse. Higher concentrations of anesthetics can produce additional effects, either directly activating or inhibiting GABA<sub>A</sub> channels. For example, a study by Banks and Pearce<sup>140</sup> showed that isoflurane and enflurane simultaneously increased the duration and decreased the amplitude of GABAergic inhibitory postsynaptic currents in hippocampal slices.

Despite the similar effects of many anesthetics on GABA<sub>A</sub> receptor function, different anesthetics act on distinct subtypes of GABA<sub>A</sub> receptors. This is well illustrated for benzodiazepine sensitivity, which requires the presence of the  $\gamma_2$  subunit subtype.<sup>141</sup> Sensitivity to etomidate has been shown to require the presence of a  $\beta_2$  or  $\beta_3$  subunit.<sup>142</sup> The presence of a  $\delta$  or

subunit in a GABA<sub>A</sub> receptor has been shown to confer insensitivity to the potentiating effects of some anesthetics.<sup>143,144</sup> Interestingly, GABA<sub>A</sub> receptors composed of  $\rho$ -type subunits (referred to as *GABA<sub>C</sub> receptors*) have been shown to be inhibited rather than potentiated by volatile anesthetics.<sup>145</sup> This property has been exploited to construct chimeric receptors composed of part of the  $\rho$ -receptor coupled to part of an  $\alpha$ ,  $\beta$ , or glycine receptor subunit. By screening these chimeras for anesthetic sensitivity, regions of the  $\alpha$ ,  $\beta$ , and glycine subunits responsible for anesthetic sensitivity have been identified. Based on the results of these chimeric studies, site-directed mutagenesis studies were performed to identify the specific amino acids responsible for conferring anesthetic sensitivity. These studies revealed two critical amino acids, near the extracellular regions of transmembrane domains 2 and 3 (TM2, TM3) of the glycine and GABA<sub>A</sub> receptors, that are required for volatile anesthetic potentiation of agonist effect.<sup>146</sup> It is not yet clear if these amino acids represent a volatile anesthetic binding site, or whether they are sites critical to transducing anesthetic-induced conformational changes in the receptor molecule. Interestingly, one of the amino acids shown to be critical to volatile anesthetic effect (TM3 site) has also been shown to be required (in the  $\beta_2/\beta_3$  subunit) for the potentiating effects of etomidate.<sup>147</sup> In contrast, the TM2 and TM3 sites do not appear to be required for potentiation by propofol, barbiturates, or neurosteroids.<sup>148</sup> A distinct amino acid in the TM3 region of the  $\beta_1$  subunit of the GABA<sub>A</sub> receptor has been shown to selectively modulate the ability of propofol to potentiate GABA agonist effects. Neurosteroid effects on GABA<sub>A</sub> receptors occur via interactions with specific sites within the transmembrane spanning regions of the  $\alpha_1$  and  $\beta_2$  subunits, distinct from those in which benzodiazepines and pentobarbital act.<sup>149</sup> Collectively, these data provide strong evidence that anesthetics act at multiple unique sites on the GABA<sub>A</sub> receptor protein.

## Other Ligand-activated Ion Channels

Ligand-gated receptors structurally similar to the GABA<sub>A</sub> receptor, including the nicotinic acetylcholine receptors (muscle and neuronal types), glycine receptors, and 5-HT<sub>3</sub> receptors, have been shown to be modulated by general anesthetics.<sup>150</sup> The muscle nicotinic receptor has served as a useful model because of its abundance and the wealth of knowledge about its structure. This nicotinic receptor subtype has been shown to be inhibited by anesthetic concentrations in the clinical range<sup>151</sup> and to be desensitized by higher concentrations of anesthetics.<sup>152</sup> Neuronal nicotinic receptors are structurally similar to the muscle type and are widely expressed in the mammalian CNS. Neuronal nicotinic receptors in molluscan neurons<sup>153</sup> and in bovine chromaffin cells<sup>154</sup> were found to be inhibited by clinical concentrations of

volatile anesthetics. Studies using cloned and expressed neuronal nicotinic receptor subunits have shown a high degree of subunit and anesthetic selectivity. In receptors composed of various combinations of  $\alpha_2$ ,  $\alpha_4$ ,  $\beta_2$ , and  $\beta_4$  subunits, acetylcholine-elicited currents are inhibited by *subanesthetic* concentrations of halothane<sup>155</sup> or isoflurane.<sup>156</sup> In contrast, these receptors are relatively insensitive to propofol, and receptors composed of only  $\alpha_7$  subunits are insensitive to both isoflurane and propofol.<sup>156,157</sup> Subsequent pharmacologic experiments using selective inhibitors of neuronal nicotinic receptors led to the conclusion that these receptors are unlikely to have a major role in immobilization by volatile anesthetics.<sup>158,159</sup> However, they might play a role in the amnestic or hypnotic effects of volatile anesthetics.<sup>160</sup>

Glycine is an important inhibitory neurotransmitter, particularly in the spinal cord and brainstem. The glycine receptor is a member of the ligand-activated channel superfamily that, like the GABA<sub>A</sub> receptor, is chloride-selective. A large number of studies have shown that clinical concentrations of volatile anesthetics potentiate glycine-activated currents in intact neurons<sup>120</sup> and in cloned glycine receptors expressed in oocytes.<sup>161,162</sup> Volatile anesthetics appear to produce their potentiating effect by increasing the affinity of the receptor for glycine, much like for GABA<sub>A</sub> receptors.<sup>161</sup> Propofol,<sup>133</sup> alphaxalone, and pentobarbital also potentiate glycine-activated currents, whereas etomidate and ketamine do not.<sup>162</sup> Potentiation of glycine receptor function may contribute to the anesthetic action of volatile anesthetics and some parenteral anesthetics.

The 5-HT<sub>3</sub> receptors are also members of the genetically related superfamily of ligand-gated receptor channels. Clinical concentrations of volatile anesthetics potentiate currents activated by 5-hydroxytryptamine in intact cells<sup>163</sup> and in cloned receptors expressed in oocytes.<sup>164</sup> In contrast, thiopental inhibits 5-HT<sub>3</sub> receptor currents<sup>163</sup> and propofol is without effect on these receptor channels.<sup>164</sup> The 5-HT<sub>3</sub> receptors may play some role in the anesthetic state produced by volatile anesthetics and may also contribute to some unpleasant anesthetic side effects such as nausea and vomiting.

## Summary

Several ligand-gated ion channels are modulated by clinical concentrations of anesthetics. Ketamine, N<sub>2</sub>O, and xenon inhibit NMDA-type glutamate receptors, and this effect may play a major role in their mechanism of action. A large body of evidence shows that many anesthetics potentiate GABA-  
**10** activated currents in the CNS. This suggests that GABA<sub>A</sub> receptors are a probable molecular target of anesthetics. Other members of the ligand-activated ion channel family, including glycine receptors, neuronal nicotinic receptors, and 5-HT<sub>3</sub> receptors, are also affected by anesthetics and remain

plausible anesthetic targets.

## How Are the Molecular Effects of Anesthetics Linked to Anesthesia in the Intact Organism?

The previous sections have described how anesthetics affect the function of a number of ion channels and signaling proteins, probably via direct anesthetic–protein interactions. However, these *in vitro* experiments do not allow for determining which, if any, of these effects of anesthetics on protein function are necessary and/or sufficient to produce anesthesia in an intact organism. A number of approaches have been employed to try to link anesthetic effects observed at a molecular level to anesthesia in intact animals. These approaches and their pitfalls are briefly explored in the following section.

### Pharmacologic Approaches

An experimental paradigm frequently used to study anesthetic mechanisms is to administer a drug thought to act specifically at a putative anesthetic target (e.g., a receptor agonist or antagonist, an ion channel activator or antagonist), then determine whether the drug has either increased or decreased the animal's sensitivity to a given anesthetic. The underlying assumption is that if a change in anesthetic sensitivity is observed, then the anesthetic is likely to act via an action on the specific target of the administered drug. However, conclusions from this approach must be tempered by a number of considerations. The drugs used to modulate anesthetic sensitivity usually have their own direct effects on CNS excitability and thus may *indirectly* affect anesthetic requirements. For example, while  $\alpha_2$ -adrenergic agonists decrease halothane MAC,<sup>165</sup> they are profound CNS depressants in their own right and produce anesthesia by mechanisms distinct from those used by volatile anesthetics. Thus, the “MAC-sparing” effects of  $\alpha_2$ -agonists provide little insight into how halothane works. A more useful pharmacologic strategy would be to identify drugs that have no effect on CNS excitability but prevent the effects of given anesthetics. Currently, however, there are no such anesthetic antagonists. Development of specific antagonists for anesthetic agents would provide a major tool for linking anesthetic effects at the molecular level to anesthesia in the intact organism, and might also be of significant clinical utility.

An alternative pharmacologic approach is to develop “litmus tests” for the relevance of anesthetic effects observed *in vitro*. One such test takes advantage of compounds that are nonanesthetic despite the predictions of the Meyer–Overton rule.<sup>23</sup> Another test uses anesthetic stereoselectivity as the discriminator, with the assumption that a target not affected with the same

stereoselectivity as that observed for whole animal anesthesia is unlikely to be relevant to the production of anesthesia.<sup>166</sup> Although these tests may increase the plausibility of a particular target, they cannot be used definitively to rule out a potential target. For example, a nonanesthetic might depress CNS excitability via its actions on an important anesthetic target site while simultaneously producing counterbalancing excitatory effects at a second site. In this case the “litmus test” would incorrectly eliminate the anesthetic site as irrelevant to whole-animal anesthesia. This example is quite plausible given the convulsant effects of many of the nonanesthetic polyhalogenated hydrocarbons. Likewise, anesthetics may act stereoselectively on some relevant targets and nonstereoselectively on others. Another sort of litmus test is to antagonize the putative anesthetic target. If anesthetic effects are mediated through this target, inactivation of the target by the antagonist should result in anesthetic resistance. Using this logic, the modest MAC-sparing effects of GABA<sub>A</sub> and glycine receptor antagonists were used to argue that both GABA<sub>A</sub> and glycine receptors mediate some but not all of the immobilizing effects of volatile anesthetics in rodents.<sup>167–169</sup> This same group used the lack of effect of neuronal nicotinic antagonists on isoflurane MAC to conclude that these receptors had no role in volatile anesthetic immobilization.<sup>158</sup> Issues of specificity and efficacy of the antagonists prevent these experiments from being definitive. Nevertheless, these results are important and consistent with the conclusions that volatile anesthetics affect the function of a large number of important neuronal proteins, and no one target is likely to mediate all of the effects of these drugs.

## Genetic Approaches

An alternative approach to study the relationship between anesthetic effects observed in vitro and whole-animal anesthesia is to alter the structure or abundance of putative anesthetic targets and determine how this affects whole-animal anesthetic sensitivity. While they also have potential flaws, genetic techniques provide the most specific and versatile methods for changing the structure or abundance of putative anesthetic targets. The first true genetic screen for mutants with altered general anesthetic sensitivity was performed in the nematode *C. elegans* by Phil Morgan and Margaret Sedensky.<sup>170</sup> They screened for altered sensitivity to immobilization of *C. elegans* by halothane, which occurs at supraclinical concentrations. The first mutant isolated had a threefold reduction in its EC<sub>50</sub> for halothane and had an interesting locomotion defect in the absence of halothane called *fainting*. Normal *C. elegans* worms crawl almost continuously whereas “fainter” mutants spontaneously stop moving for extended periods of time. In testing other previously isolated fainter mutants, Morgan and Sedensky found that, in

general, fainters were hypersensitive to halothane.<sup>171</sup> Subsequent genetic screens and mapping of fainting mutants have led to a focus on a novel presumptive cation channel, NCA-1/NCA-2, that controls halothane sensitivity in both *C. elegans* and in the fruit fly *Drosophila*.<sup>172</sup> This remarkable conservation of the anesthetic hypersensitivity phenotype across such divergent species argues for a fundamental role of NCA-1/NCA-2 in the action of halothane.

Clinical concentrations of volatile anesthetics do not immobilize *C. elegans*, but they do produce behavioral effects including loss of coordinated movement.<sup>173</sup> Crowder et al. have screened for mutants that are resistant to anesthetic-induced uncoordination and found that mutations in a set of genes encoding proteins regulating neurotransmitter release control anesthetic sensitivity.<sup>79,80</sup> The gene with the largest effect encoded syntaxin 1A, a neuronal protein highly conserved from *C. elegans* to humans and essential for fusion of neurotransmitter vesicles with the presynaptic membrane.<sup>80</sup> Importantly, some syntaxin mutations produced hypersensitivity to volatile anesthetics while others conferred resistance. These allelic differences in anesthetic sensitivity could not be accounted for by effects on the process of transmitter release itself; rather, the genetic data argued that syntaxin interacts with a protein critical for volatile anesthetic action, perhaps an anesthetic target. Subsequent experiments by others in rats have shown that expression of the same mutant syntaxin in cultured rat neurons reduces the potency of isoflurane at inhibiting neurotransmitter release in mammals.<sup>81</sup> A highly evolutionarily conserved presynaptic protein called UNC-13 in *C. elegans* has been implicated in this syntaxin-regulated volatile anesthetic mechanism.<sup>174</sup> *C. elegans unc-13* mutants are fully resistant to the effects of clinical concentrations of isoflurane, and isoflurane prevents the normal synaptic localization of UNC-13 in *C. elegans*. Whether UNC-13 is a direct target of volatile anesthetics is unknown. This same laboratory has also shown by mutant analysis that an NMDA glutamate receptor subunit is essential for nitrous oxide sensitivity in *C. elegans*<sup>175</sup> and that another glutamate receptor subunit is required for the effects of xenon.<sup>176</sup>

In *Drosophila*, clinical concentrations of volatile anesthetics disrupt negative geotaxis behavior and response to a noxious light or heat stimulus.<sup>177–179</sup> Using one or more of these anesthetics effects, Krishnan and Nash<sup>179</sup> performed a forward genetic screen for halothane resistance. The results of this screen have led to a focus on the *Drosophila* homolog of NCA-1/NCA-2. As previously discussed, mutants in the *Drosophila* homolog of NCA-1/NCA-2 are hypersensitive to halothane like the *C. elegans* mutants.<sup>172</sup> The synergy of both *Drosophila* and *C. elegans* genetics should lead to an understanding of how this channel controls volatile anesthetic sensitivity.

In mammals, the most powerful genetic model organism is the mouse,

where techniques have been developed to alter or delete any gene of interest. The GABA<sub>A</sub> receptor has been extensively studied using mouse genetic techniques.<sup>180</sup> Mice carrying mutations in  $\alpha$ ,  $\beta$ , and  $\delta$  GABA<sub>A</sub> receptor subunits have been tested for their effects on anesthetic endpoints (Table 10-1). For  $\alpha$  subunits, four knockout mutations (where the gene is fully inactivated), and one knockin mutation (where a functional but altered gene product is produced), have been examined. Knockout of the  $\alpha_1$  and  $\alpha_4$  subunits produced similar phenotypes, with a large reduction of the efficacy of isoflurane at blocking learning and memory tasks in the mutant mice compared to wild type controls.<sup>181–183</sup> Similarly, an  $\alpha_5$  knockout mouse was strongly resistant to the amnestic effects of etomidate.<sup>184</sup> The  $\alpha_1$  and  $\alpha_4$  knockouts also had small differences for halothane potency in assays of hypnosis. An  $\alpha_6$  knockout strain had normal sensitivities to halothane, enflurane, and pentobarbital in hypnosis and immobility assays.<sup>185</sup> A knockin  $\alpha_1$  mouse strain expressing a double mutated  $\alpha_1$ (S270H, L277A) subunit, has also been tested for its anesthetic sensitivity.<sup>186–188</sup> The  $\alpha_1$ (S270H) mutation had been shown to block GABA potentiation by volatile anesthetics,<sup>189</sup> but the mutation also increased native sensitivity to GABA, confounding interpretation of the data. Moreover,  $\alpha_1$ (S270H) single-mutant mice are quite abnormal behaviorally and are prone to anesthetic-induced seizure activity.<sup>190</sup> Thus, a second mutation, L277A, was introduced into the  $\alpha_1$  subunit that compensated for the change in native gating properties.<sup>186</sup> The  $\alpha_1$ (S270H, L277A) mice are viable and demonstrate grossly normal behavior. These mice are mildly resistant to the hypnotic effects of isoflurane, enflurane, and etomidate, as well as to the ataxic effects of etomidate; however, the potency of the drugs in MAC and fear-conditioning assays (a measure of learning) are not altered by the double-mutant  $\alpha_1$  subunit.

Bold indicates decreased sensitivity to that anesthetic; italics indicates lack of sensitivity.

While the anesthetic behavioral phenotypes of the α-subunit mutant mice were only incrementally different from wild type mice, β subunit mutants have profound differences for the intravenous anesthetics etomidate and propofol. The electrophysiologic experiments that formed the foundation for generation of the mutant mice showed that etomidate potently inhibited β<sub>2</sub>- and β<sub>3</sub>-containing GABA<sub>A</sub> receptors and was much less potent against β<sub>1</sub>-containing receptors.<sup>142,147</sup> Mouse β<sub>2</sub> and β<sub>3</sub> both differ from β<sub>1</sub> at amino residue 265 in the second transmembrane domain with an asparagine (N) in β<sub>2</sub> and β<sub>3</sub>, but a serine (S) in β<sub>1</sub> and a methionine (M) in an etomidate-insensitive insect GABA receptor. Electrophysiologic testing of recombinant β<sub>3</sub>(N265M) receptors revealed that these mutations blocked potentiation of the receptor by etomidate and propofol.<sup>147,191</sup> An important confirmation of the relevance of these *in vitro* studies came from Rudolph et al., who showed

that a mouse  $\beta_3$ (N265M) knockin strain was fully resistant to the immobilizing effects of etomidate, propofol, and pentobarbital (Fig. 10-6).<sup>192,193</sup> These results provided the first definitive link between an anesthetic *in vitro* action and a mammalian behavioral endpoint. However, the  $\beta_3$ (N265M) mice were not completely resistant to the hypnotic action of these anesthetics, indicating that other targets mediate this behavioral effect (Table 10-1). Interestingly, the respiratory depressant effects of etomidate and propofol are also blocked by the  $\beta_3$ (N265M) mutation, but the cardiovascular and hypothermic actions of the drugs are not.<sup>194,195</sup> The  $\beta_3$ (N265M) mice also have a modest reduction in sensitivity to the immobilizing actions of volatile anesthetics, suggesting that the  $\beta_3$  subunit may play a minor role in immobilization, but the mutant has unaltered sensitivity to the amnestic effects of isoflurane and propofol.<sup>194,196</sup> Additional evidence for the importance of the  $\beta_3$  subunit comes from selective knockout of  $\beta_3$  in mouse forebrain. In context fear conditioning assays (a measure of hippocampal-dependent memory formation), this strain was found to have an EC<sub>50</sub> for isoflurane of about threefold higher than that of the wild type strain.<sup>197</sup> The  $\beta_2$  subunit has also been shown to be important for anesthetic sensitivity. A  $\beta_2$ (N265S) mutant mouse has reduced sensitivity to etomidate, although no anesthetic endpoint is fully blocked by this mutation (Fig. 10-6).<sup>198,199</sup> Finally, strains carrying a knockout mutation of the  $\delta$  subunit of the GABA<sub>A</sub> receptor have a shorter duration of neurosteroid-induced loss-of-righting reflex, whereas their sensitivity to other intravenous and volatile anesthetics is unchanged.<sup>200</sup> Thus, the  $\delta$  subunit may play a relatively specific role in neurosteroid action.

The roles in anesthetic sensitivity of several background potassium channels have been tested in limited mouse genetic studies. A TREK-1 knockout mouse was found to be significantly, but not fully resistant to multiple volatile anesthetics for hypnotic and immobility endpoints.<sup>201</sup> The volatile anesthetic resistance of the TREK-1 knockout is substantial, particularly for halothane, where MAC was increased by 48%. Importantly, the TREK-1 knockout mice have a normal sensitivity to pentobarbital, indicating specificity for volatile anesthetics consistent with previous electrophysiologic data. Recently, Westphalen et al.<sup>202</sup> has used the TREK-1 knockout strain to test the hypothesis that TREK-1 mediates some of the presynaptic inhibitory effects of volatile anesthetics. Indeed, glutamate release from synaptosomes prepared from the TREK-1 knockout strain is significantly resistant to inhibition by halothane compared to release from wild type control synaptosomes. The role of TASK-2, another two-pore background potassium channel, has been similarly tested by measuring the MAC of a TASK-2 knockout mouse. However, unlike for TREK-1, the TASK-2 knockout has MAC values similar to wild type controls for desflurane,

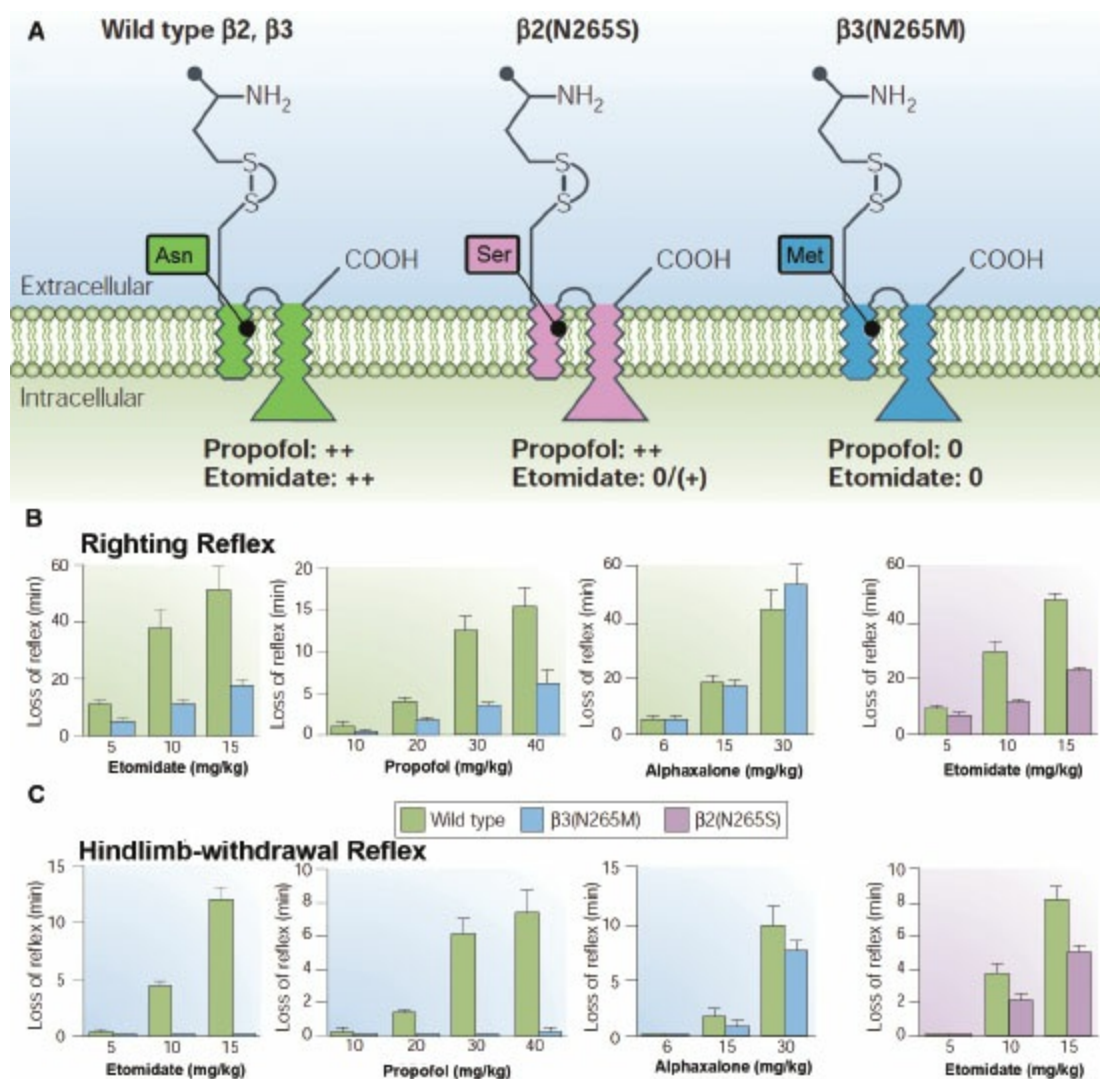

halothane, and isoflurane.<sup>104</sup> This result is somewhat surprising given that TASK-2 is strongly activated by halothane and isoflurane and may be explained by an overall reduced expression in the nervous system compared to TREK-1.<sup>107</sup> Knockout strains for TASK-1 and TASK-3 have modest, but significant volatile anesthetic resistance to hypnosis and immobility (Table 10-1),<sup>203–205</sup> consistent with a role for these channels in anesthesia.

Finally, both global and forebrain-specific knockout mouse strains of the HCN1 subunit and a global knockout of the HCN2 subunit have been generated and tested for their anesthetic sensitivity.<sup>48,116,206–208</sup> The HCN1 global knockout strain is strongly resistant to ketamine (85% increased ED<sub>50</sub>) and propofol (47% increased ED<sub>50</sub>) and normally sensitive to etomidate.<sup>116</sup> The lack of effect of etomidate indicates that the increase is not due to some nonspecific increase in sensitivities to all hypnotics. Both global and forebrain-specific HCN1 knockout strains were also mildly but significantly resistant to isoflurane and sevoflurane in assays of hypnosis and amnesia.<sup>206</sup> An HCN2 global knockout strain had reduced sensitivity to the effects of xenon on thalamic neuron currents, thalamocortical signaling, and sedation.<sup>207</sup>

## Summary

Results from both invertebrate and vertebrate genetics indicate that multiple proteins control volatile anesthetic sensitivity. Some of these may be anesthetic targets and some not. The evidence for  $\beta_3$ -containing GABA<sub>A</sub> receptors as relevant targets for etomidate and propofol, however, is quite strong. Both drugs potentiate  $\beta_3$ -containing receptors expressed heterologously; however, a missense mutation blocks this potentiation. Mice expressing this mutant receptor are fully resistant to immobilization by etomidate and propofol, but are normally sensitive to the neurosteroid anesthetic alfaxalone. Other anesthetic endpoints are not fully dependent on the  $\beta_3$  subunit, therefore other targets must be involved. For propofol and ketamine, but not etomidate, electrophysiologic and genetic data implicate the HCN1 channel as one such target. Volatile anesthetics appear to have multiple relevant targets, including GABA<sub>A</sub> receptors, some two-pore potassium channels, and HCN1 channels. Genetic evidence points to glutamate receptors and HCN2 channels as relevant to xenon's action. Other plausible anesthetic targets such as certain sodium channels, presynaptic proteins, and glycine receptors remain to be tested genetically in mice.

**Figure 10-6** Mutations in the  $\beta_2$  and  $\beta_3$  subunits of the GABA<sub>A</sub> receptor reduce sensitivity to etomidate and propofol. **A:** Knockin transgenic mice were generated with mutation of a conserved asparagine (Asn) in the second transmembrane domain to a serine (Ser) in the  $\beta_2$  subunit or a methionine (Met) in the  $\beta_3$  subunit. **B:** The sensitivities of the wild type and the two knockin mice strains were measured in a loss of righting reflex assay, which is thought to model hypnosis. Mutant sensitivities to etomidate and propofol are highly significantly different compared to wild type. The neurosteroid alphaxalone is equally potent in wild type and in the  $\beta_3(N265M)$  strain. **C:** The sensitivities of the wild type and the two knockin mice strains were measured in a hindlimb withdrawal reflex to a painful stimulus assay, which is thought to model immobility. Note the lack of significant sensitivities to either etomidate or propofol in the  $\beta_3(N265M)$  strain. (Adapted from Rudolph U, Antkowiak B. Molecular and neuronal substrates for general anaesthetics. *Nat Rev Neurosci*. 2004;5:709.)

## Where in the Central Nervous System Do Anesthetics Work?

### Immobility

Several lines of evidence indicate that the spinal cord is the main site at which anesthetics inhibit motor responses to noxious stimulation. This is, of

course, the endpoint used in most measurements of anesthetic potency. Rampil et al.<sup>209,210</sup> have shown that MAC values for fluorinated volatile anesthetics are unaffected in the rat by either decerebration<sup>209</sup> or cervical spinal cord transection.<sup>210</sup> Antognini and Schwartz<sup>211</sup> have used the strategy of isolating the cerebral circulation of goats to explore the contribution of brain and spinal cord to the determination of MAC. They found that when isoflurane is administered only to the brain, MAC is 2.9%, whereas when it is administered to the body and brain, MAC is 1.2%. Surprisingly, when isoflurane was preferentially administered to the body and not to the brain, isoflurane MAC was reduced to 0.8%,<sup>212</sup> suggesting that anesthetic action on the brain may actually sensitize the cord to noxious stimuli, through neurons in the mesencephalic locomotor region.<sup>213</sup> Anesthetic action at the spinal cord underlies MAC through multiple targets. Volatile anesthetics directly reduce excitatory synaptic transmission of spinal neurons.<sup>62,214–216</sup> Propofol depresses activity in ventral horn neurons via a GABAergic mechanism that can be blocked by the antagonist picrotoxin.<sup>217</sup> In contrast, while isoflurane inhibits both dorsal horn neurons and motoneurons, the mechanism appears to be independent of GABA receptors.<sup>217</sup> Isoflurane also suppresses interneurons of central pattern generators involved in coordinated movements.<sup>218</sup> Thus, anesthetics can alter descending, afferent, efferent, and modulatory limbs of reflex arcs for reacting to noxious stimulation.

## *Autonomic Control*

Anesthetics exert profound effects on cardiopulmonary and thermoregulatory homeostatic circuitry within autonomic centers in the brainstem and hypothalamus. Inspiratory neurons in the medulla drive phrenic motor neurons to activate diaphragmatic contraction. Halothane suppresses the spontaneous activity of these neurons in dogs by reducing glutamatergic input.<sup>219</sup> Anesthetics also perturb cardiovascular reflexes mediated by nuclei in the brainstem. For example, the nucleus ambiguus contains cardiac vagal neurons whose efferents are critical in the regulation of heart rate by the parasympathetic nervous system. In rats, both propofol and isoflurane augment the inhibitory potentials of cardiac vagal neurons in response to GABA.<sup>220</sup> Similarly, neurons in the nucleus of the solitary tract receive sensory input from carotid and aortic body baroreceptors; in vitro studies demonstrate GABA-mediated inhibition of these neurons by propofol<sup>221</sup> and isoflurane.<sup>222</sup>

## *Amnesia*

While the neurobiologic mechanisms underlying learning and memory remain

unclear, the hippocampus is a plausible anesthetic target for the suppression of memory formation. Bilateral resection of these structures induces anterograde amnesia, as demonstrated by the well-documented case of Henry Gustav Molaison, known as “Patient H.M.” Similarly, anesthetics ablate the formation of new memories and substantially alter neural activity, while leaving prior memories seemingly intact. Genetic and pharmacologic experiments support a crucial role of the hippocampus in the amnestic actions of anesthetics. The  $\alpha_5$  subtype of the GABA<sub>A</sub> receptor is primarily expressed in the hippocampus and controls synaptic transmission within this structure.<sup>223</sup> Hippocampal GABA receptors with  $\alpha_5$  subunits show conductances that are exquisitely sensitive to isoflurane<sup>224</sup> and mediate memory deficits that persist after anesthetic exposure.<sup>225</sup> Moreover,  $\alpha_5$  GABA<sub>A</sub> receptor knockout mice are resistant to amnestic effects of etomidate.<sup>184</sup> Thus,  $\alpha_5$  GABA<sub>A</sub> receptors in the hippocampus are targets of different anesthetic agents, with potential clinical significance for both intraoperative and postoperative amnesia.

## Unconsciousness

Consciousness is a complex state, which can be operationally divided into the **13** components of arousal and awareness that may have differential susceptibility to anesthetics.<sup>226</sup> *Awareness* is the ability to process and store information in order to interact with internal or external environment. In contrast, *arousal* or *wakefulness* is the state of receptivity to the external environment and is likely mediated through subcortical structures such as the reticular activating system (RAS) and other arousal centers (Fig. 10-7).

## Reticular Activating System and Arousal Centers

The RAS is a diffuse collection of brainstem neurons that mediate arousal, such that electrical stimulation in this structure arouses anesthetized animals.<sup>227</sup> The RAS includes the reticular formation, the tuberomammillary nucleus (TMN), the ventral tegmental area (VTA), and the thalamic intralaminar nucleus.

The reticular formation (RF) is a heterogeneous collection of neurons in the midbrain and pons involved in the regulation of arousal and sleep. Lesions of the midbrain RF can induce coma, while classic experiments by Moruzzi and Magoun have shown that electrical stimulation of the midbrain awakened sleeping animals. Similar stimulation paradigms in anesthetized animals induce EEG patterns of restored arousal in rats rendered unresponsive by halothane or isoflurane.<sup>228</sup> Lesions of the midbrain RF lead to coma. For the pontine RF, GABA levels are higher during wakefulness than in rapid eye movement (REM) sleep<sup>229</sup> or isoflurane-induced unconsciousness.<sup>230</sup> As the

manipulation of GABA levels in the pontine RF can prolong or shorten induction time,<sup>230</sup> the pontine RF remains a plausible direct target for ablation of arousal by anesthetic agents.

Within the hypothalamus, the TMN and the ventrolateral posterior optic nucleus (VLPO) are putative loci for anesthetic action in suppressing arousal (Fig. 10-7). These mutually inhibitory structures form a bistable control of wakefulness and nonrapid eye movement sleep.<sup>231</sup> The TMN is the sole source of excitatory histaminergic efferents in the CNS. Rats that have had bilateral lesions of the TMN or been treated with intraventricular injections of histamine receptor antagonists manifest both shortened induction and prolonged emergence with isoflurane.<sup>232</sup> Application of a GABAergic antagonist directly onto the TMN diminished the efficacy of the anesthetics propofol and pentobarbital.<sup>233</sup>  $\beta_3$ (N265M) GABA<sub>A</sub> receptor mutant mice also implicate this nucleus as a target of propofol; the inhibitory postsynaptic potentials of their TMN neurons and the hypnotic effects of propofol are reduced.<sup>234</sup> In addition to direct antagonism of the TMN, inhibitory afferents of the VLPO suppress the locus coeruleus (LC) and the perifornical area (PF) (Fig. 10-7). Although anesthetics have been shown to activate VLPO neurons, ablation of this structure does not chronically impair induction of general anesthesia.<sup>235</sup> Thus, the VLPO may contribute only indirectly to anesthetic-induced unconsciousness, whereas experimental support for the TMN as a site of anesthetic action is stronger.

**Figure 10-7** Diagram of subcortical arousal circuitry implicated in anesthetic-induced unconsciousness. The tuberomammillary nucleus (TMN) and ventrolateral preoptic nucleus (VLPO) form a bistable sleep/wake switch. The TMN also provides histaminergic output to the cerebral cortex and enhances excitatory cholinergic release from the nucleus basalis of Meynert (NBM). Orexin release from perifornical area (PF)

stabilizes the VLPO/TMN sleep switch and plays a key role in modulating outputs of the dopaminergic ventral tegmental area (VTA), the noradrenergic locus coeruleus (LC), and thalamic outputs involved in maintaining recurrent thalamocortical excitability and the integrity of networks linking distributed cortical areas. Ox, orexin; Nor, norepinephrine; His, histamine; GABA,  $\gamma$ -aminobutyric acid; ACh, acetylcholine; DA, dopamine.

The PF in the lateral hypothalamus appears to be critical in anesthetic emergence, rather than induction of unconsciousness. It is the sole source of orexin, a neurotransmitter that stabilizes the flip-flopping of the VLPO/TMN sleep switch to favor activation of the arousal-promoting TMN (Fig. 10-7). Orexin knockout animals show frequent sleep/wake transitions akin to narcolepsy. In rodents anesthetized by isoflurane, intraventricular injections of orexin A shift the EEG from burst-suppression to arousal-like patterns.<sup>236</sup> Shortened emergence from propofol<sup>234,237</sup> or dexmedetomidine<sup>234</sup> can also be induced by orexin-A injections into CSF. While ablation of arousal by either isoflurane or sevoflurane is not affected in orexin knockout animals, recovery from anesthesia is delayed,<sup>238</sup> suggesting asymmetry in the neural mechanisms underlying induction and emergence.

Suppression of the nucleus basalis of Meynert (NBM) is likely important in mediating anesthetic suppression of arousal and awareness. The NBM receives input from arousal centers (Fig. 10-7) and is the major source of excitatory cholinergic input to the thalamus, RAS, and the cerebral cortex. Norepinephrine infused into the NBM induces arousal in rats with righting reflexes ablated by desflurane.<sup>239</sup> Activation of the NBM by histamine reverses EEG slowing<sup>232</sup> and accelerates emergence from isoflurane, but not intravenous anesthetics.<sup>240</sup> Whether the NBM represents a target specific for volatile agents remains an open question.

The VTA provides dopaminergic inputs to the prefrontal cortical areas, the hippocampus, and amygdala. In contrast, the LC within the pons is the primary adrenergic source to the cortex, thalamus, and hypothalamus (Fig. 10-7). Dual inhibitors of these two pathways restore righting reflex in isoflurane-anesthetized rats.<sup>7</sup> Recent data highlight the importance of the VTA and the dopamine D1 receptor in isoflurane,<sup>241</sup> sevoflurane,<sup>242</sup> and propofol anesthesia. LC activation prolongs induction, antagonizes cortical suppression during anesthetic maintenance, and facilitates emergence through  $\alpha_1$  adrenergic receptor mechanisms.<sup>243</sup> These studies suggest that both the VTA and LC play important roles in anesthetic unconsciousness.

## Thalamus

The thalamus regulates widespread cortical excitability and relays information

to specialized cortical regions, and is a likely target for anesthetic ablation of arousal and awareness.<sup>244</sup> Anesthetic agents do not appear to induce thalamic deafferentation in relay nuclei for vision (lateral geniculate nucleus) or other sensory modalities; peripheral sensory stimulation leads to activation of corresponding cortical areas during general anesthesia<sup>245</sup> and even burst suppression.<sup>246</sup> In contrast, neurons in the thalamic reticular nuclei (TRN) and medial thalamic nuclei remain plausible potential anesthetic targets. TRN neurons process excitatory input from the cerebral cortex, dorsal thalamic nuclei, and the RAS. They are in a key position to dampen recurrent loops between thalamic and cortical neurons.<sup>244</sup> While TRN neurons are inhibited by etomidate<sup>247</sup> and isoflurane,<sup>248</sup> demonstration of their role in vivo has not been reported. Elsewhere in the thalamus, stimulation or ablation of the centromedian nuclei alter attention and arousal. Microinfusions targeting Kv1.2 potassium channels<sup>249</sup> or nicotinic cholinergic receptors<sup>250</sup> in these regions reverse volatile anesthetic hypnosis. Correlated neural activity between midline thalamic regions and cortical regions involved in attention and introspection are weakened in humans rendered unconscious by propofol<sup>251</sup> or sevoflurane.<sup>252</sup> Future study will elucidate whether anesthetics induce unconsciousness primarily at these thalamic nuclei, in their recurrent interactions with specific cortical regions, or within the cerebral cortical regions mediating awareness of space and time.

## **Cerebral Cortex**

The cerebral cortex is the major site for generating awareness of the external environment. Primary sensory areas provide focused, feed-forward activity to association and “higher” cortical areas that provide reciprocal diffuse feedback.

The disruption of feedback connections by anesthetics may contribute to impaired consciousness by attenuating the integration of information distributed among cortical regions. The late components of rat visual neuron responses to flashed stimuli are attenuated by desflurane.<sup>253</sup> These high latency responses are associated with feedback activity and mediate contextual modulation from higher cortical areas. Electrode recordings in rats have also compared the directional bias of activity between frontal and parietal cortical areas in both awake and anesthetized states. While interactions are balanced during wakefulness, feedback interactions were preferentially diminished when rats were anesthetized by isoflurane.<sup>254</sup> Human fMRI<sup>255–257</sup> and EEG studies have yielded similar findings of reduced feedback from frontal to posterior areas, with propofol,<sup>258–261</sup> sevoflurane,<sup>262</sup> or ketamine.<sup>261</sup> Direct evidence to substantiate this mechanism is pending.

The effects of anesthetics on both cortical firing rates and timing of action

potentials may contribute to the ablation of awareness by limiting both the diversity of information that can be represented and the integration of neural information.<sup>1</sup> Anesthetics alter the topology of distinct networks of distributed cortical areas subserving attention and higher cognitive processes through patterns of correlated activity. With induction of propofol- or sevoflurane-induced unconsciousness, two such networks have shown weaker correlations among constituent cortical areas: the default mode network,<sup>252,255</sup> associated with memory and consciousness,<sup>263,264</sup> and the ventral attention network,<sup>252,256,265</sup> linked with externally directed attention.<sup>266,267</sup> These networks represent potential cortical targets of anesthetic action. The weakening of correlated brain activity between regions of different networks<sup>255,256</sup> suggests that the blurring of boundaries between specialized groups of cortical areas may also contribute to impaired consciousness.

Anesthetics weaken high-frequency synchronized oscillatory cortical activity involved in integrating information into coherent representations.<sup>268</sup> In rats, isoflurane reduces high gamma range (70 to 140 Hz) synchrony in the frontal cortex, visual cortex, and hippocampus.<sup>269</sup> Recordings from humans implanted with subdural electrocorticographic electrodes revealed a reduction in high gamma band power (>75 Hz) on induction with propofol and recovery during emergence from propofol.<sup>270</sup> Analysis of EEG from humans rendered unresponsive by propofol revealed a reduction in information integration in the gamma band,<sup>258</sup> and multiple anesthetic agents cause widespread reduction in gamma band power.<sup>271</sup>

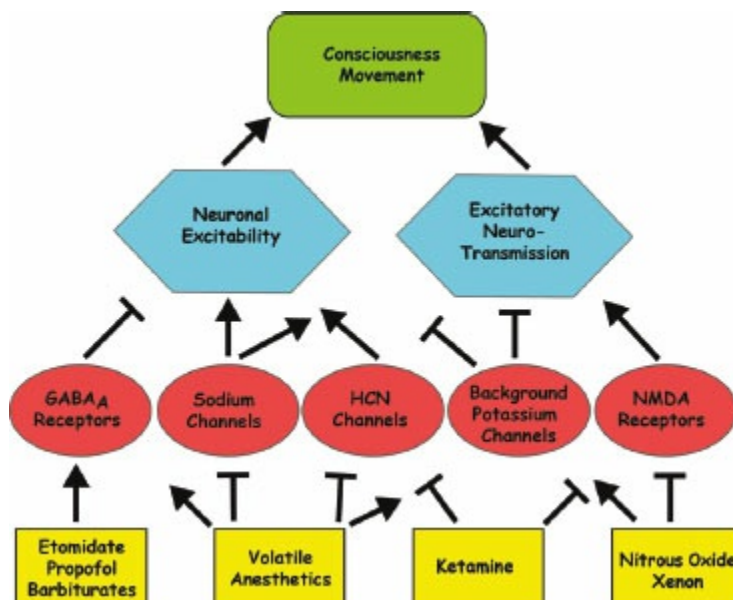

## Summary

Anesthetics suppress circuits in the spinal cord and brainstem to induce immobility and disrupt autonomic homeostasis. The hippocampus is a major site of anesthetic action for anterograde amnesia. As the neurobiologic underpinnings of arousal and awareness are distributed across brainstem, subcortical, and cortical structures, no single anatomic site is responsible for anesthetic-induced unconsciousness. Recent work has revealed that **14** networks of subcortical and thalamic nuclei are altered in the ablation of arousal. Cortical networks critical for cognitive processing of awareness are the tentative substrates for extinction of subjective percepts, noxious and **15** otherwise. Network perturbations in both frequency and temporal coding of information are putative mechanisms for altered integration and neural representation.

## Conclusions

In this chapter, evidence has been reviewed concerning the anatomic, physiologic, and molecular loci of anesthetic action. It is clear that all anesthetic effects cannot be localized to a specific anatomic site in the CNS. Indeed, considerable evidence supports the conclusion that different components of the anesthetic state are mediated by actions at disparate anatomic sites. Likewise, the actions of anesthetics cannot be localized to a single physiologic process. While there is consensus that anesthetics ultimately affect synaptic function, as opposed to intrinsic neuronal excitability, their particular effects on presynaptic and postsynaptic function vary by agent and synapse. At a molecular level, volatile anesthetics show some selectivity, but still affect the function of multiple ion channels and synaptic proteins. The intravenous anesthetics, etomidate, propofol, and barbiturates, are more specific with the GABA<sub>A</sub> receptor as their major target. Although these effects are likely mediated via direct protein–anesthetic interactions, numerous proteins can directly interact with anesthetics. Genetic data plainly demonstrate that the unitary theory of anesthesia is not correct. No single mechanism is responsible for the effects of all general anesthetics, nor does a single mechanism account for all effects of a single anesthetic. [Figure 10-8](#) provides a simple model of how the known molecular and cellular effects of general anesthetics might summate to produce anesthesia. This cartoon is not meant to include all potential molecular targets of general anesthetics; rather, only those molecules with strong support from multiple distinct investigational approaches are shown.

Although the precise set of molecular interactions responsible for producing anesthesia have not been fully elucidated, anesthetics do act via selective effects on specific molecular targets. The technological revolutions in molecular biology, genetics, neurophysiology, and neuroimaging make it likely that the next decade will provide additional answers to the anesthetic mechanism puzzle.

**Figure 10-8** A multisite model for anesthesia. Anesthetics are grouped according to similarity of mechanism. Arrows indicate activation or potentiation, and Ts indicate inhibition or antagonism. The neurophysiologic effects of general anesthetics are lumped into neuronal excitability (the probability of a neuron firing and propagating an axon potential) and excitatory neurotransmission (synaptic activity at excitatory synapses such as glutamatergic). Neuronal excitability in this context is the sum of both intrinsic and extrinsic factors (e.g., GABAergic inhibition).

# 11 Basic Principles of Clinical Pharmacology

DHANESH K. GUPTA • THOMAS K. HENTHORN

## Pharmacokinetic Principles

- Drug Absorption and Routes of Administration
- Drug Distribution
- Drug Elimination

## Pharmacokinetic Models

- Physiologic versus Compartmental Models
- Pharmacokinetic Concepts
- Compartmental Pharmacokinetic Models
- Noncompartmental (Stochastic) Pharmacokinetic Models

## Pharmacodynamic Principles

- Drug–Receptor Interactions
- Dose–Response Relationships
- Concentration–Response Relationships

## Drug Interactions

- Pharmaceutical (Physiochemical) Interactions
- Pharmacokinetic Interactions
- Pharmacodynamic Interactions

## Clinical Applications of Pharmacokinetics and Pharmacodynamics to the Administration of Intravenous Anesthetics

- Rise to Steady-state Concentration
- Manual Bolus and Infusion Dosing Schemes
- Isoconcentration Nomogram
- Context-sensitive Decrement Times
- Soft Pharmacology and Anesthesiology
- Target-controlled Infusions
- Time to Maximum Effect Compartment Concentration ( $T_{\max}$ )
- Volume of Distribution at Peak Effect ( $V_{DPE}$ )
- Front-end Pharmacokinetics
- Closed-loop Infusions
- Response Surface Models of Drug–Drug Interactions

## Conclusion

## KEY POINTS

- 1 Most drugs must pass through cell membranes to reach their sites of action. Consequently, drugs tend to be relatively lipophilic, rather than hydrophilic.
- 2 The highly lipophilic anesthetic drugs have a rapid onset of action because they rapidly diffuse into the highly perfused brain tissue. They have a very short duration of action because of redistribution of drug from the CNS to the blood.
- 3 The cytochrome P450 (CYP) superfamily is the most important group of enzymes involved in drug metabolism. It and other drug-metabolizing enzymes exhibit genetic polymorphism.
- 4 The kidneys eliminate hydrophilic drugs and relatively hydrophilic metabolites of lipophilic drugs. Renal elimination of lipophilic compounds is negligible.
- 5 The liver is the most important organ for metabolism of drugs. Hepatic drug clearance depends on three factors: the intrinsic ability of the liver to metabolize a drug, hepatic blood flow, and the extent of binding of the drug to blood components.
- 6 The volume of distribution quantifies the extent of drug distribution. The greater the affinity of tissues for a drug relative to blood, the greater its volume of distribution (i.e., lipophilic drugs have greater volumes of distribution).
- 7 Elimination clearance is the parameter that characterizes the ability of drug-eliminating tissues to irreversibly remove drugs from the body. The efficiency of the body in removing drug from the body is proportional to the elimination clearance.
- 8 All else being equal, an increase in the volume of distribution of a drug will increase its elimination half-life; an increase in elimination clearance will decrease elimination half-life.
- 9 Most drugs bring about a pharmacologic effect by binding to a specific receptor that results in a change in cellular function to produce the pharmacologic effect.
- 10 Although most pharmacologic effects can be characterized by both dose–response curves and concentration–response curves, dose–response curves cannot be used to determine whether variations in pharmacologic response are caused by differences in pharmacokinetics, pharmacodynamics, or both.
- 11 Integrated pharmacokinetic–pharmacodynamic models allow temporal characterization of the relationship between dose, plasma concentration, and pharmacologic effect.
- 12 In vitro drug–drug interactions due to pharmaceutical (physiochemical) properties of drugs can significantly alter drug bioavailability and produce unintended toxic byproducts.

- 13 Novel approaches to antagonizing neuromuscular blockade have been developed that take advantage of in vivo physiochemical drug–drug interactions, thereby avoiding some of the systemic side effects associated with inhibition of plasma acetylcholinesterase.
- 14 Distribution clearance is influenced by changes in cardiac output and regional blood flow.
- 15 Inhibition of CYP isozyme activity can make it difficult to achieve adequate analgesia when using opioids such as codeine and Tramadol that require CYP 2D6 activity for conversion to the biologically active opioid.
- 16 Serotonin syndrome can be precipitated by a wide array of drugs that are associated with serotonergic activity, including SSRIs, NSRIs, and phenylpiperidine opioids.
- 17 Simulations of multicompartmental pharmacokinetic models that describe intravenous anesthetics demonstrate that for most anesthetic dosing regimens, the distribution of drug from the plasma to the inert peripheral tissues has a greater influence on the plasma concentration profile of the drug than the elimination of drug from the body.
- 18 Target-controlled infusions are achieved with computer-controlled infusion pumps worldwide (not yet FDA-approved in the United States), and permit clinicians to make use of the drug concentration–effect relationship, optimally accounting for pharmacokinetics, and predicting the offset of drug effect.
- 19 Classic pharmacokinetic models inaccurately describe the initial several minutes of drug distribution that occur during the time of drug onset, and, therefore, overestimate the interindividual pharmacodynamic variability.
- 20 By understanding the interactions between the opioids and the sedative-hypnotics (e.g., response surface models), it is possible to select target concentration pairs of the two drugs that produce the desired clinical effect while minimizing unwanted side effects associated with high concentrations of a single drug.

In 1943, Halford<sup>1</sup> labeled thiopental as “an ideal method of euthanasia” for war surgical patients and pronounced that “open drop ether still retains primacy!” Based on this recount of the experience with thiopental at Pearl Harbor, it is impressive that cooler heads prevailed—Adams and Gray<sup>2</sup> detailed a case of a civilian gunshot wound where they carefully titrated incremental doses of thiopental without any adverse respiratory or cardiovascular events. To highlight the importance of the quiet case report versus the animated condemnation of intravenous (IV) anesthesia for patients with hemorrhagic shock, an anonymous editorial appeared in the same issue

of *Anesthesiology* that attempted to give some scientific justification for the discrepancy in opinions.<sup>3</sup> As the editorial detailed, thiopental has a small therapeutic index, and the tolerance to normal doses is decreased in extreme physical conditions (e.g., blood loss, sepsis). Therefore, just like with open drop ether, small doses of thiopental should be titrated to achieve the desired effects and avoid side effects associated with overdose. Fortuitously, the anesthesia community did not simply abandon the use of thiopental, and in 1960, Price<sup>4</sup> utilized mathematical models in order to describe the effects of hypovolemia on thiopental distribution.

Anesthetic drugs are administered with the goal of rapidly establishing and maintaining a therapeutic effect while minimizing undesired side effects. Although open-drop ether and chloroform were administered using knowledge of a dose–effect relationship, the more potent volatile agents, along with the IV hypnotics, neuromuscular junction blocking agents, and IV opioids, all require a sound knowledge of pharmacokinetics and pharmacodynamics in order to accurately achieve the desired pharmacologic effect for the desired period of time without any drug toxicity.

This chapter attempts to guide the reader through the fundamental knowledge of what the body does to a drug (i.e., pharmacokinetics) and what a drug does to the body (i.e., pharmacodynamics). The initial section of this chapter discusses the biologic and pharmacologic factors that influence the absorption, distribution, and elimination of a drug from the body. Where necessary, quantitative analyses of these processes are discussed to give readers insight into the intricacies of pharmacokinetics that cannot be easily described by text alone. The second section concentrates on the factors that determine the relationship between drug concentration and pharmacologic effect. Once again, mathematical models are presented as needed in order to clarify pharmacodynamic concepts. The third section applies concepts from the first two sections in order to describe the clinically important drug–drug interactions that are encountered in the perioperative period. The final section builds on the reader’s knowledge gained from the first two sections to apply the principles of pharmacokinetics and pharmacodynamics to determine the target concentration of IV anesthetics required and the dosing strategies necessary to produce an adequate anesthetic state. Understanding these concepts should allow the reader to integrate the anesthetic drugs of the future into a rational anesthetic regimen. Although specific drugs are utilized to illustrate pharmacokinetic and pharmacodynamic principles throughout this chapter, the principles discussed are universal. Detailed pharmacologic information of anesthetic pharmacopeia are presented in subsequent chapters of this book.

## Pharmacokinetic Principles

## Drug Absorption and Routes of Administration

### Transfer of Drugs across Membranes

For even the simplest drug that is directly administered into the blood to exert its action, it must move across at least one cell membrane to its site of action. Because biologic membranes are lipid bilayers composed of a lipophilic core sandwiched between two hydrophilic layers, only small lipophilic drugs can passively diffuse across the membrane down their concentration gradients. In order for water-soluble drugs to passively diffuse across the membrane down its concentration gradient, transmembrane proteins that form a hydrophilic channel are required. Because of the abundance of these nonspecific hydrophilic channels in the capillary endothelium of all organs except for the central nervous system (CNS), where the blood–brain barrier capillary endothelial cells have very limited numbers of transmembrane hydrophilic channels, *passive transport* of drugs from the intravascular space into the interstitium of various organs is limited by blood flow, not by the lipid solubility of the drug.<sup>5</sup>

Hydrophilic drugs can only enter the CNS after binding to drug-specific transmembrane proteins that actively transport the hydrophilic drug across the capillary endothelium into the CNS interstitium. When these transmembrane carrier proteins require energy to transport the drug across the membrane, they are able to shuttle compounds against their concentration gradients, a process called *active transport*. In contrast, when these carrier proteins do not require energy to shuttle drugs, they cannot overcome concentration gradients, a process called *facilitated diffusion*. Active transport is not limited to the CNS, but is also found in the organs related to drug elimination (e.g., hepatocytes, renal tubular cells, pulmonary capillary endothelium), where the ability to transport drugs against the concentration gradient has specific biologic advantages. Both active transport and facilitated diffusion of drugs are saturable processes that are primarily limited by the number of carrier proteins available to shuttle a specific drug.<sup>5</sup>

For lipophilic compounds transporters are not needed for the drug to diffuse across the capillary wall into tissues, but the presence of transporters does affect the concentration gradients that exist. For instance, some lipophilic drugs are transported out of tissues by ATP-dependent transporters such as p-glycoprotein (P-gp). The lipophilic potent  $\mu$ -opioid agonist, loperamide, used for the treatment of diarrhea, has limited bioavailability because of P-gp transporters at the intestine-portal capillary interface and then what does reach the circulation has its CNS penetrance limited by P-gp at the blood–brain barrier.<sup>6</sup> Conversely, lipophilic compounds can be transported into tissues, increasing the tissue concentration of the drug beyond what would be accomplished by passive diffusion. The class of transporters called

organic anion polypeptide transporters (OATPs) are located in the microvascular endothelium of the brain and transports endogenous opioids into the brain.<sup>7,8</sup> These OATPs also transport drugs. The degree to which transporter proteins may account for intra- and interindividual responses to anesthetic drugs has not been well studied to date.<sup>9</sup>

## **Intravenous Administration**

In order for a drug to be delivered to the site of drug action, it must be absorbed into the systemic circulation. Therefore, IV administration results in immediate delivery of a drug with 100% bioavailability. Although this can lead to rapid overshoot of the desired plasma concentration which can potentially result in immediate and severe side effects for drugs that have a low *therapeutic index* (the ratio of the blood concentration that produces a toxic effect in 50% of the population to the blood concentration that produces a therapeutic effect in 50% of the population). Except for IV administration, the absorption of a drug into the systemic circulation is an important determinant of the time course of drug action and the maximum drug effect produced. As the absorption of drug is slowed, the maximum plasma concentration achieved, and therefore the maximum drug effect achieved, is limited. However, as long as the plasma concentration is maintained at a level above the minimum effective plasma concentration, the drug will produce a drug effect.<sup>10</sup> Therefore, non-IV methods of drug administration can produce a sustained and significant drug effect that may be more advantageous than administering drugs by the IV route.<sup>11</sup>

*Bioavailability* is the *relative amount* of a drug dose that reaches the systemic circulation unchanged and the *rate* at which this occurs. For most intravenously administered drugs, the absolute bioavailability of drug available is close to unity and the rate is nearly instantaneous. However, the pulmonary endothelium can slow the rate at which intravenously administered drugs reach the systemic circulation if distribution into the alveolar endothelium is extensive, such as occurs with the pulmonary uptake of fentanyl. The pulmonary endothelium also contains enzymes that may metabolize intravenously administered drugs (e.g., propofol) on first pass and reduce their absolute bioavailability.<sup>12</sup>

## **Oral Administration**

For almost all therapeutic agents in all fields of medicine, oral administration is the safest and most convenient method of administration. However, this route is not utilized significantly in anesthetic practice because of the limited and variable rate of bioavailability. The absorption rate in the gastrointestinal tract is highly variable because the main determinant of the timing of

absorption is gastric emptying into the small intestines, where the surface area for absorption is several orders of magnitude greater than that of the stomach or large intestines. In addition, the active metabolism of drug by the small intestine mucosal epithelium, and the obligatory path through the portal circulation before entering the systemic circulation, contribute to decreased bioavailability of orally administered drugs.<sup>13</sup> In fact, the metabolic capacity of the liver for drugs is so high that only a small fraction of most lipophilic drugs actually reach the systemic circulation. Because of this extensive *first-pass metabolism*, the oral dose of most drugs must be significantly higher than IV to generate a therapeutic plasma concentration. The prolonged and variable time until peak concentrations are usually achieved from oral administration (between tens of minutes to hours), makes it impractical to utilize this mode to administer perioperative anesthetic agents.

Highly lipophilic drugs that can maintain a high contact time with nasal or oral (sublingual) mucosa can be absorbed without needing to traverse the gastrointestinal tract. Sublingual administration of drug has the additional advantage over gastrointestinal absorption in that absorbed drug directly enters the systemic venous circulation and therefore is able to bypass the metabolically active intestinal mucosa and the hepatic first-pass metabolism. Therefore, small doses of drug can rapidly produce significant increases in drug plasma concentration and therapeutic effect.<sup>14</sup> However, because of formulation limitations and the small surface area available for absorption, there are a limited number of drugs that are appropriate for sublingual administration (e.g., nitroglycerin, fentanyl).

### **Transcutaneous Administration**

A few lipophilic drugs have been manufactured in formulations that are sufficient to allow penetration of intact skin. Although scopolamine, nitroglycerin, opioids, and clonidine all produce therapeutic systemic plasma concentrations when administered as “drug patches,” the extended amount of time that it takes to achieve an effective therapeutic concentration limits practical application except for maintenance therapy. Attempts to speed the passive diffusion of these drugs utilizing an electric current has been described for fentanyl,<sup>15</sup> but it is still limited in its practicality.

### **Intramuscular and Subcutaneous Administration**

Absorption of drugs from the depots in the subcutaneous tissue or in muscle tissue is directly dependent on the drug formulation and the blood flow to the depot. Because of the high blood flow to muscles in most physiologic states, intramuscular absorption of drugs in solution is relatively rapid and complete. Therefore, some aqueous drugs can be administered as intramuscular injection

with rapid and predictable effects (e.g., neuromuscular junction blocking agents). The subcutaneous route of drug absorption is more variable in its onset because of the variability of subcutaneous blood flow during varying physiologic states—this is the primary reason that subcutaneous heparin and regular insulin administered perioperatively have variable times of onset and maximum effect.

### **Intrathecal, Epidural, and Perineural Injection**

Because the spinal cord is the primary site of action of many anesthetic agents, direct injection of local anesthetics and opioids into the intrathecal space bypasses the limitations of drug absorption and drug distribution of any other route of administration. This is not the case for epidural and perineural administration of local anesthetics, because not delivering the drug directly into the cerebrospinal fluid necessitates that the drug be absorbed through the dura or nerve sheath in order to reach the site of drug action. The major downside to all of these techniques is the relative expertise required to perform regional anesthetics to oral, IV, and inhalational administration of drug.

### **Inhalational Administration**

The large surface area of the pulmonary alveoli available for exchange with the large volumetric flow of blood found in the pulmonary capillaries makes inhalational administration an extremely attractive method by which to administer drugs.<sup>16</sup> New technologies have been developed which can rapidly and predictably aerosolize a wide range of drugs and thus approximate IV administration.<sup>17</sup> These devices are currently in Phase II FDA trials.

### ***Drug Distribution***

Once drug has entered the systemic circulation, it is transported through bulk flow of blood to all of the organs throughout the body. The relative distribution of cardiac output among organ vascular beds determines the speed at which organs are exposed to drug. The highly perfused core circulatory components—the brain, lungs, heart, and kidneys—receive the highest relative distribution of cardiac output and therefore are the initial organs to reach equilibrium with plasma drug concentrations.<sup>4</sup> Drug concentrations then equilibrate with the less well-perfused muscles and liver and then, finally, with the relatively poorly perfused splanchnic vasculature, adipose tissue, and bone.

Whether by passive diffusion or transporter-mediation, drug transport at

the capillaries is not usually saturable, so the amount of drug uptake by tissues and organs is limited by the blood flow they receive (i.e., flow-limited drug uptake).

Although the rate to initial drug delivery may be dependent on the relative blood flow to the organ, the rate of drug equilibration by the tissue is dependent on the ratio of blood flow to tissue content. Therefore, drug uptake rapidly approaches equilibrium in the highly perfused, but low volume, brain, kidneys, and lungs in a matter of minutes, whereas drug transfer to the less well-perfused, intermediate volume muscle tissue may take hours to approach equilibrium, and drug transfer to the poorly perfused, large cellular volumes of adipose tissue does not equilibrate for days.<sup>11</sup>

## Redistribution

**2** Highly lipophilic drugs such as thiopental and propofol rapidly begin to diffuse into the highly perfused brain tissue usually less than a minute after IV injection. Because of the low tissue volume but high perfusion of the brain, the drug concentration in the cerebral arterial blood rapidly equilibrates, usually within 3 minutes, with the concentration in the brain tissue. As drug continues to be taken up by other tissues with lower blood flows and higher tissue mass, the plasma concentration of the drug continues to rapidly decrease. Once the concentration of drug in the brain tissue is higher than the plasma concentration of drug, there is a reversal of the drug concentration gradient so that the lipophilic drug readily diffuses back into the blood and is *redistributed* to the other tissues that are still taking up drug.<sup>4,18,19</sup> This process continues for each of the organ beds, until ultimately the adipose tissue will contain the majority of the lipophilic drug that has not been removed from the body by metabolism or excretion. However, after a single bolus of a highly lipophilic drug, the brain's tissue concentration rapidly decreases below therapeutic levels due to redistribution of drug to muscle tissue, which has a larger perfusion than adipose tissue.<sup>4,19</sup> Although single, moderate doses of highly lipophilic drugs have a very short CNS duration of action because of redistribution of drug from the CNS to the blood and other, less well-perfused tissues, repeated injections of a drug allow the rapid establishment of significant peripheral tissue concentrations. When the tissue concentrations of a drug are high enough, the decrease in plasma drug concentration below therapeutic threshold becomes solely dependent on drug elimination from the body.<sup>20</sup>

## Drug Elimination

Besides being excreted unchanged from the body, a drug can be

biotransformed (metabolized) into one or more new compounds that are then eliminated from the body. Either mechanism of elimination will decrease the drug concentration in the body such that the concentration will eventually be negligible and therefore unable to produce drug effect. Elimination is the pharmacokinetic term that describes all the processes that remove a drug from the body. Although the liver and the kidneys are considered the major organs of drug elimination, drug metabolism can occur at many other locations that contain active drug metabolizing enzymes (e.g., pulmonary vasculature, red blood cells) and drug can be excreted unchanged from other organs (e.g., lungs).

*Elimination clearance* (drug clearance) is the theoretical volume of blood from which drug is completely and irreversibly removed in a unit of time.<sup>21</sup> *Total* drug clearance can be calculated with pharmacokinetic models of blood concentration versus time data.

## **Biotransformation Reactions**

Most drugs that are excreted unchanged from the body are hydrophilic and therefore readily pass into urine or stool. Drugs that are not sufficiently hydrophilic to be able to be excreted unchanged require modification into more hydrophilic, excretable compounds. Enzymatic reactions that metabolize drugs can be classified into Phase I and Phase II biotransformation reactions. Phase I reactions tend to transform a drug into one or more polar, and hence potentially excretable compounds. Phase II reactions transform the original drug by conjugating a variety of endogenous compounds to a polar functional group of the drug, making the metabolite even more hydrophilic. Often drugs will undergo a Phase I reaction to produce a new compound with a polar functional group that will then undergo a Phase II reaction. However, it is possible for a drug to undergo either a Phase I reaction alone or a Phase II reaction alone.

## **Phase I Reactions**

Phase I reactions may hydrolyze, oxidize, or reduce the parent compound. *Hydrolysis* is the insertion of a molecule of water into another molecule, which forms an unstable intermediate compound that subsequently splits apart. Thus, hydrolysis cleaves the original substance into two separate molecules. Hydrolytic reactions are the primary way amides, such as lidocaine and other amide local anesthetics, and esters, such as succinylcholine, are metabolized.

Many drugs are biotransformed by oxidative reactions. *Oxidations* are defined as reactions that remove electrons from a molecule. The common element of most, if not all, oxidations is an enzymatically mediated reaction that inserts a hydroxyl group (OH) into the drug molecule. In some instances,

this produces a chemically stable, more polar hydroxylated metabolite. However, hydroxylation usually creates unstable compounds that spontaneously split into separate molecules. Many different biotransformations are effected by this basic mechanism. Dealkylation (removal of a carbon-containing group), deamination (removal of nitrogen-containing groups), oxidation of nitrogen-containing groups, desulfuration, dehalogenation, and dehydrogenation all follow an initial hydroxylation. Hydrolysis and hydroxylation are comparable processes. Both have an initial, enzymatically mediated step that produces an unstable compound that rapidly dissociates into separate molecules.

Some drugs are metabolized by *reductive reactions*, that is, reactions that add electrons to a molecule. In contrast to oxidations, where electrons are transferred from NADPH to an oxygen atom, the electrons are transferred to the drug molecule. Oxidation of xenobiotics requires oxygen, but reductive biotransformation is inhibited by oxygen, so it is facilitated when the intracellular oxygen tension is low.

## Cytochrome P450 Enzymes

**3** The cytochrome P450 (CYP) are the superfamily of constitutive and inducible enzymes that catalyze most Phase I biotransformations. CYP3A4 is the single most important enzyme, accounting for 40% to 45% of all CYP-mediated drug metabolism. CYPs are incorporated into the smooth endoplasmic reticulum of hepatocytes and the membranes of the upper intestinal enterocytes in high concentrations. CYPs are also found in the lungs, kidneys, and skin, but in much smaller numbers. CYP isoenzymes oxidize their substrates primarily by the insertion of an atom of oxygen in the form of a hydroxyl group, while another oxygen atom is reduced to water.

Several constitutive CYPs are involved in the production of various endogenous compounds, such as cholesterol, steroid hormones, prostaglandins, and eicosanoids. In addition to the constitutive forms, production of various CYPs can be induced by a wide variety of xenobiotics. CYP drug-metabolizing activity increases after exposure to various exogenous chemicals, including many drugs. The number and type of CYPs present at any time depends on exposure to different xenobiotics. The CYP system is able to protect the organism from the deleterious effects of accumulation of exogenous compounds because of its two fundamental characteristics—broad substrate specificity and the capability to adapt to exposure to different substances by induction of different CYP isoenzymes. [Table 11-1](#) groups drugs encountered in anesthetic practice according to the CYP isoenzymes responsible for their biotransformation.

Biotransformations can be inhibited if different substrates compete for the

drug-binding site on the same CYP member. The effect of two competing substrates on each other's metabolism depends on their relative affinities for the enzyme. Biotransformation of the compound with the lower affinity is inhibited to a greater degree. This is the mechanism by which the H<sub>2</sub> receptor antagonist cimetidine inhibits the metabolism of many drugs, including meperidine, propranolol, and diazepam. The newer H<sub>2</sub> antagonist ranitidine has a different structure and causes fewer clinically significant drug interactions. Other drugs, notably calcium channel blockers and antidepressants, also inhibit oxidative drug metabolism in humans. This information allows clinicians to predict which combinations of drugs are more likely to lead to clinically significant interactions because of altered drug metabolism by the cytochrome P450 system.

**Table 11-1** Substrates for CYP Isoenzymes Encountered in Anesthesiology

<b>CYP3A4</b>	<b>CYP2D6</b>
Acetaminophen	Captopril
Alfentanil	Codeine
Alprazolam	Hydrocodone
Bupivacaine	Metoprolol
Cisapride	Ondansetron
Codeine	Oxycodone
Diazepam	Propranolol
Digitoxin	Timolol
Diltiazem	<b>CYP2B6</b>
Fentanyl	Methadone
Lidocaine	Propofol
Midazolam	<b>CYP2C9</b>
Nicardipine	Diclofenac
Nifedipine	Ibuprofen
Omeprazole	Indomethacin
Ropivacaine	<b>CYP2C19</b>
Statins	Diazepam
Sufentanil	Omeprazole
Verapamil	Propranolol
Warfarin	Warfarin

## Phase II Reactions

Phase II reactions are also known as *conjugation* or *synthetic reactions*. Many drugs do not have a polar chemical group suitable for conjugation, so conjugation occurs only after a Phase I reaction. Other drugs, such as morphine, already have a polar group that serves as a “handle” for conjugation, and they undergo these reactions directly. Various endogenous compounds can be attached to parent drugs or their Phase I metabolites to form different conjugation products. These endogenous substrates include glucuronic acid, acetate, and amino acids. Mercapturic acid conjugates result from the binding of exogenous compounds to glutathione. Other conjugation

reactions produce sulfated or methylated derivatives of drugs or their metabolites. Like the cytochrome P450 system, the enzymes that catalyze Phase II reactions are inducible. Phase II reactions produce conjugates that are polar, water-soluble compounds. This facilitates the ultimate excretion of the drug via the kidneys or hepatobiliary secretion. Like CYP, there are different families and superfamilies of the enzymes that catalyze Phase II biotransformations.

### **Genetic Variations in Drug Metabolism**

For most enzymes involved in Phase I and Phase II reactions, there are several biologically available isoforms. Drug metabolism varies substantially among individuals because of variability in the genes controlling the numerous enzymes responsible for biotransformation. For most drugs, the distribution of the rates of metabolism of the population is a unimodal distribution. If there are genetic variants (polymorphisms) that affect the rate of drug metabolism, the distribution of the rates of metabolism of the population will be a multimodal distribution. More detailed analysis of this multimodal distribution will reveal subpopulations with different rates of drug elimination, and each of the rates of drug metabolism of each of these subpopulations will be described by a unimodal distribution. For example, different genotypes result in either normal, low, or (rarely) absent plasma pseudocholinesterase activity, accounting for the well-known differences in individuals' responses to succinylcholine, which is hydrolyzed by this enzyme. Many drug-metabolizing enzymes exhibit genetic polymorphism, including CYP and various transferases that catalyze phase II reactions. However, none of these has a sex-related difference.

### **Chronologic Variations in Drug Metabolism**

The activity and capacity of the CYP enzymes increases from subnormal levels in the fetal and neonatal periods to reach normal levels at about 1 year of age. Although age is a covariate in mathematical models of drug elimination, it is not clear if these changes are related to chronologic changes in organ function (age related organ dysfunction) or to a decrease in CYP levels with increasing age. In contrast, it is clear that the neonate has a limited ability to perform phase II conjugation reactions, but after normalizing phase II activity over the initial year of life, advanced age does not affect the capacity to perform phase II reactions.

### **Renal Drug Clearance**

**4** The primary role of the kidneys in drug elimination is to excrete into urine

the unchanged, hydrophilic drugs, and the hepatic derived metabolites from Phase I and Phase II reactions of lipophilic drugs. The passive elimination of drugs by passive glomerular filtration is a very inefficient process—any significant degree of binding of the drug to plasma proteins or erythrocytes will decrease the renal drug clearance below the glomerular filtration rate. In order to make renal elimination more efficient, discrete active transporters of organic acids and bases exist in the proximal renal tubular cells. Although these transporters are saturable, they allow for the renal clearance of drugs to approach the entire renal blood flow.

In reality, renal drug clearance of actively secreted drugs can be inhibited by both passive tubular reabsorption of lipophilic drugs and active, carrier-mediated tubular reabsorption of hydrophilic drugs. Therefore, the small amount of filtered and secreted lipophilic drug is easily reabsorbed in the distal tubules, making the net renal clearance negligible. In contrast, the large amount of filtered and secreted hydrophilic drug can be passively reabsorbed if renal tubular flow decreases substantially (e.g., oliguria) and/or the urine pH favors the un-ionized form of the hydrophilic drug. Renal drug clearance, even for drugs eliminated primarily by tubular secretion, is dependent on renal function. Therefore, in patients with acute and chronic causes of decreased renal function (usually indicated by reduced creatinine clearance), including age, low cardiac output states, and hepatorenal syndrome, drug dosing must be altered in order to avoid accumulation of parent compounds and potentially toxic metabolites (e.g., lidocaine, meperidine) (Table 11-2).

**Table 11-2** Drugs with Significant Renal Excretion Encountered in Anesthesiology

Aminoglycosides	Pancuronium
Atenolol	Penicillins
Cephalosporins	Procainamide
Digoxin	Pyridostigmine
Edrophonium	Quinolones
Nadolol	Rocuronium
Neostigmine	Sugammadex

## Hepatic Drug Clearance

**5** Drug elimination by the liver depends on the intrinsic ability of the liver to metabolize the drug (intrinsic clearance,  $Cl_i$ ), and the amount of drug available to diffuse into the liver. Many types of mathematical models have been developed to attempt to accurately describe the relationship between hepatic artery blood flow, portal artery blood flow, intrinsic clearance, and drug binding to plasma proteins.<sup>22,23</sup> According to these models, the unbound concentration of drug in the hepatic venous blood ( $C_v$ ) is in equilibrium with the drug within the liver that is available for elimination. These models also

make the assumption that all of the drug delivered to the liver is available for elimination and that the elimination is a first-order process—a constant *fraction* of the available drug is eliminated per unit time. The fraction of the drug removed from the blood passing through the liver is the hepatic extraction ratio,  $E$ :

$$E = \frac{C_a - C_v}{C_a} \quad (11-1)$$

where  $C_a$  is the mixed hepatic arterial–portal venous drug concentration and  $C_v$  is the mixed hepatic venous drug concentration. The total hepatic drug clearance,  $Cl_H$ , is:

$$Cl_H = Q \cdot E \quad (11-2)$$

where  $Q$  is hepatic blood flow. Therefore, hepatic clearance is a function of hepatic blood flow and the ability of the liver to extract drug from the blood.

The ability to extract drug depends on the activity of drug-metabolizing enzymes and the capacity for hepatobiliary excretion—the intrinsic clearance of the liver ( $Cl_i$ ).

Intrinsic clearance represents the ability of the liver to remove drug from the blood in the absence of any limitations imposed by blood flow or drug binding. The relationship of total hepatic drug clearance to the extraction ratio and intrinsic clearance,  $Cl_i$ , is:

$$Cl_H = Q \cdot E = Q \left( \frac{Cl_i}{Q + Cl_i} \right) \quad (11-3)$$

The right-hand side of Equation 11-3 indicates that if intrinsic clearance is very high (many times larger than hepatic blood flow,  $Cl_i \gg Q$ ), total hepatic clearance approaches hepatic blood flow. On the other hand, if intrinsic clearance is very small ( $Q + Cl_i \approx Q$ ), hepatic clearance will be similar to intrinsic clearance. These relationships are shown in [Figure 11-1](#).

Thus, hepatic drug clearance and extraction are determined by two independent variables, intrinsic clearance and hepatic blood flow. Changes in either will change hepatic clearance. However, the extent of the change depends on the initial relationship between intrinsic clearance and hepatic blood flow, according to the nonlinear relationship:

$$E = \frac{Cl_i}{Q + Cl_i} \quad (11-4)$$

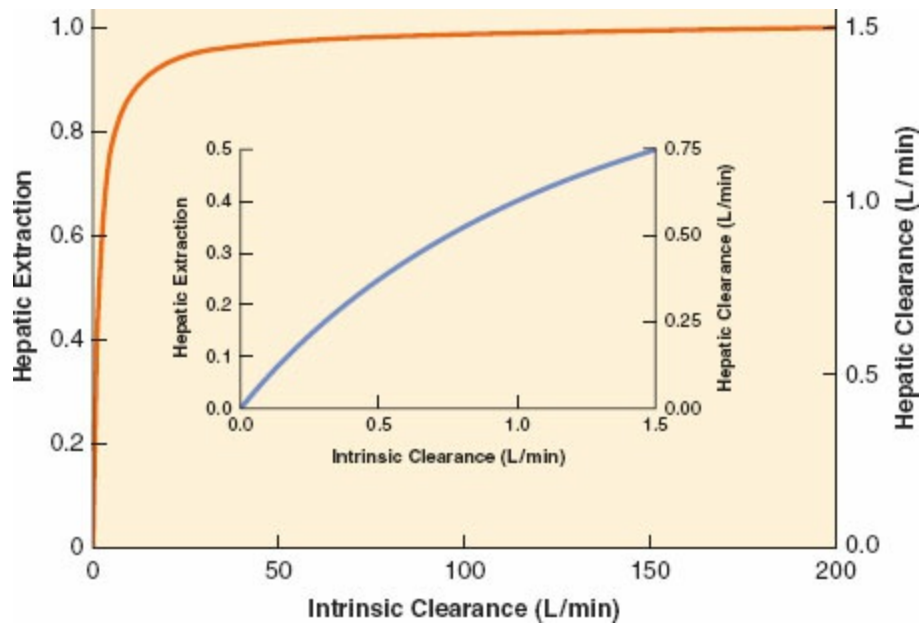

If the initial intrinsic clearance is small relative to hepatic blood flow, then the extraction ratio is also small, and Equation 11-4 reduces to the following

relationship:

$$E = \frac{Cl_i}{Q} \ll 1 \quad (11-4a)$$

Equation 11-4a indicates that doubling intrinsic clearance will produce an almost proportional increment in the extraction ratio, and, consequently, hepatic elimination clearance (Fig. 11-1, inset). However, if intrinsic clearance is much greater than hepatic blood flow, Equation 11-4 reduces to the following relationship:

**Figure 11-1** The relationship between hepatic extraction ratio ( $E$ , right y-axis), intrinsic clearance ( $Cl_i$ , x-axis), and hepatic clearance ( $Cl_H$ , left y-axis) at the normal hepatic blood flow ( $Q$ ) of 1.5 L/min. For drugs with a high intrinsic clearance ( $Cl_i \gg Q$ ), increasing intrinsic clearance has little effect on hepatic extraction, and total hepatic clearance approaches hepatic blood flow. In contrast, if the intrinsic clearance is small ( $Cl_i \leq Q$ ), the extraction ratio is similar to the intrinsic clearance (inset). (Adapted from Wilkinson GR, Shand DG. A physiologic approach to hepatic drug clearance. *Clin Pharmacol Ther.* 1975;18:377.)

$$E = \frac{Cl_i}{Cl_i} \approx 1 \quad (11-4b)$$

Equation 11-4b demonstrates that the extraction ratio is independent of intrinsic clearance and therefore a change in intrinsic clearance has a negligible effect on the extraction ratio and hepatic drug clearance (Fig. 11-1). In nonmathematical terms, high intrinsic clearance indicates efficient hepatic elimination. It is hard to enhance an already efficient process, whereas it is relatively easy to improve on inefficient drug clearance because of low intrinsic clearance.

**Figure 11-2** The relationship between liver blood flow ( $Q$ , x-axis) and hepatic clearance ( $Cl_H$ , y-axis) for different values of intrinsic clearance ( $Cl_i$ ). When the intrinsic clearance is low, hepatic elimination clearance is independent of liver blood flow—the drug elimination is limited by the capacity of the liver to metabolize the drug (i.e., the intrinsic clearance). In contrast, as intrinsic clearance increases, the hepatic elimination becomes more dependent on hepatic blood flow—the liver is able to metabolize all of the drug that it is exposed to and therefore only limited by the amount of drug that is delivered to the liver (i.e., flow limited metabolism).

For drugs with a high extraction ratio and a high intrinsic clearance, hepatic elimination clearance is directly proportional to hepatic blood flow. Therefore, any manipulation of hepatic blood flow will be directly reflected by a proportional change in hepatic elimination clearance (Fig. 11-2). In contrast, when the intrinsic clearance is low, changes in hepatic blood flow produce inversely proportional changes in extraction ratio (Fig. 11-3), and therefore the hepatic elimination clearance is essentially independent of hepatic blood flow and exquisitely related to intrinsic clearance. Therefore, classifying drugs as having either low, intermediate, or high extraction ratios (Table 11-3), allows predictions to be made on how intrinsic hepatic clearance and hepatic blood flow affect hepatic elimination clearance. This allows gross adjustments to be made in hepatically metabolized drug dosing to avoid excess accumulation of drugs (decreased hepatic elimination without dose adjustment) or subtherapeutic dosing strategies (increased hepatic elimination without dose adjustment).

**Figure 11-3** The relationship between liver blood flow ( $Q$ , x-axis) and hepatic extraction ratio ( $E$ , y-axis) for different values of intrinsic clearance ( $Cl_i$ ). When the intrinsic clearance is low, increases in hepatic blood flows cause a decrease in the extraction ratio because the liver has limited metabolic capabilities. In contrast, when the intrinsic clearance is high, the extraction ratio is essentially independent of hepatic blood flow because the liver's ability to eliminate drug is well above the amount of drug provided by normal hepatic blood flow.

**Table 11-3** Classification of Drugs Encountered in Anesthesiology According to Hepatic Extraction Ratios

<i>Low</i>	<i>High</i>
Diazepam	Alprenolol
Lorazepam	Bupivacaine
Methadone	Diltiazem
Phenytoin	Fentanyl
Rocuronium	Ketamine
Theophylline	Lidocaine
Thiopental	Meperidine
<i>Intermediate</i>	Metoprolol
Alfentanil	Morphine
Methohexital	Naloxone
Midazolam	Nifedipine
Vecuronium	Propofol
	Propranolol

Pharmacologic and pathologic manipulations of cardiac output, with its consequences on hepatic/splanchnic blood flow and renal blood flow, are important covariates when designing drug dosing strategies.<sup>24</sup> As detailed above, in states where cardiac output is decreased (e.g., heart failure, shock, spinal anesthesia), high extraction ratio drugs will have a decrease in hepatic elimination, whereas low extraction rate drugs will have minimal change in clearance.<sup>25,26</sup> In contrast, autoregulation of renal blood flow maintains a relatively constant renal elimination clearance until low urine output states eventually allow increased reabsorption of drugs from the distal tubules.<sup>27</sup>

## Pharmacokinetic Models

The concentration of drug at its site or sites of action is the fundamental determinant of a drug's pharmacologic effects. Although the blood is rarely the site of action of drug effect, the tissue drug concentration of an individual organ is a function of the blood flow to the organ, the concentration of drug in the arterial inflow of the organ, the capacity of the organ to take up drug, and the diffusivity of the drug between the blood and the organ.

### *Physiologic versus Compartment Models*

Initial pharmacokinetic models of IV and inhalational anesthetics used physiologic or perfusion models.<sup>4</sup> In these models, body tissues are lumped into groups that have similar distribution of cardiac output and capacity for drug uptake. Highly perfused tissues with a large amount of blood flow per volume of tissue are classified as the vessel rich group, whereas tissues with a balanced amount of blood flow per volume of tissue are classified as the lean tissue group or fast tissue group. The vessel-poor group (slow tissue group) are comprised of tissues that have a large capacity for drug uptake but a limited tissue perfusion. Although identification of the exact organs that make up each tissue group is not possible from the mathematical model, it is apparent that the highly perfused tissues are composed of the brain, lungs, kidneys, and a subset of muscle; the fast equilibrating tissue would be consistent with the majority of muscle and some of the splanchnic bed (e.g., liver), and the slowly equilibrating tissues contain the majority of the adipose tissue and the remainder of the splanchnic organs.

Based on these computationally and experimentally intense physiologic models, Price<sup>4,18</sup> was able to demonstrate that awakening after a single dose of thiopental was primarily a result of redistribution of thiopental from the brain to the muscle with little contribution by distribution to less well-perfused tissues or drug metabolism. This fundamental concept of redistribution applies to all lipophilic drugs and was not delineated until an accurate pharmacokinetic model had been constructed.

Perfusion-based physiologic pharmacokinetic models have provided significant insights into how physiologic, pharmacologic, and pathologic distribution of cardiac output can effect drug distribution and elimination.<sup>28,29</sup> However, verification of the predictions of these models requires measurement of drug concentrations in many different tissues, which is experimentally inefficient and destructive to the system. Therefore, simpler mathematical models have been developed. In these models, the body is comprised of one or more compartments. Drug concentrations in the blood are used to define the relationship between dose and the time course of

changes in the drug concentration. The compartments of the compartmental pharmacokinetic models cannot be equated with the tissue groups that make up physiologic pharmacokinetic models because the compartments are theoretical entities that are used to mathematically characterize the blood concentration profile of a drug. These models allow the derivation of pharmacokinetic parameters that can be used to quantify drug distribution and elimination—volume of distribution, clearance, and half-lives.

Although the simplicity of compartmental models, compared to physiologic pharmacokinetic models, has its advantages, it also has some disadvantages. For example, cardiac output is not a parameter of compartmental models, and compartmental models therefore cannot be used to predict directly the effect of cardiac failure on drug disposition.<sup>30</sup> However, compartmental pharmacokinetic models can still quantify the effects of reduced cardiac output on the disposition of a drug if a group of patients with cardiac failure is compared to a group of otherwise healthy subjects.

The discipline of pharmacokinetics is, to the despair of many, mathematically based. In the succeeding sections, formulas are used to illustrate the concepts needed to understand and interpret pharmacokinetic studies. Readers are encouraged to concentrate on the concepts, not the formulas.

## Pharmacokinetic Concepts

The disposition of most drugs follows *first-order* kinetics. A first-order kinetic process is one in which a constant fraction of the drug is removed during a finite period of time regardless of the drug amount or concentration. This fraction is equivalent to the rate constant of the process. Rate constants are usually denoted by the letter  $k$  and have units of “inverse time,” such as  $\text{min}^{-1}$  or  $\text{h}^{-1}$ . If 10% of the drug is eliminated per minute, then the rate constant is  $0.1 \text{ min}^{-1}$ . Because a constant fraction is removed per unit of time in first-order kinetics, the absolute amount of drug removed is proportional to the concentration of the drug. It follows that, in first-order kinetics, the rate of change of the amount of drug at any given time is proportional to the concentration present at that time. When the concentration is high, more drug will be removed than when it is low. First-order kinetics apply not only to elimination, but also to absorption and distribution.

Rather than using rate constants, the rapidity of pharmacokinetic processes is often described with half-lives—the time required for the concentration to change by a factor of 2. Half-lives are calculated directly from the corresponding rate constants with this simple equation:

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k} \quad (11-5)$$

Thus, a rate constant of  $0.1 \text{ min}^{-1}$  translates into a half-life of 6.93 minutes. The half-life of any first-order kinetic process, including drug absorption, distribution, and elimination, can be calculated. First-order processes asymptotically approach completion, because a constant fraction of the drug, not an absolute amount, is removed per unit of time. However, after five half-lives, the process will be almost 97% complete (Table 11-4). For practical purposes, this is essentially 100%, and therefore there is a negligible amount of drug remaining in the body.

## Volume of Distribution

**6** The volume of distribution quantifies the extent of drug distribution. The physiologic factor that governs the extent of drug distribution is the overall capacity of tissues versus the capacity of blood for that drug. Overall tissue capacity for uptake of a drug is in turn a function of the total mass of the tissues into which a drug distributes and their average affinity for the drug. In compartmental pharmacokinetic models, drugs are envisaged as distributing into one or more “boxes,” or compartments. These compartments cannot be equated directly with specific tissues. Rather, they are hypothetical entities that permit analysis of drug distribution and elimination and description of the drug concentration versus time profile.

The volume of distribution is an “apparent” volume because it represents the size of these hypothetical boxes, or compartments, that are necessary to explain the concentration of drug in a reference compartment, usually called the *central* or *plasma compartment*. The volume of distribution,  $V_d$ , relates the total amount of drug present to the concentration observed in the central compartment:

$$V_d = \frac{\text{amount of drug administered}}{\text{initial drug plasma concentration}} \quad (11-6)$$

If a drug is extensively distributed, then the concentration will be lower relative to the amount of drug present, which equates to a larger volume of distribution. For example, if a total of 10 mg of drug is present and the concentration is 2 mg/L, then the apparent volume of distribution is 5 L. On the other hand, if the concentration was 4 mg/L, then the volume of distribution would be 2.5 L.

Simply stated, the apparent volume of distribution is a numeric index of the extent of drug distribution that does not have any relationship to the actual volume of any tissue or group of tissues. It may be as small as plasma volume, or, if overall tissue uptake is extensive, the apparent volume of

distribution may greatly exceed the actual total volume of the body. In general, lipophilic drugs have larger volumes of distribution than hydrophilic drugs. Because the volume of distribution is a mathematical construct to model the distribution of a drug in the body, the volume of distribution cannot provide any information regarding the actual tissue concentration in any specific real organ in the body. However, this simple mathematical construct provides a useful summary description of the behavior of the drug in the body. In fact, the loading dose of drug required to achieve a target plasma concentration can be easily calculated by rearranging Equation 11-6 as follows:

**Table 11-4** Half-lives and Corresponding Percentage of Drug Removed

Number of Half-lives	Percentage of Drug Remaining	Percentage of Drug Removed
0	100	0
1	50	50
2	25	75
3	12.5	87.5
4	6.25	93.75
5	3.125	96.875

$$\text{Loading Dose} = V_d \times \text{Target Concentration} \quad (11-7)$$

Based on this equation, it is clear that an increase in the volume of distribution means that a larger loading dose will be required to “fill up the box” and achieve the same concentration. Therefore, any change in state because of changes in physiologic and pathologic conditions can alter the volume of distribution, necessitating therapeutic adjustments.

### Total Drug (Elimination) Clearance

**Elimination clearance** (drug clearance) is the theoretical volume of 7 blood from which drug is completely and irreversibly removed in a unit of time. Elimination clearance has the units of flow—[volume per time]. *Total* drug clearance can be calculated with pharmacokinetic models of blood concentration versus time data. Drug clearance is often corrected for weight or body surface area, in which case the units are mL/min/kg or mL/min/m<sup>2</sup>, respectively.

Elimination clearance,  $Cl$ , can be calculated from the declining blood levels observed after an IV injection, as follows:

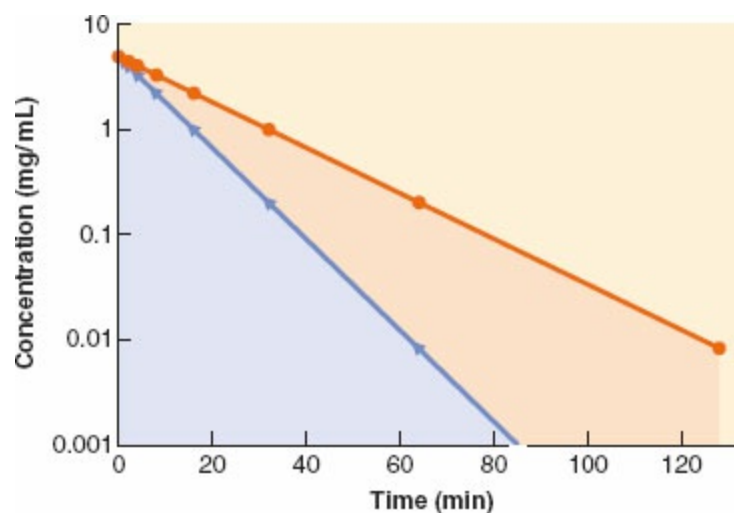

$$Cl = \frac{\text{dose of drug administered}}{\text{area under the concentration versus time curve}} \quad (11-8)$$

If a drug is rapidly removed from the plasma, its concentration will fall more quickly than the concentration of a drug that is less readily eliminated. This results in a smaller area under the concentration versus time curve, which equates to greater clearance (Fig. 11-4).

Without additional organ-specific data (e.g., urine drug concentration measurements, drug arterial inflow concentration) calculating elimination clearance from compartmental pharmacokinetic models usually does not specify the relative contribution of different organs to drug elimination. Nonetheless, estimation of drug clearance with these models has made important contributions to clinical pharmacology. In particular, these models have provided a great deal of clinically useful information regarding altered drug elimination in various pathologic conditions.

### Elimination Half-Life

Although the elimination clearance is the pharmacokinetic parameter that best describes the physiologic process of drug elimination (i.e., drug delivery to organs of elimination coupled with the capacity of the organ to eliminate the drug), the pharmacokinetic variable most often reported in textbooks and literature is the *elimination half-life* of a drug ( $t_{1/2\beta}$ ). The elimination half-life is the time during which the amount of drug in the body decreases by 50%. Although this parameter appears to be a simple summary of the physiology of drug elimination, it is actually a complex parameter, influenced by the distribution and the elimination of the drug, as follows:

**Figure 11-4** The plasma concentration (y-axis) versus time (x-axis) curve for two drugs which only differ in their elimination clearance. Notice that the areas under the curves are different, signifying that the drug that has the smaller area under the curve is more rapidly eliminated from the body than the drug that has the slower elimination clearance.

$$t_{1/2\beta} = \frac{\ln 2}{k_{\beta}} = 0.693 \times \frac{V_d}{Cl_E} \quad (11-9)$$

Therefore, when a physiologic or pathologic perturbation changes the elimination half-life of a drug, it is not a simple reflection of the change in the body's ability to metabolize or eliminate the drug. For example, the elimination half-life of thiopental is prolonged in the elderly; however, the elimination clearance is unchanged and the volume of distribution is increased.<sup>31</sup> Therefore, elderly patients need dosing strategies that accommodate for the change in the distribution of the drug rather than a decreased metabolism of the drug. In contrast, in patients with renal insufficiency, the increase in the elimination half-life of pancuronium is due to a simple decrease in renal elimination of the drug, and the volume of distribution is unchanged.<sup>32</sup>

Aside from its inability to give insight into the mechanism by which a drug is retained in the body, the elimination half-life is unable to give insight into the time that it takes for a single dose or a series of repeated drug doses to terminate its effect. Although elimination of drug from the body begins the moment the drug is delivered to the organs of elimination, the rapid termination of effect of a bolus of an IV agent is due to redistribution of drug from the brain to the blood and subsequently other tissues (e.g., muscle). Therefore, the effects of most anesthetics have waned long before even one elimination half-life has been completed, making this measure of drug kinetics incapable of providing useful information regarding the duration of action following the administration of IV agents. Thus the elimination half-life has limited utility in anesthetic practice.<sup>10</sup>

### **Effect of Hepatic or Renal Disease on Pharmacokinetic Parameters**

Diverse pathophysiologic changes preclude precise prediction of the pharmacokinetics of a given drug in individual patients with hepatic or renal disease. In addition, liver function tests (e.g., transaminases) are unreliable predictors of the degree of liver function and the remaining metabolic capacity for drug elimination. However, some generalizations can be made. In patients with hepatic disease, the elimination half-life of drugs metabolized or excreted by the liver is often increased because of decreased clearance, and, possibly, increased volume of distribution caused by ascites and altered protein binding.<sup>10,33</sup> Drug concentration at steady-state is inversely proportional to elimination clearance. Therefore, when hepatic drug clearance is reduced, repeated bolus dosing or continuous infusion of such drugs as benzodiazepines, opioids, and barbiturates may result in excessive accumulation of drug as well as excessive and prolonged pharmacologic effects. Since recovery from small doses of drugs such as thiopental and fentanyl is largely the result of redistribution, recovery from conservative doses will be minimally affected by reductions in elimination clearance. In

patients with renal failure, similar concerns apply to the administration of drugs excreted by the kidneys. It is almost always better to underestimate a patient's dose requirement, observe the response, and give additional drug if necessary.

## Nonlinear Pharmacokinetics

The physiologic and compartmental models thus far discussed are based on the assumption that drug distribution and elimination are first-order processes. Therefore, their parameters, such as clearance and elimination half-life, are independent of the dose or concentration of the drug. However, the rate of elimination of a few drugs is dose dependent, or *nonlinear*.

Elimination of drugs involves interactions with either enzymes catalyzing biotransformation reactions or carrier proteins for transmembrane transport. If sufficient drug is present, the capacity of the drug-eliminating systems can be exceeded. When this occurs, it is no longer possible to excrete a constant fraction of the drug present, and a constant amount of drug is excreted per unit time. Phenytoin is a well-known example of a drug that exhibits nonlinear elimination at therapeutic concentrations,<sup>34</sup> whereas in anesthetic practice, the extremely high doses of thiopental utilized for cerebral protection can demonstrate zero-order elimination.<sup>35</sup> In theory, all drugs are cleared in a nonlinear fashion. In practice, the capacity to eliminate most drugs is so great that this is usually not evident, even with toxic concentrations.

## Compartmental Pharmacokinetic Models

### One-Compartment Model

Although for most drugs the one-compartment model is an oversimplification, it does serve to illustrate the basic relationships among clearance, volume of distribution, and the elimination half-life. In this model, the body is envisaged as a single homogeneous compartment. Drug distribution after injection is assumed to be instantaneous, so there are no concentration gradients within the compartment. The concentration can decrease only by elimination of drug from the system. The plasma concentration versus time curve for a hypothetical drug with one-compartment kinetics is shown in [Figure 11-5](#). The decrease in plasma concentration ( $C$ ) with time from the initial concentration ( $C_0$ ) can be characterized by the simple monoexponential function:

$$C(t) = C_0 \times e^{-k_e \times t} \quad (11-10)$$

With the concentration plotted on a logarithmic scale, the concentration

versus time curve becomes a straight line. The slope of the logarithm of concentration versus time is equal to the first-order elimination rate constant ( $k_e$ ).

**Figure 11-5** The plasma concentration versus time profile plotted on both linear (*blue line*, left y-axis) and logarithmic (*red line*, right y-axis) scales for a hypothetical drug exhibiting one-compartment, first-order pharmacokinetics. Note that the slope of the logarithmic concentration profile is equal to the elimination rate constant ( $k_e$ ) and related to the elimination half-life ( $t_{1/2\beta}$ ) as described in Equation 11-9.

In the one-compartment model, drug clearance,  $Cl$ , is equal to the product of the elimination rate constant,  $k_e$ , and the volume of distribution:

$$Cl = k_e \cdot V_d \quad (11-11)$$

Combining Equations 11-5 and 11-10 yields Equation 11-9 (where  $k_e = k_\beta$ ):

$$t_{1/2\beta} = \frac{\ln 2}{k_e} = 0.693 \times \frac{V_d}{Cl_E} \quad (11-9)$$

Therefore, when it is appropriate to make the simplifying assumption of instantaneous mixing of drug into a single compartment, the elimination half-life is inversely proportional to the slope of the concentration time curve. For drugs which require consideration of their multicompartmental pharmacokinetics, the relationship among clearance, volume of distribution, and the elimination half-life is not a simple linear one such as Equation 11-9.

**8** However, the same principles apply. All else being equal, the greater the clearance, the shorter the elimination half-life; the larger the volume of distribution, the longer the elimination half-life. Thus, the elimination half-life depends on two other variables, clearance and volume of distribution, that characterize, respectively, the extent of drug distribution and efficiency of drug elimination.

## Two-Compartment Model

For many drugs, a graph of the logarithm of the plasma concentration versus time after an IV injection is similar to the schematic graph shown in [Figure 11-6](#). There are two discrete phases in the decline of the plasma concentration. The first phase after injection is characterized by a very rapid decrease in concentration. The rapid decrease in concentration during this “distribution phase” is largely caused by passage of drug from the plasma into tissues. The distribution phase is followed by a slower decline of the concentration owing to drug elimination. Elimination also begins immediately after injection, but its contribution to the drop in plasma concentration is initially much smaller than the fall in concentration because of drug distribution.

**Figure 11-6** The logarithmic plasma concentration versus time profile for a hypothetical drug exhibiting two-compartment, first-order pharmacokinetics. Note that the distribution phase has a slope that is significantly larger than that of the elimination phase, indicating that the process of distribution is not only more rapid than elimination of the drug from the body, but also responsible for most of the decline in plasma concentration in the several minutes after drug administration.

To account for this biphasic behavior, one must consider the body to be made up of two compartments: a central compartment, which includes the plasma, and a peripheral compartment ([Fig. 11-7](#)). This two-compartment model assumes that it is the central compartment into which the drug is injected and from which the blood samples for measurement of concentration are obtained, and that drug is eliminated only from the central compartment. Drug distribution within the central compartment is considered to be instantaneous. In reality, this last assumption cannot be true. However, drug uptake into some of the highly perfused tissues is so rapid that it cannot be detected as a discrete phase on the plasma concentration versus time curve.

The distribution and elimination phases can be characterized by graphic

analysis of the plasma concentration versus time curve, as shown in [Figure 11-6](#). The elimination phase line is extrapolated back to time zero (the time of injection). In [Figure 11-6](#), the zero time intercepts of the distribution and elimination lines are points *A* and *B*, respectively. The *hybrid rate constants*,  $\alpha$  and  $\beta$ , are equal to the slopes of the two lines, and are used to calculate the distribution and elimination half-lives;  $\alpha$  and  $\beta$  are called hybrid rate constants because they depend on both distribution and elimination processes.

**Figure 11-7** A schematic of a two-compartment pharmacokinetic model. See text for explanation.

At any time after an IV injection, the plasma concentration of drugs with two-compartment kinetics is equal to the sum of two exponential terms:

$$C_p(t) = Ae^{-\alpha t} + Be^{-\beta t} \quad (11-12)$$

where  $t$  = time,  $C_p(t)$  = plasma concentration at time  $t$ ,  $A$  = y-axis intercept of the distribution phase line,  $\alpha$  = hybrid rate constant of the distribution phase,  $B$  = y-axis intercept of the elimination phase line, and  $\beta$  = hybrid rate constant of the elimination phase. The first term characterizes the distribution phase and the second term characterizes the elimination phase. Immediately after injection, the first term represents a much larger fraction of the total plasma concentration than the second term. After several distribution half-lives, the value of the first term approaches zero, and the plasma concentration is essentially equal to the value of the second term ([Fig. 11-6](#)).

In multicompartmental models, the drug is initially distributed only within the central compartment. Therefore, the initial apparent volume of distribution is the volume of the central compartment. Immediately after injection, the amount of drug present is the dose, and the concentration is the extrapolated concentration at time  $t = 0$ , which is equal to the sum of the intercepts of the distribution and elimination lines. The volume of the central compartment,  $V_1$ , is calculated by modifying Equation 11-6:

$$V_1 = \frac{\text{dose}}{\text{initial plasma concentration}} = \frac{\text{dose}}{A + B} \quad (11-13)$$

The volume of the central compartment is important in clinical anesthesiology because it is the pharmacokinetic parameter that determines the peak plasma concentration after an IV bolus injection. Hypovolemia, for example, reduces the volume of the central compartment. If doses are not correspondingly reduced, the higher plasma concentrations will increase the incidence of adverse pharmacologic effects.

Immediately after IV injection, all of the drug is in the central compartment. Simultaneously, three processes begin. Drug moves from the central to the peripheral compartment, which also has a volume,  $V_2$ . This intercompartmental transfer is a first-order process, and its magnitude is quantified by the rate constant  $k_{12}$ . As soon as drug appears in the peripheral compartment, some passes back to the central compartment, a process characterized by the rate constant  $k_{21}$ . The transfer of drug between the central and peripheral compartments is quantified by the *distributional* or *intercompartmental clearance*:

$$\text{Intercompartmental Clearance} = Cl_{12} = Cl_{21} = V_1 \times k_{12} = V_2 \times k_{21} \quad (11-14)$$

The third process that begins immediately after administration of the drug is irreversible removal of drug from the system via the central compartment. As in the one-compartment model, the elimination rate constant is  $k_e$ , and *elimination clearance* is:

$$\text{Elimination Clearance} = Cl_E = V_1 \times k_e \quad (11-15)$$

The rapidity of the decrease in the central compartment concentration after IV injection depends on the magnitude of the compartmental volumes, the intercompartmental clearance, and the elimination clearance.

At equilibrium, the drug is distributed between the central and the peripheral compartments, and by definition, the drug concentrations in the compartments are equal. Therefore, the ultimate volume of distribution, termed the volume of distribution at steady-state ( $V_{ss}$ ), is the sum of  $V_1$  and  $V_2$ . Extensive tissue uptake of a drug is reflected by a large volume of the peripheral compartment, which, in turn, results in a large  $V_{ss}$ . Consequently,  $V_{ss}$  can greatly exceed the actual volume of the body.

As in the single-compartment model, in multicompartment models the elimination clearance is equal to the dose divided by the area under the concentration versus time curve. This area, as well as the compartmental volumes and intercompartmental clearances, can be calculated from the intercepts and hybrid rate constants, without having to reach steady-state

conditions.

### Three-Compartment Model

After IV injection of some drugs, the initial, rapid distribution phase is followed by a second, slower distribution phase before the elimination phase becomes evident. Therefore, the plasma concentration is the sum of three exponential terms:

$$C_p(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ge^{-\gamma t} \quad (11-16)$$

where  $t$  = time,  $C_p(t)$  = plasma concentration at time  $t$ ,  $A$  = intercept of the rapid distribution phase line,  $\alpha$  = hybrid rate constant of the rapid distribution phase,  $B$  = intercept of the slower distribution phase line,  $\beta$  = hybrid rate constant of the slower distribution phase,  $G$  = intercept of the elimination phase line, and  $\gamma$  = hybrid rate constant of the elimination phase. This triphasic behavior is explained by a three-compartment pharmacokinetic model (Fig. 11-8). As in the two-compartment model, the drug is injected into and eliminated from the central compartment. Drug is reversibly transferred between the central compartment and two peripheral compartments, which accounts for two distribution phases. Drug transfer between the central compartment and the more rapidly equilibrating, or “shallow,” peripheral compartment is characterized by the first-order rate constants  $k_{12}$  and  $k_{21}$ . Transfer in and out of the more slowly equilibrating, “deep” compartment is characterized by the rate constants  $k_{13}$  and  $k_{31}$ . In this model, there are three compartmental volumes:  $V_1$ ,  $V_2$ , and  $V_3$ , whose sum equals  $V_{ss}$ ; and three clearances: the rapid intercompartmental clearance, the slow intercompartmental clearance, and elimination clearance.

The pharmacokinetic parameters of interest to clinicians, such as clearance, volumes of distribution, and distribution and elimination half-lives, are determined by calculations analogous to those used in the two-compartment model. Accurate estimates of these parameters depend on accurate characterization of the measured plasma concentration versus time data. A frequently encountered problem is that the duration of sampling is not long enough to define accurately the elimination phase. Similar problems arise if the assay cannot detect low concentrations of the drug. Conversely, samples are sometimes obtained too infrequently following drug administration to be able to characterize the distribution phases accurately.<sup>36,37</sup> Whether a drug exhibits two- or three-compartment kinetics is of no clinical consequence.<sup>10</sup> In fact, some drugs have two-compartment kinetics in some patients and three-compartment kinetics in others. In selecting a pharmacokinetic model, the most important factor is that it accurately characterizes the measured concentrations.

**Figure 11-8** A schematic of a three-compartment pharmacokinetic model. See text for details.

In general, the model with the smallest number of compartments or exponents that accurately reflects the data is used. However, it is good to consider that the data collected in a particular study may not be reflective of the clinical pharmacologic issues of concern in another situation, making published pharmacokinetic model parameters potentially irrelevant. For instance, new data indicate that hypotension following IV administration of drug X is related to peak arterial plasma drug X concentrations 1 minute after injection, but previous pharmacokinetic models are based on venous plasma drug X concentrations beginning 5 minutes after the dose. In this case, the pharmacokinetic models will not be of use in designing dosing regimens for drug X that avoid toxic drug concentrations at 1 minute.<sup>10,38,39</sup>

Almost all earlier pharmacokinetic studies used *two-stage modeling*. With this technique, pharmacokinetic parameters were estimated independently for each subject and then averaged to provide estimates of the typical parameters for the population. One problem with this approach is that if outliers are present, averaging parameters could result in a model that does not accurately predict typical drug concentrations. Currently, most pharmacokinetic models are developed using *population pharmacokinetic modeling*, which has been made feasible because of advances in modeling software and increased computing power. With these techniques, the pharmacokinetic parameters are estimated using all the concentration versus time data from the entire group of subjects in a single stage, using sophisticated nonlinear regression methods. This modeling technique provides single estimates of the typical parameter values for the population.

### **Noncompartmental (Stochastic) Pharmacokinetic Models**

Often investigators performing pharmacokinetic analyses of drugs want to avoid the experimental requirements of a physiologic model—data or empirical estimations of individual organ inflow and outflow concentration profiles and organ tissue drug concentrations are required in order to identify

the components of the model.<sup>40</sup> Although compartmental models do not assume any physiologic or anatomic basis for the model structure, investigators often attribute anatomic and physiologic function to these empiric models.<sup>41</sup> Even if the disciplined clinical pharmacologist avoids overinterpretation of the meaning of compartment models, the simple fact that several competing models can provide equally good descriptions of the mathematical data, or that some subjects in a data set may better fit with a three-compartment model rather than the two-compartment model that provides the best fit for the other data set subjects, leads many to question whether there is a true best model architecture for any given drug. Therefore, some investigators choose to employ mathematical techniques to characterize a pharmacokinetic data set that attempt to avoid any preconceived notion of structure, and yet yield the pharmacokinetic parameters that summarize drug distribution and elimination. These techniques are classified as noncompartmental techniques or stochastic techniques and are similar to the methods based on moment analysis utilized in process analysis of chemical engineering systems. Although these techniques are often called model-independent, like any mathematical construct, assumptions must be made to simplify the mathematics. The basic assumptions of noncompartmental analysis are that all of the elimination clearance occurs directly from the plasma, the distribution and elimination of drug is a linear and first-order process, and the pharmacokinetics of the system does not vary over the time of the data collection (time-invariant). All of these assumptions are also made in the basic compartmental, and most physiologic, models. Therefore, the main advantage of the noncompartmental pharmacokinetic methods is that a general description of drug absorption, distribution, and elimination can be made without resorting to more complex mathematical modeling techniques.<sup>40</sup>

Another appealing facet of noncompartmental analysis is that the parameters that describe drug distribution (volume of distribution at steady-state,  $V_{dss}$ ) and drug elimination (elimination clearance,  $Cl_E$ ) are analogous to parameters found in other pharmacokinetic techniques. In fact, when properly defined, the estimates of these parameters from the noncompartmental approach and a well-defined compartmental model yield similar values. The main unique parameter of noncompartmental analysis is the Mean Residence Time (MRT), which is the average time a drug molecule spends in the body before being eliminated.<sup>42</sup> The MRT unfortunately suffers from the main failings of the elimination half-life derived from compartmental models—not only does it fail to capture the contribution of extensive distribution versus limited elimination to allow a drug to linger in the body, but both parameters also fail to describe the situation where the drug effect can dissipate by redistribution of drug from the site of action back into blood and then into

other, less well-perfused tissues.<sup>43</sup>

## Pharmacodynamic Principles

Much of the clinical pharmacology efforts of the late eighties through nineties were devoted to applying new computational power of desktop personal computers to deciphering the pharmacokinetics of IV anesthetics. However, the premise behind developing models to better characterize and understand the effects of various physiologic and pathologic states on drug distribution and elimination was that the relationship between a dose of drug and its effect(s) had already been characterized. As computational power and drug assay technology grew, it became possible to characterize the relationship between a drug concentration and the associated pharmacologic effect. As a result, pharmacodynamic studies since the nineties have focused on the quantitative analysis of the relationship between the drug concentration in the blood and the resultant effects of the drug on physiologic processes.

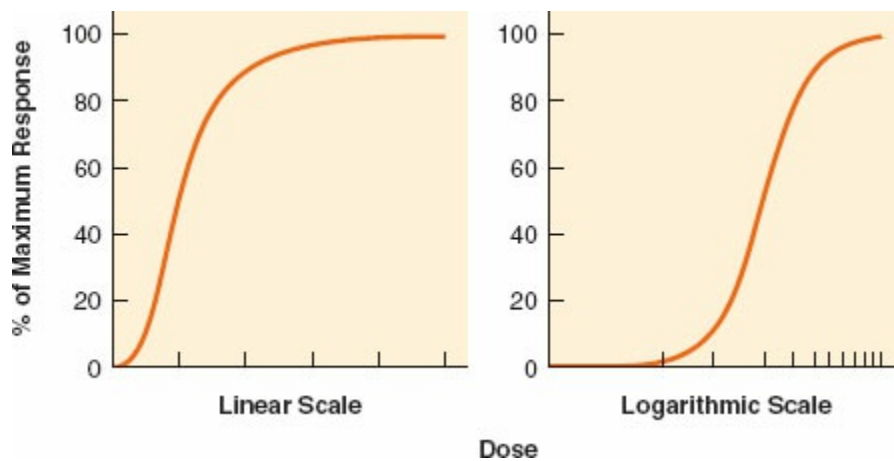

### *Drug–Receptor Interactions*

Most pharmacologic agents produce their physiologic effects by binding to a drug specific receptor, which brings about a change in cellular function. The majority of pharmacologic receptors are cell membrane bound proteins, although some receptors are located in the cytoplasm or the nucleoplasm of the cell.

Binding of drugs to receptors, like the binding of drugs to plasma proteins, is usually reversible, and follows the Law of Mass Action:

This relationship demonstrates that the higher the concentration of free drug or unoccupied receptor, the greater the tendency to form the drug–receptor complex. Plotting the percentage of receptors occupied by a drug against the logarithm of the concentration of the drug yields a sigmoid curve, as shown in [Figure 11-9](#).<sup>44</sup>

**Figure 11-9** A schematic curve of the effect of a drug plotted against dose. In the left panel, the response data is plotted against the dose data on a linear scale. In the right panel, the same response data are plotted against the dose data on a logarithmic scale yielding a sigmoid dose–response curve that is linear between 20% and 80% of the maximal effect.

The percentage of receptors occupied by a drug is not equivalent to the percentage of maximal effect produced by the drug. In fact, most receptor systems have more receptors than required to obtain the maximum drug effect.<sup>45</sup> The presence of “extra” unoccupied receptors will promote the formation of the drug–receptor complex (Law of Mass Action, Equation 11-17); therefore, near-maximal drug effects can occur at very low drug concentrations. This not only allows extremely efficient responses to drugs, but it provides a large margin of safety—an extremely large number of a drug’s receptors must be bound to an antagonist before the drug is unable to produce its pharmacologic effect. For example, at the neuromuscular junction, only 20% to 25% of the postjunctional nicotinic cholinergic receptors need to bind acetylcholine to produce contraction of all the fibers in the muscle, while 75% of the receptors must be blocked by a nondepolarizing neuromuscular antagonist to produce a significant drop in muscle strength. This accounts for the “margin of safety” of neuromuscular transmission.<sup>45</sup>

The binding of drugs to receptors and the resulting changes in cellular function are the last two steps in the complex series of events between administration of the drug and production of its pharmacologic effects. There are two primary schemes by which the binding of an agonist to a receptor changes cellular function: receptor-linked membrane ion channels called *ionophores*, and guanine nucleotide binding proteins, referred to as *G-proteins*. The nicotinic cholinergic receptor in the neuromuscular postsynaptic membrane is one example of a receptor–ionophore complex. Binding of acetylcholine opens the cation ionophore, leading to an influx of  $\text{Na}^+$  ions, propagation of an action potential, and, ultimately, muscle contraction. The  $\beta$ -amino butyric acid (GABA) receptor–chloride ionophore complex is another example of this type of effector mechanism. Binding of either endogenous

neurotransmitters (GABA) or exogenous agonists (benzodiazepines and IV anesthetics) increases  $\text{Cl}^-$  conductance, which hyperpolarizes the neuron and decreases its excitability. Adrenergic receptors are the prototypical G-protein coupled receptors. G-proteins change the intracellular concentrations of various so-called *second messengers*, such as  $\text{Ca}^{2+}$  and cyclic AMP, in order to transduce their signal and produce modified cellular behavior.

## Desensitization and Downregulation of Receptors

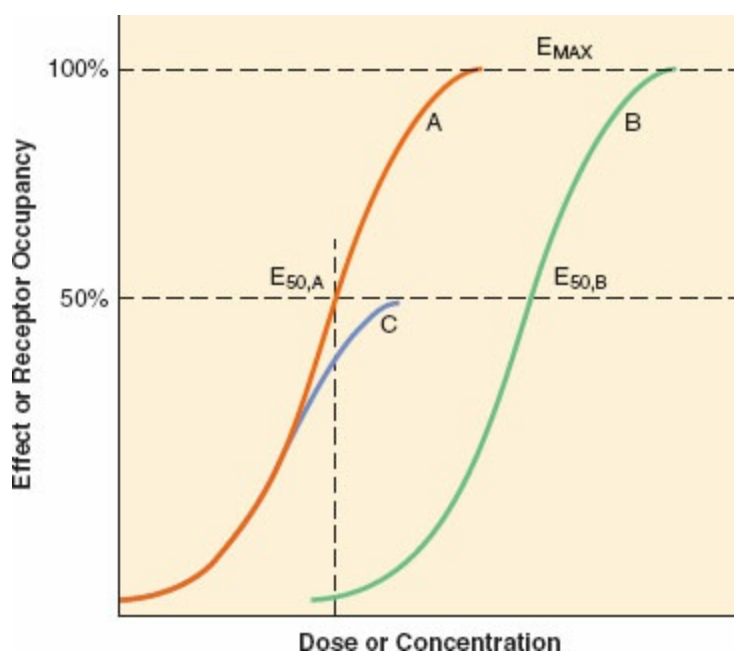

Receptors are not static entities. Rather, they are dynamic cellular components that adapt to their environment. Prolonged exposure of a receptor to its agonist leads to desensitization—subsequent doses of the agonist will produce lower maximal effects. With sustained elevation of the cytosolic second messengers downstream of the G-proteins, pathways to prevent further G-protein signaling are activated. Phosphorylation by G-protein receptor kinases and arrestin-mediated blockage of the coupling site needed to form the active heterotrimeric G protein complex prevents G protein coupled receptors from becoming active. Arrestins and other cell membrane proteins can tag receptors that have sustained activity, so that these non-G-protein receptors are internalized and sequestered so they are no longer accessible to agonists. Similar mechanisms will prevent the trafficking of stored receptors to the cell membrane. The combined increased rate of internalization and decreased rate of replenishing of receptor results in *downregulation*—a decrease in the total number of receptors. Signals that produce downregulation with sustained receptor activation are essentially reversed in the face of constant receptor inactivity. Therefore, chronically denervated neuromuscular junctions, just like cardiac tissue constantly bathed with adrenergic antagonists, will upregulate the specific receptors in an attempt to produce a signal in the face of lower concentrations of agonists.

## Agonists, Partial Agonists, and Antagonists

Drugs that bind to receptors and produce an effect are called *agonists*. Different drugs that act on the same receptor may be capable of producing the same maximal effect ( $E_{\text{max}}$ ), although they may differ in the concentration that produces the effect (i.e., potency). Agonists that differ in potency but bind to the same receptors will have parallel concentration–response curves (Fig. 11-10, curves A and B). Differences in potency of agonists reflect differences in affinity for the receptor. *Partial agonists* are drugs that are not capable of producing the maximal effect, even at very high concentrations (Fig. 11-10, curve C).

Compounds that bind to receptors without producing any changes in cellular function are referred to as *antagonists*—antagonists make it

impossible for agonists to bind their receptors. *Competitive antagonists* bind reversibly to receptors, and their blocking effect can be overcome by high concentrations of an agonist (i.e., competition). Therefore, competitive antagonists produce a parallel shift in the dose–response curve, but the maximum effect is not altered (Fig. 11-10, curves A and B). *Noncompetitive antagonists* bind irreversibly to receptors. This has the same effect as reducing the number of receptors and shifts the dose–response curve downward and to the right, decreasing both the slope and the maximum effect (Fig. 11-10, curves A and C). The effect of noncompetitive antagonists is reversed only by synthesis of new receptor molecules.

**Figure 11-10** Schematic pharmacodynamic curves, with dose or concentration on the x-axis and effect or receptor occupancy on the y-axis, that illustrate agonism, partial agonism, and antagonism. Drug A produces a maximum effect,  $E_{\max}$ , and a 50% of maximal effect at dose or concentration  $E_{50,A}$ . Drug B, a full agonist, can produce the maximum effect,  $E_{\max}$ ; however, it is less potent ( $E_{50,B} > E_{50,A}$ ). Drug C, a partial agonist, can only produce a maximum effect of approximately 50%  $E_{\max}$ . If a competitive antagonist is given to a patient, the dose response for the agonist would shift from curve A to curve B—although the receptors would have the same affinity for the agonist, the presence of the competitor would necessitate an increase in agonist in order to produce an effect. In fact, the agonist would still be able to produce a maximal effect, if a sufficient overdose was given to displace the competitive antagonist. However, the competitive antagonist would not change the binding characteristics of the receptor for the agonist and so curve B is simply shifted to the right but remains parallel to curve A. In contrast, if a noncompetitive antagonist binds to the receptor, the agonist would no longer be able to produce a maximal effect, no matter how much of an overdose is administered (curve C).

Agonists produce a structural change in the receptor molecule that initiates changes in cellular function. Partial agonists may produce a qualitatively different change in the receptor, whereas antagonists bind without producing a change in the receptor that results in altered cellular function. The underlying mechanisms by which different compounds that bind to the same receptor act as agonists, partial agonists, or antagonists are not fully understood.

## Dose–Response Relationships

Dose–response studies determine the relationship between increasing doses of a drug and the ensuing changes in pharmacologic effects. Schematic dose–response curves are shown in [Figure 11-9](#), with the dose plotted on both linear and logarithmic scales. There is a curvilinear relationship between dose and the intensity of response. Low doses produce little pharmacologic effect. Once effects become evident, a small increase in dose produces a relatively large change in effect. At near-maximal response, large increases in dose produce little change in effect. Usually the dose is plotted on a logarithmic scale ([Fig. 11-9](#), right panel), which demonstrates the linear relationship between the logarithm of the dose and the intensity of the response between 20% and 80% of the maximum effect.

Acquiring the pharmacologic effect data from a population of subjects exposed to a variety of doses of a drug provides four key characteristics of the drug dose–response relationship—potency, drug-receptor affinity, efficacy, and population pharmacodynamic variability. The *potency* of the drug—the dose required to produce a given effect—is usually expressed as the dose required to produce a given effect in 50% of subjects, the *ED50*. The *slope* of the curve between 20% and 80% of the maximal effect indicates the rate of increase in effect as the dose is increased and is a reflection of the affinity of the receptor for the drug. The maximum effect is referred to as the *efficacy* of the drug. Finally, if curves from multiple subjects are generated, the *variability* in potency, efficacy, and the slope of the dose–response curve can be estimated.

The dose needed to produce a given pharmacologic effect varies considerably, even in “normal” patients. The patient most resistant to the drug usually requires a dose two- to threefold greater than the patient with the lowest dose requirements. This variability is caused by differences among individuals in the relationship between drug concentration and pharmacologic effect, superimposed on differences in pharmacokinetics. Dose–response studies have the disadvantage of not being able to determine whether variations in pharmacologic response are caused by differences in pharmacokinetics, pharmacodynamics, or both.

## Concentration–Response Relationships

The onset and duration of pharmacologic effects depend not only on pharmacokinetic factors but also on the pharmacodynamic factors governing the degree of temporal disequilibrium between changes in concentration and changes in effect. The magnitude of the pharmacologic effect is a function of the amount of drug present at the site of action, so increasing the dose increases the peak effect. Larger doses have a more rapid onset of action because pharmacologically active concentrations at the site of action occur sooner. Increasing the dose also increases the duration of action because pharmacologically effective concentrations are maintained for a longer time.

Ideally, the concentration of drug at its site of action should be used to define the concentration–response relationship. Unfortunately, these data are rarely available, so the relationship between the concentration of drug in the blood and pharmacologic effect is studied instead. This relationship is easiest to understand if the changes in pharmacologic effect that occur during and after an IV infusion of a hypothetical drug are considered. If a drug is infused at a constant rate, the plasma concentration initially increases rapidly and asymptotically approaches a steady-state level after approximately five elimination half-lives have elapsed (Fig. 11-11). The effect of the drug initially increases very slowly, then more rapidly, and eventually also reaches a steady state. When the infusion is discontinued, indicated by point C in Figure 11-11, the plasma concentration immediately decreases because of drug distribution and elimination. However, the effect stays the same for a short period, and then also begins to decrease—there is always a time lag between changes in plasma concentration and changes in pharmacologic response. Figure 11-11 also demonstrates that the same plasma concentration is associated with different responses if the concentration is changing. At points A and B in Figure 11-11, the plasma concentrations are the same, but the effects at each time differ. When the concentration is increasing, there is a concentration gradient from blood to the site of action. When the infusion is discontinued, the concentration gradient is reversed. Therefore, at the same plasma concentration, the concentration at the site of action is higher after, compared to during, the infusion. This is associated with a correspondingly greater effect.

**Figure 11-11** The changes in plasma drug concentration and pharmacologic effect

during and after an intravenous infusion. See text for explanation. (Adapted from Stanski DR, Sheiner LB. Pharmacokinetics and pharmacodynamics of muscle relaxants. *Anesthesiology*. 1979;51:103.)

In theory, there must be some degree of temporal disequilibrium between plasma concentration and drug effect for all drugs with extravascular sites of action. However, for some drugs, the time lag may be so short that it cannot be demonstrated. The magnitude of this temporal disequilibrium depends on several factors:

- The perfusion of the organ on which the drug acts
- The tissue:blood partition coefficient of the drug
- The rate of diffusion or transport of the drug from the blood to the cellular site of action
- The rate and affinity of drug–receptor binding
- The time required for processes initiated by the drug–receptor interaction to produce changes in cellular function

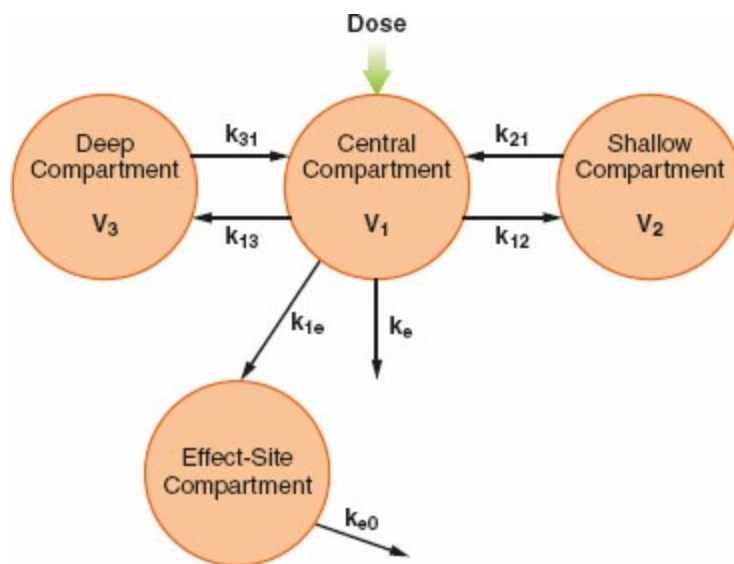

The consequence of this time lag between changes in concentration and changes in effects is that the plasma concentration will have an unvarying relationship with pharmacologic effect only under steady-state conditions. At steady state, the plasma concentration is in equilibrium with the concentrations throughout the body, and is thus directly proportional to the steady-state concentration at the site of action. Plotting the logarithm of the steady-state plasma concentration versus response generates a curve identical in appearance to the dose–response curve shown in the right panel of [Figure 11-9](#). The  $C_{p_{ss}50}$ , the steady-state plasma concentration producing 50% of the maximal response, is determined from the concentration–response curve. Like the  $ED_{50}$ , the  $C_{p_{ss}50}$  is a measure of sensitivity to a drug, but the  $C_{p_{ss}50}$  has the advantage of being unaffected by pharmacokinetic variability. Because it takes five elimination half-lives to approach steady-state conditions, it is not practical to determine the  $C_{p_{ss}50}$  directly. For drugs with long elimination half-lives, the pseudoequilibrium during the elimination phase can be used to approximate steady-state conditions, because the concentrations in plasma and at the site of action are changing very slowly.

## Combined Pharmacokinetic–Pharmacodynamic Models

**11** Integrated pharmacokinetic–pharmacodynamic models fully characterize the relationships among time, dose, plasma concentration, and pharmacologic effect. This is accomplished by adding a hypothetical “effect compartment” (biophase) to a standard compartmental pharmacokinetic model ([Fig. 11-12](#)).<sup>46–48</sup> Transfer of drug between central compartment and the effect compartment is assumed to be a first-order process, and the

pharmacologic effect is assumed to be directly related to the concentration in the biophase. The biophase is a “virtual” compartment, although linked to the pharmacokinetic model, and does not actually receive or return drug to the model and, therefore, ensures that the effect site processes do not influence the pharmacokinetics of the rest of the body. By simultaneously characterizing the pharmacokinetics of the drug and the time course of drug effect, the combined pharmacokinetic–pharmacodynamic model is able to quantify the temporal dissociation between the plasma (central compartment) concentration and effect with the rate constant for equilibration between the plasma and the biophase,  $k_{e0}$ . By quantifying the time lag between changes in plasma concentration and changes in pharmacologic effect, these models can also define the  $C_{p_{ss}50}$ , even without steady-state conditions. These models have contributed greatly to our understanding of factors influencing the response to IV anesthetics, opioids, and nondepolarizing muscle relaxants in humans.

**Figure 11-12** A schematic of a three-compartment pharmacokinetic model with the effect site linked to the central compartment. The rate constant for transfer between the plasma (central compartment) and the effect site,  $k_{1e}$ , and the volume of the effect site are both presumed to be negligible to ensure that the effect site does not influence the pharmacokinetic model. The rate constant for drug removal from the effect site, which relates the concentration in the central compartment to the pharmacologic effect is  $k_{e0}$ .

The rate of equilibration between the plasma and the biophase,  $k_{e0}$ , can also be characterized by the half-life of effect site equilibration ( $T_{1/2k_{e0}}$ ) using the formula:

$$T_{1/2k_{e0}} = \frac{\ln 2}{k_{e0}} = \frac{0.693}{k_{e0}} \quad (11-18)$$

$T_{1/2k_{e0}}$  is the time for the effect site concentration to reach 50% of the

plasma concentration when the plasma concentration is held constant. For anesthetics with a short  $T_{1/2ke0}$  (high  $k_{e0}$ ), equilibration between the plasma and the biophase is rapid and therefore there is little delay before an effect is reached when a bolus of drug is administered or an infusion of drug is initiated. However, because the decline in the effect site concentration will also depend on the concentration gradient between the effect site and the plasma, drugs that rapidly equilibrate with the biophase may take longer to redistribute away.<sup>49</sup> Therefore, the offset of drug effect is more dependent on the pharmacokinetics of the body than on the rapidity of biophase-plasma equilibration.<sup>20,49</sup>

## Population Pharmacokinetic–Pharmacodynamic Models

Population pharmacokinetic–pharmacodynamic (PKPD) modeling has emerged as a nearly essential part of study design and data analysis in the clinical pharmacology of anesthetic drugs.<sup>50</sup> Despite the term “population,” these techniques are designed to bring an individual’s specific physiologic characteristics into dose regimen selection. These analyses were made possible through the combined efforts of a theoretical statistician, Stuart Beal, and a leading clinical pharmacologist, Lewis Sheiner, and found early adoption in anesthesiology.<sup>51,52</sup> Sheiner and Beal termed their technique nonlinear mixed effects (meaning both fixed and random effects) modeling and wrote a computer program (NONMEM) to fit PKPD data from multiple individuals, and even from multiple studies, while building an overarching statistical description.<sup>53</sup> In this way a typical (or median) value for each parameter (e.g., clearance, volume,  $EC_{50}$ ) of the PKPD model (called fixed effects, or thetas,  $\theta$ , in NONMEM terminology) could be combined with a random effect variable (eta,  $\beta$ , in NONMEM) that described where on the distribution (e.g., Gaussian) of all  $\beta$ s each individual  $\beta$  lies for each parameter,  $\theta$ .<sup>50</sup>

With nonlinear mixed effects modeling it is possible to include the interindividual variability of each parameter into a PKPD model for the population(s) studied; an important concept when trying to predict the next dose administered to the next patient. Furthermore, the spread of the random effects ( $\beta$ s) can be reduced by including each individual’s demographic data, for example, genomic and physiologic factors, into the model in the form of covariates to refine the model and enhance its ability to predict the next patient’s response to a drug by inclusion of demographic data in the dose calculation.

Allometric scaling has developed as a corollary to population PKPD modeling. Allometry derives from an observation that interspecies metabolism varies by an animal’s weight raised to the 0.75 power (instead of

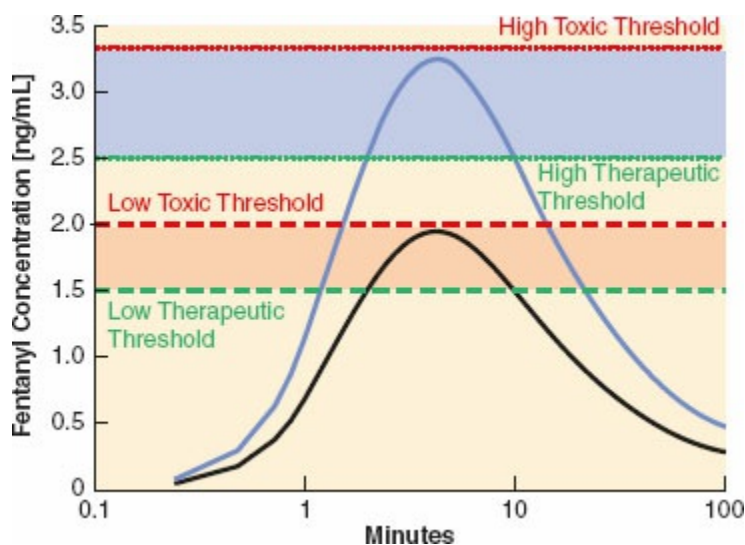

1.0).<sup>54</sup> It has been widely applied to scale pharmacokinetic models across species. More recently, allometry has been applied to intraspecies (human) scaling when developing population mixed effects PKPD models at the extremes of age (i.e., pediatric and geriatric) or size (i.e., morbid obesity).<sup>55–57</sup>

Population PKPD models were developed to facilitate individualized medicine in drug therapy. However, dosing regimens are rapidly becoming calculation-intensive, with the inclusion of increasing numbers of important covariates, especially with additional nonlinear allometric considerations. Thus, to allow precision dosing in the practice of anesthesiology, these complex calculations should ideally be incorporated into drug-specific infusion pumps (e.g., TCI pumps) or into apps the clinician can have on a PDA at the bedside.

### **Therapeutic Thresholds and Therapeutic Window**

The timing of the onset and the offset of drug action is not only dependent on the effect site's concentration profile (i.e., the drug's pharmacokinetics and pharmacodynamics), but it also depends on the minimum concentration that produces a discernible level of drug effect—the therapeutic threshold of the drug. The therapeutic threshold of a drug depends on the magnitude of the desired effect or the intensity of the stimulus being treated. For example, superficial procedures (i.e., mastectomy, melanoma excision, etc) are not as painful (Fig. 11-13, dashed green line) as orthopedic procedures (i.e., long bone instrumentation, spine fusion, etc., dotted green line). Therefore, the dose of fentanyl that produces analgesia for superficial procedures (black solid concentration profile) does not produce clinically discernible analgesia for the orthopedic procedures (i.e., below the therapeutic threshold). In contrast, the dose of fentanyl that produces analgesia for the orthopedic procedures (blue solid concentration profile) will not only provide analgesia for the superficial procedures, but it will also have a faster onset of effect because it reaches the therapeutic threshold quicker. In addition, since the larger bolus of fentanyl results in concentrations of drug that are above the toxic threshold for the superficial procedures (red dashed line, Low Toxic Threshold), the patient will have significant ventilatory depression until the effect site concentration of fentanyl decreases below this toxic threshold. This profound ventilatory depression would start approximately 2 minutes after the larger bolus of fentanyl was administered and last until 18 minutes after the larger bolus of fentanyl. The therapeutic window that should be targeted to provide adequate analgesia after a superficial procedure is below the toxic threshold (red dashed line) and above the therapeutic threshold (green dashed line). The therapeutic window that should be targeted for orthopedic

procedures has the entire window “shifted higher” (i.e., below the red dotted line and above the green dotted line).

**Figure 11-13** The effect site concentration versus time profiles after a small intravenous bolus (*solid black line*) and a larger intravenous bolus (*solid blue line*) of fentanyl. Representative therapeutic thresholds (the minimum concentration required to produce clinically discernible analgesia), and toxic threshold (the concentration above which profound opioid induced ventilatory depression occurs) are demonstrated superficial procedures, such as mastectomy (*green dashed line*, low therapeutic threshold), and for orthopedic procedures, such as long bone instrumentation (*dotted green line*, high therapeutic threshold). A given bolus of fentanyl only produces clinically discernible analgesia from the time it produces an effect site concentration above the therapeutic threshold concentration for a patient until the time when the effect site concentration decreases below the therapeutic threshold concentration. If the effect site concentration does not exceed the toxic threshold for a patient, then it does not produce profound opioid induced ventilatory depression. In contrast, if the bolus does produce an effect site concentration above the toxic threshold concentration, it will produce profound ventilatory depression that is sustained until the effect site concentration decreases below the toxic threshold concentration. For example, after superficial surgery, a small dose of fentanyl (*solid black line*) will initially produce detectable analgesia approximately 2 minutes after administration (when it crosses the low therapeutic threshold, *dashed green line*) which will last until approximately 10 minutes after administration (when the concentration decreases below the low therapeutic threshold, *green dashed line*). Since the dose does not produce a concentration above the low toxic threshold (*dashed red line*), hypoventilation will not occur after this single bolus. In contrast, for the same superficial procedure, a larger bolus of fentanyl (*solid blue line*) will initially produce analgesia less than 1 minute after administration (when it crosses the low therapeutic threshold, *dashed green line*), which will last until approximately 30 minutes after administration (when the concentration decreases below the low therapeutic threshold, *green dashed line*). Since the dose produces an effect site concentration above the toxic threshold (*dashed red line*), it will produce profound

hypoventilation from approximately 2 minutes until the effect site concentration decreases below the same toxic threshold at approximately 18 minutes. So, although the larger bolus produces a quicker onset of action and a longer duration of action, it produces toxicity for a portion of this time. After orthopedic procedures (*dotted green line* for high therapeutic threshold and *dotted red line* for high toxic threshold), a small bolus of fentanyl will be subtherapeutic and ineffective (*black solid line*) because it does not produce a concentration above the high therapeutic threshold (*dotted green line*). In contrast, a larger bolus of fentanyl produces clinically discernible analgesia from approximately 2 through 10 minutes after administration (time that *blue line* is above *green dotted line*).

## Drug Interactions

Taking into account premedication, perioperative antibiotics, IV agents used for induction or maintenance, inhalational anesthetics, opioids, muscle relaxants, the drugs used to restore neuromuscular transmission, and postoperative analgesics, 10 or more drugs may be given as relatively “routine” anesthetics. Consequently, thorough understanding of the mechanisms of drug interactions and knowledge of specific interactions with drugs used in anesthesia are essential to the safe practice of anesthesiology. Indeed, anesthesiologists often deliberately take advantage of drug interactions. For example, moderate to high doses of opioid are often utilized to decrease the amount of volatile anesthetic required to provide immobility and hemodynamic stability to surgical incision (e.g., MAC\* and MAC<sub>BAR</sub>), thereby avoiding the side effects of higher concentrations of inhaled anesthetics (e.g., vasodilation, prolonged awakening). In this section, we will examine the major classes of drug–drug interactions by detailing common examples encountered in the perioperative period.

### Pharmaceutical (Physiochemical) Interactions

#### In Vitro Interactions

Anesthesiologists often overlook the drug interactions produced by pharmaceutical (physicochemical) properties because most perioperative drugs are administered intravenously or via inhalation, and therefore have a **12** high bioavailability. However, in vitro drug–drug interactions due to physiochemical properties of drugs can significantly alter drug bioavailability and produce unintended toxic byproducts. Basic acid–base chemistry can predict many of the observed in vitro interactions. One classic example of a physiochemical drug–drug interaction that alters drug bioavailability is the formation of insoluble salts that precipitate when acidic

drugs, such as thiopental, and basic drugs, such as opioids or muscle relaxants, are “mixed” when the two drugs are administered into IV tubing with an insufficient fluid flow rate.<sup>58</sup> Another example is the observation that commercial preparations of local anesthetic solutions that contain epinephrine would have a lower pH than plain local anesthetic solutions to which epinephrine is added shortly prior to administration, because of the high acidity of the antioxidant stabilizers used in commercial preparations (i.e., sodium bisulfite or sodium pyrosulfite).<sup>59</sup> The unintended consequence of this commercial formulation is that the local anesthetic appears less effective owing to the increased concentration of the less permeable ionized form of local anesthetic that exists in acidic environments.

Although physiochemical drug interactions that affect the bioavailability of drugs are relatively easy to avoid or, at least, overcome by increasing the drug dose, some physiochemical interactions can result in unintended toxic compounds. One chemical agent often overlooked by anesthesiologists is the soda lime or Baralyme that is used in modern anesthesia machines to remove carbon dioxide from the exhaled gases. Although patients are not directly administered this agent, the gas that they inhale from the anesthesia machine often contains the byproducts of the interaction between the constituents of the exhaled gas and the carbon dioxide absorbent. While this allows the patient to receive a “heated and humidified” inhaled gas mixture, if conditions are correct, the halogenated volatile anesthetics can undergo degradation by the strong base (i.e., sodium and/or potassium hydroxide) contained in the carbon dioxide absorber.<sup>60</sup> This chemical reaction led the FDA to recommend that sevoflurane exposure should not exceed 2 MAC-hours at using fresh gas flow rates of 1 to less than 2 L/min, in order to minimize exposure to the potentially nephrotoxic haloalkene (“compound A”) formed by dehydrofluorination of sevoflurane by soda lime or Baralyme.<sup>61</sup> Although the effects of compound A on human renal function are not of great clinical concern, the strong bases in the carbon dioxide can also degrade the difluoro-ethyl containing halogenated volatile anesthetics (i.e., desflurane and isoflurane) to carbon monoxide.<sup>62</sup> These patient safety concerns led to the development and the increased use of Amsorb, a carbon dioxide adsorbent that contains calcium hydroxide lime in place of sodium and/or potassium hydroxide, and therefore causes minimal to no carbon monoxide or compound A formation.<sup>63</sup>

## **In Vivo Interactions**

Whereas many of the in vitro physiochemical interactions can result in unintended toxicity due to exposure to either subtherapeutic drug concentrations or toxic degradation products, physiochemical interactions

have been exploited to develop two novel approaches to antagonize neuromuscular junction blocking agents. The first approach, which was approved for use in the European Union in 2008 and in the United States in 2016, is the selective relaxant binding agent, sugammadex. Sugammadex is a synthetic cyclodextrin that encapsulates and electrostatically binds rocuronium. By essentially irreversibly binding plasma rocuronium, sugammadex acts as a chelator that not only rapidly decreases the free plasma rocuronium concentration but also promotes redistribution of rocuronium from the neuromuscular junction (extracellular space) to the intravascular space.<sup>64</sup> Therefore, if there is an excess of sugammadex molecules relative to rocuronium molecules, the neuromuscular blockade is antagonized. Although sugammadex was developed to antagonize neuromuscular blockade produced by rocuronium, it is also able to antagonize profound neuromuscular blockade produced by the other commonly used steroidal neuromuscular blocking agents, vecuronium and pipecuronium.<sup>65,66</sup> However, sugammadex is unable to antagonize neuromuscular blockade produced by the benzyloquinoline neuromuscular blocking agent, cisatracurium. However, molecules from the cucurbit[n]uril family can encapsulate both the steroidal and benzyloquinoline family of neuromuscular blocking agents in preclinical models and may be a more comprehensive solution for antagonism of neuromuscular blockade via molecular encapsulation.<sup>67–69</sup> An alternative approach to neuromuscular blockade antagonism is to design a molecule that can be inactivated via nonbiologic routes. This approach has led to Phase 1 studies of a new class of nondepolarizing neuromuscular blocking drugs called the fumarates (olefinic diester isoquinolinium compounds). These molecules are rapidly inactivated by the nonenzymatic formation of cysteine adducts when combined with plasma cysteine.<sup>70</sup> Therefore, cysteine administration antagonizes the neuromuscular blockade. These two novel approaches to drug development could be used to develop designer drugs that can be readily antagonized via nonbiologic routes, if the important receptor targets for sedation and amnesia components of general anesthesia are identified.

### ***Pharmacokinetic Interactions***

Drugs can alter each other's absorption, distribution, and elimination. Understanding the basis for alterations in the pharmacokinetics allows anesthesiologists to not only avoid unintentional supratherapeutic or subtherapeutic concentrations of the perioperative medications, but also to strategically employ alterations in pharmacokinetics to achieve the desired concentration profile.

### **Absorption (Uptake)**

Some drugs can alter the absorption of other drugs, by either altering the delivery of drug to site of drug absorption (uptake) or by altering the local blood flow to the site of drug administration. Although this type of drug–drug interaction will alter bioavailability, it should not alter any other pharmacokinetic parameter. Drugs like ranitidine, which alters gastric pH, and metoclopramide, which speeds gastric emptying, alter absorption from the GI tract. Vasoconstrictors that decrease local blood flow and decrease systemic uptake of drug can be beneficial when added to local anesthetic solutions because they prolong the duration of action of the local anesthetic at the site of injection and can decrease the risk of systemic toxicity from rapid absorption. However, when systemically administered, vasoactive drugs can decrease blood flow to skin and muscle, and decrease the systemic uptake of drugs given by subcutaneous or intramuscular injection. In a similar manner, vasoactive agents can alter the ventilation–perfusion ratio, thereby altering pulmonary uptake of volatile anesthetics, despite a constant inspired concentration. Because of the variability produced by vasoactive agents in drug uptake, careful thought must be given when choosing to administer drugs via non-IV route in perioperative patients.

## Distribution

Some drugs can alter the systemic distribution of other drugs. Alterations in drug distribution will change some or all of a pharmacokinetic model's volume parameters. It can also alter one or all of the *intercompartmental* clearance parameters of a multicompartamental pharmacokinetic model. There are two main mechanisms purported in textbooks and the clinical pharmacology literature by which drug–drug interactions alter drug distribution—(a) changing the volume of tissue available for drug uptake and (b) changing the amount of drug available for tissue uptake. Since the drug dose required to achieve a desired drug concentration is intimately linked to systemic drug distribution, understanding what common drug–drug interactions produce real alterations in drug distribution can avoid unintentional exposure to subtherapeutic and suprathreshold drug concentrations.

Although a drug cannot alter the actual volume of tissue available for drug uptake, changing the exposure of blood to different tissue beds changes a drug's apparent tissue volume of distribution. Therefore, drug-induced alterations of cardiac output and the distribution of cardiac output to tissues can change the distribution clearance of other drugs. Once again, vasoactive agents can alter tissue distribution by altering regional blood flow even if the total cardiac output is unchanged. Because the change in the plasma drug concentration produced by a prescribed dosing regimen is

inversely related to the distribution clearance, the drug dose must be decreased when vasoactive drugs decrease cardiac output or the distribution of cardiac output; otherwise the patient will be exposed to supratherapeutic drug concentrations.<sup>71-73</sup> In addition, the unintended cardiovascular effects of anesthetic drugs, such as the decrease in cardiac output with increasing doses of the direct myocardial depressant, halothane, or the direct arterial dilator, isoflurane, can lead to similar increases in the plasma drug concentration.<sup>74,75</sup>

There is an overabundance of clinical pharmacology literature that examines the ability of one drug to displace another drug from its protein-binding site(s), thereby increasing the concentration of unbound drug in the blood that could cause supratherapeutic concentrations and potential toxicity. When examining specific pharmacokinetic parameters, an increase in the fraction of unbound drug in the plasma could theoretically increase the total apparent volume of distribution ( $V_{ss}$ ), as more molecules of drug are available for distribution into the tissue. Although most changes in protein binding will not influence clinical drug exposure, analysis of the equations governing the steady-state pharmacokinetics suggests that drugs that are extensively protein bound, have a high hepatic extraction ratio, and have a low therapeutic index may be the exception that require dose adjustment.<sup>76</sup> However, the clinical importance of protein binding in anesthetic drugs is based on several common misconceptions regarding drug distribution. First, the number of unoccupied binding sites is several orders of magnitude higher than the number of molecules of anesthetic drug administered in clinical practice. Therefore, it is hard to envision a scenario where a significant amount of displacement could occur. Even if a drug could displace a significant amount of another drug from its protein-binding site, the liver has the capacity available to metabolize this sudden influx of free drug, thereby returning the free drug concentration to the predisplacement concentrations (i.e., flow limited metabolism). Finally, the theoretical argument supporting the importance of protein binding on highly lipophilic drugs ignores the fact that lipophilic drugs not only have flow-limited elimination clearance, but also flow-limited tissue distribution. Therefore, the equations supporting the negligible role of protein binding on flow-limited elimination clearance also generalize to include flow-limited tissue distribution.<sup>76</sup> Indirect proof of this is provided by the fact that there are no examples in the literature of drug-drug interactions that produce changes in protein binding of opioids and hypnotics that are clinically relevant.<sup>77</sup>

## **Metabolism**

Drugs that alter hepatic blood flow (i.e., vasoactive drugs, volatile anesthetics) can proportionally alter hepatic metabolism of drugs with flow-

limited clearance.<sup>71-75</sup> In addition, drugs that inhibit or induce the enzymes that catalyze biotransformation reactions can affect clearance of other concomitantly administered drugs (Table 11-5). The concomitant use of CYP isozyme inducers can usually be overcome by increasing the administered dose, especially if an easy measure of biologic activity is available or the therapeutic concentration range is known. For example, the anticonvulsant phenytoin shortens the duration of action of the nondepolarizing neuromuscular junction blocking agents by inducing CYP3A4 and therefore increasing elimination clearance of the drug.<sup>78</sup> In contrast, when CYP isozyme inhibition is present, it is more difficult to adjust the drug dose without achieving supratherapeutic, and possibly toxic drug concentrations, unless a suitable rapidly responsive measure of biologic activity is available. While it may be possible to safely administer opioids in the presence of protease inhibitors such as ritonavir, because opioids can be titrated in small doses to clinical effect, it is more difficult to titrate warfarin or glyburide when instituting short-term antifungal therapy. Furthermore, prodrugs that require CYP isozyme activity for conversion to active moieties may be difficult to titrate to adequate clinical effect if there are other sources of interindividual variability in drug dose–response. The opioid prodrugs codeine, oxycodone, hydrocodone, and tramadol all require CYP2D6 for conversion to the biologically active opioid.<sup>77</sup> Because of the high polymorphic character of the CYP2D6 enzyme, it is difficult to determine which patients who are taking selective serotonin reuptake inhibitors, that also inhibit CYP2D6 activity, would receive adequate analgesia from these opioids. Therefore, other opioids may have less variability in opioid dose–response and be better choices than these prodrugs.

**Table 11-5** Inducers and Inhibitors of Hepatic Drug Metabolism

<b>Inducers</b>
Carbamazepine
Ethanol
Glucocorticoids
Phenobarbital
Phenytoin
Rifampin
St John's wort
Tamoxifen
<b>Inhibitors</b>
Azole antifungal drugs (i.e., ketoconazole, itraconazole)
Cimetidine
Disulfiram
Grapefruit juice
Macrolide antibiotics (i.e., clarithromycin and erythromycin)
Protease inhibitors (i.e., ritonavir, indinavir, saquinavir)
Quinidine
Selective serotonin reuptake inhibitors (i.e., fluoxetine and sertraline)
CYP3A4 and CYP2D6

## Pharmacodynamic Interactions

Pharmacodynamic interactions fall into two broad classifications. Drugs can interact, either directly or indirectly, at the same receptors. Opioid antagonists directly displace opioids from opiate receptors. Cholinesterase inhibitors indirectly antagonize the effects of neuromuscular blockers by increasing the amount of acetylcholine, which displaces the blocking drug from nicotinic receptors. Pharmacodynamic interactions can also occur if two drugs affect a physiologic system at different sites.<sup>79,80</sup> For example,  $\mu$ -opioid receptor-mediated ventilatory depression can be selectively antagonized by ampakines that potentiate AMPA receptor-mediated glutamatergic excitation without mitigating opioid-induced analgesia.<sup>81</sup>

The most common example of pharmacodynamic interactions that are used to the advantage of anesthesiologists (and their patients) is the interaction between hypnotics and opioids. Hypnotics and opioids, each acting on their own specific receptors, appear to interact synergistically.<sup>82</sup> The pharmacodynamic interaction between two drugs can be characterized by utilizing response surface models.<sup>83–88</sup> The three-dimensional models are useful in delineating the concentration pairs of a hypnotic (e.g., volatile anesthetic, propofol, midazolam) and an opioid (e.g., remifentanil, alfentanil, fentanyl) that produce adequate anesthesia while minimizing undesired side effects.<sup>89</sup> (See Response Surface Models, below.)

## Serotonin Syndrome

One pharmacodynamic interaction that has become more common with the widespread use of medications that modulate the serotonergic pathway is the potentially fatal serotonin syndrome (syndrome toxicity).<sup>90,91</sup> High CNS concentrations of serotonin, can produce mental status changes (confusion, hyperactivity, memory problems), muscle twitching, excessive sweating, shivering, and fever. Classically, excessive CNS serotonin levels are associated with inhibition of monoamine oxidase, an enzyme responsible for breaking down serotonin in the brain. However, excessive intrasynaptic serotonin levels from decreased reuptake of serotonin have been associated with other antidepressant medications, including serotonin reuptake inhibitors and serotonin norepinephrine reuptake inhibitors (Table 11-6). The interaction of meperidine with MAOIs is the most classic drug–drug interaction associated with serotonin syndrome. It is important to know that other common perioperative medications, such as methylene blue, which is a potent reversible MAOI, and the phenylpiperidine series of opioids (i.e., fentanyl and its congeners, methadone, meperidine, tramadol), which act as weak serotonin reuptake inhibitors, have been reported to be associated with serotonin toxicity in small case reports.<sup>91–94</sup> Ideally, the serotonergic drug would be held until sufficient CNS drug washout can occur to mitigate any interaction. Because the SSRIs with long elimination half-lives require greater than 4 weeks for adequate CNS washout, withholding these drugs can result in worsening depression or neuropathic pain, depending on the indication for the initial serotonergic medication. Therefore, when adequate washout cannot be obtained and methylene blue must be administered, the serotonergic drug should be stopped and not reinstated for 24 hours after the last dose of methylene blue.<sup>93</sup> When methylene blue or phenylpiperidine opioids must be administered to patients taking serotonergic psychiatric medications, clinicians should have a high clinical suspicion for the development of serotonin toxicity. This is especially important in the perioperative period when other more common clinical states, such as postoperative delirium or perioperative fever, can be associated with the common symptoms of serotonin toxicity, thereby delaying diagnosis. Although cyproheptadine, a serotonin receptor antagonist, is the most common treatment for moderate to severe serotonin toxicity, it is only available as an oral formulation, thereby limiting its bioavailability in critically ill perioperative patients. Intravenous chlorpromazine is an alternative serotonin receptor antagonist that has been used successfully with concomitant supportive care.

**Table 11-6 Serotonergic Psychiatric Drugs Implicated in the Cases of Serotonin Syndrome with Methylene Blue<sup>a</sup>**

Class	Generic	Brand Name(s)
Selective serotonin reuptake inhibitors (SSRIs)	Paroxetine	Paxil, Paxil CR, Pexeva
	Fluvoxamine	Luvox, Luvox CR
	Fluoxetine	Prozac, Sarafem, Symbyax
	Sertraline	Zoloft
	Citalopram	Celexa
	Escitalopram	Lexapro
	Vilazodone	Viiibryd
Serotonin–norepinephrine reuptake inhibitors (SNRIs)	Venlafaxine	Effexor, Effexor XR
	Desvenlafaxine	Pristiq
	Duloxetine	Cymbalta
Tricyclic antidepressants (TCAs)	Amitriptyline	Amitid, Amitril, Elavil, Endep, Etrafon, Limbitrol, Triavil
	Desipramine	Norpramin, Pertofrane
	Clomipramine	Anafranil
	Imipramine	Tofranil, Tofranil PM, Janimine, Pramine, Presamine
	Nortriptyline	Pamelor, Aventyl hydrochloride
	Protriptyline	Vivactil
	Doxepin	Sinequan, Zonalon, Silenor
	Trimipramine	Surmontil

## Clinical Applications of Pharmacokinetics and Pharmacodynamics to the Administration of Intravenous Anesthetics

While no new inhaled anesthetics have been synthesized since the 1960s, IV drugs that act on the CNS continue to be developed. Anesthesiologists have become accustomed to the exquisite control of anesthetic blood (and effect site) concentrations afforded by modern volatile anesthetic agents and their vaporizers, coupled to end-tidal anesthetic gas monitoring. Although pharmacokinetic and pharmacodynamic principles and data have contributed greatly to our understanding of the behavior of IV anesthetics, their primary utility and ultimate purpose are to determine optimal dosing with as much mathematical precision and clinical accuracy as possible. In most pharmacotherapeutic scenarios outside of anesthesia care, the time scales for onset of drug effect, its maintenance, and its offset are measured in days, weeks, or even years. In such cases, global pharmacokinetic variables (and one-compartment models) such as total volume of distribution ( $V_{ss}$ ), elimination clearance ( $Cl_e$ ), and half-life ( $t_{1/2}$ ) are sufficient and utilitarian

parameters for calculating dose regimens. However, in the OR and ICU, the temporal tolerances for onset and offset of desired drug effects are measured in minutes.<sup>38,39</sup> Consequently, these global variables are insufficient to describe the details of kinetic behavior of drugs in the minutes following IV administration. This is particularly true of lipid-soluble hypnotics and opioids that rapidly and extensively distribute throughout the various tissues of the body, because distribution processes dominate pharmacokinetic behavior during the time frame of most anesthetics. In addition, the therapeutic indices of many IV anesthetic drugs are small and two-tailed (e.g., an underdose, resulting in awareness, which is a “toxic” effect). Optimal dosing in these situations requires use of all the variables of a multicompartmental pharmacokinetic model to account for drug distribution in blood and other tissues.

It is not easy to intuit the pharmacokinetic behavior of a multicompartmental system by simple examination of the kinetic variables.<sup>10</sup> Computer simulation is required to meaningfully interpret dosing or to accurately devise new dosing regimens. In addition, there are several pharmacokinetic concepts that are uniquely applicable to IV administration of drugs with multicompartmental kinetics and must be taken into account when administering IV infusions.

To achieve similar degrees of control of intravenously administered anesthetic drug concentrations in blood and in the CNS, new technologies aimed at improving IV infusion devices, as well as new software to manage the daunting pharmacokinetic principles involved, are needed. This section examines the current state of infusion devices and the pharmacokinetic and pharmacodynamic principles specifically required for precise delivery of anesthetic agents.

### *Rise to Steady-state Concentration*

The drug concentration versus time profile for the rise to steady state is the mirror image of its elimination profile. In a one-compartment model with a decline in concentration versus time that is monoexponential following a single dose, the rise of drug concentration to the steady-state concentration ( $C_{ss}$ ) is likewise monoexponential during a continuous infusion. That is, in one elimination half-life an infusion is halfway to its eventual steady-state concentration, in another half-life it reaches half of what remains between halfway and steady state (i.e., 75% of the eventual steady state is reached in two elimination half-lives), and so on for each half-life increment. The equation describing this behavior is:

$$C_p(t) = C_{ss} [1 - e^{-kt}] \quad (11-19)$$

where  $C_p(t)$  = the concentration at time  $t$ ,  $k$  is the rate constant related to the elimination half-life, and  $t$  is the time from the start of the infusion. This relationship can also be described by:

$$C_p(n) = C_{ss}[1 - (1/2)^n] \quad (11-20)$$

in which  $C_p(n)$  is the concentration at  $n$  half-lives. Equation 11-20 indicates that during a constant infusion, the concentration reaches 90% of  $C_{ss}$  after 3.3 half-lives, which is usually deemed close enough for clinical purposes.

However, for a drug such as propofol, which partitions extensively to pharmacologically inert body tissues (e.g., muscle, gut), a monoexponential equation, or single-compartment model, is insufficient to describe the time course of propofol concentrations in the first minutes and hours after beginning drug administration. Instead, a multicompartmental or multiexponential model must be used. With such a model, the picture changes drastically for the plasma drug concentration rise toward steady state. The rate of rise toward steady state is determined by the distribution rate constants to the degree that their respective exponential terms contribute to the total area under the concentration versus time curve. Thus, for the three-compartment model describing the pharmacokinetics of propofol, Equation 11-19 becomes:

$$C_p(t) = C_{ss} \left[ \frac{A}{A+B+G} (1 - e^{-\alpha t}) + \frac{B}{A+B+G} (1 - e^{-\beta t}) + \frac{G}{A+B+G} (1 - e^{-\gamma t}) \right] \quad (11-21)$$

in which  $t$  = time;  $C_p(t)$  = plasma concentration at time;  $A$  = coefficient of the rapid distribution phase and  $\alpha$  = hybrid rate constant of the rapid distribution phase;  $B$  = coefficient of the slower distribution phase and  $\beta$  = hybrid rate constant of the slower distribution; and  $G$  = coefficient of elimination phase and  $\gamma$  = hybrid rate constant of the elimination phase.  $A + B + G$  is the sum of the coefficients of all the exponential terms. For most lipophilic anesthetics and opioids,  $A$  is typically one order of magnitude greater than  $B$ , and  $B$  is in turn an order of magnitude greater than  $G$ . Therefore, distribution-phase kinetics for IV anesthetics have a much greater influence on the time to reach  $C_{ss}$  than do elimination-phase kinetics.<sup>49</sup>

For example, with propofol having an elimination half-life of approximately 6 hours, the simple one-compartment rule in Equation 11-20 tells us that it would take 6 hours from the start of a constant rate infusion to reach even 50% of the eventual steady-state propofol plasma concentration and 12 hours to reach 75%. In contrast, with a full three-compartment propofol kinetic model, Equation 11-21 accurately predicts that 50% of steady

state is reached in less than 30 minutes and 75% will be reached in less than 4 hours. This example emphasizes the necessity of using multicompartment models to describe the clinical pharmacokinetics of IV anesthetics.

### **Manual Bolus and Infusion Dosing Schemes**

Based on a one compartment pharmacokinetic model, a stable steady-state plasma concentration ( $C_{p,ss}$ ) can be maintained by administering an infusion at a rate ( $I$ ) that is proportional to the elimination of drug from the body ( $Cl_E$ ):

$$I = C_{p,ss} \times Cl_E \quad (11-22)$$

However, if the drug was only administered by initiating and maintaining this infusion, it would take one-elimination half-time to reach 50% of the target plasma concentration and three times that long to reach 90% of the target plasma concentration. In order to decrease the time until the target plasma concentration is achieved, an initial bolus (loading dose) of drug can be administered that would produce the target plasma concentration—

$$\text{Bolus} = C_{p,ss} \times V_{d,ss} \quad (11-23)$$

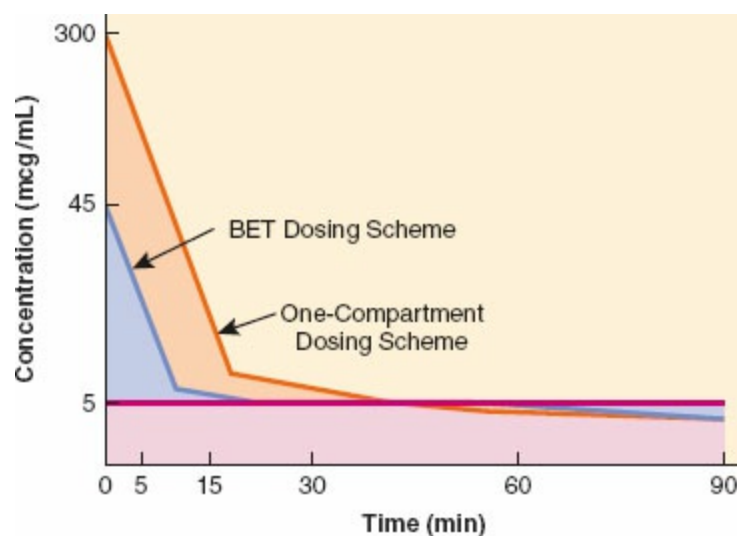

Although this method is very efficient in achieving and maintaining the target plasma concentration of a drug that instantaneously mixes and equilibrates throughout the tissues of the body (e.g., drugs modeled with a one-compartment pharmacokinetic model), utilizing the steady-state elimination clearance and volume of distribution to calculate the loading dose and maintenance infusion rate will result in plasma drug concentrations that are higher throughout the initial distribution phase (Fig. 11-14).

Using Equations 11-22 and 11-23 and  $V_{d,ss} = 262$  L and  $Cl_E = 1.7$  L/min (for a 50-year-old man who is 178 cm tall and weighs 70 kg, from Schnider et al.), the loading dose and infusion rate of propofol that is needed to achieve a steady-state plasma concentration of 5  $\mu\text{g/mL}$  is 1,300 mg (18 mg/kg) and 120  $\mu\text{g/kg/min}$ . Obviously, the loading dose of propofol is too high, compared to clinically utilized doses (1 to 2 mg/kg) while the infusion rate appears to be a clinically acceptable dose. The erroneous estimate of the loading dose is due to the fact that the initial bolus of drug is not instantaneously mixed and equilibrated with the entire volume of tissue that will eventually take up drug. Therefore, manual dosing strategies for IV anesthetics need to be modified to account for the fact that when a bolus of drug is administered, it rapidly mixes and equilibrates with the blood and only a small volume of tissue (e.g., the central compartment), and then will distribute over time into other tissues.

To design a manual bolus that more precisely achieves the desired target

plasma concentration, it is necessary to choose a bolus that is based on the small, initial volume of distribution ( $V_c$ ). To maintain the target plasma concentration, a series of infusions of decreasing rate can be used that match the elimination clearance and compensate for drug loss from the central to the peripheral compartments during the initial period of extensive drug distribution and the second period of moderate drug distribution. This manual dosing scheme has been termed the BET scheme, where B is the loading bolus dose, E is the infusion to replace drug removed by elimination clearance, and T is a continuously decreasing infusion that compensates for transfer of drug to the peripheral tissues (i.e., distribution).<sup>95</sup> An example of a BET scheme for propofol to achieve a target plasma concentration of 5  $\mu\text{g/mL}$  is shown in Table 11-7.

**Figure 11-14** A computer simulation of the plasma propofol concentration profile during and after the administration of a single bolus and infusion scheme calculated using the steady-state, one-compartment pharmacokinetic parameters (*red line*) and the BET scheme from Table 11-7 (*blue line*) to achieve a plasma concentration of 5  $\mu\text{g/mL}$ .  $V_{d,ss} = 262$  L and  $Cl_E = 1.7$  L/min for a 50-year old male who is 178 cm tall and weighs 70 kg.

### Isoconcentration Nomogram

To make the calculations of the various infusion rates required to maintain a target plasma concentration for a drug that follows multicompartment pharmacokinetics, a clinician would need access to a basic computer and the software to perform the appropriate simulations. With the appropriate formulas, this is quite feasible to do on any basic computer with any basic spreadsheet. However, even with more sophisticated pharmacokinetic software (e.g., SAAM II, WinNonLin, RugLoop, Stanpump), this is a time-consuming process that diverts the clinician's attention from the patient. In 1994, Shafer<sup>96</sup> introduced an isoconcentration nomogram for propofol that used the rise toward steady state described by a multicompartmental system

(Fig. 11-15). This graphic tool allows users to employ concentration–effect, rather than dose–effect, relationships when determining optimal dosing of IV anesthetic agents. The nomogram is constructed by calculating the plasma drug concentration versus time curve for a constant-rate infusion from a set of pharmacokinetic variables for a particular drug. From this single simulation, one can readily visualize (and estimate) the rise toward steady-state plasma drug concentration described by the drug’s pharmacokinetic model. By simulating a range of potential infusion rates, a series of curves of identical shape are then plotted on a single graph, with drug concentrations at any time that are directly proportional to the infusion rate.

**Table 11-7** The Bolus–Elimination–Infusion (BET) Scheme to Achieve a Propofol Plasma Concentration of 5 µg/mL for 120 Minutes

Bolus	2.8 mg/kg	
Infusion	238 µg/kg/min	0–10 min
	187 µg/kg/min	10–20 min
	136 µg/kg/min	20–60 min
	112 µg/kg/min	60–120 min

**Figure 11-15** Isoconcentration nomogram for determining propofol infusion rates designed to maintain a desired plasma propofol concentration. This nomogram is based on the pharmacokinetics of Schnider et al. and is plotted on a log–log scale to better delineate the early time points. Curved lines represent the plasma propofol concentration versus time plots, resulting from the various continuous infusion rates indicated along the right and upper borders (units in µg/kg/min). A horizontal line is placed at the desired target plasma propofol concentration (3 µg/mL in this case) and vertical lines are placed at each intersection of a curved concentration–time plot. The vertical lines indicate the times that the infusion rate should be set to the one represented by the next intersected curve as one moves from left to right along the horizontal line drawn at 3 µg/mL. In this example, the infusion rate would be reduced

from 300  $\mu\text{g}/\text{kg}/\text{min}$  to 275  $\mu\text{g}/\text{kg}/\text{min}$  at 2.5 minutes, to 250  $\mu\text{g}/\text{kg}/\text{min}$  at 3 minutes, to 225  $\mu\text{g}/\text{kg}/\text{min}$  at 4.5 minutes, and so on until it is turned to 100  $\mu\text{g}/\text{kg}/\text{min}$  at 260 minutes.

By placing a horizontal line at the desired plasma drug concentration (y-axis), the times (x-axis) at which the horizontal intersects the line for a particular infusion rate will represent the times at which the infusion rate should be set to the rate on the intercepting line. In the example shown (Fig. 11-15) with 25- $\mu\text{g}/\text{kg}/\text{min}$  increments, the predicted plasma propofol concentrations remain within 10% of the target from 2 minutes onward with a bias of underestimation. If it is desired that the estimated concentration never falls below the target, then the time to decrease to the next lower infusion should be at the midpoint of the subsequent interval. Extending the infusions to the subsequent midpoint times will introduce a maximum overestimation bias of approximately 17% with the illustrated infusion increments. Biases will be increased or decreased by constructing nomograms with larger or smaller infusion increments, respectively.

The nomogram can also be used to increase or reduce the targeted plasma propofol concentration. To target a new plasma drug concentration, a new horizontal line can be drawn at the desired concentration. The infusion rate that is closest to the current time intersect is the one that should be used initially, followed by the decremented rates dictated by the subsequent intercept times. For best results when increasing the target concentration, a bolus equal to the product of  $V_c$  (the central compartment volume) and the incremental change in concentration should be administered. Likewise, when decreasing the concentration, the best strategy is to turn off the infusion for the duration predicted by the applicable context-sensitive decrement time and resume the infusion rate predicted for the current time plus the context-sensitive decrement time. For instance, if after 30 minutes one wishes to decrease the target plasma propofol concentration from 3 to 2  $\mu\text{g}/\text{mL}$  (a 33% decrement at a time context of 30 minutes), one would shut off the infusion for 1 minute and 10 seconds to let the concentration fall by 33% and then restart at 75  $\mu\text{g}/\text{kg}/\text{min}$ . The estimated plasma propofol concentrations from this nomogram-guided dosing scheme are shown in Figure 11-16.

### **Context-sensitive Decrement Times**

During an infusion, drug is taken up by the inert, peripheral tissues.<sup>18</sup> Once drug delivery is terminated, recovery occurs when the effect site concentration decreases below a threshold concentration for producing a pharmacologic effect (e.g.,  $\text{MAC}_{\text{AWAKE}}$ —the concentration where 50% of

drug from the body can give some indication for the time required to reach a subtherapeutic effect, site, drug concentration, and distribution to and from the peripheral tissues also contribute to the time course of decreasing drug concentrations of the central and the effect site. For drugs with multicompartamental kinetics, the elimination half-life will always overestimate the time to recovery from anesthetic drugs. The *context-sensitive half-time* is defined as the time required for the drug concentration of the plasma to decrease by 50%, where the context is the duration of the infusion.<sup>97</sup> The context-sensitive half-time for the common synthetic opioids fentanyl, alfentanil, sufentanil, and remifentanyl are illustrated in [Figure 11-17](#).

**Figure 11-16** Simulated plasma propofol concentration history resulting from the information in the isoconcentration nomogram in [Figure 11-15](#) and extending the times to switch the infusion to the next lower increment to the midpoint of the subsequent time segment (i.e., the switch from 250 to 225  $\mu\text{g}/\text{kg}/\text{min}$  was at 5 minutes, rather than at 4.5 minutes). Note that for the first 30 minutes, this sequence predicts plasma propofol concentrations that are always slightly above 3  $\mu\text{g}/\text{mL}$  (see text). The infusion is stopped at 90 minutes in this case.

**Figure 11-17** The context-sensitive plasma half-time for fentanyl, alfentanil, sufentanil, and remifentanyl.

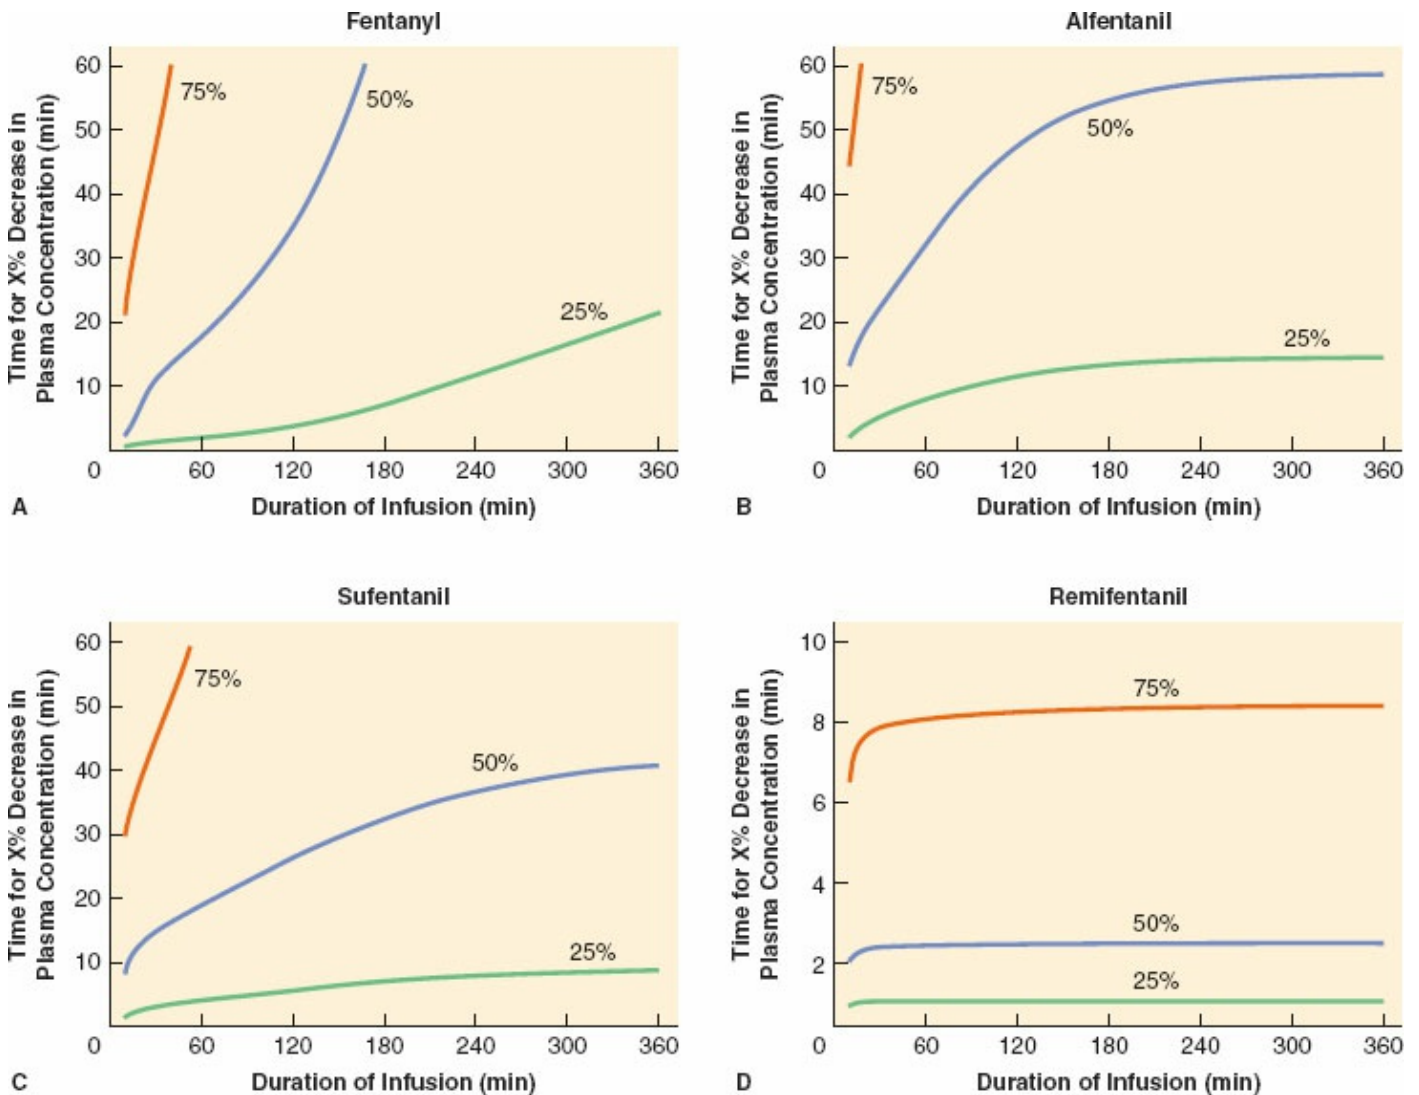

The context-sensitive half-time is not a pharmacokinetic parameter per se. It is calculated by simulating a target-controlled infusion (TCI) of a particular length (the length is the context) and then observing the time required for the plasma concentration to reach one-half of the target concentration from the time the infusion is terminated. As the length of the infusion increases, the value of the half-time increases and will eventually asymptotically approach a maximum half-time at steady state. Generally, for multicompartmental pharmacokinetic models, the half-time will always be less than the elimination half-life.

When an infusion is terminated at steady state, input into the system's central compartment is lost and net transfer of drug is no longer zero. Instead, net drug distribution immediately begins moving toward the central compartment from the peripheral compartments rather than away, as was the case during infusion, and elimination from the central compartment continues unabated by the infusion's input. Plasma or central compartment concentrations will fall relatively rapidly, compared to the elimination half-life, until set concentration ratios of central:fast and central:slow are achieved. These ratios with higher peripheral compartment drug concentrations will achieve the net drug distribution flux into the central compartment that will balance the elimination flux to create a constant elimination rate.

During the elimination phase, the multicompartmental system behaves, kinetically, as a single compartment, but only does so because there are (fixed) drug concentration ratios among the compartments. With a short infusion, the peripheral compartment drug concentrations will have only achieved low drug concentrations, and the plasma drug concentration will have to fall quite far to reach the central:peripheral drug concentration ratios needed to enter the constant elimination phase. Thus, the half-time is less with shorter infusion contexts. After a very long infusion with peripheral compartment drug concentrations reaching higher drug concentrations as they approach their steady state, plasma drug concentrations will not need to fall as much to reach the concentration ratios required for the elimination phase, and the rate of plasma drug decline will begin approaching the elimination half-life sooner, resulting in longer half-times.

One must be aware of the limitations of the context-sensitive half-time concept.<sup>10,20</sup> First, it is not a kinetic parameter; it only describes a specific simulation event. This means it cannot be extrapolated backward or, more importantly, forward to lesser or greater drug concentration decrements, as is possible with true kinetic parameters. Secondly, it cannot be directly calculated from other kinetic parameters. Rather, a model of the specific drug pharmacokinetics is programmed into a simulation with a set drug infusion regimen; tedious for pencil and paper or handheld calculator, but a simple

matter for even a modest computing device (e.g., tricyclic antidepressant [TCA] pumps and applications for smartphones). Third, the most relevant concentration decrease may not be one-half. It could be less than one-half or, as is likelier in practice, more than one-half. Therefore, simulating both the specific infusion context as well as the required percentage decrease from the target concentration should be done to get the best estimate of when a drug's effect will reach the clinically desired end point.

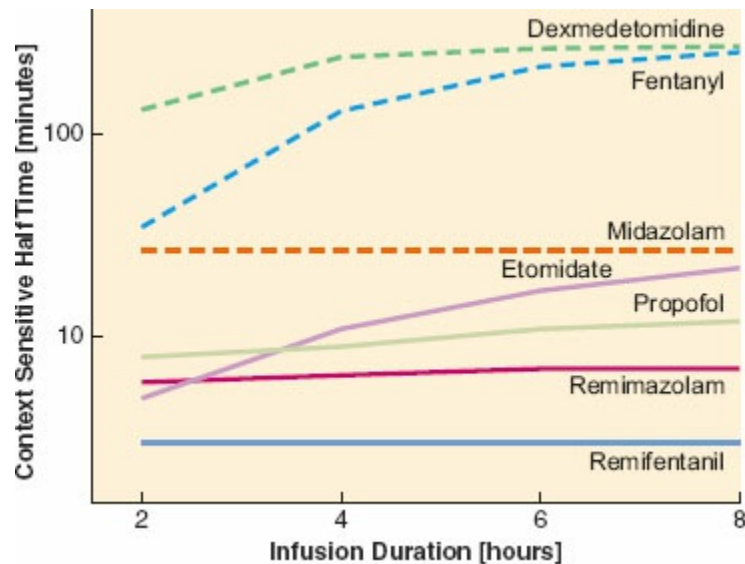

**Figure 11-18** The context-sensitive 25%, 50%, and 75% plasma decrement times for fentanyl, alfentanil, sufentanil, and remifentanil.

Although a 50% decrease in plasma concentration is an appealing and comprehensible parameter, larger or smaller decreases in plasma concentrations may be required for recovery from the drug. Simulations show that the times for different percent decreases in plasma concentration are not linear.<sup>10,20</sup> Therefore, if a 25% or 75% decrease in plasma concentration is required, simulations must be performed to calculate the context-sensitive 25% decrement time or context-sensitive 75% decrement time (Fig. 11-18). In addition, if the concentration of interest is the effect site concentration rather

than the plasma concentration, simulations can be performed to calculate the context-sensitive effect site decrement time. Finally, if a constant plasma or effect site concentration is not maintained throughout the delivery of the drug (which is typically the case with manual bolus and infusion schemes and also with varying drug requirements depending on surgical stimulation, etc.), the context-sensitive decrement times are guidelines of recovery rather than an absolute prediction of the decay in drug concentration. If precise drug administration data are known, it is possible to compute the context-sensitive decrement time for the individual situation or context. Even though the context-sensitive decrement times are limited, this concept has changed the way that IV anesthetics are described and has helped foster an increase in accurately and safely administering IV anesthetics.

### *Soft Pharmacology and Anesthesiology*

Accumulation of drug in well perfused but inactive tissue beds (i.e., skeletal muscle) results in tissue depots of drug. When the arterial concentration of drug is less than the tissue concentration of drug in any of these tissue depots, the drug redistributes from the tissue back into the plasma, thereby slowing the rate of decline of the plasma concentration. One strategy that has been used to limit tissue uptake of drug is to design active compounds that are rapidly metabolized by plasma and/or tissue enzymes into inactive metabolites—so-called soft drugs.<sup>98,99</sup> Remifentanyl is the prototypic drug that has used this approach, and its unique pharmacokinetic fingerprint (i.e., context-insensitive decrement times) resulted in development of this synthetic fentanyl analog instead of other viable candidates.<sup>48,100</sup> With the success of remifentanyl, investigators have attempted to produce hypnotics with context-insensitive decrement times (Fig. 11-19). This approach has resulted in a new benzodiazepine, several etomidate analogues, and a novel hypnotic that inhibits GABA<sub>A</sub> receptors.<sup>101-104</sup> Remimazolam, a plasma and tissue esterase metabolized benzodiazepine, is currently in Phase II studies investigating its applications to procedural sedation as well as to general anesthesia.<sup>105-107</sup> The etomidate analogues are not yet in Phase I studies. However, the preclinical data have resulted in selection of an etomidate analog that has context insensitive decrement times as well as limited adrenal suppression.<sup>108-114</sup> Further studies will determine if the etomidate analogues have a safer profile in the setting of cerebral ischemia than does etomidate.<sup>115-117</sup> Phase I studies of AZD-3043 have shown rapid onset, rapidly titratable hypnosis with a context-insensitive recovery profile.<sup>104,118-120</sup>

**Figure 11-19** The effect site context-sensitive half-times (CSHTs) for the classic anesthetic drugs and their analogous soft drugs. Note that the y-axis is in a log scale in order to allow the drugs with the CSHTs more than 30 minutes (i.e., dexmedetomidine, fentanyl, midazolam, and etomidate) to be displayed with the drugs that have the short CSHTs (i.e., remifentanyl, remimazolam, and propofol), which are almost context insensitive.

### Target-controlled Infusions

Prior to performing an anesthetic, it is possible to perform the calculations above and derive a BET scheme targeted to a predetermined plasma or effect site concentration. However, in the operating room, once the anesthetic has commenced, without the help of a computer, software, and possibly an assistant, it is laborious and difficult to make any calculations to determine how to adjust the infusion or how to bolus (or stop the infusion) to increase or decrease the target plasma concentration.<sup>121</sup> By linking a computer with the appropriate pharmacokinetic model to an infusion pump, it is possible for the physician to enter the desired target plasma concentration of a drug, and for the computer to nearly instantaneously calculate the appropriate infusion scheme to achieve this target in a matter of seconds.<sup>122</sup> Because drug accumulates at various rates among the various tissues and organs in the body, the computer continually calculates the current drug concentration and adjusts the infusion pump in order to account for the current status of drug uptake, distribution, and elimination. Therefore, the computer driven BET scheme can in fact control the infusion pump in order to achieve a steady target concentration (Fig. 11-20).

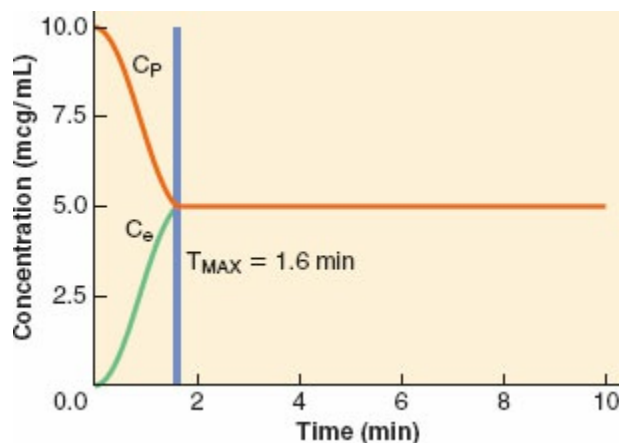

**Figure 11-20** This is a simulation of a target-controlled infusion (TCI) in which the plasma concentration is targeted at 5  $\mu\text{g}/\text{mL}$ . The *blue line* represents the predicted plasma propofol concentration of 5  $\mu\text{g}/\text{mL}$ , which in theory is attained at time  $t = 0$  and is then maintained by a variable rate infusion. The *red line* is the predicted effect site concentration under the conditions of a constant pseudo–steady-state plasma concentration. Note that 95% of the target concentration is reached in the effect site at approximately 4 minutes.

The success of this approach is influenced by the extent to which the drug pharmacokinetic and pharmacodynamic parameters programmed into the computer match those of the particular patient at hand. While this same limitation applies to the more rudimentary (non-TCI) dosing done routinely in every clinical setting, we must examine the special ramifications of pharmacokinetic—pharmacodynamic model misspecification with TCI in any discussion of its future importance in the clinical setting.

The mathematical principles governing TCI are actually quite simple. For a computer-control pump to produce and maintain a plasma drug concentration it must first administer a dose equal to the product of the central compartment,  $V_1$ , and the target concentration (Fig. 11-21). Then for each moment after that, the amount of drug to be administered into the central compartment to maintain the target concentration is equal to drug eliminated from the central compartment *plus* drug distributed from the central compartment to peripheral compartments *minus* drug returning to the central compartment from peripheral compartments. The software keeps track of the estimated drug in each compartment over time and applies the rate constants for intercompartmental drug transfer from the pharmacokinetic model to these amounts to determine drug movement at any given time. It then matches the estimated concentrations to the target concentration at any time to determine the amount of drug that should be infused. The software can also predict future concentrations, usually with the assumption that the infusion will be stopped so that emergence from anesthesia or the dissipation of drug effect will occur optimally according to the context-sensitive decrement time.

**Figure 11-21** This is a simulation of a target-controlled infusion (TCI) in which the effect site concentration ( $C_e$ ) is targeted at 5  $\mu\text{g}/\text{mL}$ . The *orange line* represents the predicted plasma propofol concentration ( $C_p$ ) that results from a bolus dose, given at time  $t = 0$ , that is predicted to purposely overshoot the plasma propofol concentration target until time  $t = T_{\text{max}}$  (1.6 minutes). At  $T_{\text{max}}$  pseudo-equilibration between the effect site and the plasma occurs and both concentrations are then predicted to be the same until the target is changed. Note that the effect site attains the target in less than half the time with effect site targeting compared to the plasma concentration targeting seen in [Figure 11-20](#).

Because there is a delay or hysteresis between the attainment of a drug concentration in the plasma and the production of a drug effect, it is advantageous to have the mathematics of this delay incorporated into TCI. By adding the kinetics of the effect site it is possible to target effect site concentrations as would be in keeping with the principle of working as closely to the relevant concentration–effect relationship as possible. A dose scheme that targets concentrations in a compartment remote from the central compartment (i.e., the effect site) has no closed form solution for calculating the infusion rate(s) needed. Instead, the solution is solved numerically and involves some additional concepts that must be considered, namely the time to peak effect,  $T_{\text{max}}$ , and the volume of distribution at peak effect,  $V_{\text{DPE}}$ . These are discussed later. In principle, targeting the effect site necessitates producing an overshoot in plasma drug concentrations during induction and for subsequent target increases. This is similar in concept to overpressurizing inhaled anesthetic concentrations to achieve a targeted end-tidal concentration. However, unlike the inspiratory limb of an anesthesia circuit, the plasma compartment seems to be closely linked to cardiovascular effects, and large overshoots in plasma drug concentration may produce unwanted side effects.

The performance of TCI is influenced by the pharmacokinetic model chosen. Although most modern TCI models, whether they target the plasma or the effect site, seem to be similar in performance, they all produce overshoot for 10–20 minutes when increasing the target concentration.<sup>36</sup> This

is because the dose adjustments made are based on calculations that utilize a central compartment that ignores the complexity of intravascular mixing, thereby overestimating the central compartment's true volume ( $V_C$ ) and overestimating the rate of transfer to the fast peripheral tissue ( $Cl_F$ ) and the size of the peripheral tissue compartment ( $V_F$ ) (Fig. 11-22). The performance of TCI is also influenced by the variance between pharmacokinetic parameters determined from group or population studies and the individual patient. Median absolute performance errors for fentanyl,<sup>123</sup> alfentanil,<sup>124</sup> sufentanil,<sup>125</sup> midazolam,<sup>126,127</sup> and propofol<sup>127,128</sup> are in the range of  $\pm 30\%$  when literature values for pharmacokinetic parameters are used to drive the TCI device and fall to approximately  $\pm 7\%$  when the average kinetics of the test subjects themselves are used.<sup>124</sup> Divergence (the percentage change of the absolute performance error) is generally quite low (approximately 1%) when target concentrations remain relatively stable, but increase to nearly 20% when the frequency of concentration steps is as frequent as every 12 minutes.<sup>36,128</sup> These data suggest that while a considerable error may exist ( $\pm 30\%$ ) between the targeted drug concentration and the one actually achieved in a patient, the concentration attained will not vary much over time. Thus, incremental adjustments in the target should result in incremental and stable new concentrations in the patient as long as the incremental adjustments are not too frequent.

**Figure 11-22** The influence of the misspecification of each of the components of the traditional three compartment pharmacokinetic models on the prolonged discrepancy (overshoot) between predicted and targeted concentrations with target-controlled infusions. The error resulting from elimination clearance was negligible and therefore not illustrated. Notice that the loading dose (based on  $V_C$ ) produces a large amount of error in the initial minutes; however, from 1 to 20 minutes, the deviation from the target concentration is largely due to the overestimation of  $Cl_F$ . The equations listed are for the respective BET infusions of the TCI system. (Reprinted with permission from Avram

MJ, Krejcie TC. Using front-end kinetics to optimize target-controlled drug infusions. *Anesthesiology*. 2003; 99:1078–1086.)

The introduction of the concept of TCI, was first described by Schwilden et al. in early 1980s. Other software systems were developed in North America by groups at Stanford University and Duke University. By the late 1990s a commercially available TCI system for propofol (Diprifusor) was introduced. This greatly increased both anesthesiologists' interest in this mode of delivery and their understanding of the concentration–effect relationships for hypnotics and opioids. In most of the world, devices for delivering propofol by TCI are commercially available from at least three companies (Graseby, Alaris, and Fresenius) with similar performance parameters.<sup>129</sup> In the United States, there are still no FDA-approved devices. For investigational purposes, Stanpump (developed by Steve Shafer at Stanford University) can be interfaced via an RS232 port to an infusion pump. Stanpump currently provides pharmacokinetic parameters for 19 different drugs, but has the ability to accept any kinetic model for any drug provided by the user. RugLoop is TCI software (developed by Michel Struys of Ghent University), which is similar to STANPUMP but operates in Windows rather than DOS and is capable of controlling multiple drug infusions simultaneously. (Information regarding RugLoop is available at <http://www.demed.be/index.html>.)

While the pharmacologic principle of relating a concentration rather than a dose is scientifically sound, few studies have actually attempted to determine whether TCI improves clinical performance or outcome. Only a few limited studies have actually compared manual infusion control versus TCI. Some have shown better control and a more predictable emergence with TCI,<sup>129,130</sup> whereas others have simply shown no advantage.<sup>131,132</sup>

TCI principles continue to be developed beyond the scope of IV anesthesia techniques. TCI has been used to provide postoperative analgesia with alfentanil.<sup>133,134</sup> In this system, a desired target plasma alfentanil concentration was set in the range of 40 to 100 ng/mL. A demand by the patient automatically increased the target level by 5 ng/mL. Lack of a demand caused the system to gradually reduce the targeted level. The quality of analgesia was judged to be superior to standard morphine PCA.

Similarly, TCI has been used to provide patient-controlled sedation with propofol.<sup>135,136</sup> The TCI was set to 1 µg/mL and a demand by the patient increased the level by 0.2 µg/mL. As with the TCI analgesia system, the lack of a demand caused the system to gradually reduce the targeted plasma propofol concentration. The timing and increment of the decrease were adjusted by the clinician. Over 90% of patients were satisfied with this method of sedation.

## ***Time to Maximum Effect Compartment Concentration ( $T_{max}$ )***

Earlier in this chapter, the delay between attaining a plasma concentration and an effect site concentration was described (Fig. 11-11). This delay, or hysteresis, is presumed to be a result of transfer of drug between the plasma compartment,  $V_c$ , and an effect compartment,  $V_e$ , as well as the time required for a cellular response. By simultaneously modeling the plasma drug concentration versus time data (pharmacokinetics) and the measured drug effect (pharmacodynamics), an estimate of the drug transfer rate constant,  $k_{e0}$ , between plasma and the putative effect site can be estimated.<sup>47</sup> However, estimates of  $k_{e0}$ , like all rate constants, are model specific.<sup>137,138</sup> That is,  $k_{e0}$  cannot be transported from one set of kinetic parameters determined in one specific pharmacokinetic–pharmacodynamic study to any other set of pharmacokinetic parameters. Likewise, it is not valid to compare estimates of  $k_{e0}$  among studies of the same drug or across different drugs and, therefore, one should not be surprised that reported values for  $k_{e0}$  for the same drug vary markedly among studies. The model-independent parameter that characterizes the delay between the plasma and effect site is the time to maximal effect, or  $T_{max}$ .<sup>138</sup> Accordingly, if the  $T_{max}$  and the pharmacokinetics for a drug are known from independent studies, a  $k_{e0}$  can be estimated by numeric techniques for the independent kinetic set that would produce the known effect site  $T_{max}$ .

The concept of a transportable, model-independent parameter that characterizes the kinetics of the effect site is important for robust effect site-targeted, computer-controlled infusions. This is because there are many more pharmacokinetic studies characterizing a wider variety of patient types and groups in the literature than there are complete pharmacokinetic–pharmacodynamic studies. By making the generally valid assumption that interindividual differences are small in a drug's rate of effect site equilibration, it is possible with a known  $T_{max}$  to estimate effect site kinetics for a drug across a wide variety of patient groups where only the pharmacokinetics are known. This cannot be done in a valid manner using  $k_{e0}$  or  $t^{1/2} k_{e0}$  alone.<sup>137,138</sup>

## ***Volume of Distribution at Peak Effect ( $V_{DPE}$ )***

While the plasma concentration can be brought rapidly to the targeted drug concentration by administering a bolus dose to the central compartment ( $C \times V_c$ ) and then held there by a computer-controlled infusion (Fig. 11-20), the time for the effect site to reach the target concentration will be much longer than  $T_{max}$  (4 minutes for propofol effect site concentration to reach 95% of that targeted). It is possible to calculate a bolus dose that will attain the

estimated effect site concentration at  $T_{\max}$  without overshoot in the effect site. However, plasma drug concentration will be overshoot (Fig. 11-19). This is done by combining the concept of describing drug distribution as an expanding volume of distribution that starts at  $V_c$  and approaches  $V_\beta$  (the apparent volume of distribution during the elimination phase) over time with the concept of  $T_{\max}$ .<sup>139,140</sup>

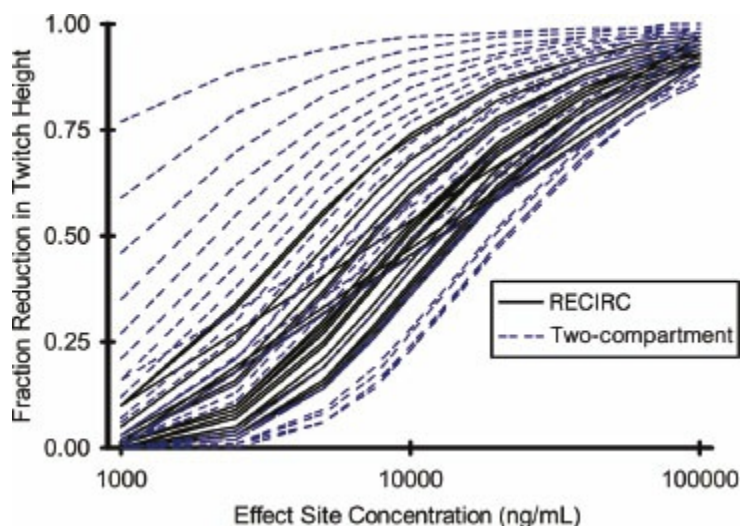

Volume of distribution over time is calculated by dividing the total amount of drug remaining in the body by the plasma drug concentration at each time,  $t$ . The time-dependent volume at the time of peak effect (or  $T_{\max}$ ) is  $V_{DPE}$ . The product of the targeted effect site concentration and  $V_{DPE}$  plus the amount lost to elimination in the time to  $T_{\max}$  becomes the proper bolus dose that will attain the target concentration at the effect site as rapidly as possible without overshoot. In practical terms this bolus is given at time  $t = 0$ , after which the infusion stops until time  $t = T_{\max}$ . It then resumes infusing drug in its normal “stop loss” manner.

Some software programs for controlling TCIs include this concept in their algorithms. In the case of the propofol kinetics used to construct the isoconcentration nomogram in Figure 11-15, the pharmacokinetic–pharmacodynamic parameter set of Schnider et al.<sup>141</sup> predicts a  $T_{\max}$  of 1.6 minutes, a  $V_{DPE}$  of 16.62 L, and an elimination loss of 23.8% of the dose over 1.6 minutes in a 70-kg man. Thus the proper propofol bolus for a targeted effect site propofol concentration of 5  $\mu\text{g}/\text{mL}$  is 109 mg. The computer-controlled infusion pump will deliver this dose as rapidly as possible and then begin a targeted infusion for 5  $\mu\text{g}/\text{mL}$  at  $t = 1.6$  minutes (Fig. 11-21).

## Front-end Pharmacokinetics

Classic PK-PD models make the simplifying assumptions that there is instantaneous and complete mixing of drug in the intravascular space—a mathematical construct without regard for the physiology that drives drug disposition.<sup>142–144</sup> Therefore, the classic PK models inaccurately describe the initial/central distribution volume ( $V_c$ ), as a result of which they misestimate intercompartmental clearances and are unable to characterize cardiac output and its distribution.<sup>36,39,71,142,144–147</sup> Misspecification of  $V_c$  also results in **19** misspecification of the effect site kinetics and compensates by overestimating interindividual PD variability.<sup>36,144,147</sup> Physiologically based PK-PD models that can accurately estimate distribution volumes and clearances result in more realistic estimates of PD variability (Fig. 11-23).<sup>147</sup> Another source of PK and PD variability is cardiac output and its distribution.<sup>71,144,145,147,148</sup> Cardiac output and its distribution influences PK by modifying the distribution of drug to tissue compartments. In addition, cardiac output influences PD by changing the blood-effect site equilibration

rate (Fig. 11-24).<sup>147</sup> Because they cannot characterize cardiac output and its distribution, classic PK-PD models will be unable to identify the changes in cardiac output and its distribution that are the result of alterations in physiology related to sex, age, body composition, or pathologic processes.<sup>149,150</sup> Therefore, classic PK-PD models will not identify factors that solely alter cardiac output and its distribution as a source of PK variability and will overestimate the true PD.<sup>36,147,151,152</sup>

**Figure 11-23** The misestimation of the central distribution volume ( $V_c$ ) by a traditional compartmental PK-PD model results in more interindividual variability in pharmacodynamic estimates than pharmacodynamic estimates from a high-resolution, recirculatory PK-PD model. This figure uses Monte-Carlo simulation of the effect site concentration–pharmacologic effect relationships to demonstrate the interindividual variability from a traditional compartmental PK-PD model (2 COMP, *blue dashed lines*) and a high-resolution recirculatory PK-PD model (RECIRC, *black solid lines*). (Adapted from the rocuronium data of Kuipers JA, Boer F, Olofsen E, et al. Recirculatory pharmacokinetics and pharmacodynamics of rocuronium in patients: the influence of cardiac output. *Anesthesiology*. 2001;94:47–55.)

The term *front-end pharmacokinetics* refers to the intravascular mixing, pulmonary uptake, and recirculation events that occur in the first few minutes during and after IV drug administration.<sup>39</sup> These kinetic events and the drug concentration versus time profile that results are important because the peak effect of rapidly acting drugs occurs during this temporal window.<sup>38,147,153,154</sup> Although it has been suggested that front-end pharmacokinetics be used to guide drug dosing,<sup>36</sup> current TCI does not incorporate front-end kinetics into the models from which drug infusion rates are calculated. As described above, not doing so introduces further error.

TCI relies on pharmacokinetic models that are based on the simplifying assumption of instantaneous and complete mixing within  $V_c$ . However, the determination of  $V_c$  is routinely overestimated in most pharmacokinetic

studies. Overestimation of  $V_C$ , when used to calculate TCI infusion rates, results in plasma drug concentrations that overshoot the desired target concentration, especially in the first few minutes after beginning TCI. Furthermore, correct description of drug distribution to tissues is dependent on an accurate  $V_C$  estimate, so inaccuracies caused by not taking front-end pharmacokinetics into account may be persistent and result in undershoot as well as overshoot. Simulation indicates that pharmacokinetic parameters derived from studies in which the drug is administered by a short (approximately 2 minutes) infusion better estimate  $V_C$  and tissue-distribution kinetics than those from a rapid IV bolus infusion.<sup>36,37</sup> When the latter drug administration method is used, full characterization of the front-end recirculatory pharmacokinetics is required to obtain valid estimates of  $V$  for use in TCI.<sup>36,37</sup>

**Figure 11-24** The effects of cardiac output on the blood–effect site equilibration rate ( $k_{e0}$ ) when the PK-PD model is a high-resolution “recirculatory” model (*black circles*) versus a traditional compartmental model (triangles). While the traditional model has a moderate correlation between measured cardiac output and  $k_{e0}$  and significant systematic error (*grey line*), the high-resolution recirculatory model has a very strong correlation between measured cardiac output and  $k_{e0}$  (*black line*). Therefore, for lipophilic drugs with flow limited tissue-distribution (i.e., opioids, hypnotics, etc.), a high-resolution PK-PD model provides a physiologic basis for transfer of drug from the blood to the effect site. In addition, these high-resolution PK-PD models can quantitate the effects of physiologic perturbations on the PK and PD of these drugs more accurately than the traditional compartmental models. (Adapted from the rocuronium data of Kuipers JA, Boer F, Olofsen E, et al. Recirculatory pharmacokinetics and pharmacodynamics of rocuronium in patients: the influence of cardiac output. *Anesthesiology*. 2001;94:47–55.)

## Closed-loop Infusions

When a valid, and nearly continuous, measure of drug effect is available, drug delivery can be automatically titrated by feedback control. Such systems have been used experimentally for control of blood pressure,<sup>155</sup> oxygen delivery,<sup>156</sup> blood glucose,<sup>157</sup> neuromuscular blockade,<sup>158</sup> and depth of anesthesia.<sup>159–165</sup> A target value for the desired effect measure (the output of the system) is selected and the rate of drug delivery (the input into the system) is dependent on whether the effect measure is above, below, or at the target value. Thus the output feeds back and controls the input. Standard controllers (referred to as *proportional-integral-derivative* [PID] *controllers*) adjust drug delivery based on both the integral, or magnitude, of the deviation from target and the rate of deviation, or the derivative.

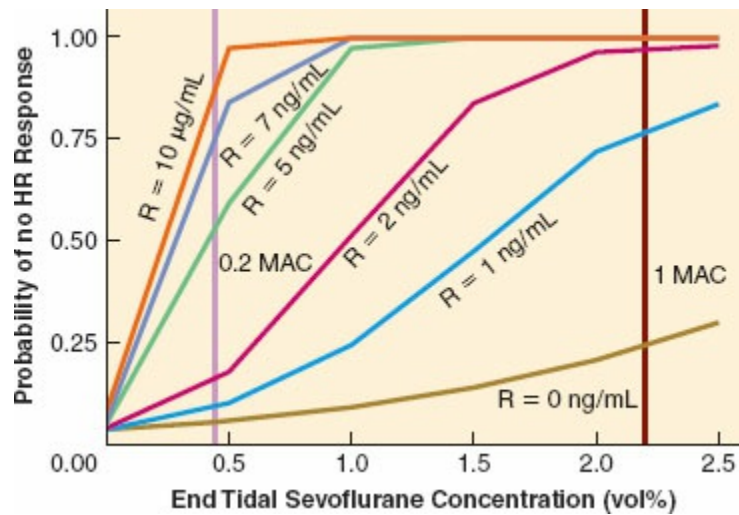

Under a range of responses, standard PID controllers work quite well. However, they have been shown to develop unstable characteristics in situations where the output may vary rapidly and widely. Schwilden et al.<sup>161</sup> proposed a controller in which the output (measured response) controls not only the input (drug infusion rate), but also the pharmacokinetic model driving the infusion rate. This is known as a *model-driven* or *adaptive* closed-loop system. Such a system has performed well in clinical trials,<sup>160</sup> and in a simulation of extreme conditions it was demonstrated to outperform a standard PID controller.<sup>163</sup>

Closed-loop systems for anesthesia are the most difficult to design and implement because the precise definition of “anesthesia” remains elusive, as does a robust monitor for “anesthetic depth.”<sup>88</sup> Because modification of consciousness must accompany anesthesia, processed EEG parameters that correlate with level of consciousness, such as the Bispectral Index (BIS), electroencephalographic entropy, and auditory evoked potentials, make it possible to undertake closed-loop control of anesthesia. There is keen interest in further developing these tools to make them more reliable, because advances in pharmacokinetic modeling, including the effect compartment, the implementation of such models into drug delivery systems, and the creation of adaptive controllers based on these models, has made routine closed-loop delivery of anesthesia imaginable.<sup>159</sup> Over the past 10 years, clinical trials investigating closed-loop delivery of propofol or propofol and remifentanyl have demonstrated superior efficiency in drug delivery and emergence from anesthesia with closed-loop devices compared to manual titration by experienced anesthesia providers.<sup>167–172</sup> So far it has been difficult to bring a true closed-loop system to market in medical applications, because of the regulatory agency hurdles. From a regulatory point of view, an open-loop TCI system is much easier to attain and offers many of the benefits of actual closed-loop systems. Unless there is a regulatory or a design “breakthrough,” closed-loop systems for anesthesia will likely remain in the theoretical and experimental realms.<sup>173,174</sup>

## Response Surface Models of Drug–Drug Interactions

During the course of an operation, the level of anesthetic drug administered is adjusted to ensure amnesia to ongoing events, provide immobility to noxious stimulation, and blunt the sympathetic response to noxious stimulation. Although it is possible to achieve an adequate anesthetic state with a high dose of a sedative-hypnotic alone (i.e., a volatile anesthetic or propofol), the effect site drug concentration necessary is often associated with excessive hemodynamic depression<sup>80</sup> and excessively deep plane of hypnosis that may be associated with longstanding morbidity or mortality.<sup>175,176</sup> Therefore, to limit side-effects, an opioid and a sedative-hypnotic are administered together. Although the administration of two volatile anesthetics or a volatile anesthetic and propofol produce a net-additive effect, the combination of an opioid and a sedative-hypnotic are synergistic for most pharmacologic effects. By understanding the interactions between the opioids and the sedative-hypnotics, it is possible to select target concentration pairs of the two drugs that produce the desired clinical effect while minimizing unwanted side-effects associated with high concentrations of a single drug (e.g., hemodynamic instability, prolonged respiratory depression).

Studies designed to evaluate the pharmacodynamic interactions between an opioid and a sedative-hypnotic have traditionally focused on the effects of adding one or two fixed doses or concentrations of the opioid to several defined concentrations or doses of the sedative-hypnotic.<sup>79,80,177–184</sup> Graphic demonstrations of these interaction data are most commonly performed by demonstrating a shift of parallel dose–response curves (Fig. 11-25). An alternative mathematical model is the isobologram—iso-effect curves that show dose combinations that result in equal effect (Fig. 11-26). Isobolographic analysis has the additional benefit of characterizing the interaction between the two drugs as additive, antagonistic, or synergistic (Fig. 11-27), whereas shifts of dose–response curves require more complex concentrations to determine if the interaction demonstrated by a leftward shift in the curve is more than additive.

**Figure 11-25** The effect of adding remifentaniil on the concentration—effect curve for sevoflurane induced analgesia (no hemodynamic response to a 5 second, 50 mA tetanic stimulation in volunteers). Each curve represents the concentration—effect relation for sevoflurane with a fixed effect site concentration of remifentaniil. The leftward shift in the curves indicates that remifentaniil decreases the amount of sevoflurane needed to produce adequate analgesia. The changes in the slopes of the concentration—response curves indicate that there is significant pharmacodynamic synergy between sevoflurane—remifentaniil. Also note that there is a ceiling effect to this pharmacodynamic interaction—the magnitude of the leftward shift decreases as the remifentaniil concentration increases. (Adapted from Manyam SC, Gupta DK, Johnson KB, et al. Opioid-volatile anesthetic synergy: a response surface model with remifentaniil and sevoflurane as prototypes. *Anesthesiology*. 2006;105:267–278.)

An alternative mathematical model that can fully characterize the complete spectrum of interaction between two drugs for all possible concentrations and effects is the response surface model.<sup>84,87</sup> The surface morphology of a response surface not only demonstrates whether the interaction is additive, synergistic, or antagonistic, but the model itself can quantitatively describe the degree of interaction between the two drugs. Furthermore, isobolograms can be derived from the projection of the response surface onto the appropriate horizontal effect plane (Fig. 11-28), and concentration—response curves can be derived from taking a vertical slice through a response surface in the plane perpendicular to the fixed-opioid concentration of interest (Fig. 11-28).<sup>84,87,88</sup> Therefore, response surface models can be viewed as generalizations of the traditional pharmacodynamic methods of analysis. The major limitation of response surface models is that they require a large number of pharmacodynamic measurements across all possible concentration pairing to accurately characterize the entire surface.<sup>185</sup> This is most efficiently done in the laboratory setting utilizing volunteers who can be exposed to subtherapeutic (e.g., below the level that guarantees amnesia) and suprathreshold drug concentration pairs. However, because

response surface models characterize the drug concentration pairs that provide adequate anesthesia and also adequate recovery from anesthesia, these models provide information that are not normally available from studies that generate an isobologram from surgical patients.

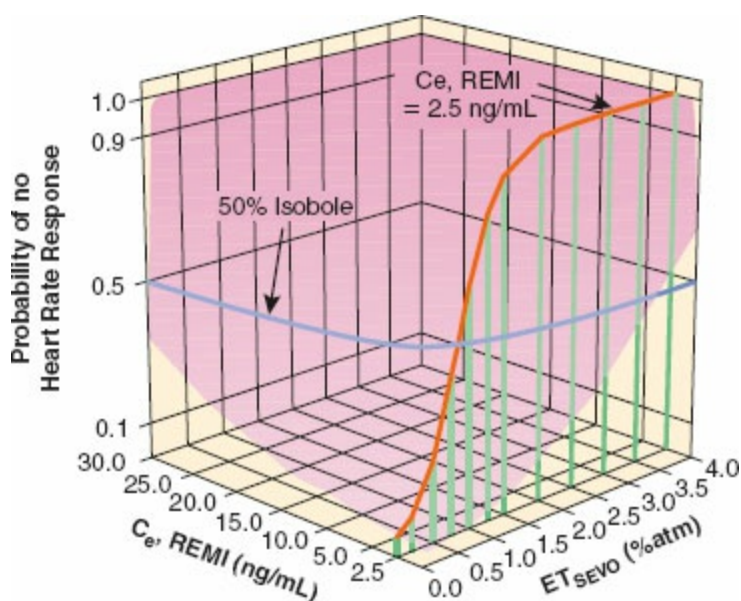

**Figure 11-26** Remifentanil–sevoflurane interaction for sedation (*green line*) and analgesia to electrical tetanic stimulation (*red line*) for volunteers. The respective 95% isoboles demonstrate the myriad target concentration pairs of remifentanil and sevoflurane that have a 95% probability of producing the desired pharmacodynamic end point. (Adapted from Manyam SC, Gupta DK, Johnson KB, et al. Opioid-volatile anesthetic synergy: a response surface model with remifentanil and sevoflurane as prototypes. *Anesthesiology*. 2006;105:267–278.)

**Figure 11-27** Isoboles to demonstrate additive (*blue line*), synergistic (*green line*), and antagonistic (*red line*) interactions between Drug A and Drug B.

Isobolograms and response surface models clearly demonstrate that there are multiple target concentration pairs of an opioid and a sedative-hypnotic that can provide adequate anesthesia—a 95% probability of no hemodynamic response to a noxious stimulus and 95% probability of clinically adequate

sedation.<sup>85,86,89</sup> Combining the response surface pharmacodynamic models with pharmacokinetic models allows computer simulations to be performed to identify the target concentration pair of the opioid and the sedative-hypnotic that produces an adequate anesthetic and yet optimizes one or more pharmacodynamic end points, such as the speed of awakening from anesthesia, drug-induced respiratory depression, or drug acquisition costs.<sup>82,86</sup> For sevoflurane–remifentanil anesthetics, these types of pharmacokinetic–pharmacodynamic simulations demonstrate the benefit of minimizing the administered dose of even the low solubility volatile anesthetic sevoflurane to near 0.5 MAC to take advantage of the pharmacokinetic efficiency of remifentanil, especially as the duration of anesthesia increases (Fig. 11-29 and Table 11-8).<sup>86</sup> These response surface models can accurately predict loss of responsiveness and loss of response to painful stimuli as well as emergence from anesthesia and the time at which a patient will require analgesia in the recovery room.<sup>186–189</sup> In addition, these pharmacodynamic targets can be incorporated into closed-loop controllers to deliver closed-loop anesthesia.<sup>172</sup>

**Figure 11-28** A response surface model characterizing the remifentanil–sevoflurane interaction for analgesia to electrical tetanic stimulation. The projection of the response surface onto the 50% probability horizontal plane results in the 50% effect isobole while the projection of the response surface onto the 2.5 ng/mL remifentanil effect site concentration vertical plane results in the sevoflurane concentration–response curve under 2.5 ng/mL of remifentanil. (Adapted from Manyam SC, Gupta DK, Johnson KB, et al. Opioid-volatile anesthetic synergy: a response surface model with remifentanil and sevoflurane as prototypes. *Anesthesiology*. 2006;105:267–278.)

**Figure 11-29** The optimal target concentration pairs of remifentanil and sevoflurane to maintain adequate analgesia (95% isobole for analgesia to electrical tetanic stimulation) and result in the most rapid emergence for anesthetics of various durations. For example, for a 2-hour anesthetic, target concentrations of 0.93 vol% sevoflurane, and 4.9 ng/mL remifentanil would result in a 5.8-minute time to awakening. As the duration of anesthesia increases, a minimum sevoflurane target concentration of 0.75 vol% is reached. (Adapted from Manyam SC, Gupta DK, Johnson KB, et al. Opioid-volatile anesthetic synergy: a response surface model with remifentanil and sevoflurane as prototypes. *Anesthesiology*. 2006;105:267–278.)

**Table 11-8** The Optimal Target Concentration Pairs of Sevoflurane and Remifentanil for Anesthetics 30 to 900 Minutes in Duration

Duration of Anesthetic (h)	Shortest Recovery Time (min)	Effect Site Remifentanil Concentration (ng/mL)	Remifentanil Infusion Rate ( $\mu\text{g}/\text{kg}/\text{min}$ )	End-Tidal Sevoflurane Concentration (vol%)
0.5	4.5	4.1	0.15	1.1
1	5.0	4.3	0.16	1.05
2	5.8	4.9	0.18	0.93
4	6.7	5.2	0.19	0.88
7–24	7.2–7.7	6.1	0.22	0.75

## Conclusion

Since World War II, we have moved from characterizing all anesthetics by a dose–response relationship to developing sophisticated models to characterize the synergistic interaction between sedative-hypnotics and opioids and having the physical devices and the computer support to accurately administer drugs to achieve the desired concentrations at the effect site of drug action. The rational selection of drug target concentrations required to achieve adequate anesthesia and minimize side effects (e.g., prolonged awakening, hemodynamic depression) and the methods by which to efficiently achieve those concentration targets with minimal overshoot requires a solid understanding of the clinical pharmacology of anesthetics. As new drugs enter

the anesthetic armamentarium, careful characterization of their pharmacokinetic and pharmacodynamic properties will allow them to be safely and appropriately utilized as part of a balanced anesthetic.<sup>88</sup>

## KEY POINTS

- 1 The heart's cartilaginous skeleton, myocardial fiber orientation, valves, coronary blood supply, and conduction system determine its mechanical capabilities.
- 2 The cardiac myocyte is engineered for contraction and relaxation.
- 3 Changes in sarcomere muscle tension and length observed in isolated cardiac muscle are translated into alterations in pressure and volume in the intact heart.
- 4 The pressure–volume diagram provides a useful framework for the analysis of atrial and ventricular systolic and diastolic function.
- 5 The end-systolic and end-diastolic pressure–volume relations determine the operating range of each cardiac chamber.
- 6 Heart rate, preload, afterload, and myocardial contractility determine pump performance.
- 7 Preload is the quantity of blood that a chamber contains immediately before contraction.
- 8 Afterload is the external resistance to chamber emptying after contraction begins and the aortic valve opens.
- 9 Myocardial contractility is the force of contraction under controlled heart rate and loading conditions; contractility may be quantified using pressure–volume relation, isovolumic contraction, or ejection phase analysis.
- 10 The ability of a cardiac chamber to effectively collect blood at a normal filling pressure defines its diastolic function.
- 11 Diastole is a complex sequence of temporally related, heterogeneous events; no single index comprehensively describes diastolic function.
- 12 Left ventricular diastolic dysfunction is responsible for heart failure in as many as 50% of patients.
- 13 Invasive analysis of diastolic function may be conducted using the pressure–volume model.
- 14 Transmitral and pulmonary venous blood flow velocities derived using pulse wave Doppler echocardiography are commonly used to noninvasively measure diastolic function.
- 15 The restraining forces of the pericardium are important determinants of chamber filling and ventricular interdependence.
- 16 The atria are reservoirs, conduits, and contractile chambers.

## Introduction

The heart is a phasic, variable speed, electrically self-activating muscular pump that provides its own blood supply. The two pair of atria and ventricles are elastic chambers arranged in series that supply equal amounts of blood to the pulmonary and systemic vasculature. Myocardium in the atria and

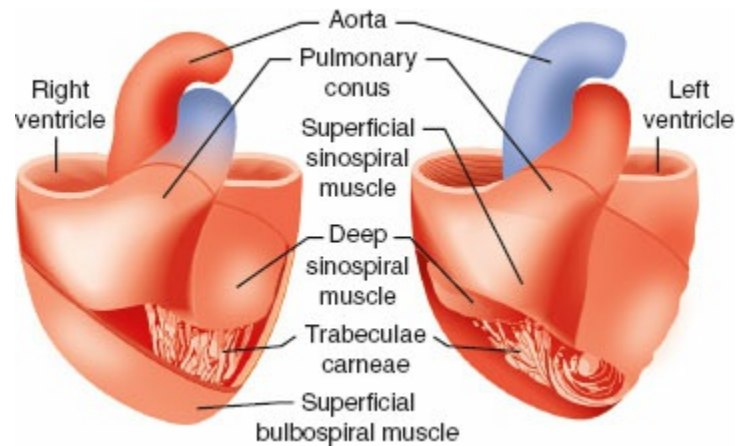

ventricles responds to stimulation rate and muscle stretch before (preload) and after (afterload) contraction begins. Coronary arterial blood vessels supply oxygen and metabolic substrates to the heart. The mechanical characteristics of the myocardium and its response to changes in autonomic nervous system activity allow the heart to adapt to rapidly changing physiologic conditions. The inherent contractile properties of the atria and ventricles and the ability of these chambers to adequately fill without excessive pressure are the major determinants of overall cardiac performance. As a result, abnormalities in either systolic or diastolic function may cause heart failure. Comprehensive knowledge of cardiac anatomy and physiology is essential for the practice of anesthesiology. This chapter describes the fundamentals of cardiac anatomy and physiology in adults. The authors will focus on the left atrium and ventricle (LA and LV, respectively) for the vast majority of the subsequent discussion unless otherwise noted.

## Gross Anatomy

### *Architecture*

A flexible, cartilaginous structure forms the heart's skeleton composed of the annuli of the cardiac valves, the aortic and pulmonary arterial (PA) roots, the **1** central fibrous body, and the left and right fibrous trigones. This foundation creates support for the valves and maintains the heart's structural integrity as internal pressures vary. A small quantity of superficial subepicardial muscle also inserts into the cartilaginous skeleton, but most atrial and ventricular muscle directly arises from and inserts within adjacent surrounding myocardium. Myocardial fibers are continuously interwoven and cannot be separated into distinct "layers." The atria contain two relatively thin orthogonal bands of myocardium, whereas the LV and, to a lesser extent the right ventricle (RV), consist of the interdigitating deep sinospiral, the superficial sinospiral, and the superficial bulbospiral muscles ([Fig. 12-1](#)). The angle of the myocardial fibers changes within the ventricular wall's thickness from the subendocardium to the subepicardium. Myocardial fibers of the LV are oriented in perpendicular, oblique, and helical planes from the cardiac base (superior in the mediastinum) to its apex. This arrangement reverses direction at approximately the LV's midpoint, creating an overall fiber architecture that mimics a flattened "figure of eight." This fiber orientation facilitates LV chamber shortening along the heart's longitudinal axis and produces a distinctive torsional twisting (analogous to "wringing" of a wash cloth) motion during contraction. The twisting effect substantially enhances the LV's ability to eject blood, as loss of this helical-rotational action reduces ejection fraction in patients with heart failure.<sup>1</sup> Elastic recoil of the systolic

twist during LV relaxation is also an important determinant of early diastolic filling, especially during hypovolemia and exercise.<sup>2</sup> In contrast to the subepicardial and subendocardial layers, midmyocardial fibers are arranged in a circumferential orientation and act almost exclusively to decrease chamber diameter during contraction.

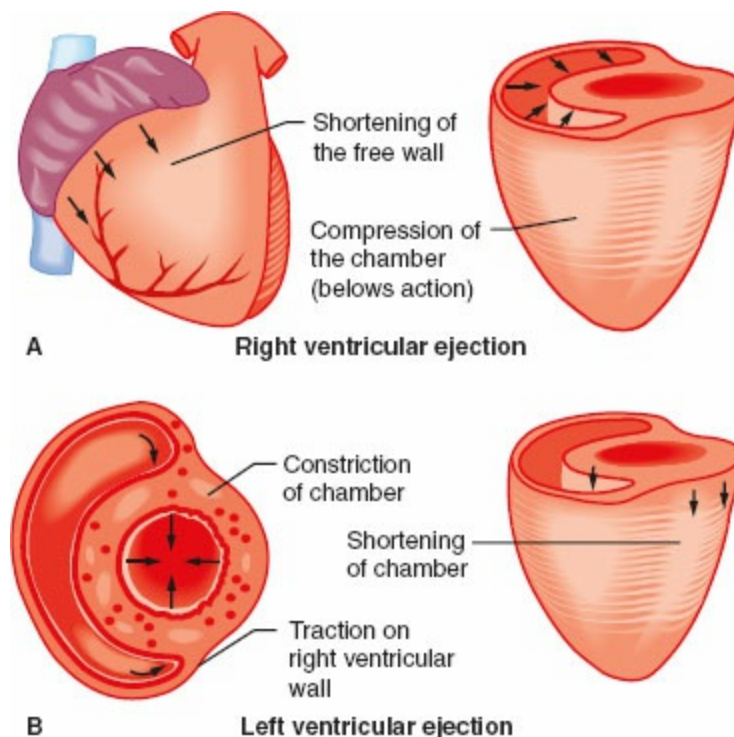

**Figure 12-1** Illustration depicting the components of the myocardium. The outer muscle layers pull the base of the heart toward the apex. The inner circumferential layers constrict the lumen, particularly of the LV.

The LV free walls taper in thickness from base to apex because the relative amount of midmyocardium gradually declines. LV and RV subendocardium and LV midmyocardium extending from the LV anterior wall contribute to the interventricular septum, which thickens toward the LV chamber during contraction under normal conditions because the majority of the septum is composed of LV myocardium. However, RV hypertrophy resulting from an increase in afterload (e.g., pulmonary arterial [PA] hypertension) may cause paradoxical motion of the interventricular septum. Regional differences in LV wall thickness and fiber orientation also contribute to load-dependent alterations in LV mechanics.<sup>3</sup> Irregular ridges of subendocardium (“trabeculae carneae” [Latin for “meaty ridges”]) are present within the RV chamber, and to a lesser extent, in the LV apex. The precise physiologic significance of the trabeculae carneae is unknown.

The LV apex and interventricular septum are relatively fixed in space within the mediastinum during contraction and relaxation. In contrast, the LV’s lateral and posterior walls shift position to the anterior and to the right during systole. This motion changes the orientation of the LV longitudinal axis from a position that favors LV filling (perpendicular to the mitral valve) to one that facilitates ejection (orthogonal to the LV outflow tract and aortic valve). The movement of the lateral and posterior LV walls during contraction is also responsible for the point of maximal impulse palpable on the left chest wall. The combined effects of subendocardial and subepicardial contraction,

papillary muscle shortening, and elastic recoil produced by ejection of blood into the aortic root causes the LV base to descend toward the apex during contraction. Thus, normal electrical activation of the LV causes its long axis to shorten, reduces its chamber diameter, and produces torsional rotation of its apex in an anterior-right direction (Fig. 12-2). Differential changes in wall tension also create an apex-to-base intraventricular pressure gradient during LV ejection. This action enhances the transfer of stroke volume from the LV to the ascending aorta and proximal great vessels.

The crescent-shaped RV is located anterior and to the right of the LV. The RV propels venous blood into the compliant, low-pressure PA vasculature. The RV's walls are thinner and contain fewer cardiac myocytes than the LV. The RV is exposed to only 15% to 20% of the LV's peak systolic wall stress. Embryologically distinct inflow and outflow tracts exist in the RV. As a result, RV contraction is less temporally uniform than the LV and is more peristaltic in nature. The RV free wall uses the interventricular septum for structural support during contraction. The contracting LV also provides additional external assistance to RV during the latter chamber's contraction. These two factors combine to improve the RV's mechanical advantage above its contractile ability alone, and in so doing, partially compensate for the chamber's thinner walls. This allows the RV to eject an identical stroke volume to the LV during each cardiac cycle. Nevertheless, the RV more easily decompensates when afterload increases because the RV is able to produce less than 20% of the total stroke work than the thicker, more muscular LV generates. However, the RV's greater compliance allows the chamber to more easily accommodate acute increases in preload than the stiffer LV.

**Figure 12-2** Illustration depicting the contraction characteristics and modes of emptying

of the RV and LV. The volumes ejected by each ventricle are equal, but the LV requires a more circumferential muscular wall to eject its volume at a pressure that is approximately four to five times greater than that in the right ventricle.

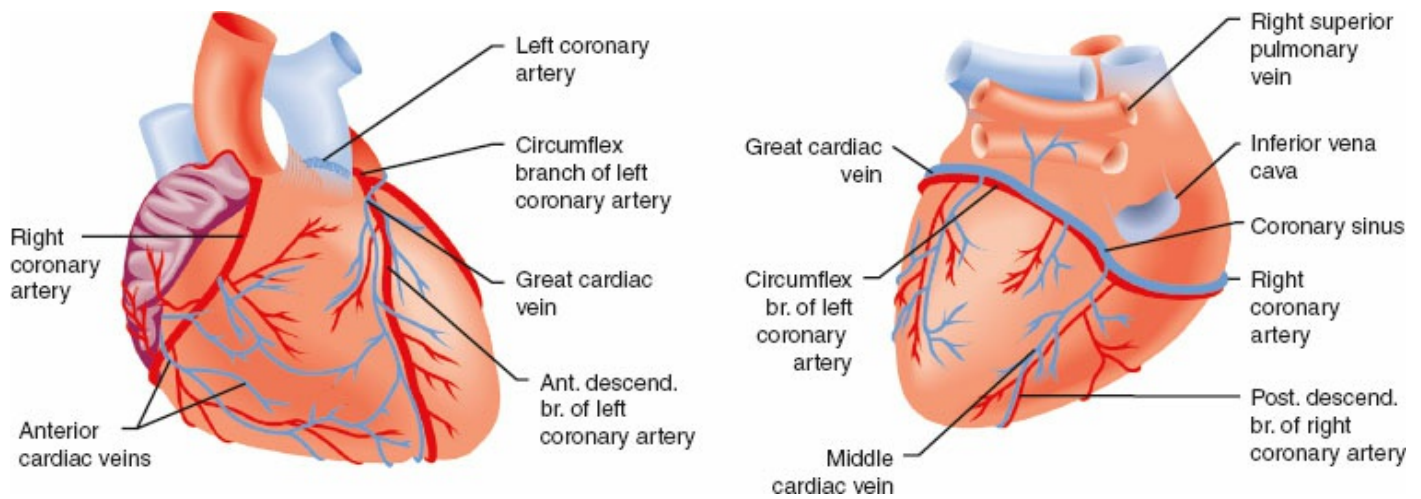

## Valve Structure

Two pairs of translucent, macroscopically avascular valves ensure unidirectional movement of blood through the normal heart. The pulmonic and aortic valves separate the RV and LV from the PA and aorta, respectively. The valves open and close passively in response to pressure gradients produced during contraction and relaxation, respectively. The pulmonic valve leaflets are named for their anatomic locations (right, left, and anterior), whereas the aortic valve leaflets correspond to the adjacent coronary artery ostium if present (right, left, and non). The orifice areas of the pulmonic and aortic valves are nearly equal to the corresponding cross-sectional areas of their annuli during ejection. The sinuses of Valsalva are dilated segments of aortic root immediately superior to each aortic leaflet. Hydraulic flow vortices occur within the sinuses that prevent adherence of the valve leaflets to the aortic wall during ejection and facilitate valve closure by preserving leaflet mobility during diastole.<sup>4</sup> These actions prevent the valve leaflets from inadvertently occluding the right and left coronary ostia. The proximal PA does not contain sinuses of Valsalva.

Located between the LA and the LV, the mitral valve has two leaflets (the oval-shaped anterior and the crescent-shaped posterior) and a prolate ellipsoid (saddle-shaped) three-dimensional structure.<sup>5,6</sup> Coaptation of the leaflets occurs along a central curve with the anterior leaflet creating a convex border. Despite the differences in their shapes, the anterior and posterior leaflets have similar cross-sectional areas because the posterior leaflet occupies a greater percentage of the annular circumference. Anterior-lateral and posterior-medial commissures connect the leaflets in these annular locations and are located above each corresponding papillary muscle. A positive pressure gradient between the LA and LV develops during late LV relaxation as LV pressure falls below LA pressure, driving open the mitral valve and allowing blood to flow from the LA into the LV (early ventricular filling). LV untwisting and elastic recoil of the chamber further contribute to this process. The mitral valve closes as rapidly increasing LV hydraulic pressure during early systole forces the leaflets in a superior direction. The chordae tendinae act as restricting cables to limit this superior motion of the mitral leaflets, facilitating their coaptation. When functioning properly, the chordae tendinae prevent the mitral leaflets from prolapsing or inverting into the LA. Conversely, chordal rupture is a common cause of mitral regurgitation because excessive leaflet motion beyond the coaptation zone occurs, allowing

unobstructed retrograde blood flow from the pressurized LV into the low-pressure LA outlet. Primary and secondary chordae tendinae attach to the leaflet edges and bodies, respectively, whereas tertiary chordae insert into the distal posterior leaflet or the myocardium immediately adjacent to the annulus. The papillary muscles are composed of subendocardial myocardium that contract with the LV. Each papillary muscle normally has chordal attachments to both mitral leaflets. Papillary muscle contraction tensions the chordae, providing another mechanism by which the chordae prevent excessive leaflet motion. Tightening of the mitral annulus through a sphincter-like contraction of the surrounding subepicardium also aids in mitral valve closure. The mitral valve apparatus is very important for normal LV function for two major reasons. First, the valve apparatus assures unidirectional blood flow from the LA to the LV by preventing reflux of blood into the LA and pulmonary veins during LV contraction. In addition to chordal rupture previously mentioned, papillary muscle ischemia or infarction may cause the mitral apparatus to fail, resulting in acute mitral regurgitation. Second, the mitral apparatus also contributes to LV systolic function because papillary muscle shortening assists LV apical contraction. This latter effect often becomes apparent during mitral valve replacement because many chordal attachments to the papillary muscles are intentionally severed. This compromise of mitral apparatus structure reduces LV ejection fraction and may contribute to difficult weaning from cardiopulmonary bypass in some patients undergoing mitral valve replacement, especially those with pre-existing LV systolic dysfunction.

The tricuspid valve is normally composed of anterior, posterior, and septal leaflets.<sup>7</sup> The posterior leaflet is usually smaller than the anterior and septal leaflets. The tricuspid valve assures unidirectional movement of blood from the RA and RV. Identification of a septal papillary muscle can be used to distinguish the morphologic RV from the LV in patients with some forms of congenital heart disease (e.g., transposition of the great vessels). A lateral segment of myocardium stretching between the apical aspects of anterior and septal papillary muscles, known as the moderator band, separates the embryologic RV inflow and outflow tracts. Unlike the mitral valve, the tricuspid valve does not have a collagenous annulus. Instead, the tricuspid leaflets originate from the atrioventricular groove that separates the RA from the RV. Notably, the proximal right coronary artery lies within this groove, and the vessel must be carefully avoided during tricuspid valve repair or replacement.

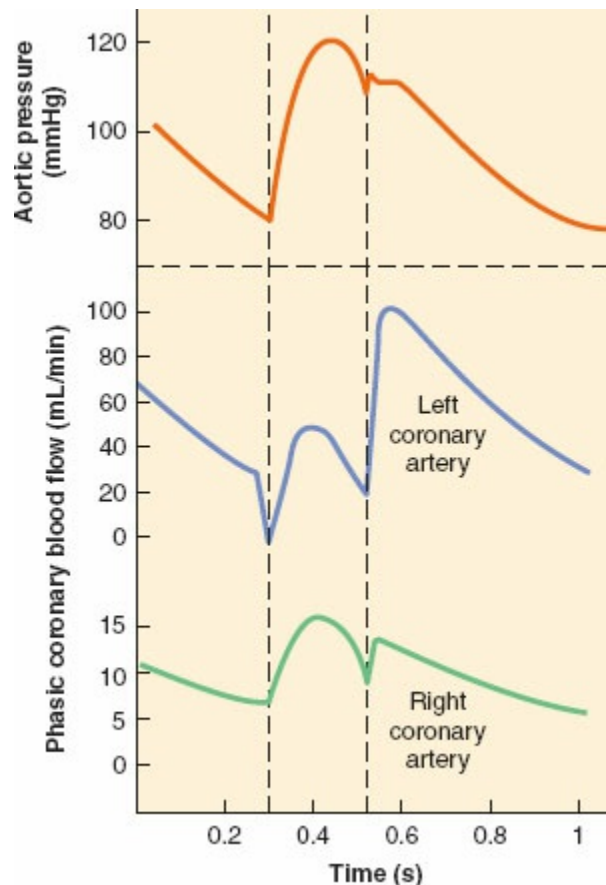

**Figure 12-3** An anterior view of the heart (left) shows right coronary and left anterior descending coronary arteries. A posterior view (right) shows left circumflex and posterior descending coronary arteries. The anterior cardiac veins from the RV and the coronary sinus, which drain primarily the LV, empty into the RA.

### Coronary Blood Supply

The left anterior descending, left circumflex, and right coronary arteries (LAD, LCCA, and RCA, respectively) supply blood to the LV (Fig. 12-3). Most coronary blood flow to the LV myocardium occurs during diastole because aortic pressure exceeds LV pressure. A critical stenosis or acute occlusion of the LAD, LCCA, or RCA almost invariably produces myocardial ischemia or infarction accompanied by regional contractile dysfunction that is easily predicted based on the known distribution of each coronary artery's blood supply. The LAD and its diagonal branches supply the medial LV anterior wall, the anterior two-thirds of the interventricular septum, and the LV apex. The LCCA and its marginal branches perfuse the anterior and posterior aspects of the lateral wall. The RCA provides blood flow to the medial portions of the posterior wall and the posterior one-third of the interventricular septum. The major epicardial coronary vessel that feeds the posterior descending coronary artery (PDA) determines the "dominance" of the coronary circulation. A "right dominant" circulation (RCA supplies blood to the PDA) is observed in approximately 80% of patients, whereas a "left dominant" circulation (LCCA perfuses the PDA) occurs in the remaining 20%. Distal connections or collateral vessels between the major coronary arteries may also provide an alternative route of blood flow to regions of myocardium that lie distal to a severe stenosis or occlusion. Notably, the development of coronary collaterals in response to chronic myocardial ischemia is highly variable and quite unpredictable in patients with coronary artery disease. A single coronary artery (2:1 ratio of RCA to LCCA) provides blood flow to the posterior-medial papillary muscle in two-thirds of patients. Thus, RCA or LCCA occlusion may produce acute posterior-medial papillary muscle ischemia or infarction and, as

a result, new mitral regurgitation. However, this is not always the case, as both vessels perfuse the posterior-medial papillary muscle in the remaining patients.<sup>8</sup> In contrast to the variable blood supply to the posterior-medial papillary muscle, the anterior-lateral papillary muscle has a robust dual supply (LAD and LCCA), rendering this papillary muscle less susceptible to ischemic dysfunction than its counterpart.

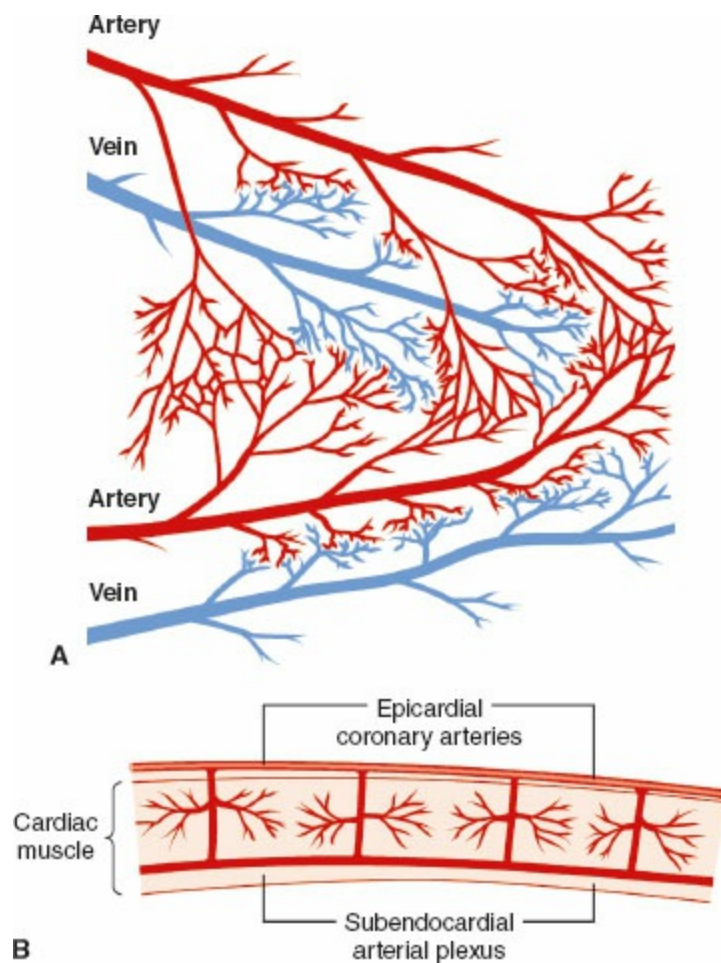

Coronary blood flow to the RA, LA, and RV occurs during both systole and diastole because aortic pressure most often exceeds the pressure within each of these chambers unless profound hypotension is present (Fig. 12-4).  The RCA and its branches supply blood flow to most of the RV, although distal diagonal and septal branches of the LAD also perfuse the RV anterior wall. Thus, either RCA or LAD occlusion may cause RV ischemia or infarction with resulting contractile dysfunction. Branches of the LCCA are the major sources of blood supply to the LA. As a result, LCCA occlusion often causes acute decompensation of LA contractility, whereas a compensatory increase in LA contractility (based on a Frank–Starling mechanism) is most often observed if the LAD is acutely occluded.<sup>9</sup> Branches of both the RCA and the LCCA supply the RA. For example, either the RCA (55% of patients) or the LCCA perfuses the sinoatrial (SA) node. The RCA usually supplies blood to the atrioventricular (AV) node, but the LCCA may also perfuse the AV node depending on the coronary circulation's right or left dominance. The clinical implications of these relationships are clear: Critical stenosis or acute occlusion of either the RCA or LCCA may interrupt normal atrial or AV node conduction and cause bradyarrhythmias.

**Figure 12-4** Schematic representation of blood flow in the left and right coronary arteries during phases of the cardiac cycle. Note that most left coronary flow occurs during diastole while right coronary flow (and coronary sinus flow) occurs mostly during late systole and early diastole.

The proximal branches of the RCA, LCCA, and LAD are located on the epicardial surface of the heart and give rise to intramural vessels that penetrate perpendicularly or obliquely deep into the myocardium. Except for the thin tissue layer on the endocardial surface of each chamber, the heart's blood supply is derived almost entirely from perforating branches of the three major epicardial coronary arteries. The penetrating branches divide into dense capillary networks located parallel to the myocardial bundles. Arterial branches with diameters between 50 and 500  $\mu\text{m}$  form interconnecting anastomoses (Fig. 12-5), whereas vessels between 100 and 200  $\mu\text{m}$  in diameter form a plexus within the subendocardium. Coronary collaterals between different branches of the same coronary artery or between branches of two different coronary arteries are also variably present. Coronary collateral blood flow is usually minimal in the absence of a hemodynamically significant stenosis because the driving pressure across the collateral vessel is equal. However, if a main artery supplying one branch of a collateral vessel is severely stenotic or occluded, a pressure gradient develops that diverts blood flow from the patent artery into the myocardial distribution of the occluded artery through the collateral vessel. It stands to reason that the degree of coronary collateral formation often determines whether patients with

coronary artery disease will develop anginal symptoms in response to increases in myocardial oxygen consumption.

**Figure 12-5 A:** Diagram of the arterial-to-arterial and venous-to-venous anastomoses of the coronary arterial system, which allow diversion of flow if one distribution becomes blocked. **B:** Diagram of the epicardial coronary vessels lying on the cardiac muscle surface, the penetrating deep vessels, and the subendocardial arterial plexus connecting the deep vessels.

The main coronary venous drainage of the heart retraces the course of the major coronary arteries along the AV and interventricular grooves. There are three major coronary veins: the great cardiac vein courses along the AV groove and the LAD; the anterior cardiac vein is located adjacent to the RCA; and the middle cardiac vein is associated with PDA. Most often, there are two coronary veins located along either side of each major coronary arterial branch. The main coronary veins converge into the coronary sinus that empties into the posterior aspect of the right atrium immediately above the tricuspid valve.<sup>10</sup> Approximately 85% of total coronary blood flow returning from the LV empties into the coronary sinus, whereas the remaining flow drains directly into the atrial and ventricular cavities through the Thebesian veins. The RV veins drain into the anterior cardiac veins that empty individually into the RA.

The coronary capillary network is similar in structure to that observed in other tissue beds. The capillary to myofibril density in myocardium is approximately 1:1 because of the heart's exceptionally high metabolic demand. Adjacent capillaries are usually separated by the diameter of single myocyte. The capillary distribution is quite uniform throughout the atria and ventricles (3,000 and 4,000/mm<sup>2</sup>) except in the AV node and interventricular septum, where it is substantially reduced. This observation provides an anatomic rationale explaining why the proximal portion of the RV and LV conduction system may be more vulnerable to ischemia. As in other capillary beds, coronary capillaries are the sites for oxygen and carbon dioxide exchange and for the movement of larger molecules (e.g., glucose) across the endothelium without the impediment of vascular smooth muscle.

### *Impulse Conduction*

The mechanism by which the heart is electrically activated is critical for its performance. The SA node is the primary cardiac pacemaker. Decreases in firing rate, delays or blockade of normal conduction, or the presence of secondary pacemakers (e.g., AV node, bundle of His) may supersede the dominance of SA automaticity. The anterior, middle (Wenckebach), and posterior (Thorel) internodal pathways rapidly transmit the initial SA node depolarization across the RA to the AV node. Bachmann's bundle (a branch of the anterior internodal pathway) transmits the SA node depolarization across the LA through the atrial septum. Histologic examination of atrial myocytes rarely allows differentiation of cells that are specifically involved in the internodal pathway, but the unique conducting characteristics of these specialized myocytes may be clearly identified in the electrophysiology laboratory. The heart's cartilaginous skeleton electrically isolates the atria from the ventricles. As a result, atrial depolarization is directed solely to the RV and LV through the AV node, which pierces this cartilaginous framework. Because AV node conduction velocity is quite slow compared with the pathways proximal and distal to it, the AV node is responsible for the sequential contraction pattern of the atria and the ventricles. Accessory pathways that bypass the AV node and establish abnormal conduction between the atria and ventricles may precipitate supraventricular tachyarrhythmias. This is the putative mechanism by which the bundle of Kent produces Wolff–Parkinson–White syndrome. The AV node transmits its depolarization to the His bundle, which further transmits the signal to the RV and LV via the right and left bundle branches, respectively, through Purkinje fibers within the endocardium. The conduction velocity through the His bundle, the bundle branches, and the Purkinje network is very rapid, assuring coordinated RV and LV depolarization and contraction. The relatively

homogeneous distribution of Purkinje fibers throughout the LV myocardium produces temporally uniform contractile activation of the chamber (functional syncytium). Notably, artificial RV epicardial pacing (as is sometimes used during cardiac surgery) does not rely on this normal conduction sequence and, as a result, causes dyssynchronous LV activation that may be erroneously interpreted as a new ischemia-induced regional wall motion abnormality. Chronic RV apical pacing may also contribute to LV dysfunction and subsequent heart failure because of long-term imposition of contractile dyssynchrony.<sup>11</sup> Indeed, restoration of the normal electrical activation sequence is the basis upon which cardiac resynchronization therapy improves LV contractile function in patients with heart failure.<sup>12</sup>

## Coronary Physiology

Blood supply to the LV is directly dependent on the difference between the aortic diastolic pressure and LV end-diastolic pressure (coronary perfusion pressure) and inversely related to the vascular resistance to flow, which varies to the fourth power of the vessel radius (Poiseuille law). Two other determinants of coronary flow are vessel length and blood viscosity, but these factors are relatively constant. Resting coronary blood flow in the adult is approximately 250 mL/min (1 mL/min/g; 5% of normal adult cardiac output). Cyclical changes in aortic pressure and the resistance to flow resulting from physical compression of the intramural coronary arteries govern the pulsatile pattern of LV coronary flow. The LV subendocardium is exposed to a higher pressure than the subepicardium during systole, and the intraventricular tissue pressure actually exceeds peak developed LV pressure. As a result, the subendocardial layer is much more susceptible to ischemia when a flow-limiting coronary stenosis, pressure-overload hypertrophy, or pronounced tachycardia is present. Coronary blood flow is also reduced when aortic diastolic pressure is low, such as occurs in severe aortic valvular insufficiency. Elevated LV end-diastolic pressure, as typically observed in heart failure, also reduces coronary perfusion pressure and blood flow. Venous blood flow in the coronary sinus peaks during late systole because the contracting LV compresses major venous drainage channels.

Another important determinant of coronary blood flow is coronary vascular resistance (estimated using the ratio of coronary blood flow to perfusion pressure), which also varies substantially during the cardiac cycle. While coronary perfusion certainly changes in response to aortic, intramyocardial, and coronary venous pressures, the primary regulator of coronary blood flow is the variable resistance imparted by coronary vascular smooth muscle. For example, activation of the sympathetic nervous system increases coronary vascular smooth muscle tone, thereby making coronary

vascular resistance greater. The degree of smooth muscle stretch (myogenic factor) also influences coronary vascular tone and resistance. However, metabolic factors are the primary physiologic determinants of coronary vascular tone and myocardial perfusion. The ratio of subepicardial to subendocardial blood flow remains near unity throughout the cardiac cycle despite the differentially greater systolic compressive forces exerted on the subendocardium.  $\beta$  adrenoceptor-mediated vasodilation and local release of metabolic autocrine substances (e.g., adenosine) produced by the myocardium itself act to offset this greater resistance to flow in the subendocardium. The relative maintenance of subendocardial blood flow despite compression is also related to the redundancy of arteriolar and capillary anastomoses within the subendocardium.

The heart normally extracts between 75% and 80% of arterial oxygen content, by far the greatest oxygen extraction of all the body's organs. The majority of myocardial oxygen consumption results from the magnitude of LV pressure during isovolumic contraction and the rate at which this pressure develops. The LV's diameter and wall thickness also have profound effects on myocardial oxygen consumption as dictated by the Law of Laplace (see below). Heart rate is the primary determinant of myocardial oxygen consumption in the intact heart. Increases in myocardial contractility, preload, and afterload are also associated with greater myocardial oxygen consumption. Cardiac oxygen extraction is near maximal under resting conditions and cannot substantially increase during exercise. As a result, the primary mechanism by which myocardium is able to meet its oxygen requirements during exercise is through enhanced oxygen delivery, which is proportional to coronary blood flow when hemoglobin concentration is constant. Thus, it is not surprising that myocardial oxygen consumption is the most important determinant of coronary blood flow. For example, myocardial oxygen consumption and corresponding coronary blood flow increase by a magnitude of four- to fivefold during strenuous physical exercise. The difference between maximal and resting coronary blood flow (coronary reserve) determines the magnitude with which coronary blood flow can rise during exercise-induced increases in myocardial oxygen consumption. Coronary vascular resistance is greater in the resting, perfused heart than in the contracting heart. These data suggest that increases in coronary blood flow exceed those of perfusion pressure in response to greater myocardial oxygen consumption when the heart is contracting versus when it is quiescent. The precise mechanisms responsible for this close correlation between myocardial oxygen consumption and coronary vasomotor tone remain elusive. The factors responsible for coronary autoregulation (maintenance of coronary blood flow despite changes in perfusion pressure) and reactive hyperemia (the several-fold increase in coronary blood flow

above baseline after a brief period of myocardial ischemia) are also not clearly understood. Metabolic coronary vasodilation in response to enhanced myocardial oxygen consumption during exercise occurs, at least in part, as a result of enhanced local release of metabolic substrates (e.g., adenosine, ADP) combined with sympathetic nervous system stimulation of the coronary vasculature. This latter effect causes a “feed-forward” vasodilation of small coronary arterioles by activating  $\beta$  adrenoceptors.<sup>13</sup> An  $\alpha$  adrenoceptor-induced vasoconstriction also occurs in larger coronary arteries during exercise. Although seemingly counterintuitive, this differential vasoconstriction of larger caliber upstream coronary arteries serves two important functions: reduction of vascular compliance and attenuation of the wide swings in coronary blood flow normally observed during the cardiac cycle. These actions act to preserve coronary perfusion to the more vulnerable LV subendocardium when heart rate, inotropic state, and myocardial oxygen consumption are elevated. In contrast to the important role of the cardiac sympathetic nerves, parasympathetic innervation has a relatively minor direct effect on coronary blood flow regulation despite its well-known negative inotropic and chronotropic actions.

The aforementioned conclusions about sympathetic nervous system control of the coronary circulation are based on alterations in the slope of the myocardial oxygen consumption–coronary venous oxygen tension relation during graded exercise in the presence of exogenous  $\alpha$  or  $\beta$  adrenoceptor blockade. The  $\beta$  adrenoceptor appears to account for only one-fourth of the total coronary vasodilation observed during exercise-induced hyperemia, but most of this vasodilation is most likely related to local or autocrine metabolic factors that act on coronary vascular smooth muscle with or without the additional modulation by vascular endothelium. Adenine nucleotides from red blood cells or the myocardium itself may activate endothelial purinergic receptors to produce coronary vasodilation during exercise.<sup>14</sup> Many factors have been proposed to individually or collectively modulate coronary blood flow at the arteriolar or capillary level, including adenosine, bradykinin, nitric oxide, arterial oxygen or carbon dioxide tension, acid–base status, osmolarity, plasma electrolyte (e.g.,  $K^+$ ,  $Ca^{2+}$ ) concentrations, and various products of arachidonic acid metabolism. Many of these factors exert predictable direct effects. For example, hypoxia or ischemia decreases arterial oxygen tension and pH concomitant with increases in carbon dioxide tension, adenosine release, and the plasma concentrations of  $K^+$  and  $Ca^{2+}$ . These changes collectively augment coronary blood flow during exercise, but none individually is solely responsible for this vasodilation. Adenosine receptor blockade does not alter coronary blood flow under resting conditions or during exercise. Similarly, inhibition of nitric oxide (NO) production or antagonism of adenosine triphosphate-sensitive potassium ( $K_{ATP}$ ) channels

does not affect the myocardial oxygen consumption–coronary venous oxygen content relationship during graded exercise. Nevertheless, it is quite clear that NO and  $K_{ATP}$  channels are important regulators of myocardial oxygen supply–demand relations under resting conditions. Adenosine released during hypoxia or ischemia also causes coronary vasodilation, and  $K_{ATP}$  channel activation mediates this effect. Adenosine and  $K_{ATP}$  channels also play a central role in reactive hyperemia after brief myocardial ischemia, but neither mediator appears to be required for coronary autoregulation. Indeed, the  $K_{ATP}$  channel may act to reduce coronary vascular smooth muscle tone and maintain a higher basal level of coronary blood flow during resting conditions. While not acting as a local metabolic vasodilator of small coronary arteries and arterioles per se, NO may dilate larger epicardial coronary vessels in response to downstream vasodilation and prevent excessive sheer stress on coronary vascular endothelium. Endothelin and thromboxane  $A_2$  produce direct coronary vasoconstriction in vitro, but the precise role of these substances on the regulation of coronary blood flow in vivo has not been defined.

## Cardiac Myocyte Anatomy and Function

### *Ultrastructure*

The heart contracts and relaxes nearly three billion times during an average lifetime, based on an average heart rate of 70 beats per minute and a life expectancy of 75 years. A review of cardiac myocyte ultrastructure provides **2** important insights into how this remarkable feat is possible. The sarcolemma is the external membrane of the cardiac muscle cell. The sarcolemma contains ion channels (e.g.,  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ), ion pumps and exchangers (e.g.,  $Na^+-K^+$  ATPase,  $Ca^{2+}$ -ATPase,  $Na^+-Ca^{2+}$  or  $Na^+-H^+$  exchangers), G protein-coupled and other receptors (e.g.,  $\beta_1$  adrenergic, muscarinic, adenosine, opioid), and transporter enzymes that regulate intracellular ion concentrations, facilitate signal transduction, and provide metabolic substrates required for energy production. Deep invaginations of the sarcolemma, known as transverse (T) tubules, penetrate the internal structure of the myocyte at regular intervals. The T-tubules assure rapid, simultaneous transmission of the depolarizing impulses that initiate myocyte contraction. The cardiac myocyte is densely packed with mitochondria that are responsible for production of large quantities of high-energy phosphates (e.g., ATP) needed for contraction and relaxation. The sarcomere is the fundamental contractile unit of cardiac muscle. The myofilaments within each sarcomere are arranged in parallel cross-striated bundles of thin (containing actin, tropomyosin, and the troponin complex) and thick (primarily composed of myosin and its supporting proteins) fibers. Sarcomeres are connected in

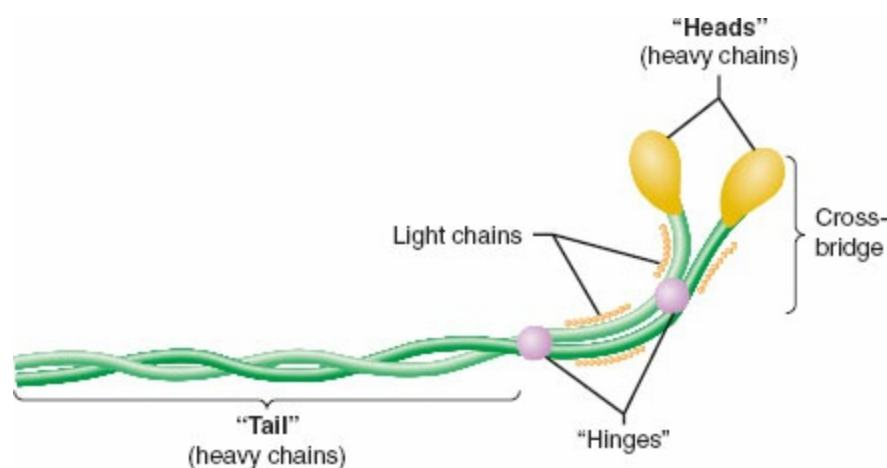

series and produce characteristic shortening and thickening of the long and short axes of each myocyte, respectively, during contraction.

Observations from light and electron microscopy led to the definition of the sarcomere's distinctive structural features. The area of overlap of thick and thin fibers characterizes the "A" band. This band lengthens as the sarcomere shortens during contraction. The "I" band represents the region of the sarcomere that contains thin filaments alone, and this band is reduced in width as the cell contracts. Each "I" band is bisected by a "Z" (from the German *zuckung* [twitch]) line, which delineates the border between two adjacent sarcomeres. As a result, the length of each sarcomere contains a complete "A" band and two symmetric one-half "I" bands located between "Z" lines. A central "M" band is also present within the "A" band. This "M" band is composed of thick filaments spatially constrained in a cross-sectional hexagonal matrix by myosin-binding protein C. A densely intertwined network of sarcoplasmic reticulum (SR) invests each bundle of contractile proteins and functions as a  $\text{Ca}^{2+}$  reservoir. This SR network assures homogeneous distribution and reuptake of activator  $\text{Ca}^{2+}$  throughout the myofilaments during contraction and relaxation, respectively. The SR subsarcolemmal cisternae are specialized structures located immediately adjacent to, but not continuous with, the sarcolemmal and transverse tubular membranes. The cisternae are packed with ryanodine receptors that function as the primary  $\text{Ca}^{2+}$  release channel for the SR. The contractile machinery and the mitochondria that power it occupy more than 80% of the total volume of the cardiac myocyte. This observation emphasizes that mechanical function, and not new protein synthesis, is the predominant activity of the cardiac myocyte. Intercalated discs connect adjacent myocytes through the fascia adherens and desmosomes that link actin and other proteins between cells, respectively. The intercalated discs also provide a seamless electrical connection between myocytes via large, nonspecific ion channels (known as "gap junctions") that facilitate intercellular cytosolic diffusion of ions and small molecules.

### **Contractile Apparatus**

Myosin, actin, tropomyosin, and the three-protein troponin complex compose the six major components of the contractile apparatus. Myosin (molecular weight of approximately 500 kDa; length, 0.17  $\mu\text{m}$ ) contains two interwoven chain helices with two globular heads that bind to actin and two additional pairs of light chains. Enzymatic digestion of myosin divides the structure into light (containing the tail section of the complex) and heavy (composed of the globular heads and the light chains) meromyosin. The elongated tail section of the myosin complex (light meromyosin) functions as the main structural

support of the molecule (Fig. 12-6). The globular heads of the myosin dimer contain two “hinges,” located at the junction of the distal light chains and the tail helix, that play an essential role in myofilament shortening during contraction. These globular structures bind to actin, thereby activating an ATPase that is involved in hinge rotation and release of actin during contraction and relaxation, respectively. The activity of this actin-activated myosin ATPase is a major determinant of the maximum velocity of sarcomere shortening. Notably, adult and neonatal atrial and ventricular myocardium contain several different myosin ATPase isoforms that are distinguished by their relative ATPase activity. The myosin molecules are primarily arranged in series along the length of the thick filament, but are abutted “tail-to-tail” in the center of the thick filament. This orientation facilitates shortening of the distance between “Z” lines during contraction as the thin filaments are drawn symmetrically toward the sarcomere’s center.

**Figure 12-6** Schematic illustration of the myosin molecule demonstrating double helix tail, globular heads that form cross bridges with actin during contraction, two pairs of light chains, and “hinges” (cleavage sites of proteolytic enzymes) that divide the molecule into meromyosin fragments (see text).

The light chains contained within the myosin complex serve “regulatory” or “essential” roles. Regulatory myosin light chains may favorably modulate myosin–actin interaction through  $\text{Ca}^{2+}$ -dependent protein kinase phosphorylation, whereas essential light chains serve an as yet undefined obligate function in myosin activity because their removal denatures the myosin molecule. Discussion of myosin light chain isoforms is beyond the scope of this chapter, but it is important to note that isoform switches from ventricular to atrial forms have been observed in left ventricular hypertrophy that may contribute to contractile dysfunction.<sup>15</sup> In addition to myosin and its binding protein, thick filaments contain titin, a long elastic protein that attaches myosin to the “Z” lines. Titin is thought to be a “length sensor” that establishes progressively greater passive restoring forces as sarcomere length

approaches its maximum or minimum (similar to a bidirectional spring).<sup>16</sup> Compression and stretching of titin occur during decreases and increases in muscle load, thereby resisting further sarcomere shortening and lengthening, respectively. Thus, titin is a third important elastic element (in addition to actin and myosin) that contributes to the stress-strain mechanical properties of cardiac muscle.<sup>17</sup>

Actin is the major component of the thin filament. Actin is a 42-kDa, ovoid-shaped, globular protein (“G” form; 5.5 nm in diameter) that exists as a filamentous (F) polymer in cardiac muscle. F-actin binds ADP and a divalent cation ( $\text{Ca}^{2+}$  or  $\text{Mg}^{2+}$ ), but unlike myosin, the molecule does not directly hydrolyze high-energy nucleotides (e.g., ATP). F-actin is wound in double-stranded helical chains of G-actin monomers that resemble two intertwined strands of pearls. A single complete helical revolution of filamentous actin is approximately 77 nm in length and contains 14 G-actin monomers. Actin derives its name from its function as the “activator of myosin” ATPase through its reversible binding with myosin. The hydrolysis of ATP by this actin–myosin complex provides the chemical energy required to produce the conformational changes in the myosin heads that drive the contraction–relaxation cycle within the sarcomere. Tropomyosin is one of two major inhibitors of actin–myosin interaction. Tropomyosin (length of 40 nm; weight between 68 and 72 kDa) is a rigid double-stranded  $\alpha$ -helix protein. A single disulfide bond links the two helices of tropomyosin. Human tropomyosin contains both  $\alpha$  and  $\beta$  isoforms (34 and 36 kDa, respectively) and may be present as a homo- or heterodimer.<sup>18</sup> Tropomyosin serves to stiffen the thin filament through its position within the longitudinal cleft between intertwined F-actin polymers (Fig. 12-7). However, the primary function of tropomyosin is its  $\text{Ca}^{2+}$ -dependent interaction with troponin complex proteins. This tropomyosin–troponin interaction provides the microscopic link between sarcolemmal membrane depolarization to actin–myosin binding (excitation–contraction coupling). Cytoskeletal proteins, including actinin and nebulin, anchor the thin filaments to the “Z” lines.<sup>19</sup>

The troponin proteins serve complementary yet distinct roles as regulators of the contractile apparatus.<sup>20</sup> The troponin complexes are arranged at 40-nm intervals along the length of the thin filament. Troponin C (so named because this molecule binds  $\text{Ca}^{2+}$ ) exists in a highly conserved, single isoform in cardiac muscle. Troponin C is composed of a central nine-turn  $\alpha$  helix separating two globular regions that contain four discrete amino acid sequences capable of binding divalent cations. Two (termed sites I and II) of the four amino acid–cation binding sequences are  $\text{Ca}^{2+}$ -specific. This feature allows the troponin C molecule to respond to the acute changes in intracellular  $\text{Ca}^{2+}$  concentration that accompany contraction and relaxation. Cardiac troponin I (inhibitor) is a 23-kDa protein that exists in a single

isoform. Troponin I alone weakly prevents the interaction between actin and myosin, but when combined with tropomyosin, the troponin I–tropomyosin complex becomes the primary inhibitor of actin–myosin binding. Troponin I contains a serine residue that may be phosphorylated by protein kinase A via cAMP, reducing troponin C–Ca<sup>2+</sup> binding and enhancing relaxation during administration of  $\beta_1$  adrenoceptor agonists (e.g., dobutamine) or phosphodiesterase fraction III inhibitors (e.g., milrinone). Troponin T (so named because it binds other *t*roponin molecules and *t*ropomyosin) is the largest of the troponin proteins and exists in four major isoforms. Troponin T anchors the other troponin molecules and influences the relative Ca<sup>2+</sup> sensitivity of the complex.<sup>21</sup>

**Figure 12-7** Cross-sectional schematic illustration demonstrating the structural relationship between the troponin–tropomyosin complex and actin under resting conditions (left panel) and after Ca<sup>2+</sup> binding to troponin C (right panel, see text).

### Calcium–Myofilament Interaction

A series of conformational changes in the troponin–tropomyosin complex occur as a result of Ca<sup>2+</sup>–troponin C binding that culminate in exposure of the myosin-binding site on the actin molecule. During conditions in which intracellular Ca<sup>2+</sup> concentration is low (10<sup>−7</sup> M; diastole), very little Ca<sup>2+</sup> is bound to troponin C, and a troponin complex constrains each tropomyosin molecule to the outer region of the groove between F-actin filaments. This configuration blocks cross-bridge formation and prevents myosin–actin interaction. Thus, the troponin–tropomyosin complex creates a basal inhibitory state under resting conditions. A 100-fold increase in intracellular Ca<sup>2+</sup> concentration (10<sup>−5</sup> M) occurs as a result of sarcolemmal depolarization (systole). Opening of L- and T-type sarcolemmal Ca<sup>2+</sup> channels allows Ca<sup>2+</sup> influx into the myocyte from the extracellular compartment and stimulates Ca<sup>2+</sup>-dependent Ca<sup>2+</sup> release from the SR through its ryanodine receptors. When Ca<sup>2+</sup> is bound to troponin C, troponin C elongates and its interactions with troponin I and T are enhanced. This allosteric rearrangement and the

altered binding characteristics that it produces weaken the interaction between troponin I and actin, allow repositioning of the tropomyosin molecule along the F-actin filaments, and reverse the baseline inhibition of actin–myosin binding by tropomyosin.<sup>22</sup> As a result, Ca<sup>2+</sup> binding to troponin C is directly linked to a series of changes in regulatory protein structure, negating inhibition of the binding site for myosin on the actin molecule and allowing cross-bridge formation to occur. This antagonism of inhibition is fully reversible: Ca<sup>2+</sup> dissociation from troponin C restores the original troponin–tropomyosin conformation on F-actin and facilitates relaxation.

A Ca<sup>2+</sup>-ATPase located in the SR membrane (sarcoendoplasmic reticulum Ca<sup>2+</sup>-ATPase, SERCA) removes most of the Ca<sup>2+</sup> ions from the myofilaments and the cytosol after membrane repolarization. This Ca<sup>2+</sup> is stored (approximately 10<sup>-3</sup> M) in the SR bound to calsequestrin and calreticulin until the next sarcolemmal depolarization. The Na<sup>+</sup>-Ca<sup>2+</sup> exchanger and a Ca<sup>2+</sup>-ATPase located within the sarcolemmal membrane also remove a small quantity of Ca<sup>2+</sup> from the sarcoplasm. Phospholamban is a small protein (6 kDa) located in the SR membrane that partially inhibits the activity of the dominant form (type 2a) of cardiac SERCA under baseline conditions. However, phosphorylation of this protein by protein kinase A blocks this inhibition and enhances the rate of SERCA uptake of Ca<sup>2+</sup> into the SR.<sup>23</sup> This action increases the rate and extent of relaxation (positive lusitropic effect) and augments the amount of Ca<sup>2+</sup> available for the next contraction (positive inotropic effect). Thus, a cAMP-dependent protein kinase that is responsive to β<sub>1</sub> adrenoceptor stimulation or phosphodiesterase fraction III inhibition regulates SERCA activity. This observation explains why positive inotropic drugs such as dobutamine and milrinone also augment relaxation.

### **Myosin–Actin Interaction**

The biochemistry of sarcomere contraction is most often described using a simplified four-component model (Fig. 12-8).<sup>24</sup> High-affinity binding of ATP to the catalytic domain of myosin initiates the series of events that cause sarcomere contraction. Myosin ATPase hydrolyzes the ATP molecule into ADP and inorganic phosphate, but the reaction products do not immediately dissociate from myosin. Instead, an “active” complex is formed that retains the reaction’s chemical energy as potential energy. In the absence of actin, subsequent dissociation of ADP and phosphate from myosin is the rate-limiting step of myosin ATPase. The muscle remains relaxed under these conditions. However, the activity of myosin ATPase is markedly increased when the myosin–ADP–phosphate complex is bound to actin, and the chemical energy obtained from ATP hydrolysis is transferred into mechanical work. Attachment of myosin to its binding site on the actin molecule releases the

phosphate anion from the myosin head, producing a unique molecular conformation within the cross-bridge structure that generates tension in both myofilaments.<sup>25</sup> Release of ADP and the stored potential energy from this activated conformation produce rotation of the cross-bridge (power stroke) at the hinge point separating the myosin helical tail region from the globular myosin head and its associated light chain proteins. Each cross-bridge rotation generates 3 to  $4 \times 10^{-12}$  N of force and moves myosin 11 nm along the actin molecule.<sup>26</sup> Completion of myosin head rotation and ADP release does not immediately dissociate the myosin-actin complex, but leaves it in a low-energy bound (rigor) state. Separation of myosin and actin requires binding of a new ATP molecule to myosin. The process is then repeated, provided that there is an adequate ATP supply and troponin-tropomyosin inhibition does not block the myosin-binding site on actin.

**Figure 12-8** Schematic illustration of the actin filaments and its individual monomers and active myosin-binding sites ( $m$ ; left panel). The myosin head is dissociated from actin by binding with adenosine triphosphate (ATP). Subsequent ATP hydrolysis and release of inorganic phosphate ( $P_i$ ) “cocks” the head group into a tension-generating configuration. Attachment of the myosin head to actin allows the head to apply tension to the myosin rod and the actin filament. The right panel illustrates  $Ca^{2+}$  binding to troponin C, which causes troponin I to decrease its affinity for actin. As a result in a conformational shift in tropomyosin position (see text), seven sites on actin monomers are revealed.

Several factors may affect the efficiency of cross-bridge biochemistry and myocardial contractility independent of autonomic nervous system activity or administration of vasoactive drugs. A direct relationship between myosin

ATPase activity and the maximal velocity of unloaded muscle shortening ( $V_{max}$ ) exists. The normal increase in intracellular  $Ca^{2+}$  concentration that occurs after sarcolemmal depolarization (from  $10^{-7}$  to  $10^{-5}$  M) enhances baseline myosin ATPase activity fivefold before it interacts with actin, increasing  $V_{max}$ . Contractile force also depends on sarcomere length immediately before sarcolemmal depolarization. This length-dependent activation (Frank–Starling effect) may be related to an increase in myofilament  $Ca^{2+}$  sensitivity, favorable alterations in spacing between myofilaments, or titin-induced elastic recoil. An abrupt increase in load during contraction (Anrep effect) or after a prolonged pause between beats (Woodworth phenomenon) transiently enhances contractile force through a length-dependent activation mechanism. Increased myofilament  $Ca^{2+}$  sensitivity and greater SR  $Ca^{2+}$  release are the putative mechanisms responsible for the positive inotropic effect of faster cardiac myocyte stimulation frequency (Treppe phenomenon; see below).

## Law of Laplace

The Law of Laplace allows translation of changes in tension and length observed in the cardiac myocyte into alterations in pressure and volume that occur in the intact heart.<sup>27</sup> A pressurized, spherical shell is a simple model for relating cardiac myocyte tension and length to LV pressure and volume (Fig. 12-9). The geometry of the LV more closely resembles a prolate ellipsoid,<sup>28</sup> but a pressurized sphere is quite useful for the purposes of the current discussion. Tension development in each myocyte increases LV wall stress ( $\sigma$ ; tension exerted over a cross-sectional area) that is transformed into pressure ( $p$ ) when applied to a fluid (blood). Three assumptions are used in this derivation of the Law of Laplace: first, the LV is spherical in shape with an internal radius ( $r$ ) and uniform wall thickness ( $h$ ); second,  $\sigma$  is presumed to be constant throughout the thickness of the LV wall; and third, the LV exists in static equilibrium (i.e., is not actively contracting). In this model, “ $p$ ” is the force acting to distend the LV, whereas “ $\sigma$ ” represents the force resisting this distension. It can be easily shown that  $\sigma = pr/2h$ , indicating that wall stress varies directly with pressure and chamber radius and inversely with wall thickness. Despite the model’s assumptions and simplicity, this version of the Law of Laplace allows appreciation of the factors that alter LV wall stress and how cardiac pathology influences them. For example, the chronically elevated LV pressure ( $p$ ) that occurs in the presence of severe aortic valve stenosis or uncontrolled essential hypertension increases  $\sigma$  because these variables are directly related. Similarly, LV dilation associated with chronic mitral regurgitation also increases  $\sigma$  because the internal diameter ( $r$ ) of the LV is larger. Notably, increases in wall stress in either of these circumstances causes

greater myocardial oxygen consumption because each myocyte uses more energy when developing greater tension.<sup>29</sup> Conversely, an increase in wall thickness ( $h$ ) decreases  $\sigma$ . This observation emphasizes that hypertrophy is an essential compensatory response to elevated wall stress that reduces the developed tension in each myocyte. More complete descriptions of the Law of Laplace have been derived in which more anatomically realistic LV geometry and wall stress are used, but the fundamental principles relating wall stress to pressure, radius, and wall thickness remain essential elements in these models.<sup>30,31</sup>

**Figure 12-9** This schematic diagram depicts the opposing forces within a theoretical LV sphere that determine the Law of Laplace. LV pressure ( $P$ ) pushes the sphere apart, whereas wall stress ( $\sigma$ ) holds the sphere together.  $r$ , LV radius;  $h$ , LV thickness. ## The Cardiac Cycle

The temporal relationship between the electrical, mechanical, and valvular events that occur during the cardiac cycle<sup>32</sup> are illustrated in [Figure 12-10](#). The QRS complex of the electrocardiogram indicates that RV and LV depolarization has occurred. This electrical activation initiates contraction (systole) and is associated with rapid increases in pressure in both chambers ( $LV > RV$ ). When RV and LV pressures are greater than RA and LA pressures, the tricuspid and mitral valves close, respectively, and produce first heart sound ( $S_1$ ). Isovolumic contraction, rapid ejection, and slower ejection phases are the three major phases of LV systole. During LV isovolumic contraction, LV volume is constant because both the aortic and mitral valves are closed. However, LV shape becomes more spherical because of decreases in longitudinal dimension. The maximal rate of increase in LV pressure

( $+dP/dt$ ), a commonly used index of myocardial contractility, also occurs during LV isovolumic contraction. In contrast to the synchronous LV, the peristaltic-like contraction of the RV inflow and outflow tracts precludes true isovolumic contraction in the RV.<sup>33,34</sup> The pressures in the aortic and pulmonic roots reach their minima before the corresponding valves open. When LV and RV pressures are greater than aortic and PA pressures, respectively, rapid ejection of approximately two-thirds of the end-diastolic volume of each chamber occurs. The kinetic energy of LV and RV contraction is stored as potential energy in the elastic aorta and PA, respectively, which is then released to the corresponding distal vascular beds during diastole. The relative compliance of the proximal systemic and PA vasculature determines the magnitude of this stored potential energy. As aortic and PA pressures reach their maximum values, ejection falls dramatically and stops entirely when the ventricles begin to repolarize. Aortic and PA pressures briefly exceed LV and RV pressures as this slower ejection phase comes to an end, and the corresponding valves close in response to these reversed pressure gradients. Valve closure causes the second heart sound (S<sub>2</sub>); this event denotes end-systole. S<sub>2</sub> is normally split because the pulmonic valve closes slightly after the aortic valve.

**Figure 12-10** Mechanical and electrical events of the cardiac cycle showing also the LV volume curve and the heart sounds. Note the LV isovolumic contraction (ICP) and the relaxation period (IRP), during which there is no change in LV volume because aortic and mitral valves are closed. The LV decreases in volume as it ejects its contents into the aorta. During the first third of systolic ejection (the rapid ejection period), the curve of emptying is steep. ECG, electrocardiogram.

Isovolumic relaxation, early ventricular filling, diastasis, and atrial systole are the four phases of LV diastole. LV volume is constant during isovolumic relaxation because both the aortic and mitral valves are closed. LV pressure very rapidly declines as the myofilaments uncouple. The mitral valve opens when LA pressure exceeds LV pressure, and the pressure gradient between the chambers drives blood stored in the LA into the LV. LV pressure continues to fall after the mitral valve opens<sup>35</sup> because sarcomere relaxation is incomplete and recoil of compressed elastic components occurs. This process establishes a time-dependent pressure gradient between the LA and LV.<sup>36</sup> The instantaneous LA pressure immediately before mitral valve opening combined with the rate and extent with which LV pressure declines are the primary determinants of the pressure gradient between the two chambers.<sup>37</sup> Early LV filling is quite rapid: the peak velocities of mitral blood flow during early filling and aortic blood flow during ejection are similar (approximately 1 m/s).<sup>38</sup> Transmitral blood flow causes a vortex ring to form within the LV, which facilitates selective filling of the LV outflow tract because of the LV's structural asymmetry.<sup>39</sup> Age and cardiac disease (e.g., myocardial ischemia, pressure-overload hypertrophy) often delay LV relaxation, an important cause of diastolic dysfunction because the LA-to-LV pressure gradient is reduced, early LV filling is attenuated, and vortex ring formation is partially inhibited.<sup>40,41</sup> LV pressure will continue to fall to subatmospheric values if blood flow across the mitral valve is experimentally prevented.<sup>42</sup> This "diastolic suction" effect assures that the LV continues to fill even if LA pressure is zero (e.g., during profound hypovolemia or intense exercise).<sup>43</sup> The early filling phase of diastole normally provides 70% to 75% of final stroke volume. During the third phase of diastole, the LA acts as a conduit for pulmonary venous blood flow to flow freely through the open mitral valve into the LV. Less than 5% of total stroke volume enters the LV during diastasis, which may be shortened or eliminated by tachycardia.<sup>44</sup> The final phase of diastole is atrial systole. LA contraction again creates a positive pressure LA to LV gradient and stimulates active blood flow. The sphincter-like anatomy of the pulmonary venous-LA junction largely prevents retrograde blood flow into the pulmonary veins unless LA pressure is markedly elevated (e.g., heart failure, severe mitral regurgitation). Atrial systole normally generates 15% to 25% of final stroke volume, but this

percentage increases when delayed LV relaxation or reduced LV compliance is present. Thus, it is common for patients with such abnormalities to develop acute hemodynamic instability when LA contraction suddenly becomes timed improperly (e.g., AV conduction block) or disappears entirely (e.g., atrial fibrillation).

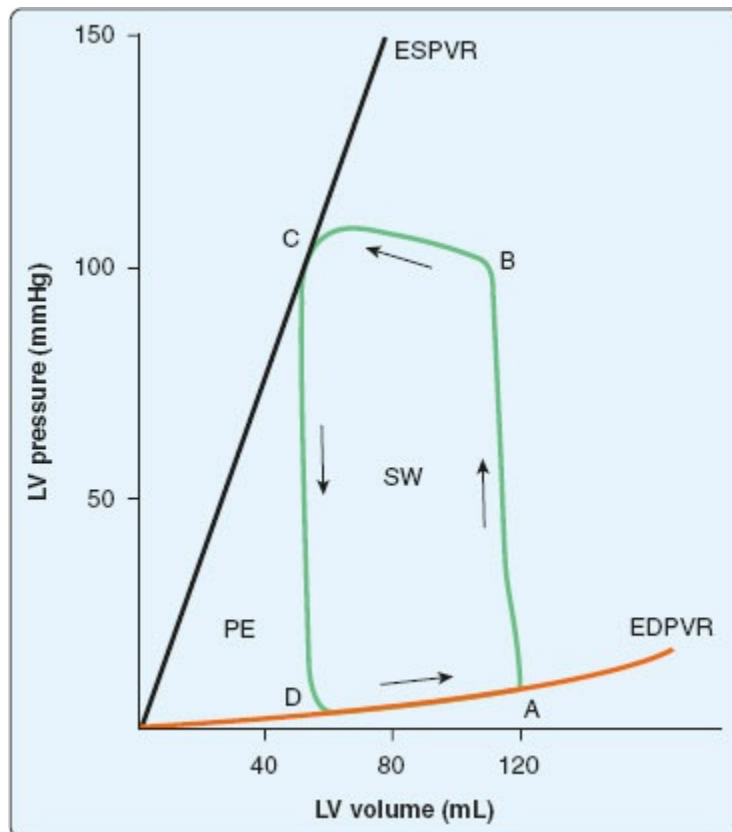

Three major deflections are observed in the LA pressure waveform during sinus rhythm. LA contraction follows the P wave of atrial depolarization and produces the “a” wave of atrial systole. An increase in LA preload or contractility augments the magnitude of the “a” wave. The rate of deceleration of the “a” wave is an index of LA relaxation.<sup>45</sup> A second small increase in LA pressure occurs with the onset of LV contraction because the mitral valve closes. This deflection is known as the “c” wave. The final “v” wave results from LA filling during LV systole and early relaxation as pulmonary venous return enters the LA while the mitral valve is closed. Mitral regurgitation or reduction in LA compliance enhances the magnitude of this “v” wave.<sup>46</sup> Similar changes in the RA pressure waveform deflections also occur. Indeed, the RA “a-c-v” morphology is easily observed in the external jugular veins when examining most patients in supine position.

## The Pressure–Volume Diagram

A simultaneous temporal plot of continuous LV pressure and volume creates a phase–space diagram that is useful for analysis of LV systolic and diastolic function (Fig. 12-11). The LV pressure–volume (P–V) diagram proceeds in a counterclockwise direction. End-diastole initiates the cardiac cycle (point A, Fig. 12-11). This is followed by isovolumic contraction, in which a rapid increase in LV pressure occurs without change in LV volume. When LV pressure is greater than aorta pressure, the aortic valve opens (point B, Fig. 12-11). Ejection of blood from the LV volume into the aorta and the proximal great vessels causes a precipitous decline in LV volume. The aortic valve closes when LV pressure drops below aortic pressure (point C, Fig. 12-11). When LV pressure falls below LA pressure during isovolumic relaxation, the mitral valve opens (point D, Fig. 12-11) and LV filling then occurs, causing a large increase in LV volume concomitant with a small increase in LV pressure during the remainder of diastole. This final stage completes a single circuit (cardiac cycle) around the P–V diagram.

The LV P–V diagram allows recognition of major cardiac events (e.g., aortic and mitral valve opening and closing) without formal electrocardiographic correlation. The lower right and upper left corners of the P–V diagram identify the LV end-diastolic and end-systolic volumes (EDV and ESV, respectively), which facilitate calculation of stroke volume (SV;  $EDV - ESV$ ) and ejection fraction (EF;  $SV/EDV$ ). The normal EDV and ESV are

approximately 120 and 40 mL, respectively. Thus, SV is 80 mL and EF is 67%. The area of the LV P–V diagram defines stroke work for the cardiac cycle. An increase in preload is indicated by a rightward shift of the right side of the LV P–V diagram. Elevated height (greater LV systolic pressure) and a narrower width (reduced SV) of the LV P–V diagram indicates the presence of increased afterload. A series of LV P–V diagrams may be acquired as a result of an acute change in LV loading conditions over several cardiac cycles and is useful for determining contractile state, chamber compliance, and mechanical efficiency. Changes in preload or afterload may be produced mechanically (e.g., transient inferior vena caval or proximal aortic occlusion) or pharmacologically (e.g., intravenous infusion of nitroglycerin or phenylephrine) to generate a nested set of differentially loaded LV P–V diagrams. These loops may then be used to determine the end-systolic pressure–volume relation (ESPVR), the slope of which (“end-systolic elastance” [ $E_{es}$ ]) is a relatively heart-rate– and load-independent index of myocardial contractility in vivo.<sup>47</sup> The same set of LV P–V diagrams may also be used to calculate the end-diastolic pressure–volume relationship (EDPVR) and quantify LV compliance.<sup>27</sup> The ESPVR and EDPVR establish the operational range of the LV and define the LV’s mechanical characteristics during systole and diastole, respectively.<sup>48</sup> The triangular space that lies between ESPVR and EDPVR to the left of the steady-state LV P–V diagram is the potential energy remaining in the system and is often used to quantify the LV’s energetics and mechanical efficiency.<sup>49</sup> The principles of pressure–volume analysis have also been successfully applied to the study of RV and LA function.<sup>50,51</sup>

**Figure 12-11** This illustration depicts the steady-state LV pressure–volume diagram. The cardiac cycle proceeds in a time-dependent counterclockwise direction (*arrows*). Points A, B, C, and D correspond to LV end-diastole (closure of the mitral valve), opening of the aortic valve, LV end-systole (closure of the aortic valve), and opening of the mitral valve, respectively. Segments AB, BC, CD, and DA represent isovolumic contraction, ejection, isovolumic relaxation, and filling, respectively. The LV is constrained to operate within the boundaries of the end-systolic and end-diastolic pressure–volume relations (ESPVR and EDPVR, respectively). The area inscribed by the LV pressure–volume diagram is stroke work (SW) performed during the cardiac cycle. The area to the left of the LV pressure–volume diagram between ESPVR and EDPVR is the remaining potential energy (PE) of the system. (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan’s Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis, MO: Elsevier Saunders; 2011:107.)

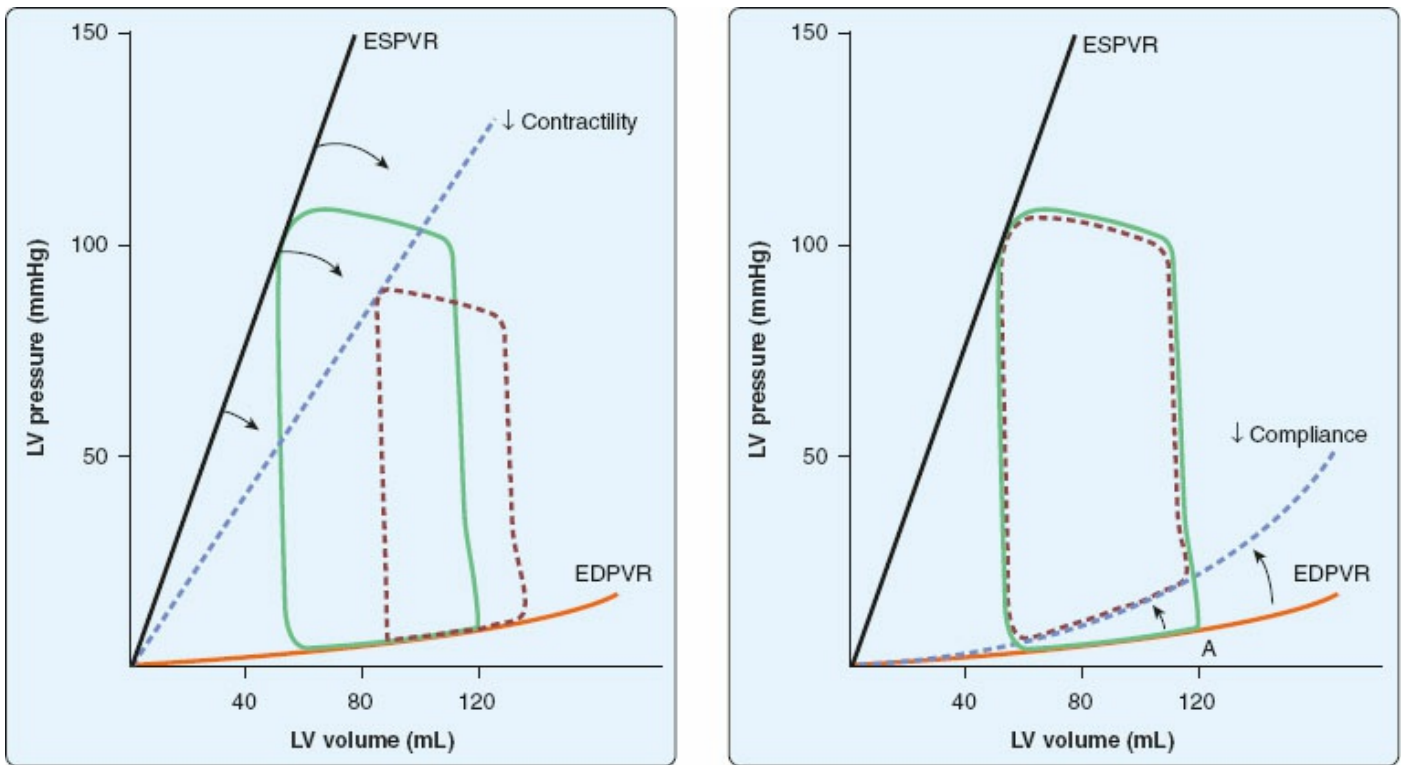

LV systolic or diastolic heart failure may be clearly depicted using P–V analysis.<sup>52</sup> Pure LV systolic dysfunction is represented by a reduction in the ESPVR slope and often occurs in conjunction with LV dilation, as illustrated by a right shift of the P–V diagram without a substantial change in the position of EDPVR (Fig. 12-12). The increase in preload (right shift) is a compensatory response to depression of myocardial contractility that serves to maintain stroke volume, but occurs at a cost of elevated LV filling pressure, greater LV volume, and increased myocardial oxygen consumption. An increase in EDPVR defines a reduction in LV compliance consistent with LV diastolic dysfunction because LV pressure is greater for a given LV volume. In pure diastolic heart failure, myocardial contractility is preserved (ESPVR is

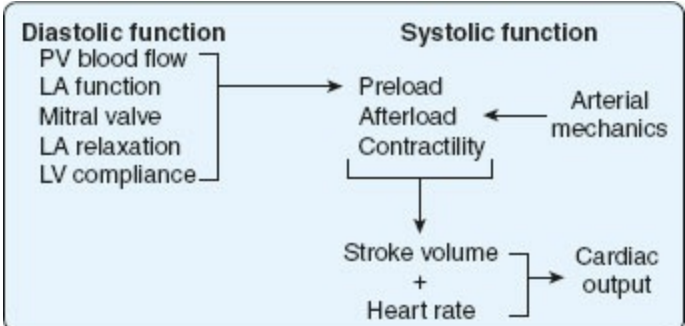

unchanged), but clinical symptoms are present because LV filling pressures are elevated. Simultaneously depressed ESPVR and elevated EDPVR are observed in the presence of combined LV systolic and diastolic dysfunction. Under these circumstances, the LV operates in a restricted range of preload and afterload conditions. Stroke volume and cardiac output are often substantially compromised as a result, leading to global tissue malperfusion.

## Determinants of Systolic Function

The LV's ability to collect and eject blood determines its overall performance. The amount of blood that the LV contains before the onset of contraction (preload), the arterial resistance to emptying that the LV must overcome during ejection (afterload), and the contractile properties of the LV myocardium (inotropic state) determine the stroke volume for each cardiac cycle (Fig. 12-13). These three factors combine with the heart rate and **6** rhythm to determine cardiac output. The LV's structural integrity is essential to its efficiency as a pump. For example, an anomalous route of blood flow from the chamber (e.g., a ventricular septal defect with left to right shunt) or valvular dysfunction (e.g., severe mitral regurgitation) may reduce forward flow because blood is diverted into lower pressure outlets (the RV or the LA in these examples, respectively) and is not ejected directly into the aorta. Pulmonary venous blood flow, LA and mitral valve function, pericardial forces, and the active (relaxation) and passive (compliance) diastolic properties of the LV determine the LV's ability to fill properly at normal pressure (approximately 10 mmHg).<sup>53</sup> Perturbations in any of these variables attenuates optimal LV filling and may contribute to the development of heart failure independent of LV systolic dysfunction per se.

**Figure 12-12** These schematic illustrations demonstrate alterations in the steady-state LV pressure–volume diagram produced by a reduction in myocardial contractility as indicated by a decrease in the slope of the end-systolic pressure–volume relation (ESPVR; left panel) and a decrease in LV compliance as indicated by an increase in the position of the end-diastolic pressure–volume relation (EDPVR; right panel). These diagrams emphasize that heart failure may result from LV systolic or diastolic dysfunction independently. (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan’s Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis, MO: Elsevier Saunders; 2011:109.)

**Figure 12-13** This illustration depicts the major factors that determine LV diastolic (left) and systolic (right) function. Note that pulmonary venous (PV) blood flow, LA function, mitral valve integrity, LA relaxation, and LV compliance combine to determine LV preload. (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan’s Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis, MO: Elsevier Saunders; 2011:111.)

**Heart Rate**

The contractile state of isolated cardiac muscle is directly related to its

stimulation frequency. This phenomenon is known as the Bowditch, “staircase,” or “Treppe” effect, or the “force-frequency” relationship. Improved  $\text{Ca}^{2+}$  cycling efficiency and increased myofilament  $\text{Ca}^{2+}$  sensitivity are most likely responsible for the Bowditch effect. Maximal contractile force is generated at 150 to 180 stimulations/min in isolated cardiac muscle. These experimental data support the clinical observation of ideal matching of cardiac output to venous return at heart rates of approximately 175 beats/min during intense aerobic exercise in trained endurance athletes. Contractility begins to decrease at heart rates exceeding 175 beats/min because LV relaxation abnormalities begin to develop. Insufficient  $\text{Ca}^{2+}$  uptake from the contractile apparatus, attenuated LV diastolic filling time, and reduced coronary perfusion resulting from an inadequate duration of diastole combine to contribute to the reduction in inotropic state and cardiac output during profound tachycardia. Thus, tachyarrhythmias or rapid pacing may cause profound hemodynamic compromise, even in otherwise healthy individuals. The Bowditch effect is a particularly important mechanism by which contractility is enhanced and adequate arterial blood pressure is maintained in disease states characterized by profound impairments in LV filling (e.g., pericardial tamponade, constrictive pericarditis). The “interval-strength” effect is another manifestation of the Bowditch phenomenon in which the force of LV contraction is augmented after an extrasystole.<sup>54</sup> Notably, the Bowditch effect is most likely of little consequence within a typical physiologic range of heart rate (e.g., 50 to 150 beats/min) in the normal heart.<sup>55</sup>

## Preload

Sarcomere length in vitro immediately before myocyte contraction is a useful way to appreciate the concept of “preload,” but this microscopic definition is difficult to envision in vivo considering the LV’s complex three-dimensional structure. Instead, EDV is most often used to define LV preload because **7** this volume of blood establishes the precontraction length of each LV sarcomere and is directly related to LV end-diastolic wall stress. Real-time quantification of LV EDV continues to be quite challenging from a clinical perspective. Experimental methods used to measure LV EDV (e.g., sonomicrometry, conductance catheter technology) are very precise but impractical because they require invasive instrumentation.<sup>56,57</sup> Noninvasive methods, including radionuclide angiography or dynamic magnetic resonance imaging, may also be used to measure LV EDV, but these imaging techniques cannot be used in the operating room or intensive care unit. Three-dimensional transesophageal echocardiography (TEE) is increasingly used to provide real-time estimates of LV EDV and EF during surgery,<sup>58–60</sup> but this

technique may be difficult to apply during rapidly changing hemodynamic conditions. Cardiac anesthesiologists often estimate LV EDV using two-dimensional TEE in the transgastric LV midpapillary short axis view to measure or visually estimate LV end-diastolic area or diameter. A decrease in LV preload is usually inferred when there is a reduction in end-diastolic area and diameter, although marked arterial vasodilation may also produce similar findings.

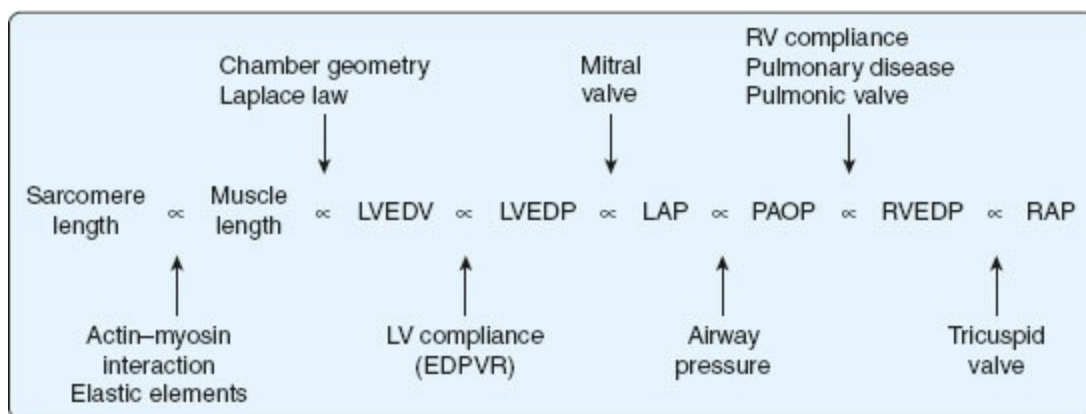

Other clinically used indices of LV preload have inherent limitations (Fig. 12-14). Advancing a fluid-filled catheter into the LV allows measurement of LV end-diastolic pressure, which is related to EDV through the exponential EDPVR curve. This invasive technique is possible only in the cardiac catheterization laboratory or the operating room. In lieu of this method, other pressures “upstream” from the LV are more commonly used to estimate LV EDV, including mean LA, pulmonary capillary occlusion (wedge), pulmonary arterial diastolic, RV end-diastolic, and RA (central venous) pressures. The integrity of the structures that separate each site of measurement from the LV influences the relative accuracy of these methods. For example, a correlation between central venous and LV end-diastolic pressures assumes that pulmonary disease, airway pressure during respiration, RV or pulmonary vascular disease, LA dysfunction, mitral valve abnormalities, or abnormal LV compliance have not adversely affected the fluid column between the RA and the LV. This is not the case in many patients with significant pulmonary or cardiac disease. For example, there is a well-known lack of correlation between LV EDV, pulmonary artery occlusion pressure, and central venous pressure in patients with LV dysfunction,<sup>61</sup> in whom accurate measurement of LV preload may be especially important to optimize hemodynamics.

## Afterload

The additional load to which cardiac muscle is exposed after contraction has begun is termed “afterload.” This concept is intuitively clear when **8** studying isolated cardiac muscle under experimental conditions, but it is more difficult to quantify when the LV’s interaction with the arterial vasculature is considered in vivo. Four components determine LV afterload in the intact cardiovascular system: the size and mechanical behavior of arterial blood vessels; terminal arteriolar vasomotor tone, which establishes total arterial resistance; LV end-systolic wall stress, which is defined by LV pressure development and the changes in LV geometry required to generate it; and the physical properties and volume of blood as a hydraulic fluid. This section will focus on LV afterload, but the methods used to estimate RV afterload are virtually identical to those used to quantify LV afterload.<sup>62</sup> Nevertheless, the reader should appreciate that two major differences exist between the LV and

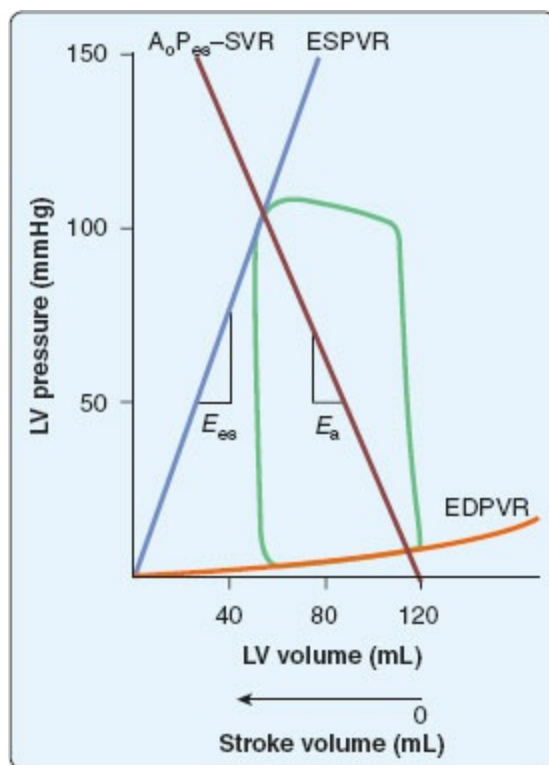

the RV afterload systems: the systemic circulation is substantially less compliant than pulmonary arterial vasculature and, as mentioned previously, the LV is less sensitive to changes in afterload than is the RV.

The most comprehensive description of LV afterload is aortic input impedance [ $Z_{in}(\omega)$ ], defined as the ratio of continuous aortic pressure (the forces acting on the blood) to blood flow (the motion that those forces creates). Power spectral or Fourier series analysis is used to calculate  $Z_{in}(\omega)$  from high-fidelity measurements of pressure and blood flow.  $Z_{in}(\omega)$  includes the frequency-dependent characteristics of the arterial vasculature, including its viscoelastic effects and wave reflection properties. This methodology is quite useful from a biomechanical engineering perspective, but has limited practical applicability. Another definition of LV afterload quantifies the mechanical forces to which the LV is exposed at the end of ejection as LV end-systolic wall stress. As previously mentioned, a large decline in LV volume occurs after the aortic valve opens, concomitant with elevated LV pressure and increased wall thickness. The Law of Laplace indicates that changes in these variables cause a pronounced increase in LV end-systolic wall stress, which reaches its maximum value during early LV ejection and subsequently falls.<sup>28</sup> These alterations in LV systolic wall stress during ejection are important. Maximal LV systolic wall stress is a potent stimulus for myocyte hypertrophy in the presence of chronic increases in afterload, such as may be observed in patients with severe aortic valve stenosis or uncontrolled essential hypertension.<sup>63</sup> The area under the LV systolic wall stress curve is directly related to myocardial oxygen consumption.<sup>64</sup> At end-systole, the forces driving further ejection and those resisting it are equal. Thus, LV end-systolic wall stress is also a determinant of stroke volume.

**Figure 12-14** This schematic diagram depicts factors that influence experimental and clinical estimates of sarcomere length as a pure index of the preload of the contracting LV myocyte. LVEDV and LVEDP, LV end-diastolic volume and end-diastolic pressure, respectively; EDPVR, end-diastolic pressure–volume relation; LAP, left atrial pressure; PAOP, pulmonary artery occlusion pressure; RV, right ventricle; RVEDP, RV end-diastolic pressure; RAP, right atrial pressure. (Reproduced with permission from Kaplan

Afterload may also be approached from a mechanical systems perspective, because the LV and the arterial vasculature must be appropriately matched to assure optimal energy transfer between them. In this “coupling” model, the LV and arterial circulation are considered elastic chambers in series. LV-arterial coupling is described using the ratio of LV elastance ( $E_{es}$ ) and effective arterial elastance ( $E_a$ ), each of which is determined in the P–V plane (Fig. 12-15).<sup>65</sup>  $E_a$  may also be estimated as the ratio of end-systolic arterial pressure to stroke volume, and has been clinically applied to approximate LV afterload using this definition. Arteriolar resistance and the compliance of the proximal great vessels influence  $E_a$ , but  $E_a$  does not include arterial frequency dependence or wave reflection properties and cannot be used as a quantitative index of LV afterload as a result.

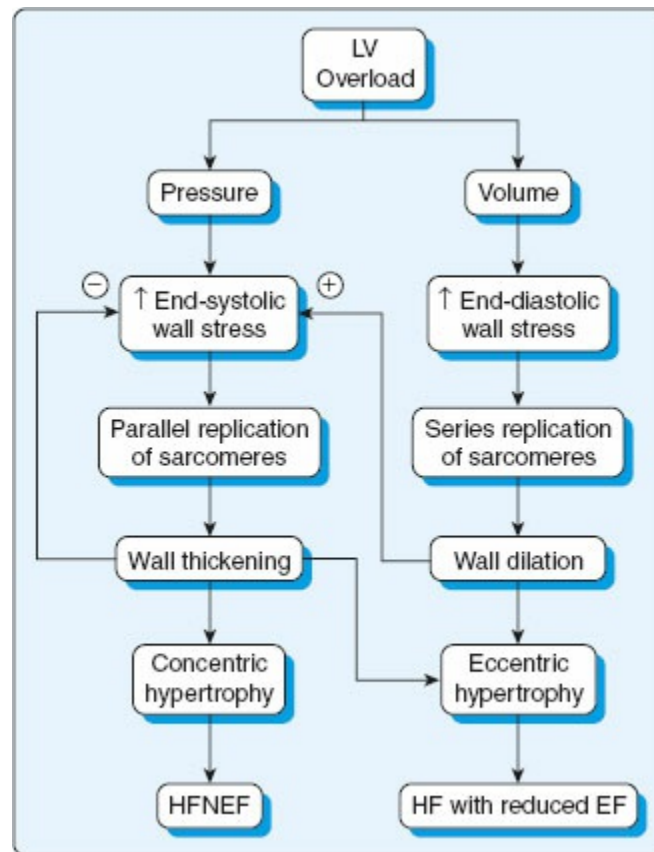

**Figure 12-15** This schematic diagram illustrates the LV end-systolic pressure–volume and aortic end-systolic pressure–stroke volume relations (ESPVR and  $A_0P_{es}$ -SVR, respectively) used to determine LV-arterial coupling as the ratio of end-systolic elastance ( $E_{es}$ ; the slope of ESPVR) and effective arterial elastance ( $E_a$ ; the slope of  $A_0P_{es}$ -SVR). EDPVR = end-diastolic pressure–volume relation. (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis, MO: Elsevier Saunders; 2011:114.)

The most commonly used clinical estimate of LV afterload is systemic vascular resistance calculated as  $([MAP - RAP] \cdot 80)/CO$ , where MAP and

RAP are mean arterial and right atrial pressures, respectively, CO is cardiac output, and 80 is a constant that converts  $\text{mmHg}\cdot\text{min}^{-1}\cdot\text{L}^{-1}$  to  $\text{dynes}\cdot\text{sec}\cdot\text{cm}^{-5}$ . Systemic vascular resistance primarily reflects the resistance of terminal arterioles, which is a major component of afterload. However, similar to LV end-systolic wall stress and  $E_a$ , systemic vascular resistance does not consider the mechanical properties of the blood and arterial walls, ignores the frequency-dependence of arterial pressure and blood flow, and does not account for arterial wave reflection. Notably, these components of LV afterload are of greater importance in elderly patients or in the presence of atherosclerosis,<sup>66</sup> clinical circumstances in which quantitative evaluation of afterload may be especially relevant. In general, systemic vascular resistance is best used as a nonparametric estimate, but not as a quantitative index, of LV afterload produced by vasoactive medications or cardiovascular disease.<sup>67</sup>

The failing LV is especially sensitive to increases in afterload.<sup>68</sup> Activation of the sympathetic nervous system serves to improve contractility in the presence of LV systolic dysfunction, but this response also causes unintentional but equally important increases in LV afterload that often negates the expected increase in cardiac output. LV hypertrophy is also an important adaptation response to chronic increases in LV afterload that reduces LV wall stress by increasing wall thickness (Fig. 12-16). However, this compensatory response also inadvertently increases myocardial oxygen consumption and reduces LV compliance. These effects make the hypertrophied LV more susceptible to myocardial ischemia and diastolic dysfunction, respectively. Thus, decreasing LV afterload by reducing the inciting stress is the most important objective in the clinical management of heart failure.

**Figure 12-16** LV pressure- and volume-overload produce compensatory responses based on the nature of the inciting stress. Wall thickening reduces (-) whereas chamber dilation increases (+) end-systolic wall stress as predicted by the Law of Laplace. LV pressure-overload hypertrophy has been linked to heart failure with normal ejection fraction (HFNEF), but LV volume-overload most often causes heart failure (HF) with reduced ejection fraction (EF). ## Myocardial Contractility

Myocardial contractility is the force that cardiac muscle is capable of producing during contraction under controlled loading conditions and stimulation rate. Determining myocardial contractility is relatively easy in isolated cardiac muscle, but this measurement is remarkably difficult in the intact heart. The ability to quantify inotropic state has important implications during the clinical management of patients with LV or RV contractile dysfunction, but a “gold standard” of myocardial contractility independent of heart rate and loading conditions remains elusive. Inotropic state and loading conditions are inextricably connected in the sarcomere<sup>69</sup> and thus, it most likely not feasible to measure contractility as an independent variable. To date, indices derived from LV P-V analysis, isovolumic contraction, and ejection are the major approaches to the measurement of contractility in vivo, all of which have limitations.

The ratio of continuous LV pressure-to-volume during the cardiac cycle is termed “time-varying elastance” [ $E(t)$ ], such that  $E(t) = P(t)/[V(t) - V_0]$ , where  $P(t)$  and  $V(t)$  are the time-dependent changes in LV pressure and volume, respectively, and  $V_0$  is LV volume at zero mmHg of LV pressure.<sup>70</sup> In this model, maximum LV elastance ( $E_{\max}$ ) occurs at or very close to the left upper corner of the steady-state LV P–V diagram. As mentioned previously, a nested set of LV P–V diagrams may be generated by an acute change in loading conditions; each loop in this set has a distinct  $E_{\max}$ . These  $E_{\max}$  values are linearly related and establish the ESPVR (Fig. 12-17). The slope of ESPVR (end-systolic elastance;  $E_{es}$ ) is an afterload-insensitive index of contractility because the analysis from which it is derived is performed at end-systole. Alterations in contractile state are reflected in changes in  $E_{es}$ . For example, dobutamine increases  $E_{es}$ , and the magnitude of this increase quantifies the positive inotropic effect of the drug. Another contractile index based on the Frank–Starling principle relating preload to cardiac output may also be derived from the same series of LV P–V diagrams. The area of each LV P–V diagram (stroke work; SW) in this nested set of loops and its corresponding EDV are linearly related, such that  $SW = M_{sw} \cdot (EDV - V_{sw})$ , where  $M_{sw}$  and  $V_{sw}$  are the slope and volume intercept of the relation. The slope of this “preload recruitable stroke work” relation has been shown to quantify changes in contractility in a relatively load-independent manner.<sup>71</sup>  $E_{es}$  and  $M_{sw}$  are not used on a routine basis in clinical anesthesiology because invasive measurement of LV pressure and volume is generally required for their derivation, and extensive offline analysis must be performed. Nevertheless, both indices of inotropic state are useful conceptual tools with which to understand LV, RV, and atrial contractility in the intact heart.

Indices of global myocardial contractility may also be derived during isovolumic contraction using the LV pressure waveform. The most commonly used isovolumic index of contractility is  $dP/dt$ . This index requires invasive measurement of continuous LV pressure and is most often recorded in the cardiac catheterization laboratory, but may also be estimated noninvasively using TEE.<sup>72</sup> LV  $+dP/dt$  sensitively indicates changes in contractile state, but its absolute value is less important than the magnitude of its change in response to an intervention such as administration of an inotropic drug (e.g., epinephrine). LV  $+dP/dt$  is generally considered to be afterload-independent because the aortic valve opens after the maximal rate of rise of LV pressure occurs. However,  $+dP/dt$  is highly dependent on preload, and another index of contractility based on LV P–V analysis that accounts for this preload dependence has been developed and applied in laboratory and clinical settings.<sup>73</sup> LV mass, chamber geometry, and valve disease also influence  $+dP/dt$ . Decreases in global LV inotropic state caused by regional myocardial ischemia may also not be accurately quantified with  $+dP/dt$ , because

compensatory increases in contractility occur in the surrounding nonischemic myocardium, thereby effectively normalizing overall function. Other isovolumic indices of contractility based on  $+dP/dt$ , including the rate of rise of LV pressure at a predetermined LV pressure (e.g.,  $dP/dt$  measured at 40 mmHg) or the ratio of  $dP/dt$  to maximum LV pressure ( $dP/dt/P$ ) have also been used, but these measures do not provide unique information compared with  $+dP/dt$ .

**Figure 12-17** This illustration depicts the method used to derive the LV end-systolic pressure–volume relation (ESPVR) from a series of differentially loaded LV pressure–volume diagrams generated by abrupt occlusion of the inferior vena cava in a canine heart *in vivo*. The maximal elastance ( $E_{max}$ ; pressure/volume ratio) for each pressure–volume diagram is identified as its left upper corner, and a linear regression analysis is used to define the slope ( $E_{es}$ ; end-systolic elastance) and volume intercept of the ESPVR (top panel). The effects of isoflurane (0.6, 0.9, and 1.2 minimum alveolar concentration) on the ESPVR are illustrated in the bottom panel. C<sub>1</sub>, control 1 (before isoflurane); C<sub>2</sub>, control 2 (after isoflurane). (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan’s Cardiac Anesthesia: The Echo Era*. 6th ed. St.

Ejection fraction is the most commonly used clinical index of LV contractility. Ejection fraction is usually measured with two- or three-dimensional echocardiography, but other methods, including radionuclide angiography and magnetic resonance imaging (MRI), also provide reliable estimates of this ejection phase index of inotropic state. In the operating room, two-dimensional TEE midesophageal four- or two-chamber windows can be obtained at end-systole and end-diastole and analyzed using Simpson rule of discs to determine EF. However, this technique is rather time-consuming and is impractical when hemodynamics are unstable. Instead, regional approximations of EF, such as fractional shortening and fractional area change (FAC), are often used by examining midpapillary short axis diameter and area, respectively, at end-systole and end-diastole. For example, FAC is determined as  $EDA - ESA/EDA$ , where EDA and ESA are end-diastolic and end-systolic areas, respectively, measured by tracing the LV's endocardial borders (Fig. 12-18). All ejection phase indices of contractility are dependent on loading conditions and inotropic state. Thus, interpretation of EF, FAC, or fractional shortening must be considered within the clinical context under which the data were obtained. For example, profoundly depressed EF in a patient with severe hypertension may occur because afterload is markedly increased, and not because myocardial contractility is grossly impaired. Ejection phase indices may also be inaccurate in the presence of mitral or aortic valve disease or a ventricular septal defect. Indeed, EF may be greater than normal during acute mitral regurgitation because a substantial portion of blood flow from the LV is diverted into the LA during systole and not because the LV is inherently "hyperdynamic."

## Determinants of Diastolic Function

Each chamber of the heart must fill adequately under normal pressures to facilitate optimal function during the subsequent contraction. We will emphasize LV diastolic function in the current section of this chapter, but the readers should be aware that the diastolic properties of the RV and atria are also important for the heart's overall performance. Because diastole is an inherently complex sequence of temporally related events (Table 12-1), no single index of LV diastolic function completely characterizes this phase of the cardiac cycle or selectively predicts those patients who may be at greatest risk of developing heart failure related to abnormal diastolic function.<sup>74</sup> Notably, nearly one-half of patients with heart failure do not have overt evidence of LV systolic dysfunction (e.g., a reduction in LV EF).<sup>75</sup> Hypertensive elderly women who are obese and have renal

insufficiency, anemia, or atrial fibrillation appear to be at greatest risk of developing this “heart failure with normal ejection fraction” (HFNEF; also known as “diastolic heart failure”).<sup>76</sup> Delayed LV relaxation, reduced compliance, and abnormal LV-arterial coupling have been implicated in the pathophysiology of HFNEF (Table 12-1).<sup>77,78</sup> Thus, LV diastolic dysfunction is a major cause of HFNEF. The severity of and response to medical therapy in HFNEF are key factors that establish exercise tolerance<sup>79</sup> and predict prognosis.<sup>80</sup> From the anesthesiologist’s perspective, LV diastolic function is a major determinant of the LV’s response to changes in loading conditions. Many volatile and intravenous anesthetics affect LV relaxation and filling in the normal and failing heart.<sup>81</sup> As a result, preoperative determination of the presence, severity, and underlying etiology of LV diastolic dysfunction (Table 12-2) is important when caring for patients undergoing surgery in which large shifts in intravascular volume are anticipated. Isolated LV diastolic dysfunction is also an independent risk factor for adverse cardiovascular events, including mortality, in patients undergoing major surgery.<sup>82</sup>

### **Invasive Assessment of LV Relaxation**

Removal of  $\text{Ca}^{2+}$  from the contractile apparatus and the sarcoplasm is an active, energy-dependent process that results in rapid dissociation of contractile proteins and recoil of compressed elastic elements. Failure of actin–myosin cross bridges to properly dissociate or abnormal removal of intracellular  $\text{Ca}^{2+}$  delays relaxation in the intact LV.<sup>83</sup> As mentioned previously, early LV filling is dependent on the rate and extent of LV relaxation and thus, is attenuated when relaxation is delayed. Under these circumstances, final EDV becomes more dependent on the contribution of atrial systole. As a result, acute onset of atrial fibrillation often causes heart

failure in patients with disease states in which pronounced delays in LV relaxation occur (e.g., hypertrophic cardiomyopathy). Myocardial ischemia caused by acute occlusion of a major coronary artery is also a frequent cause of delayed LV relaxation and may be accompanied by reductions in LV compliance that further limit LV filling, cause LA and pulmonary venous hypertension, and contribute to the development of pulmonary edema.<sup>84</sup>

Measuring the rate with which LV pressure declines during isovolumic relaxation is the most common technique for quantifying LV relaxation. This type of analysis generally requires invasive measurement of continuous LV pressure and is usually reserved for the cardiac catheterization laboratory. Several indices of LV relaxation may be derived using this method, among which the maximum rate of LV pressure decline ( $-dP/dt$ ; analogous to  $+dP/dt$  during isovolumic contraction) and a time constant ( $\tau$ ) of LV relaxation are the most common. LV  $-dP/dt$  is not an ideal as an index of LV relaxation because this parameter is essentially a “snapshot” of relaxation that is affected by the value of LV end-systolic pressure. LV pressure decay during relaxation is exponential between aortic valve closure and mitral valve opening. A time constant ( $\tau$ ) derived using the equation:  $P(t) = P_0e^{-t/\tau}$ , where  $P(t)$  is time-dependent LV pressure,  $P_0$  is LV pressure at end-systole,  $e$  is the natural exponent, and  $t$  is time after LV end-systole, is used to quantify relaxation. Despite the limitations of this simple model,<sup>85,86</sup> an increase in  $\tau$  indicates that a delay in LV relaxation has occurred. This technique has been used to quantify delays in LV relaxation during cardiac disease (e.g., myocardial ischemia,<sup>87</sup> pressure-overload hypertrophy<sup>88</sup>) or as a result of administration of negative inotropic medications including volatile anesthetics.<sup>89</sup> In contrast, reductions in  $\tau$  (indicative of more rapid relaxation) are observed during tachycardia, sympathetic nervous system activation, or administration of positive inotropic drugs. From a clinical standpoint, LV relaxation and its pharmacologic modulation are very important in heart failure. LV relaxation is modestly dependent on afterload under normal conditions,<sup>27</sup> but this afterload-sensitivity of LV relaxation is especially pronounced in the failing heart.<sup>90</sup> Thus, medications that reduce afterload not only augment LV systolic function but also simultaneously enhance LV relaxation (decrease  $\tau$ ) in patients with heart failure.<sup>68</sup> This latter effect improves early LV filling dynamics and reduces congestive signs and symptoms.

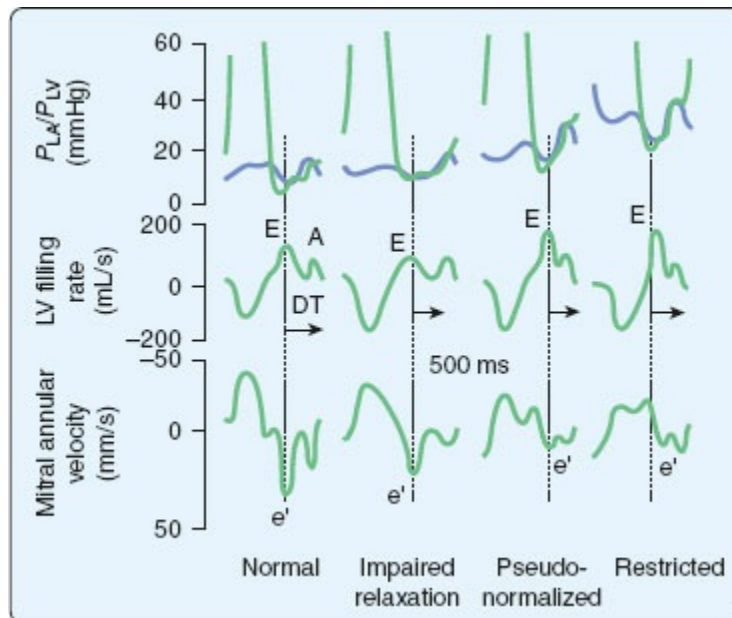

### ***Invasive Assessment of LV Filling and Compliance***

Indices of LV filling may be calculated using invasive or noninvasive (e.g., two- or three-dimensional echocardiography, radionuclide angiography, cardiac MRI) measurement of continuous LV volume. The first derivative of

LV volume waveform with respect to time ( $dV/dt$ ) creates a biphasic waveform with peaks occurring during early LV filling (E) and atrial systole (A). The transmitral blood flow velocity signal acquired during LV filling using pulse wave Doppler echocardiography (see below) closely resembles this  $dV/dt$  waveform. Development of heart failure causes characteristic **13** changes in  $dV/dt$  morphology that are identical to the “delayed relaxation,” “pseudonormal,” and “restrictive” filling patterns measured using pulse wave Doppler (Fig. 12-19).<sup>91</sup> Invasive analysis of LV filling with continuous LV volume and its first derivative is limited almost exclusively to the laboratory and is of little practical value in clinical anesthesiology except as a teaching tool.

As mentioned earlier in the discussion, EDPVR is an index of LV compliance derived from a nested set of LV P–V diagrams. The relationship between end-diastolic pressure (EDP) and EDV is exponential such that  $EDP = Ae^{K(EDV)} + B$ , where  $K$  is the modulus of chamber stiffness and  $A$  and  $B$  are curve-fitting constants. An increase in  $K$  indicates that the LV is less compliant, that is, higher LV pressure is required to distend the LV to a given volume. Parallel upward shifts in the EDPVR, such as seen in pericardial tamponade, represent an exception, because the value of  $K$  remains constant under these circumstances even though LV pressure is greater at each LV volume.<sup>52</sup> Thus, the relative position of the EDPVR in P–V phase space may be more important than the actual value of  $K$  itself because a shift in EDPVR up or to the left indicates that a higher LV pressure is required to achieve a similar LV volume.<sup>92</sup>

The diastolic stress–strain relation is another model frequently used to experimentally describe LV compliance. Myocardium is an elastic material that follows Hooke law, developing resisting forces (stress;  $\sigma$ ) as muscle length (strain;  $\epsilon$ ) increases during LV filling. The relationship is also exponential such that  $\sigma = \alpha(e^{\beta\epsilon} - 1)$ , where  $\alpha$  is the coefficient of gain and  $\beta$  is the modulus of myocardial stiffness.<sup>93</sup> Similar to the EDPVR, an increase in  $\beta$  occurs when the stress–strain relationship shifts up or to the left and may be observed in pathologic conditions characterized by fundamental structural abnormalities that adversely influence myocardial stiffness (e.g., hypertrophic cardiomyopathy, amyloidosis). EDPVR and myocardial stress–strain relations are generally not used clinically because analysis required to examine these relationships is complicated, time-consuming, and limited to steady-state hemodynamic conditions.

**Figure 12-19** This illustration depicts the simultaneous relationships between LA and LV pressures ( $P_{LA}$  and  $P_{LV}$ , respectively; top panels), LV filling rate during early filling (E) and atrial systole (A; middle panels), and early mitral annular velocity (e; bottom panels) under normal conditions and during evolving diastolic dysfunction (impaired relaxation, pseudonormal, and restrictive). Note the initial lengthening of E wave deceleration time (DT) during impaired relaxation and the subsequent shortening of DT as diastolic function worsens.
