The duration between aortic valve closure (end-systole) and mitral valve opening (onset of transmitral blood flow) defines isovolumic relaxation time (IVRT), a commonly used noninvasive index of LV relaxation that is usually measured using M-mode or pulse wave Doppler echocardiography. The rate of LV relaxation and the difference between LV end-systolic pressure and LA pressure when the mitral valve opens determines IVRT in the absence of aortic or mitral valve disease.<sup>94</sup> It should be readily apparent that IVRT is dependent on both LV relaxation and loading conditions. Indeed, IVRT is seldom used alone to quantify LV relaxation, but is most often combined with the transmitral blood flow velocity pattern to more comprehensively define the rate and extent of LV relaxation.

Noninvasive analysis of LV diastolic function is based on Doppler echocardiographic evaluation of transmitral blood flow velocity.<sup>95</sup> A pulse wave Doppler echocardiography sample volume is placed between the tips of the mitral leaflets to obtain a high-resolution transmitral blood flow velocity envelope. The normal pattern of transmitral blood flow velocity has two peaks: an early “E” peak associated with early LV filling and a late “A” peak

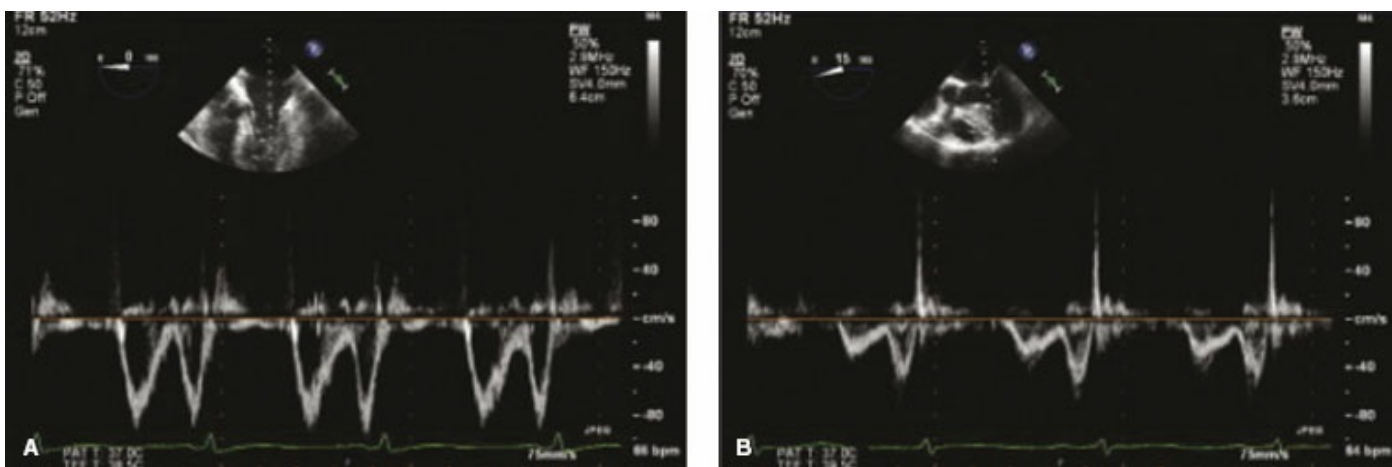

corresponding to LA systole.<sup>96</sup> The ratio of the peak E and A wave velocities is commonly used to quantify the relative contributions of early LV filling and atrial systole to EDV. The time elapsed as the E wave velocity declines from its peak value to zero is known as the deceleration time; this parameter is often used with IVRT to quantify LV relaxation. For example, an increase in E wave deceleration time indicates that early LV filling is prolonged because LV relaxation is delayed. Age affects LV diastolic function because a progressive slowing of LV relaxation occurs. As a result, IVRT, deceleration time, and A wave velocity increase with age, whereas E wave velocity and E/A ratio decrease.<sup>97</sup> The aging heart becomes less compliant, especially in the presence of coexisting essential hypertension and LV hypertrophy. This change predisposes the elderly to develop heart failure.<sup>98</sup>

The reversal of E/A with advancing age is an example of a “delayed relaxation” pattern of LV diastolic dysfunction. This transmitral blood flow velocity pattern is the least severe of three abnormal LV filling patterns that describe the continuum of abnormal LV diastolic function. Clinical symptoms, exercise tolerance, New York Heart Association (NYHA) functional class, and mortality are closely correlated with the relative severity of LV diastolic dysfunction quantified using this method.<sup>99</sup>  $E/A < 1$  characterizes “delayed relaxation” and indicates that early LV filling is attenuated and the LA’s contribution to filling is enhanced (atrial kick).<sup>91</sup> The “delayed relaxation” pattern is often observed in patients with essential hypertension, pressure-overload LV hypertrophy, and myocardial ischemia (Fig. 12-20).

As diastolic dysfunction worsens, a “pseudonormal” pattern replaces the “delayed relaxation” profile. This pseudonormal pattern occurs because E/A becomes  $> 1$  (similar to the normal profile, thus the term “pseudonormal”) as LA pressures increase to compensate for the further reduction in LV compliance. Thus, E wave velocity “normalizes” because the LA–LV pressure gradient increases when the mitral valve opens. Other indices of diastolic function (e.g., pulmonary venous blood flow velocity, tissue Doppler imaging) are required to distinguish the “pseudonormal” from a normal transmitral blood flow velocity profile. Alternatively, administration of a small bolus of a vasodilator (e.g., nitroglycerin) may convert a “pseudonormal” profile into a “delayed relaxation” pattern by transiently reducing LA pressure.<sup>100</sup> A “restrictive pattern” of transmitral blood flow velocity is the most severe form of LV diastolic dysfunction in which LA hypertension is present and LV compliance is further reduced. The E/A becomes  $> 2$  as the LA–LV pressure gradient is further augmented by increased LA pressure (causing a larger peak E wave velocity), concomitant with progressive LA contractile dysfunction (decline in peak A wave velocity). Failure of a “restrictive” filling pattern to respond to administration of a vasodilator and revert to a “pseudonormal” or “delayed relaxation” pattern

carries a grim prognosis in patients with heart failure, unless a mechanical circulatory support device is implanted or cardiac transplantation is performed.<sup>95</sup>

Abnormal LV diastolic function may also be determined using analysis of the pulmonary venous blood flow velocity pattern obtained with pulse wave Doppler echocardiography.<sup>101</sup> Most often, the pulmonary venous blood flow velocity is used in combination with transmitral blood flow velocity when quantifying the severity of LV diastolic dysfunction.<sup>102</sup> Two large positive deflections (forward flow from the pulmonary veins into the LA) and a single, small negative deflection (retrograde flow from the LA to the pulmonary veins, termed “atrial reversal”) establish the normal pulmonary venous blood flow velocity pattern. The first positive deflection is known as the “S” (systolic) wave, and occurs while the mitral valve is closed (LV systole and early diastole).<sup>103</sup> This “S” wave results from LA relaxation, which stimulates forward movement of blood from the pulmonary veins into the LA. The mitral valve annulus also descends toward the LV apex during systole, drawing additional blood from the pulmonary veins into the LA (similar to an engine piston).<sup>104</sup> This latter action is attenuated when LV contractility is depressed, emphasizing that the LV systolic function has a direct impact on LA filling. Transmission of the RV systolic pressure pulse through the pulmonary circulation further contributes to LA filling. After the mitral valve opens, blood stored in the LA during LV systole enters the LV, an event which allows additional blood to flow from the pulmonary veins into the LA. This causes the second positive deflection (“D” [diastolic] wave) of the pulmonary venous blood flow velocity pattern. The “D” wave is dependent on the extent of early LV filling and LV compliance.<sup>105</sup> LA preload, LA contractility, and LV pressure during late diastole determine the magnitude of the “atrial reversal” (Ar) wave.<sup>106</sup>

**Figure 12-20** Transmitral blood flow velocity waveforms obtained using pulse wave Doppler echocardiography under normal conditions (left) and during delayed relaxation (right). (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan's*

**Figure 12-21** Pulmonary venous blood flow velocity waveforms obtained using pulse wave Doppler echocardiography under normal conditions (left panel) and in the presence of increased LA pressure (right panel). (Reproduced with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis, MO: Elsevier Saunders; 2011:125.)

The ratio of “S” to “D” waves and the peak velocity of the “Ar” wave increase with age.<sup>96</sup> These findings emphasize that LA function is more important to LV filling in the elderly. As LV diastolic function worsens, LA pressures increase and the “S” wave is attenuated (Fig. 12-21). The presence of this blunted “S” wave allows the echocardiographer to distinguish between normal and “pseudonormal” transmitral blood flow velocity patterns because  $S/D < 1$  in the latter condition.<sup>101</sup> Such alterations in S/D become even more exaggerated in the presence of a “restrictive” filling pattern because LV diastolic and LA pressures are further elevated. Indeed, the “S” wave may be entirely abolished or even reversed (blood flow refluxing from the LA into the pulmonary veins) concomitant with an enhanced “D” wave in the presence of “restrictive” pathophysiology. Thus, pulmonary venous blood flow velocity patterns provide very useful information about LV diastolic dysfunction. Pulmonary venous blood flow patterns are also important when grading the severity of mitral regurgitation because LA pressure rises rapidly during the “S” phase as a result of regurgitant blood flow from the LV to the LA. Profound blunting or reversal of the “S” wave under these circumstances indicates that moderate or severe mitral regurgitation is present, respectively. Other indices of diastolic function, including tissue Doppler imaging<sup>107</sup> and color M-mode propagation velocity,<sup>108</sup> may also be used to define the progression of LV diastolic dysfunction. The reader is referred to [Chapter 27](#) for a detailed discussion of the echocardiographic assessment of diastolic function.

## Pericardium

The pericardium contains the heart, proximal great vessels, vena cavae, and pulmonary veins. The pericardium acts to separate the heart from other structures in the mediastinum and limits the heart's movement through **15**

its diaphragmatic and great vessel attachments. The fluid in the pericardium acts as a lubricant and consists of a combination of plasma ultrafiltrate, lymph, and myocardial interstitial fluid (total volume of 15 to 35 mL). The pericardium is much less compliant than myocardium, and has very limited volume reserve (Fig. 12-22).<sup>109</sup> As a result, an acute increase in pericardial volume (e.g., tamponade) causes a pronounced elevation in pericardial pressure that substantially restricts filling of the cardiac chambers.<sup>110</sup> The pericardium normally restrains expansion of the low-pressure atria and RV because these chambers have thinner walls than the LV. Indeed, pericardial restraint is the primary determinant of the diastolic pressure–volume relations of the RA, LA, and RV, whereas the compliance of these chambers alone is less important. The pericardium also profoundly affects LV filling.<sup>111</sup> As mentioned earlier, a parallel upward shift of the EDPVR occurs in response to an acute increase in pericardial pressure.<sup>112</sup> This shift in the EDPVR indicates that LV pressure must be greater for each LV volume and explains why LV filling is impaired during tamponade physiology. While the pericardium is acutely noncompliant, a slow increase in pericardial pressure (e.g., chronic pericardial effusion or biventricular dilatation) causes the pericardium to gradually expand in size. This compensatory response increases the pericardium’s compliance and reduces its restraining forces, thereby allowing the heart to continue functioning without imminent hemodynamic collapse.

**Figure 12-22** Pressure–volume relation of the pericardium (*blue line*) compared with the LV end-diastolic pressure–volume relation (EDPVR; *red line*). Note that large increases in pericardial volume occur after reserve volume is exceeded. (Reproduced

with permission from Kaplan JA, Reich DL, Savino JS. *Kaplan's Cardiac Anesthesia: The Echo Era*. 6th ed. St. Louis, MO: Elsevier Saunders; 2011:127.)

Ventricular interdependence is the influence of the pressure and volume of one ventricle on the function of the other. The pericardium plays a central role in ventricular interdependence because it provides equal restraint of the RV and the LV. As a result, a rapid increase in RV pressure and volume (e.g., volume overload, acute increase in pulmonary arterial pressure) causes the pressure within the pericardium to increase as well. This action compresses the LV, reducing its effective compliance and impairing its filling.<sup>113</sup> Not surprisingly, LV distention has a similar effect on the RV and limits RV filling through an identical mechanism.<sup>114</sup> Ventricular interdependence may be readily appreciated by examining changes in RV and LV filling during spontaneous ventilation.<sup>115</sup> Because intrathoracic pressure declines during inspiration, venous return to the right side of the heart increases and produces modest dilation of the RV. The result of this RV distention is a corresponding increase in pericardial restraint of the LV, which limits LV filling and causes a small decrease in stroke volume and mean arterial pressure. This ventricular interaction effect between the RV and LV is reversed during expiration. Directly opposite effects on RV and LV filling occur during inspiration and expiration in the presence of positive-pressure ventilation. The hemodynamic consequences of ventricular interdependence form the basis of respiratory cycle-induced pulse pressure and stroke volume variation, which have been shown to be the useful dynamic indices of preload in conscious and anesthetized patients.<sup>116</sup> Notably, pericardial tamponade<sup>117</sup> or constrictive pericarditis<sup>118</sup> exaggerates the normal respiratory changes in RV and LV filling and produces pulsus paradoxus. It is especially important to appreciate that spontaneous ventilation is crucial in these conditions because negative intrathoracic pressure assists venous return, whereas cardiovascular collapse may occur with the initiation of positive pressure ventilation because venous return becomes profoundly limited.

## **Atrial Function**

The mechanical properties of the LA are often overlooked in discussions of cardiac physiology. This is unfortunate because the LA acts as a contractile chamber, a reservoir (storage of blood before mitral valve opening), and a conduit (an extension of the pulmonary veins). The LA's function is critical to LV performance. The maximum velocity of shortening of LA myocardium is equal to or greater than LV myocardium under similar loading conditions.<sup>119</sup> LA emptying fraction (similar to LV EF) is dependent on LA contractility, preload, and LV compliance, unless the LA becomes so dilated that its

myofilaments are stretched far beyond their normal operating length.<sup>120</sup> This magnitude of LA dilation may occur when LA pressures are chronically elevated because of severe LV diastolic dysfunction or mitral regurgitation. Under these conditions, the LA may no longer be capable of contributing to EDV as a contractile chamber. The LA's response to changes in autonomic nervous system activity, inotropic medications, and anesthetics is very similar to that of the LV.<sup>121,122</sup> LV compliance and pressure during late diastole determine the afterload with which the LA is confronted during its contraction. Thus, the LA must perform greater work in the presence of LV diastolic dysfunction because its afterload is increased. Like the RV, the LA is more susceptible to acute increases in afterload than is the LV, because the LA has less muscle mass and thinner walls. As a result, the LA emptying fraction may initially increase early during developing LV failure,<sup>123</sup> but subsequently decline as LA contractile dysfunction occurs concomitant with chamber dilatation.<sup>124</sup> LV diastolic dysfunction also causes remodeling and reduced compliance of the LA, which also further limit pulmonary venous return.

The LA also serves reservoir and conduit functions. LA relaxation, LV base descent during systole, transmission of RV stroke volume, and LA compliance determine LA reservoir function. LA ischemia, hypertrophy, or dilation attenuate reservoir function, as do LV or RV contractile dysfunction.<sup>104,106</sup> Disease states in which LA compliance is selectively reduced are associated with impaired LA filling and contribute to pulmonary venous congestion.<sup>46,125</sup> The LA appendage plays an important role in LA filling, as exclusion or excision of the LA appendage reduces the compliance of the LA chamber as a whole.<sup>126,127</sup> LA appendage exclusion procedures are often performed during cryoablation for treatment of chronic atrial fibrillation, and reduced LA compliance concomitant with elevated pulmonary venous pressures may be anticipated despite restoration of sinus rhythm.

Exercise enhances both LA contractility and reservoir function.<sup>128</sup> The latter effect is important because greater reservoir capacity causes a larger LA–LV pressure gradient during early LV filling, thereby facilitating additional blood flow to the LV during conditions requiring greater LV stroke volume and cardiac output. Conduit function is also augmented in endurance athletes.<sup>129</sup> As the LA begins to dilate in healthy elderly subjects, compensatory increases in LA emptying fraction and declines in passive LA emptying occur.<sup>130</sup> LA dilation initially augments the ratio of LA reservoir to LV stroke volume (termed “storage fraction”),<sup>131</sup> but this beneficial effect comes at a cost: the dilation increases in LA wall stress, which may contribute to eventual LA contractile dysfunction and the development of atrial arrhythmias.<sup>132</sup>

## KEY POINTS

- 1 Drugs that mimic the effects of acetylcholine are most commonly used in ophthalmology.
- 2 Anticholinesterases prolong the actions of acetylcholine by preventing its metabolism; these drugs are used clinically for reversal of neuromuscular blockade and treatment of central anticholinergic syndrome.
- 3 Muscarinic antagonists inhibit the effects of acetylcholine mediated through the parasympathetic nervous system.
- 4 The cardiovascular effects of endogenous and synthetic catecholamines are dependent on their specificity for  $\alpha$ - and  $\beta$ -adrenoceptor subtypes.
- 5 Catecholamines have well-documented utility in the treatment of acute left ventricular dysfunction, but may cause arrhythmias, hypertension, and myocardial ischemia.
- 6  $\alpha_1$ -Adrenoceptor antagonists not only reduce arterial pressure but also produce reflex tachycardia and orthostatic hypotension, especially in patients with hypovolemia.
- 7 The  $\alpha_2$ -adrenoceptor agonists clonidine and dexmedetomidine are used extensively for sedation, anxiolysis, and analgesia.
- 8  $\beta$ -Blockers play major roles in the treatment of hypertension, coronary artery disease, myocardial infarction, and heart failure.
- 9 Milrinone and levosimendan are important medications for the management of acute left ventricular dysfunction and cause synergistic positive inotropic effects when administered with catecholamines by enhancing intracellular cAMP-mediated signaling.
- 10 Vasopressin is the most potent arterial vasoconstrictor currently available and is useful for treatment of vasoplegia associated with sepsis or cardiac surgery.
- 11 Calcium channel blockers reduce arterial pressure and dilate coronary

arteries, but some of these drugs also affect sinoatrial node automaticity and atrioventricular node conduction. These latter actions may be beneficial in the presence of supraventricular tachyarrhythmias.

12 Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are useful for the treatment of hypertension and heart failure.

## Introduction

This chapter discusses the pharmacology of medications that affect the autonomic nervous and cardiovascular systems. A thorough understanding of the pharmacology of cholinergic and anticholinergic drugs, endogenous and synthetic catecholamines, sympathomimetics,  $\alpha_1$ -antagonists,  $\alpha_2$ -agonists,  $\beta$ -blockers, phosphodiesterase inhibitors, digitalis glycosides, vasopressin, and antihypertensive medications including nitrovasodilators, calcium ( $\text{Ca}^{2+}$ ) channel blockers, and angiotensin-converting enzyme (ACE) inhibitors is essential for the practice of anesthesiology. Each of these drug classifications will be reviewed in detail, with primary emphasis on their cardiovascular actions.

## Cholinergic Drugs

Cholinergic drugs mimic (e.g., agonists such as methacholine), enhance (e.g., anticholinesterase inhibitors including neostigmine), or block (e.g., antagonists such as atropine) the actions of acetylcholine (ACh) in autonomic ganglia and skeletal muscle at nicotinic receptors or in parasympathetic postganglionic neurons through muscarinic receptors. In general, cholinergic drugs have greater site-specificity and exert more prolonged effects than the primary neurotransmitter. Compared with the plethora of medications that affect the sympathetic nervous system (see below), there are relatively few drugs in current clinical use that influence the function of parasympathetic nervous system by modulating ACh's actions or metabolism. ACh itself has virtually no therapeutic applications because of its diffuse action, extensive side effect profile, and rapid hydrolysis by acetylcholinesterase and butyrylcholinesterase (pseudocholinesterase). Topical ACh eye drops are **1** occasionally used when acute miosis is required during ophthalmologic surgery (e.g., cataract extraction) or for the treatment of glaucoma. Under these circumstances, systemic cholinergic effects are usually not observed because little ACh uptake occurs and ACh is quickly metabolized.

## Cholinergic Agonists

Synthetic cholinergic agonists are not used in anesthesia practice, but

understanding of their pharmacology remains important because anesthesiologists often encounter patients who are treated with them (Fig. 13-1; Table 13-1). ACh is a quaternary ammonium compound that causes changes in membrane conformation when it interacts with postsynaptic receptors, increasing the permeability to  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$  ions down their respective electrochemical gradients and causing membrane depolarization. Structure-activity relationships identified two important binding sites on the postsynaptic ACh receptor that are crucial for this process: the “ester” site that binds this moiety of the molecule and an “ion” site through which the quaternary amine is bound. Subtle differences in the chemical structure of cholinergic drugs are capable of producing more muscarinic and less nicotinic specificity while simultaneously reducing the rate of the drug’s metabolism. Two major classes of cholinergic agonists have been developed based on modification of these structural components: choline esters and alkaloids. For example,  $\beta$ -methylation of the choline moiety produces methacholine, a synthetic cholinergic drug that is a muscarinic agonist and is almost entirely resistant to cholinesterase hydrolysis. Methacholine is used almost exclusively as a provocative agent for identifying the presence of reactive airway disease in subjects who do not have clinically apparent signs or symptoms of asthma. Methacholine causes bronchoconstriction, increases airway secretions, and reduces peak expiratory flow rate via activation of bronchial muscarinic  $\text{M}_3$  receptors.<sup>1</sup> Not surprisingly, methacholine may also produce bradycardia and hypotension as a result of  $\text{M}_3$  receptor activation in myocardium and vascular endothelium, respectively. Methacholine-induced stimulation of  $\text{M}_3$  receptors activates the pertussis toxin-insensitive  $\text{G}_{q/11}$  protein coupled-phospholipase C-inositol triphosphate ( $\text{IP}_3$ )-mediated signaling cascade, culminating in endothelial nitric oxide synthase activation, nitric oxide production, and dilation of vascular smooth muscle.<sup>2</sup> Use of methacholine is relatively contraindicated in patients with known asthma or chronic obstructive pulmonary disease, essential hypertension, recent cerebrovascular accident, or myocardial infarction because marked bronchospasm or profound hypotension may occur. Indeed, emergency airway equipment, oxygen, inhaled  $\beta_2$ -adrenoceptor agonists, and resuscitative medications should be readily available during methacholine provocative testing.

+, stimulation; -, inhibition.

Bethanechol is a choline ester (a carbamate derivative of methacholine) that is relatively selective for the M<sub>3</sub> receptors in the urinary and gastrointestinal tracts with relative sparing of the cardiovascular and respiratory systems. Bethanechol is useful for treatment of nonobstructive urinary retention during the postoperative period or in some cases of neurogenic bladder as an alternative to chronic catheterization.<sup>3</sup> Bethanechol also increases gastrointestinal motility and stimulates peristalsis. The drug was previously used for treatment of postoperative abdominal distention, gastric atony, and gastroesophageal reflux disease, but more efficacious medications are now available for these conditions. Carbamylcholine is another choline ester derivative that is used topically to produce miosis in patients with wide-angle glaucoma. Pilocarpine is an alkaloid cholinergic agonist used as a topical miotic agent to reduce intraocular pressure in patients with glaucoma. Oral pilocarpine may also be used to increase salivary and lacrimal gland production in patients with xerostomia after head and neck irradiation or in those with Sjögren syndrome.<sup>4</sup> Finally, muscarinic agonists may also be useful for treatment of cognitive impairment in patients with Alzheimer disease.

## Cholinesterase Inhibitors

**2** Cholinesterase inhibitors (anticholinesterases) are essential to anesthesiologists because these medications are used to produce the sustained cholinergic effect necessary to overcome nondepolarizing neuromuscular blockade. These drugs are also used for treatment of myasthenia gravis, glaucoma, and, less commonly, intestinal or urinary bladder atony and have important anesthetic implications. The pharmacology of anticholinesterases as neuromuscular blockade reversal medications is described in detail in [Chapter 21](#); the current discussion will focus solely on the actions of these drugs as cholinergic-mimetics. In contrast to organophosphate compounds (e.g., pesticides such as malathion and parathion; nerve toxins including sarin, soman, and VX) that irreversibly inhibit acetylcholinesterase and butyrylcholinesterase, clinically used cholinesterase inhibitors (e.g., neostigmine, edrophonium) reversibly inhibit these enzymes, which very rapidly hydrolyze ACh (half-life of microseconds) into acetate and choline molecules under normal conditions, thereby inactivating the neurotransmitter. This inhibition of acetylcholinesterase and butyrylcholinesterase allows the actions of ACh at postganglionic muscarinic receptors to be markedly amplified, resulting in intense parasympathetic nervous system activity similar to that produced by direct cholinergic agonists. The unimpeded accumulation of ACh also causes dual actions on autonomic nervous system ganglia and skeletal muscle, initially stimulating but subsequently depressing neurotransmission through their nicotinic receptors. Similar initial stimulation followed by depression of central nervous system cholinergic receptors also occurs with exposure to a lethal dose of an anticholinesterase, for example, when an organophosphate overdose occurs during its use as a pesticide or when the agent is used as a chemical weapon during warfare or a terrorist attack.<sup>5</sup>

Clinically used cholinesterase inhibitors are either carbamoyl esters (including neostigmine, physostigmine, and pyridostigmine) or quaternary ammonium alcohols (edrophonium; [Fig. 13-2](#)). Three areas on the acetylcholinesterase molecule are capable of binding inhibitory ligands: two are located in the active center of the enzyme (the acyl pocket and a choline subsite, referred to collectively as the “esteratic” site), whereas the third is a peripheral “anionic” site.<sup>6</sup> The specificity and duration of action of cholinesterase inhibitors depend on their binding site, affinity, and rate of hydrolysis. For example, edrophonium reversibly binds to the choline subsite, but the cholinesterase inhibitor’s chemical structure facilitates its rapid renal excretion and contributes to the drug’s relatively short duration of action (approximately 1 hour). The carbamate cholinesterase inhibitors also bind to acetylcholinesterase’s “esteratic” site, but these drugs are more slowly

metabolized because their carbamoyl ester linkage is less susceptible to hydrolysis, thereby extending their clinical duration of action to approximately 4 hours. In contrast, organophosphates bind irreversibly to the active center of anticholinesterase and require stimulated hydrolysis of the phosphate–enzyme complex to restore the enzyme’s activity with drugs such as pralidoxime (2-PAM). Organophosphates are particular insidious toxins because they may be odorless, are rapidly absorbed through the skin, are very lipid-soluble, and move freely into the central nervous system.<sup>7</sup>

The most prominent pharmacologic effects of the cholinesterase inhibitors are their actions on muscarinic receptors, but when used to reverse nondepolarizing neuromuscular blockade, the intended target of these drugs is the nicotinic receptors at the motor end-plate of skeletal muscle. Notably, higher concentrations of ACh are required to activate nicotinic than muscarinic receptors. Thus, the relative excess of ACh needed to overcome nondepolarizing neuromuscular blockade of nicotinic receptors predictably causes profound stimulation of muscarinic receptors and cholinergic side effects. As a result, administration of a muscarinic antagonist (e.g., atropine, glycopyrrolate) is most often required to block the side effects of cholinesterase inhibitors (e.g., bradycardia, hypotension, bronchospasm, sialorrhea, miosis, increased intestinal motility, sphincter relaxation) while sparing the actions of these drugs at the nicotinic receptors. Unlike neostigmine, pyridostigmine, and edrophonium, physostigmine is a tertiary amine that readily crosses the blood–brain barrier and inhibits acetylcholinesterase in the central nervous system. As a result, physostigmine is effective for the treatment of atropine or scopolamine overdose (these muscarinic antagonists also penetrate the blood–brain barrier) and central anticholinergic syndrome (see below).<sup>8</sup>

**Figure 13-2** Chemical structures of clinical anticholinesterases.

Echothiophate iodide is the only clinically used organophosphate cholinesterase inhibitor, which is applied topically for the treatment of glaucoma because of its miotic effect. The drug's primary advantage over other topical glaucoma medications is its prolonged duration of action. Indeed, echothiophate may remain clinically effective for several weeks after cessation of therapy. Topical absorption of echothiophate is highly variable but can be considerable. As a result, succinylcholine may have a prolonged duration of action in patients treated with echothiophate. Despite this theoretical concern, the use of succinylcholine should not be expressly avoided when the depolarizing neuromuscular blocker is clinically indicated.

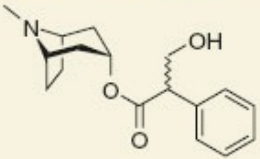

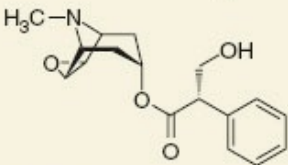

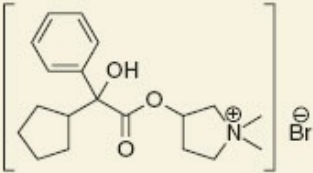

## Muscarinic Antagonists

The muscarinic antagonists atropine, scopolamine, and glycopyrrolate are commonly used in anesthesia practice (Table 13-2). Atropine and scopolamine are belladonna alkaloids that are derived from a variety of plant species (including deadly nightshade shrub, jimson weed, and henbane) and have been used for millennia as toxins and therapeutic agents. Muscarinic antagonists are competitive inhibitors of ACh at parasympathetic muscarinic

receptors and act to increase heart rate; inhibit salivary, bronchial, and gastrointestinal secretions; attenuate gastric acid production; reduce gastrointestinal motility; cause bronchodilation; and antagonize the muscarinic side effects of anticholinesterases during reversal of neuromuscular blockade. Notably, the drugs also bind to presynaptic muscarinic receptors on norepinephrine-secreting postganglionic neurons. This action may enhance sympathetic nervous system activity because Ach-induced stimulation of these presynaptic receptors normally inhibits norepinephrine release, whereas muscarinic blockade abolishes this inhibition.<sup>9</sup> Anesthesiologists first used atropine to mitigate excessive salivation and attenuate vagal-mediated bradycardia during open-drop ether or chloroform anesthesia. These antiquated indications are no longer of relevance in modern practice, but anesthesiologists continue to exploit the antisialagogue effect of muscarinic antagonists (particularly glycopyrrolate) in preparation for fiberoptic intubation or during some otolaryngology or dental procedures in adults and children. Although the potencies of atropine, scopolamine, and glycopyrrolate are quite different, the drugs have little or no muscarinic receptor subtype specificity, and as a result, exert similar anticholinergic effects in most target organs except for the heart and central nervous system. In contrast, selective muscarinic subtype receptor antagonists have also been synthesized and are now used extensively for treatment of overactive bladder conditions<sup>10</sup> without causing pronounced adverse systemic anticholinergic effects.

**Table 13-2** Comparative Effects of Muscarinic Antagonists

Name	Chemical Structure	Duration IV (hrs)	Duration IM (hrs)	CNS	Heart Rate	Antisialagogue Effect	Mydriasis Cycloplegia
Atropine		0.25–0.5	2–4	Stimulation	+++	+	+
Scopolamine		0.5–1	4–6	Sedation	0	++	+
Glycopyrrolate		2–4	6–8	0	+	++	0

Atropine and scopolamine are tertiary amines that easily penetrate the blood–brain barrier and produce central nervous system effects. For example,

scopolamine is primarily a central nervous system depressant that causes sedation, amnesia, and euphoria. When combined with an intravenous long-acting opioid (e.g., morphine, meperidine), these properties made scopolamine particularly useful as intramuscular premedication for patients undergoing cardiac or major noncardiac surgery before midazolam was introduced into clinical practice in the 1980s. Transdermal scopolamine is currently used for prophylaxis against kinetosis (motion sickness) and is also effective for the treatment of postoperative nausea and vomiting, but the drug may be associated with anticholinergic side effects despite this route of administration. Lower doses of atropine are relatively devoid of central nervous system effects, but higher doses ( $\geq 2$  mg; used most often in combination with an anticholinesterase inhibitor to reverse neuromuscular blockade or for the treatment of symptomatic bradyarrhythmias) often produce restlessness, disorientation, hallucinations, and delirium. In contrast to atropine and scopolamine, the synthetic muscarinic antagonist glycopyrrolate is a quaternary amine that does not cross the blood–brain barrier and is devoid of central nervous system effects. When combined with glycopyrrolate's more prolonged duration of action, this latter property makes the muscarinic antagonist more attractive for routine clinical use in anesthesiology than atropine.

Atropine, and to a lesser extent glycopyrrolate, increase heart rate when sinus bradycardia occurs as a result of vagal stimulation (e.g., peritoneal traction during abdominal surgery) or inhibition of cardiac sympathetic nerve traffic during spinal or epidural anesthesia. Atropine is also a treatment of choice for symptomatic bradyarrhythmias (e.g., second- or third-degree heart block). Conversely, atropine must be used with extreme caution when tachycardia is deleterious (e.g., coronary artery stenosis, aortic valve stenosis, hypertrophic obstructive cardiomyopathy, pheochromocytoma, thyroid storm). Paradoxically, very low doses of atropine ( $< 0.1$  mg) may decrease heart rate<sup>11</sup> through blockade of presynaptic parasympathetic neuron M<sub>1</sub> receptors.<sup>12</sup> Scopolamine most often produces little or no change in heart rate when administered through an intramuscular route for premedication. Notably, both clinically used belladonna alkaloids are capable of producing a paradoxical bradycardia when lower doses of these drugs are administered (scopolamine to a greater extent than atropine). Atropine and scopolamine cause mydriasis and cycloplegia because they exert muscarinic antagonist effects on Ach-mediated cranial nerve II (afferent) and III (efferent) control of pupillary reactivity and ocular accommodation. Indeed, atropine-mimetics are widely used in ophthalmology because pupillary dilation facilitates visual inspection of the posterior chamber and retina. Not surprisingly, muscarinic antagonists are relatively contraindicated in patients with narrow-angle glaucoma because pupillary dilation thickens the peripheral iris and narrows

the iridocorneal angle, thereby mechanically impairing aqueous humor drainage and increasing intraocular pressure. Muscarinic antagonists inhibit sympathetic nervous system innervation of sweat glands because ACh is the neurotransmitter in these postganglionic neurons. Pediatric patients are particularly susceptible to develop hyperthermia when treated with these drugs because children are more reliant on sweating to maintain normal body temperature than adults. Muscarinic antagonists may also be relatively contraindicated in febrile patients for similar reasons.

**Figure 13-3** Chemical structures of inhaled muscarinic antagonists.

Ipratropium and tiotropium are muscarinic antagonists that resemble atropine and are used for the treatment of reactive airway disease (Fig. 13-3).<sup>13,14</sup> The drugs are bronchial smooth muscle dilators that are administered using metered-dose inhalers. Bronchodilation produced by ipratropium and tiotropium is less pronounced than that observed with  $\beta_2$ -adrenoceptor agonists. Nevertheless, ipratropium and tiotropium effectively inhibit airway reactivity induced by a variety of provocative substances (methacholine, histamine, prostaglandin F<sub>2- $\alpha$</sub> ), but they are ineffective against leukotriene-induced bronchoconstriction. Neither drug substantially affects mucociliary clearance. Because of their quaternary ammonium structures, ipratropium and tiotropium are poorly absorbed into the systemic circulation and do not produce adverse anticholinergic side effects with the exception of xerostomia. The inhaled muscarinic antagonists may be more efficacious in patients with chronic obstructive pulmonary disease than in those suffering from asthma.<sup>15</sup>

## Muscarinic Antagonist Toxicity

Atropine and other muscarinic antagonists cause symptoms associated with blockade of ACh at parasympathetic and sympathetic (sweat glands) postganglionic neurons (Table 13-3). The familiar medical school mnemonic “dry as a bone; red as a beet; blind as a bat; hot as a hare; mad as a hatter” summarizes these effects. The central nervous system effects of muscarinic antagonists are particularly noteworthy because muscarinic ACh receptors are abundant in the brain, blockade of which may result in psychoactive effects

including excitation, restlessness, sedation, confusion, hallucinations, stupor, delirium, psychosis, seizures, or coma. These alterations in sensorium associated with centrally acting muscarinic antagonists are characteristic features of central anticholinergic syndrome (known as “postoperative delirium” when it occurs after emergence from general anesthesia) and may persist well beyond the expected duration of the offending drug’s metabolism. Antihistamines, tricyclic antidepressants, phenothiazines, benzodiazepines, and a variety of other medications are also associated with central anticholinergic syndrome (Table 13-4). As mentioned previously, the treatment of choice for central anticholinergic syndrome is the tertiary amine anticholinesterase physostigmine, which crosses the blood–brain barrier and increases ACh concentrations in the central nervous system. Physostigmine is most often administered in 1 or 2 mg doses to avoid producing peripheral cholinergic activity. Importantly, the duration of action of physostigmine may be shorter than that of the muscarinic antagonist. As a result, repeated treatment with physostigmine may be required if symptoms recur. Nevertheless, the drug must be used with caution because of unopposed cholinergic agonist effects in the absence of a muscarinic antagonist.

## Fundamentals of Catecholamine Pharmacology

$\alpha$ -,  $\beta$ -, and dopamine-adrenergic receptor subtypes mediate the cardiovascular effects of endogenous (epinephrine, norepinephrine, dopamine) and synthetic (dobutamine, isoproterenol) catecholamines (Table 13-5). These substances stimulate  $\beta_1$ -adrenoceptors located on the sarcolemmal membrane of atrial and ventricular myocytes to varying degrees. Activation of  $\beta_1$ -adrenoceptors causes positive chronotropic (increase in heart rate), dromotropic (faster conduction velocity), inotropic (greater contractility), and lusitropic (shorter relaxation) effects. A stimulatory guanine nucleotide-binding ( $G_s$ ) protein couples the  $\beta_1$ -adrenoceptor to the intracellular enzyme adenylyl cyclase (Fig. 13-4). Agonist occupation of the  $\beta_1$ -adrenoceptor accelerates the formation of the second messenger cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). Activation of this signaling cascade has three major consequences in myocardial calcium ( $Ca^{2+}$ ) homeostasis: first, greater  $Ca^{2+}$  availability for contractile activation; second, increased efficacy of activator  $Ca^{2+}$  at troponin C of the contractile apparatus; and third, faster removal of  $Ca^{2+}$  from the contractile apparatus and the sarcoplasm after contraction. The first two of these actions directly increase contractility (inotropic effect), whereas the third facilitates more rapid myocardial relaxation during early diastole (lusitropic effect). Not surprisingly, treatment of left ventricular (LV) dysfunction is the major reason why catecholamines are used during the

perioperative period. The relative density and functional integrity of the  $\beta_1$ -adrenoceptor and its downstream signaling cascade substantially influence the clinical efficacy of catecholamines because receptor downregulation and abnormal intracellular  $\text{Ca}^{2+}$  homeostasis commonly occur in the presence of LV dysfunction.<sup>16,17</sup> Notably,  $\beta_2$ -adrenoceptors are also present in myocardium (atrial > ventricular).<sup>18</sup> These  $\beta_2$ -adrenoceptors are also linked to adenylyl cyclase through  $G_s$  proteins and act to partially preserve myocardial responsiveness to catecholamine stimulation in the presence of  $\beta_1$ -adrenoceptor dysfunction or downregulation.<sup>19,20</sup>

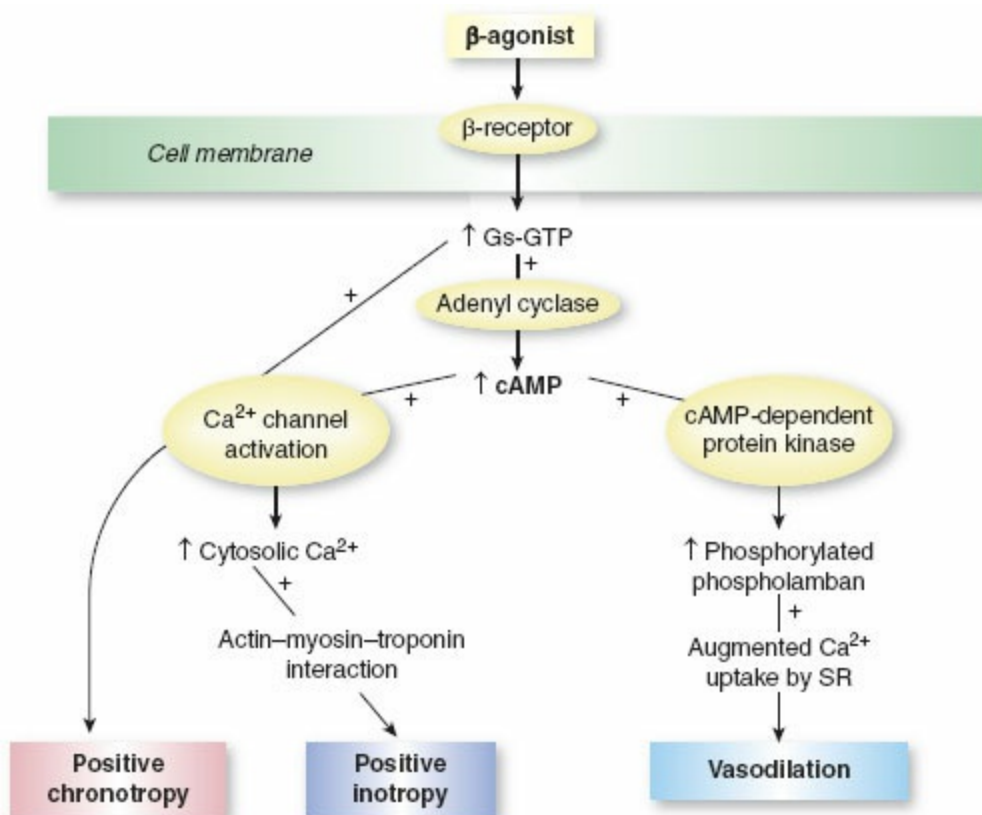

**Table 13-3** Atropine Toxicity

Dose Range (mg)	Muscarinic Antagonist Effects
0.5–1.0	Increased heart rate; xerostomia (dry mouth); thirst; lack of sweating; mild pupillary dilation
2–5	Tachycardia; palpitations; mydriasis; cycloplegia; restlessness or confusion; inability to swallow, urinate, defecate, or sweat; hot skin
10 or greater	Profound tachycardia, mydriasis, and cycloplegia; hot, red skin; fever; hallucinations; delirium; coma; death

Bench-to-bedside review: Inotropic drug therapy after adult cardiac surgery: a systematic literature review. *Crit Care*. 2005;9:266–279.)

The tissue-specific distribution of  $\alpha$ - and  $\beta$ -adrenoceptor subtypes combines with differences in each catecholamine's chemical structure and its relative selectivity for adrenoceptors to determine the actions of catecholamines in other perfusion beds. This selectivity is often dose-related. Dopamine provides a particularly useful (although not strictly accurate) pedagogical illustration of this principle. Lower doses of this catecholamine ( $< 3 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) predominantly stimulate dopamine subtype 1 and 2 receptors ( $\text{DA}_1$  and  $\text{DA}_2$ , respectively) and cause splanchnic and renal arterial vasodilation. Progressively larger doses of dopamine sequentially activate  $\beta_1$ - (5 to  $10 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) and  $\alpha_1$ -adrenoceptors ( $> 10 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ), enhancing contractility and causing arterial vasoconstriction, respectively.  $\alpha_1$ -Adrenoceptors are major regulators of vasomotor tone in arteries, arterioles, and veins. Thus, catecholamines with substantial  $\alpha_1$ -adrenoceptor agonist activity (e.g., norepinephrine) increase systemic vascular resistance and reduce venous capacitance through arterial and venous vasoconstriction, respectively. Phospholipase-inositol 1,4,5-triphosphate signaling through an inhibitory guanine nucleotide-binding ( $\text{G}_i$ ) protein mediates this  $\alpha_1$ -adrenoceptor vasoconstriction (Fig. 13-5). This cascade opens  $\text{Ca}^{2+}$  channels, releases  $\text{Ca}^{2+}$  from intracellular stores (sarcoplasmic reticulum and

calmodulin), and activates several  $\text{Ca}^{2+}$ -dependent protein kinases. These actions act in concert to increase intracellular  $\text{Ca}^{2+}$  concentration and cause contraction of vascular smooth muscle.  $\alpha_1$ -Adrenoceptors predominate in many vascular beds, but  $\beta_2$ -adrenoceptors are the most common adrenoceptor subtype in skeletal muscle. Catecholamine-induced activation of  $\beta_2$ -adrenoceptors produces arteriolar vasodilation through adenylyl cyclase-mediated signaling. The result of this vasodilation is increased blood flow to skeletal muscle, which facilitates the “fight or flight” response to a perceived threat.

The actions of each specific catecholamine on heart rate, myocardial contractility, and LV preload and afterload combine to determine its overall effect on arterial pressure. For example, if a catecholamine acts primarily through the  $\alpha_1$ -adrenoceptor, an increase in arterial pressure may be predicted because enhanced arterial and venous vasomotor tone increases systemic vascular resistance (greater afterload) and facilitates venous return to the heart (increased preload), respectively. In contrast, a catecholamine with primarily  $\beta$ -adrenoceptor activity and little or no effect on the  $\alpha_1$ -adrenoceptor should modestly decrease arterial pressure because reductions in systemic vascular resistance (through  $\beta_2$ -adrenoceptor activation) offset increases in cardiac output caused by tachycardia and enhanced myocardial contractility ( $\beta_1$ -adrenoceptor effects). All catecholamines have the potential to cause detrimental increases in myocardial oxygen consumption in patients with flow-limiting coronary artery stenoses and may produce acute myocardial ischemia as a result. Thus, the use of a catecholamine to support LV function in a patient with heart failure and coronary artery disease should be approached with caution. For this reason, afterload reduction is usually a more prudent approach to improve cardiac output and reduce congestive symptoms in a patient with coronary artery disease complicated by heart failure.

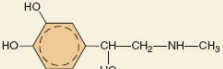

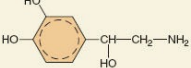

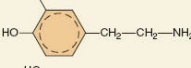

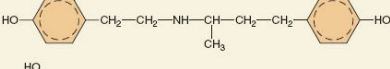

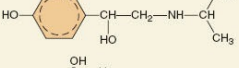

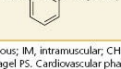

## Epinephrine

Methylation of norepinephrine by phenylethanolamine *N*-methyltransferase converts the norepinephrine into epinephrine in adrenal medullary chromaffin cells. Epinephrine is stored in and released from specific chromaffin cells that differ from those that store norepinephrine. These epinephrine- and norepinephrine-containing chromaffin cell types appear to release their respective catecholamines somewhat selectively to differing stimuli. For example, chromaffin cells storing epinephrine are especially sensitive and release this catecholamine in response to histamine exposure, whereas nicotinic agonists cause release of norepinephrine.<sup>21</sup> Epinephrine exerts its major cardiovascular effects through activation of  $\alpha_1$ -,  $\beta_1$ -, and  $\beta_2$ -

adrenoceptors. Epinephrine is the quintessential positive inotropic molecule. Epinephrine stimulates  $\beta_1$ -adrenoceptors located on the cell membranes of sinoatrial (SA) node cells and cardiac myocytes to increase heart rate and myocardial contractility, respectively. Epinephrine-induced activation of  $\beta_1$ -adrenoceptors also enhances the rate and extent of myocardial relaxation. This action improves ventricular filling during early diastole. The combination of these actions on heart rate and LV systolic and diastolic function markedly increases cardiac output. For example, increases in cardiac index of 0.1, 0.7, and 1.2 L  $\text{min}^{-1} \cdot \text{m}^2$  were observed during intravenous infusion of epinephrine (0.01, 0.02, and 0.04  $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) in humans.<sup>22</sup> The initial tachycardia that occurs during administration of an intravenous infusion of epinephrine is often partially attenuated over time as baroreceptor-mediated reflexes are activated. Epinephrine is particularly useful for the treatment of acute biventricular failure during cardiac surgery because it predictably increases cardiac output. Epinephrine (0.01 to 0.03  $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) caused similar hemodynamic effects with less pronounced tachycardia compared with dobutamine (2.5 to 5.0  $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) in patients after coronary artery bypass graft surgery.<sup>23</sup> The authors recommend the use of epinephrine as the primary inotropic drug for the treatment of acute LV dysfunction after cardiopulmonary bypass because it produces very predictable increases in cardiac output compared with its synthetic derivatives. Data indicating that routine use of dobutamine in cardiac surgery adversely affects outcome support this recommendation.<sup>24</sup> Epinephrine also enhances cardiac output and oxygen delivery without producing deleterious tachycardia in patients with sepsis. However, epinephrine's efficacy as an inotropic drug is often limited because of the catecholamine's propensity to cause atrial or ventricular arrhythmias. Epinephrine increases conduction velocity and reduces refractory period in the AV node, His bundle, Purkinje fibers, and ventricular muscle. The positive dromotropic effect of epinephrine on AV nodal conduction may produce supraventricular tachyarrhythmias or cause pronounced increases in ventricular rate in the presence of atrial flutter or fibrillation. Either of these clinical conditions may inadvertently cause hypotension because profound tachycardia compromises coronary perfusion and LV filling time. Epinephrine may also increase the automaticity of latent pacemakers because spontaneous diastolic depolarization is enhanced. Irritability in other parts of the conduction system may also precipitate ventricular arrhythmias including premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation, especially in the presence of a pre-existing arrhythmogenic substrate (e.g., regional myocardial ischemia or infarction, cardiomyopathy).

**Table 13-5** Comparative Effects of Endogenous and Synthetic Catecholamines

Name	Chemical Structure	$\beta_1$	$\beta_2$	$\alpha_1$	Dopamine <sub>1</sub>	Dose Range	Clinical Indications	Major Side Effects
Epinephrine		++++	+++	++++	0	IV: 0.01–0.2 $\mu\text{g}/\text{kg}/\text{min}$ Bolus: 1 mg IV q 3–5 min IM(1:1,000): 0.1–0.5 mg	Shock (cardiogenic, vasodilatory) Bronchospasm Anaphylaxis Symptomatic bradycardia unresponsive to atropine/pacing	Arrhythmias Myocardial ischemia Sudden cardiac death Hypertension Stroke
Norepinephrine		+++	+	++++	0	IV: 0.01–0.2 $\mu\text{g}/\text{kg}/\text{min}$	Shock (cardiogenic, vasodilatory)	Arrhythmias Bradycardia Peripheral ischemia Hypertension Tissue necrosis with extravasation
Dopamine		++++	++	+++	++++	IV: 2–20 $\mu\text{g}/\text{kg}/\text{min}$	Shock (cardiogenic, vasodilatory) Symptomatic bradycardia unresponsive to atropine/pacing	Hypertension Arrhythmias Myocardial ischemia Peripheral ischemia (high doses)
Dobutamine		++++	+++	+	0	IV: 2–20 $\mu\text{g}/\text{kg}/\text{min}$	Low cardiac output (CHF, cardiogenic shock, sepsis-induced myocardial dysfunction) Symptomatic bradycardia unresponsive to atropine/pacing	Tachycardia Arrhythmias Myocardial ischemia Hypertension Hypotension
Isoproterenol		++++	++++	0	0	IV: 2–10 $\mu\text{g}/\text{kg}/\text{min}$	Bradycardias Diseased heart	Arrhythmias Myocardial ischemia Hypertension Hypotension

Abbreviations: IV, intravenous; IM, intramuscular; CHF, congestive heart failure; AS, aortic stenosis; HCM, hypertrophic obstructive cardiomyopathy. Modified from Linn KA, Pagel PS. Cardiovascular pharmacology. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia Fundamentals*. Philadelphia, PA: Wolters Kluwer; 2015:234–235.

Epinephrine causes vasoconstriction in cutaneous, mesenteric, splenic, and renal perfusion territories because it is an  $\alpha_1$ -adrenoceptor agonist, but the catecholamine also simultaneously vasodilates arterial blood vessels supplying skeletal muscle as a result of  $\beta_2$ -adrenoceptor activation.<sup>25</sup> Thus, epinephrine's overall effects on blood flow are dependent on the organ-specific distribution of  $\alpha_1$ - and  $\beta_2$ -adrenoceptors. These actions are also dose-dependent: lower doses ( $<0.02 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) of epinephrine stimulate  $\beta_2$ -adrenoceptors, causing vasodilation and modest declines in arterial pressure. In contrast, higher doses ( $>0.1 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) of the catecholamine activate  $\alpha_1$ -adrenoceptors, increasing systemic vascular resistance and arterial pressure. Higher doses of epinephrine also cause intense renal arterial vasoconstriction resulting from the combination of direct  $\alpha_1$ -adrenoceptor agonist effects and indirect facilitation of renin release. The increase in arterial pressure associated with a large bolus dose (e.g., 1 mg in adults) of epinephrine improves coronary blood flow and survival during cardiopulmonary resuscitation.<sup>26</sup> As a result, epinephrine is the drug of choice in the American Heart Association Adult Advanced Cardiac Life Support protocols for malignant ventricular arrhythmias, pulseless electrical activity, and asystole.<sup>27</sup>

The venous circulation also contains a high density of  $\alpha_1$ -adrenoceptors. As a result, epinephrine produces venoconstriction and enhances venous return to the heart (preload). Epinephrine causes vasoconstriction of the pulmonary arterial vascular smooth muscle and increases pulmonary arterial pressures through  $\alpha_1$ -adrenoceptor activation. These actions may be especially pronounced in patients with pulmonary arterial hypertension (e.g., cor pulmonale, congenital heart diseases with left-to-right shunt).  $\alpha_1$ - and  $\beta_2$ -adrenoceptors exist in the coronary circulation, but selective activation of either of these receptor subtypes does not represent the major mechanism by which epinephrine affects coronary blood flow. Instead, increases in coronary

blood flow observed during administration of epinephrine occur principally because of metabolic autoregulation. Indeed, increases in myocardial oxygen consumption resulting from increases in heart rate, contractility, preload, and afterload are responsible for coronary vasodilation. Nevertheless, epinephrine may directly constrict epicardial coronary arteries and reduce coronary blood flow in the presence of pre-existing maximal coronary vasodilation (e.g., acute myocardial ischemia distal to a severe coronary stenosis) through direct  $\alpha_1$ -adrenoceptor stimulation.

The vasoconstrictor properties of epinephrine make it useful for several other clinical applications. Subcutaneous infiltration of epinephrine is used to substantially reduce or nearly eliminate bleeding during dental, otolaryngology, plastic surgery, and orthopedic surgery procedures. The mixture of a local anesthetic (e.g., lidocaine) with a dilute concentration of epinephrine reduces blood loss associated with tumescent anesthesia for liposuction. The vasoconstriction produced by epinephrine also substantially decreases the risk of adverse cardiovascular side effects (e.g., hypertension, arrhythmias) because the catecholamine is slowly absorbed under these circumstances. Anesthesiologists routinely use epinephrine as a vasoconstrictor to delay the absorption of local anesthetics and thereby prolong the duration of neuraxial anesthesia or peripheral nerve blocks. This effect also decreases serum anesthetic concentration and reduces the risk of systemic toxicity. Mucosal vasoconstriction resulting from inhalation of aerosolized racemic epinephrine (containing a mixture of the levo- and dextrorotary optical isomers) is frequently used to treat airway edema associated with prolonged endotracheal intubation, airway trauma, or croup. Intramuscular injection of epinephrine may be preferred to inhalation of the catecholamine in pediatric patients with severe croup because rebound edema may occur when using the latter technique as a result of the relatively short half-life of inhaled epinephrine.<sup>28</sup> Finally, epinephrine-induced activation of  $\beta_2$ -adrenoceptors in airway smooth muscle causes bronchodilation in patients with reactive airway disease. Epinephrine also decreases antigen-mediated release of histamine and leukotrienes from mast cells, which makes the catecholamine useful for the treatment of bronchospasm associated with anaphylaxis.<sup>29</sup>

Prior administration of  $\alpha$ - or  $\beta$ -adrenoceptor antagonists profoundly influences the epinephrine's cardiovascular effects. For example, epinephrine causes more pronounced increases in systemic vascular resistance and arterial pressure when administered in the presence of the nonselective  $\beta$ -blocker propranolol because  $\beta_2$ -adrenoceptor-mediated arterial vasodilation no longer opposes  $\alpha_1$ -adrenoceptor-induced vasoconstriction.  $\beta$ -Blockade also competitively inhibits epinephrine-induced  $\beta_1$ -adrenoceptor activation. This competitive inhibition attenuates the positive chronotropic and inotropic

effects of the catecholamine. Indeed, the hemodynamic effects of epinephrine may be quite similar to those of the synthetic pure  $\alpha_1$ -adrenoceptor agonist phenylephrine (see below) in the presence of complete  $\beta_1$ - and  $\beta_2$ -adrenoceptor blockade. Conversely, epinephrine's  $\beta_2$ -adrenoceptor-mediated vasodilation is unmasked in the presence of  $\alpha_1$ -adrenoceptor blockade, and the catecholamine may produce hypotension under these conditions.  $\alpha_2$ -Adrenoceptor antagonists (e.g., cocaine) enhance the intensity and duration of action of the epinephrine's cardiovascular effects by inhibiting its reuptake.

## Norepinephrine

Norepinephrine is the endogenous neurotransmitter released from postganglionic sympathetic nervous system nerve terminals. Norepinephrine activates  $\alpha_1$ -,  $\alpha_2$ -, and  $\beta_1$ -adrenoceptors, but this catecholamine has little effect on  $\beta_2$ -adrenoceptors, unlike its methylated derivative epinephrine. As a result of this adrenoceptor selectivity, norepinephrine predictably enhances myocardial contractility and causes intense arterial vasoconstriction. These actions dramatically increase arterial pressure while cardiac output remains relatively unchanged. In contrast, administration of a pure  $\alpha_1$ -adrenoceptor agonist (e.g., phenylephrine) produces dose-related declines in cardiac output in normal and failing myocardium by increasing LV afterload because  $\beta_1$ -adrenoceptors are not stimulated and resulting increases in contractility do not occur. Unlike epinephrine, norepinephrine usually does not cause tachycardia because elevated arterial pressure activates baroreceptor-mediated reflexes, effectively balancing the direct positive chronotropic effects of  $\beta_1$ -adrenoceptor stimulation. In general, greater increases in diastolic arterial pressure and systemic vascular resistance occur during administration of norepinephrine compared with similar doses of epinephrine. Norepinephrine constricts venous capacitance vessels through  $\alpha_1$ -adrenoceptor stimulation. This action increases venous return (preload), and combined with a  $\beta_1$ -adrenoceptor-mediated positive inotropic effect, modestly augments stroke volume despite concomitant increases in LV afterload.

Norepinephrine is most often used for treatment of refractory hypotension resulting from pronounced vasodilation. Norepinephrine is an established treatment in patients with septic shock<sup>30</sup> that is unresponsive to volume administration or other vasoactive medications because the catecholamine increases arterial pressure, cardiac index, and urine output. Norepinephrine, most often in combination with nitric oxide scavenger methylene blue, is also useful for the management of vasoplegic syndrome.<sup>31</sup> This hypotensive state is associated with low systemic vascular resistance and frequently occurs during or after prolonged cardiopulmonary bypass in patients undergoing cardiac surgery. The potent vasoconstrictor vasopressin has largely supplanted

norepinephrine in this clinical setting. Norepinephrine increases coronary perfusion pressure in patients with severe coronary artery disease, but the catecholamine also dramatically increases myocardial oxygen consumption and may produce acute myocardial ischemia in the presence of flow-limiting coronary stenoses despite the improvement in diastolic arterial pressure. Norepinephrine may also cause spasm of internal mammary or radial artery grafts used during coronary artery surgery as a result of activation of  $\alpha_1$ -adrenoceptors. Ventricular and supraventricular arrhythmias are sometimes observed during administration of norepinephrine, but the arrhythmogenic potential of norepinephrine is less than that of epinephrine. As a result, substitution of norepinephrine for epinephrine may be appropriate when hemodynamically significant atrial or ventricular arrhythmias are present.

Norepinephrine stimulates pulmonary arterial  $\alpha_1$ -adrenoceptors and causes dose-related increases in pulmonary arterial pressures that may precipitate right ventricular (RV) dysfunction or failure because the RV is relatively intolerant to acute increases in afterload compared with the more muscular, thicker walled LV. An inhaled selective pulmonary vasodilator (e.g., nitric oxide, prostacyclin) may help to attenuate norepinephrine's direct pulmonary vasoconstrictor effects when the catecholamine is used in patients with pulmonary hypertension and depressed myocardial contractility. Alternatively, lower doses of norepinephrine may be administered directly through a left atrial catheter in patients with LV failure and pulmonary hypertension because metabolism in peripheral tissues reduces the quantity of norepinephrine that is returned to the pulmonary vasculature through the venous circulation. This selective left atrial route of norepinephrine administration enhances coronary perfusion pressure while simultaneously increasing LV contractility. These actions may decrease biventricular filling pressures and increase cardiac output. When arterial pressure is normal or modestly reduced, norepinephrine causes dose-dependent decreases in hepatic, skeletal muscle, splanchnic, and renal blood flow through  $\alpha_1$ -adrenoceptor-induced vasoconstriction. However, norepinephrine increases perfusion pressure and blood flow to these vascular beds when arterial pressure is profoundly reduced. Nevertheless, sustained reductions in renal, mesenteric, and peripheral vascular blood flow represent a major limitation of prolonged use of norepinephrine. Activation of renal dopamine receptors with low-dose dopamine or the selective DA<sub>1</sub> agonist fenoldopam to partially counteract the deleterious actions of norepinephrine on renal blood flow may preserve renal perfusion and urine output but most likely does not reduce the incidence or severity of acute kidney injury in patients with hypotension. Norepinephrine should be administered through a central venous catheter to avoid the possibility of tissue necrosis from extravasation.

## Dopamine

Dopamine is the biochemical precursor of norepinephrine. The catecholamine activates several adrenergic and dopaminergic receptor subtypes in a dose-related fashion. Lower doses (below  $3 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) selectively activate DA<sub>1</sub> receptors to dilate renal, mesenteric, and splenic arterial blood vessels and increase renal and splanchnic blood flow. Lower doses of dopamine also reduce norepinephrine release from pre- and postganglionic sympathetic neurons through a DA<sub>2</sub>-receptor-mediated mechanism. As a result of these actions, lower doses of dopamine modestly decrease arterial pressure. Moderate doses (3 to  $8 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) of dopamine activate both  $\alpha_1$ - and  $\beta_1$ -adrenoceptors, resulting in elevated arterial pressure and positive inotropic effects. In contrast, high doses (in excess of  $10 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) of dopamine act primarily on  $\alpha_1$ -adrenoceptors to increase arterial pressure through arteriolar vasoconstriction. Unfortunately, this dose-response description of dopamine pharmacodynamics is overly simplistic because differences in receptor density and regulation, drug interactions, and patient variability cause a wide, often unpredictable range of clinical responses<sup>32</sup> even in healthy individuals.<sup>33</sup> For example, it was once presumed that low doses of dopamine provided renal protective effects through DA<sub>1</sub>-receptor-mediated increases in renal blood flow. However, this hypothesis was subsequently not supported because even low doses of dopamine are capable of producing simultaneous  $\alpha_1$ - and  $\beta_1$ -adrenoceptor activation that may attenuate or abolish the catecholamine's intended renal dopaminergic effect. Conversely, renal blood flow and urine output may be preserved (and are certainly not reduced) during administration of higher doses of dopamine because DA<sub>1</sub> receptors continue to be activated despite a predominant  $\alpha_1$ -adrenoceptor agonist effect. Varied responses such as these may explain why the results of several clinical trials indicated that dopamine does not consistently provide renal protective effects despite improvements in renal perfusion and urine output. A meta-analysis of 61 clinical trials involving 3,359 patients demonstrated that low-dose dopamine transiently increased urine output, but the catecholamine did not reduce the incidence or severity of renal dysfunction or prevent mortality.<sup>34</sup> Thus, the use of low-dose dopamine to maintain or enhance renal function and prevent acute kidney injury is no longer recommended.<sup>35</sup>

Dopamine is still occasionally used as a positive inotropic medication in patients with acute LV dysfunction, although the authors prefer to use more potent catecholamines that have more predictable pharmacodynamic profiles (e.g., epinephrine, norepinephrine) with or without a cardiac phosphodiesterase fraction III inhibitor (e.g., milrinone) for this purpose in their practices. Dopamine increases myocardial contractility through

activation of  $\beta_1$ -adrenoceptors. Dopamine also stimulates arterial and venous  $\alpha_1$ -adrenoceptors, increasing LV afterload and enhancing venous return, respectively. As a result of these combined actions on  $\alpha_1$ - and  $\beta_1$ -adrenoceptors, dopamine increases arterial pressure and cardiac output. The use of dopamine for the treatment of hypotension in the presence of depressed contractility is limited to some degree in patients with pre-existing pulmonary arterial hypertension or heart failure with elevated LV filling pressures. For example, right atrial, mean pulmonary arterial, and pulmonary capillary occlusion pressures were greater in patients undergoing cardiac surgery receiving dopamine compared with dobutamine despite producing similar increases in cardiac output. Dopamine may also cause more pronounced tachycardia than epinephrine in cardiac surgery patients. An arterial vasodilator (e.g., sodium nitroprusside) may be used to blunt dopamine-induced increases in LV afterload and thereby further enhance cardiac output. However, inotrope-vasodilators (e.g., milrinone, levosimendan) are more commonly used for this purpose in modern anesthesia practice than this older “dopamine plus nitroprusside (‘dopride’)” strategy. Like epinephrine and norepinephrine, dopamine directly increases myocardial oxygen consumption and may cause or worsen myocardial ischemia in the presence of hemodynamically significant coronary stenoses.

## Dobutamine

Commercial preparations of the synthetic catecholamine dobutamine contain two stereoisomers (– and +), both of which stimulate  $\beta$ -adrenoceptors, but these (–) and (+) stereoisomers cause opposing agonist and antagonist effects on  $\alpha_1$ -adrenoceptors, respectively.<sup>36</sup> As a result, dobutamine is a potent stimulator of  $\beta$ -adrenoceptors, but the drug has little effect on  $\alpha_1$ -adrenoceptors when it is administered at infusion rates less than  $5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ . This unique pharmacology allows dobutamine to enhance myocardial contractility and simultaneously reduce arterial vasomotor tone through  $\beta_1$ - and  $\beta_2$ -adrenoceptor activation, respectively. These actions combine to markedly improve LV-arterial coupling, enhance myocardial efficiency, and increase cardiac output in the presence or absence of LV dysfunction.<sup>37</sup> The favorable effects of dobutamine on mechanical matching between the LV and the arterial vasculature also partially explain the declines in mitral regurgitation observed when dobutamine is administered to patients with dilated cardiomyopathy and increased LV filling pressures.<sup>38</sup> The dobutamine (–) isomer progressively stimulates the  $\alpha_1$ -adrenoceptor as infusion rates increase above  $5 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ . This action mitigates the magnitude of vasodilation resulting from  $\beta_2$ -adrenoceptor activation and effectively preserves LV preload, afterload, and arterial pressure. The  $\alpha_1$ -

adrenoceptor agonist effect of higher doses of dobutamine also serves to blunt the baroreceptor reflex-mediated tachycardia that might otherwise occur. Nevertheless, dobutamine often increases heart rate by direct  $\beta_1$ -adrenoceptor-mediated positive chronotropic and dromotropic effects. In fact, dobutamine produced significantly higher heart rates than epinephrine at equivalent values of cardiac index in patients after coronary artery surgery.<sup>23</sup> Dobutamine directly increases myocardial oxygen consumption and may cause acute myocardial ischemia in patients with flow-limiting coronary stenoses. This is the underlying principle behind dobutamine stress echocardiography as a diagnostic tool for the detection of coronary artery disease because regional wall motion abnormalities in the affected coronary perfusion territories occur in response to the myocardial oxygen supply–demand mismatch during transient infusion of the drug.<sup>39</sup> Conversely, dobutamine often reduces heart rate in patients with heart failure because increases in cardiac output and oxygen delivery improve tissue perfusion and reduce chronically elevated sympathetic nervous system tone. Dobutamine may also favorably decrease myocardial oxygen consumption in the failing heart because stimulation of  $\beta_2$ -adrenoceptors decreases LV preload and afterload and, consequently, LV end-diastolic and end-systolic wall stress, respectively.

Dobutamine modestly decreases pulmonary arterial pressures and pulmonary vascular resistance through  $\beta_2$ -adrenoceptor stimulation. Thus, dobutamine may be a useful positive inotropic drug in intensive care unit patients with pulmonary arterial hypertension.<sup>40</sup> As previously mentioned, dopamine, in contrast to dobutamine, activates  $\alpha_1$ -adrenoceptors in the pulmonary arterial and venous capacitance vessels, and these effects increase pulmonary arterial pressures and LV preload, respectively. As a result, dobutamine may be preferred over dopamine in heart failure patients with elevated pulmonary vascular resistance and LV filling pressures. However, this dobutamine-induced pulmonary vasodilation has the potential to exacerbate ventilation–perfusion mismatch, increase transpulmonary shunt, and contribute to relative hypoxemia. Dobutamine may also improve renal perfusion by increasing cardiac output, but unlike dopamine, the drug does not directly activate DA<sub>1</sub> receptors to cause renal arterial vasodilation. Unfortunately, several clinical trials demonstrated that use of dobutamine was linked to an increased incidence of major adverse cardiac events including mortality in patients with decompensated heart failure despite the theoretical beneficial cardiovascular effects of the drug.<sup>41,42</sup> Dobutamine also produced adverse events in patients undergoing cardiac surgery.<sup>24</sup> As a result of these and other compelling data, the authors have personally eliminated the use of dobutamine for positive inotropic support in patients with LV dysfunction undergoing cardiac surgery. Nevertheless, dobutamine remains a useful drug for the treatment of depressed myocardial contractility in patients with

## Isoproterenol

Isoproterenol is a nonselective  $\beta$ -adrenoceptor agonist synthetic catecholamine derived from dopamine. Isoproterenol has a low affinity for and does not exert activity at the  $\alpha$ -adrenoceptor. As a result, isoproterenol increases heart rate and myocardial contractility and decreases arterial pressure through  $\beta_1$ - and  $\beta_2$ -adrenoceptor agonist effects, respectively. Historically, isoproterenol was used for “pharmacologic pacing” in patients with symptomatic bradyarrhythmias or AV conduction block (e.g., Mobitz type II second-degree block, third-degree block) because of the drug’s positive chronotropic effects. Isoproterenol was also used during cardiac transplantation to increase heart rate and enhance myocardial contractility in the denervated donor organ. However, transcutaneous or transvenous pacing has largely replaced the catecholamine for heart rate control in modern practice, especially in view of the drug’s propensity to precipitate adverse supraventricular and ventricular tachyarrhythmias.<sup>44</sup> Isoproterenol was previously used to treat RV dysfunction resulting from severe pulmonary arterial hypertension because the drug reduces pulmonary vascular resistance by stimulating  $\beta_2$ -adrenoceptors in pulmonary arterial vascular smooth muscle, but selective inhaled pulmonary vasodilators (e.g., nitric oxide, prostaglandin I<sub>2</sub>) are more effective and are associated with fewer adverse side effects. Thus, although the clinical applicability of isoproterenol is quite limited at present, the comparison of the pharmacology of isoproterenol with other catecholamines merits continued discussion.

Isoproterenol causes  $\beta_2$ -adrenoceptor–mediated arteriolar vasodilation in renal, mesenteric, splenic, and skeletal muscle circulations. These actions reduce systemic vascular resistance and decrease arterial pressure. Isoproterenol causes direct positive chronotropic and dromotropic effects and increases heart rate because of  $\beta_1$ -adrenoceptor activation. Tachycardia also occurs because hypotension stimulates baroreceptor reflex-mediated increases in heart rate. Isoproterenol is a positive inotropic drug, but cardiac output may not increase because tachycardia interferes with LV filling dynamics and  $\beta_2$ -adrenoceptor–mediated venodilation decreases LV preload. For example, isoproterenol, unlike dobutamine, did not increase cardiac output in patients undergoing coronary artery or valve replacement surgery. Predictably, the hemodynamic effects of isoproterenol cause dose-related increases in myocardial oxygen consumption. The synthetic catecholamine also reduces coronary perfusion pressure and decreases diastolic filling time. These alterations in myocardial oxygen supply–demand relations may contribute to the development of acute myocardial ischemia or cause subendocardial

necrosis, even in the absence of coronary artery disease. Thus, isoproterenol may be especially deleterious in patients with flow-limiting coronary stenoses.

## Selective $\beta_2$ -Adrenoceptor Agonists

A number of short- and long-acting selective  $\beta_2$ -adrenoceptor agonists, including metaproterenol, albuterol, salmeterol, and fenoterol, are currently in clinical use for treatment of asthma and chronic obstructive pulmonary disease. A hydroxyl substitution on the phenyl ring or a large moiety attached to the amino group of a catecholamine's basic chemical structure increases the molecule's relative  $\beta_2$ -adrenoceptor affinity. These drugs stimulate  $\beta_2$ -adrenoceptors in bronchial smooth muscle to produce bronchodilation, reduce airway resistance, and improve obstructive symptoms. Reductions in histamine and leukotriene release from pulmonary mast cells, and improvements in mucociliary function may also contribute to beneficial effects of selective  $\beta_2$ -adrenoceptor agonists in patients with reactive airway disease.<sup>45</sup> To minimize the systemic side effects of  $\beta_2$ -adrenoceptor activation (e.g., tremor, anxiety, restlessness), the drugs are usually aerosolized and administered using a metered-dose inhaler. However, the  $\beta_2$ -adrenoceptor selectivity of these drugs progressively decreases and  $\beta_1$ -adrenoceptor-mediated adverse effects (e.g., tachycardia, arrhythmias) become more apparent as larger doses are used. Terbutaline is another  $\beta_2$ -adrenoceptor agonist that is administered subcutaneously or intramuscularly and may be useful in the management of status asthmaticus.

## Fenoldopam

Fenoldopam mesylate is an intravenous selective  $DA_1$ -receptor agonist that does not exert activity at  $\alpha$ - or  $\beta$ -adrenoceptors.<sup>35</sup> The drug dilates mesenteric, splenic, and renal arterioles, increases renal blood flow, decreases renal vascular resistance, reduces systemic vascular resistance, improves creatinine clearance, and promotes both natriuretic and diuretic effects. Fenoldopam was initially developed as an antihypertensive medication because of its actions as a vasodilator,<sup>46</sup> but the drug may also be capable of protecting the kidney against radiographic contrast-induced nephropathy, presumably by virtue of enhanced renal blood flow.<sup>47,48</sup> This potential to block renal injury, particularly in the presence of hypotension or pre-existing kidney damage, prompted intense investigation of fenoldopam as a possible renal protective agent. For example, a large meta-analysis based primarily on small single center studies suggested that fenoldopam may reduce the risk of acute tubular necrosis, the need for renal replacement therapy, and overall

mortality in patients with or at risk for acute kidney injury.<sup>49</sup> Unfortunately, large randomized controlled clinical trials have failed to support these promising early results. Fenoldopam did not provide renal protection against contrast-induced nephropathy.<sup>50</sup> Similarly, fenoldopam did not decrease the need for dialysis in intensive care unit patients with early acute tubular necrosis,<sup>51</sup> nor did the DA<sub>1</sub>-receptor agonist reduce the requirement for renal replacement therapy or 30-day mortality in patients with acute kidney injury undergoing cardiac surgery.<sup>52</sup> Thus, despite the fact that fenoldopam is a potent direct renal vasodilator and promotes increased urine output, the drug does not appear to exert clinically meaningful protection against renal injury. Intravenous fenoldopam has a rapid onset of action as an antihypertensive medication. The drug undergoes hepatic metabolism and is excreted in the urine. The elimination half-life of fenoldopam is approximately 5 minutes. Unlike the findings with intravenous nitrovasodilators (see below), tolerance to fenoldopam's antihypertensive effects does not appear to occur. Rebound hypertension has also not been observed with abrupt discontinuation of the drug. The most common adverse effects of fenoldopam are related to its effects as a vasodilator and include hypotension, tachycardia, flushing, dizziness, headache, tachycardia, and nausea.

## Sympathomimetics

### *Ephedrine*

The sympathomimetic drug ephedrine exerts both direct and indirect actions on adrenoceptors. Endocytosis of ephedrine into  $\alpha_1$ - and  $\beta_1$ -adrenoceptor presynaptic postganglionic nerve terminals displaces norepinephrine from the synaptic vesicles. The displaced norepinephrine is then released to activate the corresponding postsynaptic receptors to cause arterial and venous vasoconstriction and increased myocardial contractility, respectively. This indirect action is the ephedrine's predominant pharmacologic effect. Indeed, ephedrine's initial cardiovascular effects resemble those of epinephrine because dose-related increases in heart rate, cardiac output, and systemic vascular resistance are observed. However, ephedrine is less potent than epinephrine, and the indirect acting sympathomimetic's duration of action is longer than that of the endogenous catecholamine. Ephedrine also directly stimulates  $\beta_2$ -adrenoceptors, which limits the increases in arterial pressure that occur as a result of  $\alpha_1$ -adrenoceptor activation. Tachyphylaxis to ephedrine's hemodynamic effects occurs with repetitive administration of the drug because presynaptic norepinephrine stores are quickly depleted and ephedrine is released from synaptic vesicles as a false neurotransmitter instead. In contrast, tachyphylaxis does not occur with epinephrine because

the endogenous catecholamine directly stimulates  $\alpha$ - and  $\beta$ -adrenoceptors independent of norepinephrine displacement and release. Notably, drugs that block the ephedrine uptake into adrenergic nerves (e.g., cocaine) and those that deplete norepinephrine reserves (e.g., reserpine) predictably attenuate the cardiovascular effects of ephedrine. The most common clinical use of ephedrine during anesthesia is treatment of acute decreases in arterial pressure concomitant with bradycardia. Ephedrine was previously used for the treatment of hypotension in laboring parturients because the drug increases uterine blood flow, but phenylephrine may be preferred in this setting because ephedrine crosses the placenta and may cause fetal acidosis.<sup>53</sup>

## *Phenylephrine*

The chemical structure of phenylephrine is similar to epinephrine: unlike the endogenous catecholamine, the sympathomimetic drug does not contain a hydroxyl group on the phenyl ring. As a result of this minor structural difference, phenylephrine almost exclusively stimulates  $\alpha_1$ -adrenoceptors to increase venous and arterial vasomotor tone while exerting little or no effect on  $\beta$ -adrenoceptors. In contrast to ephedrine, phenylephrine acts directly on the  $\alpha_1$ -adrenoceptor and is not dependent on presynaptic norepinephrine displacement to produce its cardiovascular effects. Phenylephrine constricts venous capacitance vessels and causes cutaneous, skeletal muscle, mesenteric, splenic, and renal vasoconstriction. These actions increase LV preload and afterload and cause dose-related increases in arterial pressure. Predictably, baroreceptor reflex-mediated decreases in heart rate also occur. Cardiac output usually remains relatively constant when LV function is normal, but cardiac output may decline when LV function is impaired<sup>54</sup> because failing myocardium is more sensitive to acute increases in afterload.<sup>55</sup> Phenylephrine also increases pulmonary artery pressures through pulmonary arterial vasoconstriction and greater venous return. Unlike endogenous or synthetic catecholamines, phenylephrine is not arrhythmogenic. Intravenous boluses or infusions of phenylephrine are most often used for treatment of hypotension in the presence of normal or elevated heart rate.

## **$\alpha_1$ -Adrenoceptor Antagonists**

On the basis of the previous discussion, it should be readily apparent that blockade of the  $\alpha_1$ -adrenoceptor in arterial and venous vascular smooth muscle causes vasodilation by inhibiting the actions of endogenous catecholamines and other sympathomimetic amines at this receptor subtype. For this reason,  $\alpha_1$ -adrenoceptor blockers were previously used for the treatment of essential hypertension, but  $\beta$ -blockers, ACE inhibitors,

angiotensin II receptor blockers (ARBs), Ca<sup>2+</sup> channel blockers, diuretics, and nitrates have largely replaced these drugs for this clinical indication in modern practice.  $\alpha_1$ -Adrenoceptor antagonists (e.g., prazosin) are certainly very effective antihypertensive medications, but many patients complained that the side effect profile, including debilitating orthostatic hypotension, baroreceptor reflex-mediated tachycardia<sup>56</sup> with or without palpitations, nasal congestion, and fluid retention, was intolerable during chronic use of these drugs. The presence of  $\alpha_1$ -adrenoceptor blockade also has the potential to cause unopposed  $\beta_1$ - and  $\beta_2$ -adrenoceptor activity. For example, epinephrine will activate only  $\beta_1$ - and  $\beta_2$ -adrenoceptors because the  $\alpha_1$ -adrenoceptor agonist effects of the catecholamine are inhibited. As a result, epinephrine produces pronounced tachycardia (a  $\beta_1$  effect) and severe hypotension (activation of  $\beta_2$  receptors causing arterial and venous vasodilation) when administered in the presence of an  $\alpha_1$ -adrenoceptor blocker. Similarly, norepinephrine and ephedrine only activate  $\beta_1$ -adrenoceptors because their  $\alpha_1$ -adrenoceptor agonist actions are inhibited. The pure  $\alpha_1$ -agonist phenylephrine also exerts little or no effect as a vasoconstrictor under these conditions. The response of a given vascular bed to an  $\alpha_1$ -adrenoceptor antagonist is dependent on its intrinsic level of vasoconstriction, as blood vessels with higher vascular smooth muscle tone will generally be more responsive to  $\alpha_1$ -adrenoceptor blockade.

Phenoxybenzamine is an orally administered, relatively nonselective  $\alpha$ -adrenoceptor antagonist that binds irreversibly to  $\alpha_1$ - and  $\alpha_2$ -adrenoceptors (the ratio of selectivity for these receptor subtypes is approximately 100:1). Because phenoxybenzamine's actions at  $\alpha$ -adrenoceptors are irreversible, synthesis of new receptors is required to reverse the drug's effects as a vasodilator. Phenoxybenzamine's prolonged half-life after oral administration also contributes to its sustained actions at the  $\alpha$ -adrenoceptor. Phenoxybenzamine is used almost exclusively to normalize arterial pressure before surgery in patients with pheochromocytoma.<sup>57</sup> The slow onset of  $\alpha$ -adrenoceptor blockade produced by phenoxybenzamine occurs because the molecule requires structural modification to become pharmacologically active. As a result, several weeks of treatment may be required to obtain adequate control of arterial pressure. Restoration of normal intravascular volume status is also an important goal of phenoxybenzamine therapy because hypovolemia resulting from elevated serum norepinephrine and epinephrine concentrations contributes to hemodynamic instability during pheochromocytoma resection. Subsequent addition of a  $\beta$ -adrenoceptor antagonist also helps in achieving these goals and also serves to protect the myocardium from the adverse effects of chronic catecholamine stimulation. These combined interventions facilitate greater cardiovascular stability during pheochromocytoma resection, which is usually associated with additional

release of norepinephrine and epinephrine into the circulation during tumor manipulation. The most prominent side effect of phenoxybenzamine therapy is orthostatic hypotension, which may be especially severe in the presence of pre-existing hypertension or hypovolemia. Vasopressin may be required to treat refractory hypotension associated with phenoxybenzamine overdose.

The competitive  $\alpha_1$ - and  $\alpha_2$ -adrenoceptor antagonist phentolamine is also used in patients with pheochromocytoma. In contrast to phenoxybenzamine, the effects of phentolamine are reversible (half-life less than 10 minutes) and new receptor synthesis is not required to restore  $\alpha$ -adrenoceptor activity and vascular smooth muscle tone. Phentolamine is a potent intravenous vasodilator that rapidly decreases arterial pressure, but in doing so, also causes baroreceptor reflex-mediated tachycardia. Blockade of cardiac  $\alpha_2$ -adrenoceptors by phentolamine may contribute to the development of arrhythmias. Phentolamine also exerts antihistamine and cholinergic activity, the latter of which may produce abdominal cramping and diarrhea. Because the drug causes hypotension and tachycardia, phentolamine is relatively contraindicated and should only be used with extreme caution in patients with flow-limiting coronary artery stenoses. Phentolamine is occasionally used as a local vasodilator to prevent tissue necrosis when iatrogenic extravasation of a vasoconstrictor (e.g., norepinephrine, phenylephrine) has occurred. The  $\alpha$ -adrenoceptor antagonist may also be effective when treating refractory hypertension associated with clonidine withdrawal or tyramine exposure in patients receiving a monoamine oxidase inhibitor.

Unlike phenoxybenzamine and phentolamine, prazosin is a relatively selective antagonist of  $\alpha_1$ -adrenoceptors ( $\alpha_1$  to  $\alpha_2$  ratio of approximately 1,000:1) that causes arterial and venous vasodilation.  $\alpha_2$ -Adrenoceptor modulation of norepinephrine release from postganglionic sympathetic neurons remains intact. As a result, baroreceptor reflex-mediated tachycardia is substantially attenuated after administration of prazosin. Nevertheless, orthostatic hypotension is an important clinical side effect of prazosin when the drug is used for the treatment of hypertension. Prazosin undergoes hepatic metabolism. The drug also increases the ratio of high- to low-density lipoproteins. In contrast with ACE inhibitors, prazosin does not improve survival in patients with heart failure and the drug is no longer recommended for this clinical indication as a result. Other  $\alpha_1$ -adrenoceptor antagonists (e.g., terazosin, doxazosin, tamsulosin) are used for the treatment of benign prostatic hyperplasia because the prostate contains a large number of  $\alpha_{1A}$ -adrenoceptors.<sup>58</sup> Patients who are treated with these medications occasionally present for surgery, and anesthesiologists should be aware that anesthetic-induced vasodilation might be exacerbated in the presence of these urologic  $\alpha_1$ -adrenoceptor antagonists.

## $\alpha_2$ -Adrenoceptor Agonists: Clonidine and Dexmedetomidine

The  $\alpha_2$ -adrenoceptor agonists clonidine and dexmedetomidine are commonly used by anesthesiologists and pain medicine specialists for sedation, anxiolysis, and analgesia.<sup>59,60</sup> Clonidine binds to  $\alpha_2$ -adrenoceptors and inhibits norepinephrine release from presynaptic postganglionic sympathetic neurons.  $\alpha_2$ -Adrenoceptor agonists block sympathetic nerve traffic through pre- and postsynaptic mechanisms in the central nervous system and also inhibit spinal presynaptic sympathetic nerve transmission. Clonidine is a partial  $\alpha_2$ -adrenoceptor agonist with relative selectivity for  $\alpha_2$ - versus  $\alpha_1$ -receptors of approximately 200:1. Because of its sympatholytic effects, clonidine was originally used for the treatment of hypertension. Activation of  $\alpha_2$ -adrenoceptors in the vasomotor center, attenuation of peripheral norepinephrine release from postganglionic sympathetic neurons, and stimulation of central nervous system imidazoline receptors are postulated mechanisms for the antihypertensive effect of clonidine.<sup>61,62</sup> Clonidine blunts centrally mediated sympathetic nervous system tone, decreases serum norepinephrine and norepinephrine concentrations, and reduces activation of the renin–angiotensin–aldosterone axis. In addition, clonidine stimulates parasympathetic nervous system activity, which, when combined with withdrawal of sympathetic tone, produces bradycardia. Unlike other antihypertensive medications, clonidine does not affect baroreceptor-mediated reflex control of heart rate.<sup>63</sup> The  $\alpha_2$ -adrenoceptor agonist is generally not associated with orthostatic hypotension when used in patients with hypertension, unlike  $\alpha_1$ -antagonists or ACE inhibitors. Nevertheless, hypotension and bradycardia may occur when large doses of the drug are administered. These effects are easily reversed with conventional vasoactive medications.

Clonidine continues to be used as an antihypertensive medication, but the drug also reduces volatile and intravenous anesthetic requirements, blunts the hemodynamic responses to laryngoscopy and endotracheal intubation, promotes intraoperative cardiovascular stability, partially attenuates the sympathetic stress response associated with surgery, and decreases postoperative tissue oxygen requirements.<sup>64–66</sup> Clonidine and other  $\alpha_2$ -adrenoceptor agonists including dexmedetomidine were shown to reduce the risk of myocardial ischemia and infarction and decrease perioperative mortality in patients undergoing major vascular or cardiac surgery, in a meta-analysis of 23 controlled trials in which more than 3,395 patients were enrolled.<sup>67</sup> These anti-ischemic actions were presumably related to the drug's sympatholytic effects, which reduce myocardial oxygen consumption. Clonidine augments the effects of local anesthetics and opioids and increases their duration of action when used for neuraxial and regional anesthesia.<sup>68</sup> As

a result, clonidine decreases the incidence and severity of side effects associated with local anesthetics and opioids because the quantities of these latter drugs required for anesthesia and analgesia are reduced. Clonidine is effective as a postoperative analgesic and also has well-documented utility in the treatment of chronic regional pain syndrome and neuropathic pain. The sedative and anxiolytic effects of clonidine are attributed to activation of  $\alpha_2$ -adrenoceptors in the locus coeruleus. Notably, clonidine does not substantially inhibit respiratory drive in the presence or absence of opioids despite the  $\alpha_2$ -adrenoceptor agonist's sedative effect.<sup>69</sup> Thus, clonidine's sedative–analgesic effects may be exploited without undo concern about the potential for respiratory depression. Hyperglycemia may occur in patients treated with clonidine because the  $\alpha_2$ -adrenoceptor agonist inhibits insulin release. This side effect may be especially important in patients with poorly controlled diabetes mellitus. Finally, anesthesiologists may occasionally encounter patients who are receiving clonidine to mitigate withdrawal symptoms associated with treatment of a substance abuse disorder.<sup>70</sup>

Discontinuation of clonidine may be necessary during the perioperative period if a patient is unable to ingest oral medications, but abrupt withdrawal of the  $\alpha_2$ -adrenoceptor agonist often results in severe hypertension associated with tachycardia, headache, anxiety, tremor, and diaphoresis. Under these circumstances, invasive monitoring of arterial pressure in an intensive care unit setting and treatment of hypertension with other intravenous medications may be necessary until oral clonidine therapy can be resumed.  $\beta$ -Blockers should not be used alone under such circumstances because unopposed  $\alpha_1$ -adrenoceptor stimulation causes profound vasoconstriction, thereby worsening the hypertensive emergency. Alternatively, transdermal clonidine may be used to mitigate or prevent drug withdrawal–induced hypertensive emergency in those patients who are unable to consume the medication. It is important to note that transdermal clonidine requires approximately 48 hours after initial application to achieve therapeutic serum concentrations.

Dexmedetomidine is approximately sevenfold more selective for the  $\alpha_2$ -adrenoceptor ( $\alpha_2$  to  $\alpha_1$  ratio of 1,600:1) and has a substantially shorter context-sensitive half-life than clonidine. These characteristics make an intravenous infusion of dexmedetomidine useful for sedation, amnesia, and analgesia in the operating room and intensive care unit.<sup>71,72</sup> Like clonidine, dexmedetomidine reduces anesthetic requirements during general, neuraxial, and regional anesthesia; decreases heart rate, arterial pressure, and plasma catecholamine concentrations; attenuates intraoperative cardiovascular lability; and does not cause clinically significant respiratory depression. This latter feature is especially beneficial in the setting of elective fiberoptic intubation or weaning from mechanical ventilation. Dexmedetomidine's relative preservation of respiratory drive and its lack of

effects on electrophysiologic monitoring make the  $\alpha_2$ -adrenoceptor agonist useful for functional neurosurgery.<sup>73</sup> Dexmedetomidine exerts neuroprotective effects against cerebral ischemia and hypoxia; this neuroprotection appears to be related to a direct cytoprotective effect.<sup>74</sup> Dexmedetomidine also facilitates perioperative care of obese patients with obstructive sleep apnea and those undergoing bariatric surgery because the drug provides analgesia, reduces opioid requirements, and does not substantially depress respiration.<sup>75</sup> When used as a sedative in the intensive care patients, dexmedetomidine reduced the incidence of delirium, the duration of mechanical ventilation, the length of intensive care unit stay, and mortality compared with midazolam.<sup>76</sup> Dexmedetomidine may be associated with hypothermia because the drug lowers the threshold body temperature at which compensatory thermoregulation mechanisms are activated.

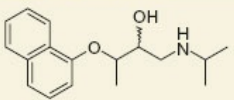

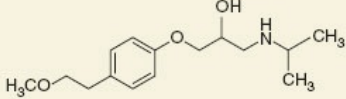

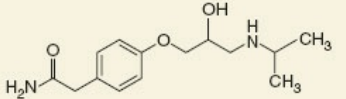

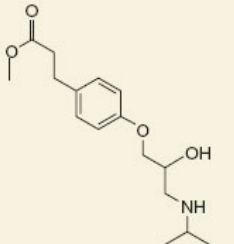

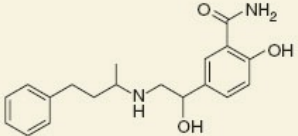

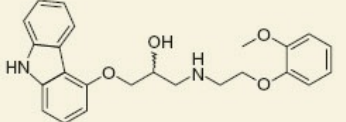

## **$\beta$ -Adrenoceptor Antagonists ( $\beta$ -Blockers)**

Many of the cardiovascular effects of  $\beta$ -adrenoceptor antagonists (more commonly called “ $\beta$ -blockers”) may be anticipated based on the previous discussion of catecholamines. The peer-reviewed literature describing the actions, uses, and potential limitations of  $\beta$ -blockers is exhaustive. It is not the authors’ intention to review this literature in detail; instead, we wish to highlight the major effects and clinical applications of the most ubiquitous drugs in cardiovascular pharmacology.  $\beta$ -Blockers produce important anti-ischemic effects and are a first-line therapy for patients with ST- and non-ST-segment elevation, myocardial infarction in the absence of cardiogenic shock, hemodynamically significant bradyarrhythmias, or reactive airway disease. These medications have been repeatedly shown to reduce morbidity and mortality associated with myocardial infarction in a large number of clinical trials.  $\beta$ -Blockers bind to  $\beta_1$ -adrenoceptors and inhibit the actions of circulating catecholamines and norepinephrine released from postganglionic sympathetic neurons. As a result, heart rate and myocardial contractility are reduced. The decrease in heart rate produced by  $\beta$ -blockers prolongs diastole, increases coronary blood flow to the LV, enhances coronary collateral perfusion to ischemic myocardium, and improves oxygen delivery to the coronary microcirculation. These combined effects serve to reduce myocardial oxygen demand while simultaneously increasing supply.  $\beta$ -Blockers have also been shown to inhibit platelet aggregation. This latter action is particularly important during acute myocardial ischemia or evolving myocardial infarction because platelet aggregation at the site of an atherosclerotic plaque may worsen a coronary stenosis or produce acute occlusion of the vessel.  $\beta$ -Blockers are very effective for the treatment of essential hypertension, produce antiarrhythmic effects through negative chronotropic actions, and

have well-established roles in the treatment of heart failure, hypertrophic obstructive cardiomyopathy, aortic dissection, thyrotoxicosis, pheochromocytoma, and migraine headache prophylaxis. Topical  $\beta$ -blockers are also used for treatment of open-angle glaucoma. Perhaps, of most relevance to anesthesiologists, perioperative administration of  $\beta$ -blockers has been shown to reduce the incidence of nonfatal myocardial infarction in patients undergoing noncardiac surgery.<sup>77,78</sup> These drugs are specifically recommended for patients with documented or multiple risk factors for myocardial ischemia,<sup>79</sup> but not those without convincing evidence of coronary artery disease.<sup>80,81</sup>

Propranolol is the prototypical  $\beta$ -blocker against which all other medications in this pharmacologic class are compared (Table 13-6). Propranolol and other  $\beta$ -blockers are chemically related to isoproterenol and contain an aromatic moiety linked to the ethanolamine group, the latter of which allows interaction with the  $\beta$ -adrenoceptor. Additions to the molecule's aromatic group determine the degree of  $\beta_1$ -adrenoceptor specificity. All  $\beta$ -blockers have a chiral center; the negative enantiomer of each drug is biologically active. The relative selectivity of  $\beta$ -blockers for  $\beta_1$ - and  $\beta_2$ -adrenoceptors, their lipid solubility, and the presence or absence of intrinsic sympathomimetic ability (e.g., partial stimulation of the  $\beta_1$ -adrenoceptor), myocardial membrane stabilizing activity, and additional cardiovascular actions combine with each drug's pharmacokinetic effects to distinguish individual  $\beta$ -blockers from one another. The ability to prevent isoproterenol-induced increases in heart rate defines each  $\beta$ -blocker's potency (propranolol is considered the standard in these determinations). Propranolol is a "first-generation" (nonselective)  $\beta$ -blocker that competitively inhibits both  $\beta_1$ - and  $\beta_2$ -adrenoceptors, whereas metoprolol, atenolol, and esmolol are classified as "second-generation"  $\beta$ -blockers because these drugs are selective for the  $\beta_1$ -adrenoceptor. Notably, this  $\beta_1$ -adrenoceptor selectivity is relative because larger doses of second-generation  $\beta$ -blockers inhibit both  $\beta_1$ - and  $\beta_2$ -adrenoceptors. "Third-generation"  $\beta$ -blockers exert other cardiovascular effects in addition to their actions at  $\beta$ -adrenoceptors. For example, labetalol blocks  $\alpha_1$ -adrenoceptors; carvedilol exerts antioxidant and anti-inflammatory actions; bucindolol has intrinsic sympathomimetic effects because it is a partial agonist of  $\beta_1$ -adrenoceptors; and nebivolol produces nitric oxide-mediated vasodilation through its actions on vascular endothelium.

**Table 13-6** Comparative Effects of  $\beta$ -blockers

Name	Chemical Structure	$\beta_1$	Selectivity $\beta_2$	$\alpha_1$	Plasma Half-life (hrs)	Intrinsic Sympathomimetic Activity	Membrane Stabilizing Activity	Lipid Solubility	Metabolism
Propranolol		+	+	0	3-4	0	+	+++	Liver
Metoprolol		+	0	0	3-4	0	0	++	Liver
Atenolol		+	0	0	6-9	0	0	+	Renal
Esmolol		+	0	0	0.15	0	0	+	RBC esterase
Labetalol		+	+	+	6	+	0	+	Liver
Carvedilol		+	+	+	2-8	0	+	+++	Liver

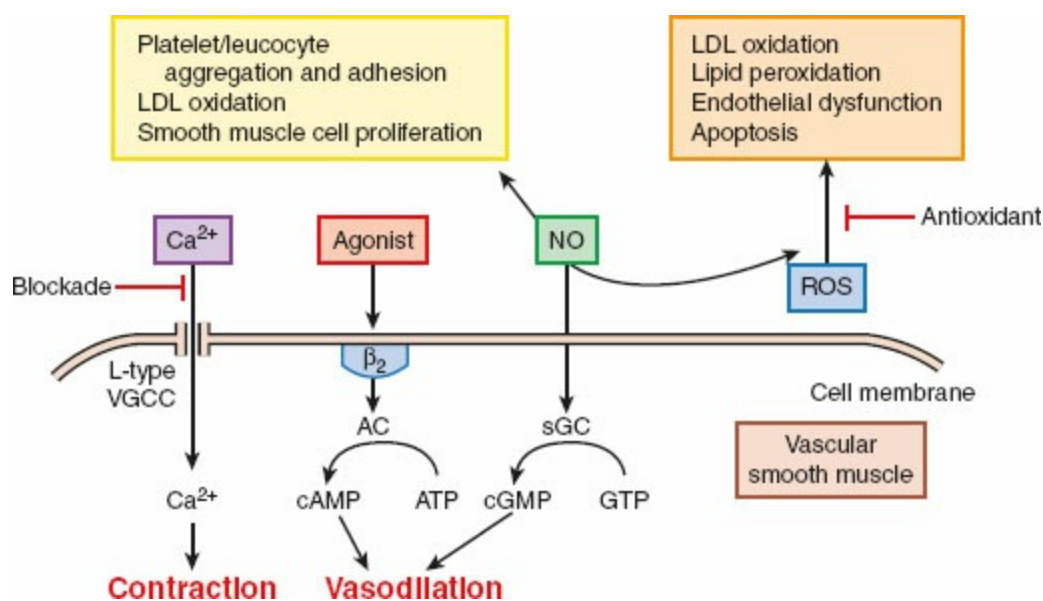

RBC, red blood cell.

The reductions in heart rate and myocardial contractility produced by  $\beta$ -blockers are more pronounced in the presence of increased sympathetic nervous system tone (e.g., surgical stress, exercise, heart failure) because vagal activity is usually the predominant factor regulating cardiovascular homeostasis during basal conditions. Nonselective  $\beta$ -blockers initially reduce cardiac output as a result of negative chronotropic and inotropic effects concomitant with arterial vasoconstriction mediated through blockade of vascular smooth muscle  $\beta_2$ -adrenoceptors and compensatory sympathetic stimulation of  $\alpha_1$ -adrenoceptors. The initial increase in systemic vascular resistance that occurs with a nonselective  $\beta$ -blocker gradually declines during long-term administration.<sup>82</sup> Selective  $\beta_1$ -blockers with or without  $\alpha_1$ -adrenoceptor antagonist activity, and those with direct vasodilator effects, generally reduce systemic vascular resistance and preserve cardiac output to varying degrees despite simultaneous depression of myocardial contractility.  $\beta$ -Blockers are used extensively for the treatment of hypertension, but the precise mechanisms by which  $\beta$ -blockers that do not have specific additional vasodilating properties are able to reduce arterial blood pressure remain to be clearly defined (Fig. 13-6). Stimulation of  $\beta_1$ -adrenoceptors in renal

juxtaglomerular cells by the sympathetic postganglionic neurons causes renin secretion and activates the renin–angiotensin–aldosterone axis (see below). Many  $\beta$ -blockers inhibit this renin release, but their antihypertensive effects usually occur before plasma renin concentrations decline.<sup>83</sup> Similarly, some  $\beta$ -blockers also do not substantially affect renin metabolism and yet are quite effective at reducing arterial pressure in hypertensive patients. It is also unlikely that  $\beta$ -blockers cause antihypertensive effects through a decrease in centrally mediated sympathetic nervous system tone because drugs with markedly different lipid solubility are equally effective at decreasing arterial pressure.  $\beta$ -Blockers most likely do not favorably modulate postganglionic sympathetic neuron norepinephrine release despite the presence of presynaptic  $\beta$ -adrenoceptors that are known to stimulate release of the neurotransmitter. Clearly, selective  $\beta$ -blockers that do not affect  $\beta_2$ -adrenoceptor viability (“second-generation”) and those that inhibit  $\alpha_1$ -adrenoceptors or produce vasodilation through other mechanisms also decrease arterial pressure (Fig. 13-6).<sup>84</sup> Nevertheless, nonselective  $\beta$ -blockers such as propranolol are valuable antihypertensive medications independent of these alternative vasodilating characteristics.

$\beta$ -Blockers have been a mainstay in the pharmacologic treatment of acute myocardial ischemia and infarction since their introduction into clinical practice in the 1960s. As mentioned previously,  $\beta$ -blockers directly reduce myocardial oxygen consumption and improve coronary perfusion, thereby enhancing myocardial oxygen supply–demand relations and decreasing ischemic burden. These actions reduce the magnitude of myocardial necrosis, preserve LV systolic function, attenuate the development of malignant ventricular arrhythmias, decrease mortality, and improve long-term functional capacity. The results supporting the use of  $\beta$ -blockers in acute myocardial infarction are among the most convincing data ever published in the medical literature. Many placebo-controlled randomized double-blind clinical trials demonstrated unequivocally that  $\beta$ -blockers are not only effective for treatment of acute myocardial infarction but also substantially decrease the risk of developing a subsequent infarction in patients with coronary artery disease.<sup>85,86</sup> Indeed, the estimated overall reduction in mortality associated with use of  $\beta$ -blockers in myocardial infarction is approximately 25%.<sup>87</sup>  $\beta$ -Blockers also have well-established efficacy for the chronic treatment of heart failure. The use of  $\beta$ -blockers in heart failure was initially viewed with skepticism because administration of a drug that further depresses myocardial contractility would appear to be counterintuitive. However, sympathetic nervous system tone is chronically elevated in heart failure, and this excessive sympathetic activity produces a series of alterations in  $\beta_1$ -adrenoceptor density and function, intracellular signal transduction, contractile protein expression, and  $\text{Ca}^{2+}$  homeostasis that promote

mitochondrial dysfunction, stimulate myocyte apoptosis (programmed cell death), cause pathologic ventricular remodeling, and accelerate disease progression.<sup>88,89</sup> Clinical trials demonstrated that  $\beta$ -blockers significantly decrease mortality in patients with heart failure independent of disease severity.<sup>90</sup> In fact, some large randomized studies were halted before completion because patients with moderate to severe heart failure receiving  $\beta$ -blockers had markedly improved mortality compared with those treated with placebo.<sup>91</sup>  $\beta$ -Blockers mitigate clinical symptoms, improve exercise tolerance, reduce the need for and duration of subsequent hospitalization, and decrease the risk of sudden cardiac death in patients with heart failure.<sup>92</sup>

**Figure 13-6** Schematic illustration of potential mechanism by which  $\beta$ -blockers produce vasodilation; abbreviations: VGCC, voltage-gated  $Ca^{2+}$  channel; AC, adenylyl cyclase; NO, nitric oxide; sGC, soluble guanylyl cyclase; ROS, reactive oxygen species; LDL, low-density lipoprotein. (Modified with permission from Toda N. Vasodilating  $\beta$ -adrenoceptor blockers as cardiovascular therapeutics. *Pharmacol Ther*, 2003, 100:215–234. Copyright 2003 Elsevier Inc. All rights reserved.)

The electrophysiologic effects of  $\beta$ -blockers make these drugs quite useful for the treatment of tachyarrhythmias.  $\beta$ -Blockers reduce SA node automaticity, inhibit the activity of subsidiary ectopic pacemakers, decrease impulse conduction velocity through atrial conduction pathways, prolong conduction time through the AV node, and increase the AV node's refractory period. Both  $\beta_1$ - and  $\beta_2$ -adrenoceptors mediate these negative chronotropic and dromotropic effects.<sup>20</sup> Some  $\beta$ -blockers also exert membrane-stabilizing activity that may theoretically contribute to their antiarrhythmic efficacy, but these “quinidine-like” actions are most likely only of clinical relevance when a  $\beta$ -blocker overdose has occurred.  $\beta$ -Blockers are used to reduce ventricular rate in patients with sinus tachycardia, atrial fibrillation or flutter,

supraventricular tachycardia, and re-entrant tachyarrhythmias (e.g., Wolff–Parkinson–White, Lown–Ganong–Levine).  $\beta$ -Blockers inhibit tachycardia in response to laryngoscopy and endotracheal intubation.  $\beta$ -Blockers also attenuate baroreceptor-mediated reflex sinus tachycardia in response to vasodilator therapy. For example, administration of a  $\beta$ -blocker mitigates the reflex tachycardia associated with an  $\alpha_1$ -adrenoceptor antagonist used to reduce arterial pressure in pheochromocytoma.  $\beta$ -Blockers also attenuate the development of cardiomyopathy resulting from elevated catecholamine concentrations in this disease. When combined with intravenous vasodilator therapy (e.g., sodium nitroprusside, clevidipine), the negative chronotropic and inotropic effects of  $\beta$ -blockers reduce heart rate and proximal ascending aortic shear stress in acute Stanford type A (DeBakey type I or II) aortic dissection. Analogously,  $\beta$ -blockers reduce the risk of aortic dissection and the rate of ascending aortic dilatation in patients with Marfan’s syndrome by decreasing pulsatile hydraulic forces on the proximal aortic root.<sup>93</sup>  $\beta$ -Blockers decrease heart rate and inhibit the development of tachyarrhythmias in hyperthyroidism and thyroid storm, in part by preventing the peripheral conversion of thyroxine to its more active triiodothyronine form. As a result,  $\beta$ -blockers are useful adjuncts to propylthiouracil in the treatment of hyperthyroidism.  $\beta$ -Blocker-induced declines in heart rate concomitant with depression of myocardial contractility substantially reduce dynamic LV outflow tract pressure gradient and the magnitude-associated mitral regurgitation while improving symptoms in patients with hypertrophic obstructive cardiomyopathy.<sup>94</sup>

Topical  $\beta$ -blockers (e.g., timolol, betaxolol) are used for the treatment of open-angle glaucoma. These drugs reduce aqueous humor production but do not affect pupil size or accommodation, unlike topical anticholinergic medications. It is important to recognize that these topical  $\beta$ -blockers may be systemically absorbed and thus, may exert adverse cardiovascular or pulmonary side effects. As a result, topical  $\beta$ -blockers may be relatively contraindicated in patients with symptomatic bradyarrhythmias or bronchospastic lung disease. A role for  $\beta$ -blockers in prophylaxis against migraine headache is well established, but the mechanism for this beneficial effect remains unclear.<sup>95</sup>  $\beta$ -Blockers may also be useful for reducing sympathetically mediated symptoms, including palpitations, tachycardia, and tremor, associated with performance situations that provoke anxiety (e.g., public speaking, oral examinations). Similarly,  $\beta$ -blockers may also be helpful in controlling sympathetic nervous system activation that occurs with drug withdrawal in patients with substance use disorders.

$\beta$ -Blockers are associated with a number of important adverse effects. Despite the well-established beneficial effects of  $\beta$ -blockers in patients with heart failure, the negative inotropic effects of these drugs may worsen heart

failure symptoms and lead to further decompensation in some patients with severe LV dysfunction. Abrupt withdrawal of a  $\beta$ -blocker after long-term treatment may produce myocardial ischemia and infarction or cause sudden cardiac death in susceptible patients with critical coronary artery stenoses. Because of the electrophysiologic effects of  $\beta$ -blockers, second- or third-degree heart block may occur in patients with pre-existing AV conduction abnormalities or those treated with other negative dromotropic drugs (e.g., diltiazem, verapamil).<sup>96</sup> Nonselective  $\beta$ -blockers inhibit  $\beta_2$ -adrenoceptors in arterial vascular smooth muscle. The resulting vasoconstriction may occasionally worsen vascular insufficiency in patients with peripheral vascular disease or precipitate Raynaud's phenomenon in susceptible individuals. Nevertheless,  $\beta$ -blockers remain a mainstay in the treatment of patients with peripheral vascular disease because the vast majority of these patients also have clinically significant coronary artery disease that substantially increases their risk of myocardial ischemia, arrhythmias, and mortality. Propranolol and other first-generation  $\beta$ -blockers inhibit bronchial  $\beta_2$ -adrenoceptors and may cause potentially fatal bronchoconstriction in patients with asthma or chronic obstructive pulmonary disease. Long-term use of  $\beta_1$ -blockers (e.g., atenolol) for the treatment of hypertension, myocardial ischemia and infarction, or heart failure must be approached with caution in patients with reactive airway disease because the  $\beta_1$ -selectivity of these drugs is not absolute and suitable alternative medications are available (e.g.,  $\text{Ca}^{2+}$  channel blockers, nitrates, ACE inhibitors) to manage these conditions. Nevertheless, a selective  $\beta_1$ -adrenoceptor antagonist may be advantageous in some patients with coronary artery disease who also suffer from chronic obstructive pulmonary disease.<sup>97</sup>  $\beta$ -Blockers also interfere with carbohydrate and lipid metabolism. Endogenous catecholamines stimulate glycogenolysis, lipolysis, and gluconeogenesis, promoting the release of glucose into the circulation when hypoglycemia is present. Nonselective  $\beta$ -blockers may inhibit this physiologic response to and recovery from hypoglycemia, especially in patients with type I diabetes mellitus. Nonselective  $\beta$ -blockers also attenuate the sympathetically mediated tremor, tachycardia, and anxiety associated with hypoglycemia. Thus, nonselective  $\beta$ -blockers may be relatively contraindicated in patients with poorly controlled diabetes who often develop hypoglycemic episodes, and drugs with  $\beta_1$ -selectivity may be preferred in this setting.<sup>98</sup>

### **Propranolol**

As mentioned previously, propranolol is the prototypical nonselective  $\beta$ -blocker. Available in oral and intravenous forms, propranolol inhibits  $\beta_1$ - and  $\beta_2$ - but not  $\alpha_1$ -adrenoceptors and possesses some degree of membrane

stabilization activity at higher doses, but does not exert intrinsic sympathetic activity. The medication is highly lipophilic, easily absorbed from the stomach, and undergoes extensive first-pass hepatic metabolism. A high degree of variability between patients is observed in propranolol metabolism between patients. Liver disease and reductions in hepatic blood flow, but not renal impairment, delay the drug's metabolism and require dose adjustment. Propranolol is used for treatment of hypertension and symptomatic coronary artery disease. Despite a relatively short half-life (approximately 4 hours), propranolol can most often be administered using a twice-per-day dosing regimen because of a persistent antihypertensive effect. Several weeks of propranolol treatment are often required to achieve optimal reduction in arterial pressure. Inhibition of tachycardia during exercise indicates adequate  $\beta$ -blockade. Intravenous propranolol was used for treatment of tachyarrhythmias, but esmolol is preferred for this indication in current clinical practice because of its short half-life. The landmark Beta-Blocker Heart Attack Trial demonstrated that propranolol therapy substantially decreases mortality (7.2% compared with 9.8%) in patients with acute myocardial infarction.<sup>99</sup> Use of propranolol has gradually decreased with the widespread application of other  $\beta_1$ -selective blockers and third-generation drugs with other cardiovascular actions.

### *Metoprolol*

Metoprolol is relatively selective for  $\beta_1$ -adrenoceptors but has no intrinsic sympathetic or membrane stabilization activity. The drug is available in oral and intravenous forms. Like propranolol, oral metoprolol is rapidly absorbed, but the drug does undergo first-pass hepatic metabolism by cytochrome P450 2D6 that limits its initial availability. The kidney excretes less than 10% of the drug in its original form. Metoprolol's half-life of 3 to 4 hours allows twice-per-day dosing in patients with normal metabolism, but an extended release form is also available that allows once-daily administration. The half-life of metoprolol is doubled in patients who are poor cytochrome P450 2D6 metabolizers; these individuals are approximately fivefold more likely to develop adverse side effects after oral metoprolol administration.<sup>100</sup> Metoprolol is commonly used for treatment of hypertension, angina pectoris, acute myocardial infarction, and chronic heart failure.<sup>101</sup>

### *Atenolol*

Like metoprolol, atenolol is a selective inhibitor of  $\beta_1$ -adrenoceptors and does not possess intrinsic sympathetic or membrane stabilization activity. The drug has a longer half-life (6 to 9 hours) than metoprolol that facilitates a daily

dosing regimen. The liver does not metabolize atenolol, most of which is excreted in its original form by the kidney. As a result, the dose of atenolol must be reduced in patients with moderate to severe renal insufficiency. The lack of first-pass hepatic metabolism reduces variability in plasma atenolol concentrations between patients after oral administration.<sup>102</sup> Similar to other  $\beta$ -blockers, atenolol is used for the treatment of hypertension, coronary artery disease, acute myocardial infarction, and heart failure.

### *Esmolol*

Esmolol is a relatively selective  $\beta_1$ -blocker. The chemical structure of esmolol is very similar to that of propranolol and metoprolol, but esmolol contains an additional methylester group that facilitates the drug's rapid metabolism via hydrolysis by red blood cell esterases, resulting in an elimination half-life of approximately 9 minutes. The quick onset and rapid metabolism of esmolol makes the drug very useful for the treatment of acute tachycardia and hypertension during surgery. Esmolol is most often administered as an intravenous bolus, which causes almost immediate dose-related decreases in heart rate and myocardial contractility; arterial pressure most often falls as a result of these direct negative chronotropic and inotropic effects. Esmolol is often used to attenuate the sympathetic nervous system response to laryngoscopy, endotracheal intubation, or surgical stimulation, particularly in patients with known or suspected coronary artery disease who may be at risk for acute myocardial ischemia. Esmolol is also useful for rapid control of heart rate in patients with supraventricular tachyarrhythmias (e.g., atrial fibrillation, atrial flutter). Finally, esmolol effectively blunts the sympathetically mediated tachycardia and hypertension that occur shortly after the onset of seizure activity during electroconvulsive therapy. Because esmolol does not appreciably block  $\beta_2$ -adrenoceptors due to its relative  $\beta_1$ -selectivity, hypotension is more commonly observed after administration of this drug compared with other nonselective  $\beta$ -blockers.

### *Labetalol*

Labetalol is composed of four stereoisomers that inhibit  $\alpha$ - and  $\beta$ -adrenoceptors to varying degrees.<sup>103</sup> One of the four stereoisomers is an  $\alpha_1$ -adrenoceptor antagonist, another is a nonselective  $\beta$ -blocker, and the remaining two do not appreciably affect adrenergic receptors. The net effect of this mixture is a drug that selectively inhibits  $\alpha_1$ -adrenoceptors while simultaneously blocking  $\beta_1$ - and  $\beta_2$ -adrenoceptors in a nonselective manner. The intravenous formulation of labetalol contains a ratio of  $\alpha_1$ - to  $\beta$ -blockade of approximately 1:7. Blockade of the  $\alpha_1$ -adrenoceptor causes arteriolar

vasodilation and decreases arterial pressure through a reduction in systemic vascular resistance. This property makes the drug very useful for the treatment of perioperative hypertension. Despite its nonselective  $\beta$ -blocking properties, labetalol is also a partial  $\beta_2$ -adrenoceptor agonist; this latter characteristic also contributes to vasodilation. Labetalol-induced inhibition of  $\beta_1$ -adrenoceptors decreases heart rate and myocardial contractility. Stroke volume and cardiac output are essentially unchanged as a result of the combined actions of labetalol on  $\alpha_1$ - and  $\beta_2$ -adrenoceptors. Unlike other vasodilators, labetalol produces vasodilation without triggering baroreceptor reflex tachycardia because the drug blocks anticipated increases in heart rate mediated through  $\beta_1$ -adrenoceptors. This latter action is beneficial for the treatment of hypertension in the setting of acute myocardial ischemia. Labetalol is also useful for controlling arterial pressure without producing tachycardia in patients with hypertensive emergencies and those with acute aortic dissection. Labetalol has been shown to attenuate the sympathetic nervous system response to laryngoscopy and endotracheal intubation, although the drug's relatively long elimination half-life (approximately 6 hours) limits its utility in this setting.

### **Carvedilol**

Carvedilol is another third-generation  $\beta$ -blocker that inhibits  $\beta_1$ -,  $\beta_2$ -, and  $\alpha_1$ -adrenoceptors.<sup>104</sup> Like labetalol, the drug causes arterial vasodilation because it is an  $\alpha_1$ -adrenoceptor antagonist. The drug is a membrane stabilizer but lacks intrinsic sympathomimetic activity. Carvedilol exerts important antioxidant and anti-inflammatory effects: the drug not only suppresses production of reactive oxygen species, but it also is a scavenger of these free radical intermediates. The antioxidant and anti-inflammatory actions of carvedilol inhibit the uptake of deleterious oxidized low-density lipoproteins into coronary vascular endothelium and protect myocardium against ischemia-reperfusion injury, in part by attenuating recruitment, chemotaxis, and activation of cytotoxic neutrophils.<sup>105</sup> Carvedilol is commonly used in the treatment of hypertension, stable angina pectoris, and acute myocardial infarction, but the drug has been shown to be particularly efficacious in patients with heart failure. Several large clinical trials provided convincing evidence that carvedilol improves LV function, reverses or slows the progression of pathologic LV remodeling, decreases the need for and the duration of subsequent hospitalization, and substantially reduces mortality in chronic heart failure resulting from a variety of underlying causes including coronary artery disease.<sup>106</sup> In fact, the beneficial effects of carvedilol appear to be greater than those of metoprolol in heart failure, and several experts have opined that carvedilol should be the preferred therapeutic option in this

clinical setting.<sup>107</sup> Carvedilol is very lipophilic, is nearly entirely absorbed after oral administration, and, similar to propranolol and metoprolol, undergoes extensive first-pass hepatic oxidative metabolism via cytochrome P450 2D6 with little or no dependence on the kidney for elimination.

## Phosphodiesterase Inhibitors

The phosphodiesterases are structurally related enzymes that hydrolyze the second messengers cAMP and cGMP and terminate their physiologic effects in a variety of tissues. At least seven different phosphodiesterase isoform subtypes have been identified. Inhibitors of these enzymes enhance the intracellular effects of cAMP and cGMP by preventing their metabolism. The phosphodiesterase inhibitors currently in clinical use are somewhat isoenzyme-selective at lower doses, but this selectivity is lost when higher doses of these medications are used. Myocardium and vascular smooth muscle contain the type III phosphodiesterase isoenzyme (PDE III), which is bound to the sarcoplasmic reticulum and cleaves cAMP to adenosine monophosphate (AMP).<sup>108</sup> Selective inhibition of cardiac PDE III by bipyridine compounds such as milrinone and inamrinone alters intracellular  $\text{Ca}^{2+}$  regulation to enhance myocardial contractility without affecting catecholamine release or activation of  $\beta_1$ -adrenoceptors. PDE III inhibitors increase cAMP concentration, enhance protein kinase A activity, and phosphorylate voltage-dependent  $\text{Ca}^{2+}$  channels<sup>109</sup> and phospholamban, the major sarcoplasmic reticulum regulatory protein.<sup>110</sup> These actions combine to increase transsarcolemmal  $\text{Ca}^{2+}$  influx into the cardiac myocyte and promote  $\text{Ca}^{2+}$ -induced  $\text{Ca}^{2+}$  release from its sarcoplasmic reticulum, thereby exerting a positive inotropic effect because larger quantities of  $\text{Ca}^{2+}$  are available for contractile activation. Inhibition of cAMP metabolism also stimulates greater  $\text{Ca}^{2+}$  uptake into the sarcoplasmic reticulum. As a result, PDE III inhibitors enhance the rate and extent of myocardial relaxation. This positive lusitropic effect serves to improve diastolic function in many patients with heart failure.

PDE III inhibitors cause pronounced arterial and venous vasodilation by blocking cGMP-metabolism and facilitating the actions of this second messenger in vascular smooth muscle. The proclivity of PDE III inhibitors to simultaneously enhance contractility and cause vasodilation defines these medications as “inodilators.” PDE III inhibitors cause relatively greater vasodilation than drugs with  $\beta_2$ -adrenoceptor agonist activity, including dobutamine and isoproterenol. This reduction in LV afterload increases cardiac output, improves LV-arterial coupling, and enhances mechanical efficiency. Intravenous or inhalational administration of PDE III inhibitors also reduces pulmonary vascular resistance, an action that may be particularly helpful in patients with pulmonary arterial hypertension who are undergoing

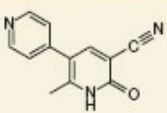

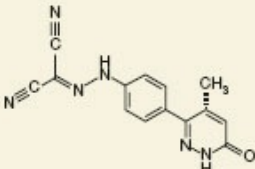

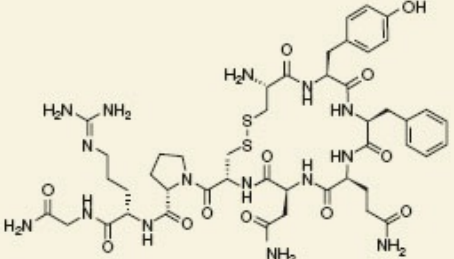

cardiac surgery or transplantation.<sup>111,112</sup> However, this pulmonary vasodilation is capable of increasing intrapulmonary shunt and contributing to the development of hypoxemia. PDE III inhibitors also dilate venous capacitance vessels and reduce preload. Notably, decreases in preload and afterload resulting from administration of a PDE III inhibitor often lead to reductions in myocardial oxygen consumption in patients with heart failure despite simultaneous positive inotropic, lusitropic, and chronotropic effects.<sup>113</sup> In general, mean arterial pressure is either maintained or may be modestly reduced during administration of PDE III inhibitors provided that intravascular volume is adequately supplemented because increases in cardiac output are capable of compensating for reductions in afterload.

PDE III inhibitors cause increases in heart rate that are less pronounced than those observed during administration of catecholamines. Indeed, a selective  $\beta_1$  adrenoceptor antagonist may abolish the positive chronotropic effects of a PDE III inhibitor without depressing the latter drug's positive inotropic effect. PDE III inhibitors may precipitate the development of malignant ventricular arrhythmias because these drugs increase intracellular cAMP and  $\text{Ca}^{2+}$  concentrations.<sup>114</sup> PDE III inhibitors block platelet aggregation, suppress neointimal hyperplasia associated with endothelial injury, and attenuate the proinflammatory effects of cardiopulmonary bypass.<sup>115</sup> In addition, these drugs dilate native epicardial coronary arteries and arterial bypass conduits.<sup>116</sup> As a result, PDE III inhibitors have the potential to exert important anti-ischemic effects in patients with coronary artery disease undergoing CABG surgery. The efficacy of PDE III inhibitors is reduced in the failing heart, but not to the extent observed with  $\beta_1$  adrenoceptor agonists. Thus, PDE III inhibitors will continue to enhance myocardial contractility despite concomitant  $\beta$  adrenoceptor downregulation and dysfunction.<sup>113</sup> This pharmacologic property stimulated the conduct of a number of large clinical trials designed to evaluate the utility of orally administered PDE III inhibitors for the treatment of chronic severe heart failure. Although PDE III inhibitors did enhance cardiac performance and improve apparent quality of life in these studies, the drugs also significantly increased mortality resulting from ventricular arrhythmias and sudden cardiac death.<sup>117</sup> Hence, while the use of PDE III inhibitors is contraindicated for the treatment of chronic heart failure, these drugs continue to be of central importance for the treatment of acute LV dysfunction during cardiac surgery and in the intensive care unit. The authors often use the combination of a **9** PDE III inhibitor and a  $\beta_1$ -adrenoceptor agonist when weaning patients with pre-existing LV systolic dysfunction from cardiopulmonary bypass because these drugs produce synergistic effects on cAMP-mediated intracellular signaling.

Milrinone (Table 13-7) and inamrinone are PDE III inhibitors that have

been used extensively for inotropic support during and after cardiac surgery. Milrinone is 15- to 20-fold more potent than the chemically similar compound inamrinone. Milrinone enhances myocardial contractility and causes arterial and venous vasodilation, thereby improving the likelihood of successful weaning of patients with poor LV function from cardiopulmonary bypass.<sup>118</sup> The pharmacokinetics and pharmacodynamics of milrinone were extensively studied in patients undergoing cardiac surgery<sup>119</sup> and those in the intensive care unit.<sup>120</sup> Milrinone loading doses of 25 or 50  $\mu\text{g} \cdot \text{kg}^{-1}$  and infusion rates ranging between 0.375 and 0.75  $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$  are useful for increasing cardiac output and oxygen delivery in these clinical settings. Inamrinone was the first clinically used phosphodiesterase III inhibitor and exerted cardiovascular effects that were almost identical to those of milrinone, but use of the drug for the treatment of LV dysfunction was abandoned because of its propensity to cause profound thrombocytopenia during prolonged use.<sup>121</sup>

**Table 13-7** Comparative Effects of Milrinone, Levosimendan, and Vasopressin

Name	Chemical Structure	Mechanism of Action	Dose Range	Clinical Indications	Major Side Effects
Milrinone		PDE III inhibition	Load: 25–50 $\mu\text{g}/\text{kg}$ IV: 0.375–0.75 $\mu\text{g}/\text{kg}/\text{min}$	Acute LV dysfunction	Arrhythmias Myocardial ischemia Sudden cardiac death Hypertension Stroke
Levosimendan		Myofilament $\text{Ca}^{2+}$ sensitization PDE III Inhibition $\text{K}_{\text{ATP}}$ channel opener	Load: 12–24 $\mu\text{g}/\text{kg}$ IV: 0.05–0.2 $\mu\text{g}/\text{kg}/\text{min}$	Acute LV dysfunction Heart failure	Tachycardia Hypotension
Vasopressin		$\text{V}_1$ (vascular smooth muscle) and $\text{V}_2$ (renal collecting tubules) agonist	IV: 0.01–0.1 U/min	Shock (vasodilatory, cardiogenic) Cardiac arrest	Arrhythmias Hypertension Myocardial ischemia Reduced cardiac output Peripheral ischemia Splanchnic vasoconstriction

## Levosimendan

Myofilament  $\text{Ca}^{2+}$  sensitizers are positive inotropic, vasodilating drugs that enhance myocardial contractility by increasing the  $\text{Ca}^{2+}$  sensitivity of the contractile apparatus.<sup>122</sup> Levosimendan (Table 13-7) is the only drug in this class that is currently available, although a number of other myofilament

Ca<sup>2+</sup> sensitizers were previously studied in clinical trials. Levosimendan is used extensively in Europe for short-term treatment of heart failure<sup>123</sup> and for inotropic support in patients undergoing cardiac surgery.<sup>124</sup> However, use of the drug in the United States is relatively limited because it remains unclear whether levosimendan provides any clinically meaningful unique advantages over conventional therapy.<sup>125</sup> Levosimendan was initially touted as a treatment for acute decompensation of chronic heart failure that would decrease morbidity and mortality, but the myofilament Ca<sup>2+</sup> sensitizer did not reduce the incidence of death or major adverse cardiac events compared with dobutamine.<sup>126</sup> Intermittent ambulatory treatment with levosimendan also did not improve functional capacity or quality of life in patients with advanced heart failure.<sup>127</sup> Levosimendan produced rapid improvement of symptoms in patients with acute decompensated heart failure, but the drug also increased the risk of cardiovascular-related complications.<sup>123</sup> As a result of these and other recent clinical trials, the future of levosimendan as a treatment for heart failure is uncertain.

Levosimendan exerts its positive inotropic and vasodilator actions through three major mechanisms.<sup>128</sup> First, levosimendan binds to troponin C (TnC) and stabilizes the Ca<sup>2+</sup>-bound conformation of the regulatory protein in a Ca<sup>2+</sup>-dependent manner. This action prolongs the interaction between actin and myosin filaments and enhances the rate and extent of myocyte contraction to increase myocardial contractility. The Ca<sup>2+</sup>-dependence of levosimendan–TnC binding prevents relaxation abnormalities that would otherwise be expected to occur. Second, levosimendan is a potent PDE III inhibitor that produces positive inotropic and lusitropic effects and causes systemic, pulmonary, and coronary vasodilation. Finally, levosimendan opens ATP-dependent K<sup>+</sup> (K<sub>ATP</sub>) channels, which contribute to the drug's vasodilator properties and may also produce the additional benefit of myocardial protection against reversible<sup>129</sup> and irreversible<sup>130</sup> ischemic injury. Levosimendan decreases LV filling pressures, mean arterial pressure, and pulmonary and systemic vascular resistances and increases cardiac output in patients with heart failure. The modest reductions in arterial pressure observed with levosimendan are similar to those produced by milrinone and usually respond to volume administration. Levosimendan also improves LV-arterial coupling and mechanical efficiency, while causing only minimal increases in heart rate and myocardial oxygen consumption. Similar to the findings in the setting of heart failure, levosimendan also improves cardiac performance concomitant with reductions in pulmonary capillary occlusion pressure and systemic vascular resistance in patients with normal and depressed LV systolic function undergoing cardiac surgery.<sup>131</sup> Levosimendan has a biologically active metabolite (OR-1896) that most likely contributes to the parent drug's more prolonged hemodynamic effects compared with

catecholamines or PDE III inhibitors.<sup>132</sup>

## Digitalis Glycosides

The search for new drugs that chronically enhance myocardial contractility in failing heart has been astonishingly disappointing despite decades of intense cardiovascular pharmacology research.<sup>133</sup> Digitalis glycosides continue to be the only currently available class of positive inotropic drugs for oral treatment of mild to moderate heart failure, and these medications have been used for centuries. Digitalis glycosides are naturally occurring substances found in several plant species including “foxglove” (*Digitalis purpurea*). The most commonly prescribed digitalis glycosides are digoxin and digitoxin, but a number of related compounds are also used clinically. Digitalis glycosides enhance contractile function, but this positive inotropic effect is relatively minor when compared with other drugs used for the treatment of acute LV dysfunction. Digitalis glycosides selectively bind to the  $\alpha$ -subunit of the sarcolemmal  $\text{Na}^+$ - $\text{K}^+$  ATPase on its extracellular surface and reversibly inhibit the enzyme.<sup>134</sup> An increase in extracellular  $\text{K}^+$  concentration partially inhibits this digitalis- $\text{Na}^+$ - $\text{K}^+$  ATPase binding. As a result, administration of  $\text{K}^+$  is capable of reversing digitalis toxicity resulting from hypokalemia. Inhibition of sarcolemmal  $\text{Na}^+$ - $\text{K}^+$  ATPase indirectly increases  $\text{Ca}^{2+}$  availability, thereby enhancing myocardial contractility. The  $\text{Na}^+$ - $\text{K}^+$  ATPase enzyme normally trades three  $\text{Na}^+$  ions (intracellular to extracellular) for two  $\text{K}^+$  ions (extracellular to intracellular) against their corresponding cation concentration gradients. Inhibition of this energy-dependent ion exchange produces modestly increases intracellular  $\text{Na}^+$  concentration, which reduces  $\text{Ca}^{2+}$  extrusion from the myoplasm by the sarcolemmal  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchanger. The additional  $\text{Ca}^{2+}$  is stored in the sarcoplasmic reticulum and then released during the next contraction. In contrast to other drugs that increase myocardial contractility, tachyphylaxis to the positive inotropic effects of digitalis glycosides does not occur. The mechanism of action of digitalis glycosides is similar to that implicated for the Treppe (“staircase”) phenomenon (see [Chapter 12](#)), in which a rapid increase in heart rate causes a delay in  $\text{Na}^+$ - $\text{K}^+$  ATPase activity, leading to a transient increase in intracellular  $\text{Na}^+$  concentration and enhanced contractile force mediated by favorable  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchange.

The increase in myocardial contractility produced by digitalis glycosides is associated with declines in LV preload and afterload, LV wall tension, and myocardial oxygen consumption in the failing heart. Heart rate remains unchanged. Because digitalis glycosides augment contractility and improve cardiac output, these drugs reduce the chronically elevated sympathetic nervous system activity that is a characteristic feature of heart failure.

Reductions in norepinephrine concentrations and consequently, declines in LV afterload, also occur in response to this withdrawal of sympathetic tone. The decrease in sympathetic nervous system activity observed with digitalis glycosides is also related to the direct actions of these drugs on cardiac baroreceptors. These combined actions play important roles in reducing morbidity and mortality in patients with heart failure.<sup>135</sup> However, digitalis-induced inhibition of Na<sup>+</sup>-K<sup>+</sup> ATPase also causes profound alterations in electrophysiology (e.g., SA and AV nodes, conduction pathways, His–Purkinje fibers) because the enzyme maintains normal resting membrane potential. Withdrawal of sympathetic and increases in parasympathetic nervous system activity further modulate the direct electrophysiologic effects of digitalis glycosides. Thus, it is not surprising that digitalis glycosides often cause a wide variety of arrhythmias including sinus bradycardia or arrest, AV conduction delays, and second- or third-degree heart block. Notably, toxic levels of digitalis glycosides may paradoxically increase sympathetic nervous system tone and precipitate the development of ventricular tachyarrhythmias. Digitalis glycosides have a low therapeutic ratio and narrow margin of safety. As a result, mortality resulting from arrhythmias is directly related to a digitalis drug's plasma concentration. Digitalis glycosides are most often used for management of supraventricular tachyarrhythmias with rapid ventricular response during the perioperative period because the drugs prolong conduction time in the AV node.

## Vasopressin

Vasopressin (antidiuretic hormone; [Table 13-7](#)) is a peptide hormone **10** released from the posterior pituitary that regulates water reabsorption in the kidney and exerts potent hemodynamic effects independent of adrenoceptors. Vasopressin receptors consist of three subtypes (V<sub>1</sub>, V<sub>2</sub>, and V<sub>3</sub>), all of which are five-subunit helical membrane proteins coupled to G proteins. Vasopressin's cardiovascular effects are predominately mediated through V<sub>1</sub> receptors, which are located in the cell membrane of vascular smooth muscle.<sup>136</sup> Activation of the V<sub>1</sub> receptor subtype stimulates phospholipase C and triggers hydrolysis of inositol 4,5-bisphosphate (PIP<sub>2</sub>) to inositol 1,4,5-triphosphate (IP<sub>3</sub>) and diacyl glycerol (DAG). These second messengers increase intracellular Ca<sup>2+</sup> concentration and produce contraction of the vascular smooth muscle cell. V<sub>2</sub> receptors are present on renal collecting duct cells and, when activated, increase reabsorption of free water, whereas V<sub>3</sub> receptors are located in the pituitary gland itself and act as autacoid modulators.

Along with the sympathetic nervous system and renin–angiotensin–aldosterone axis, endogenous vasopressin plays an essential role in the

maintenance of arterial pressure. Exogenous administration of vasopressin does not substantially affect arterial pressure in conscious, healthy patients because activation of central V<sub>1</sub> receptors in the area postrema enhances baroreceptor reflex-mediated inhibition of efferent sympathetic nervous outflow that counterbalances the elevated system vascular resistance resulting from V<sub>1</sub>-induced arterial vasoconstriction. In contrast, vasopressinergic mechanisms are essential for maintaining arterial pressure under conditions in which sympathetic nervous system or renin–angiotensin–aldosterone axis dysfunction is present. Indeed, exogenous administration of vasopressin has been shown to effectively support arterial pressure when a relative vasopressin deficiency exists (e.g., catecholamine-refractory hypotension, vasodilatory shock, sepsis, cardiac arrest). ACE inhibitors and ARBs used to treat hypertension also affect autonomic nervous system and renin–angiotensin–aldosterone axis function. Intraoperative hypotension that is relatively refractory to administration of catecholamines or sympathomimetics has been repeatedly described in patients who are treated with these medications. General or neuraxial anesthesia also reduces sympathetic nervous system tone, resulting in decreased plasma stress hormone concentrations including vasopressin. Under these circumstances, administration of vasopressin activates V<sub>1</sub> vascular smooth muscle receptors and rapidly increases arterial pressure during anesthesia by causing arterial vasoconstriction. Vasopressin therapy has been shown to reduce mortality associated with acute vasodilatory states such as anaphylaxis. In addition, infusion of vasopressin is indicated for the treatment of severe hypotension after prolonged cardiopulmonary bypass in patients who are otherwise unresponsive to phenylephrine or norepinephrine (vasoplegia).

Vasopressin is a useful drug for the treatment of sepsis and cardiac arrest. Vasodilation that is refractory to fluid resuscitation combined with a relative deficiency of endogenous vasopressin is a characteristic feature of sepsis. Inadequate sympathetic nervous system and renin–angiotensin–aldosterone axis responses to hypotension are also present in sepsis. Administration of vasopressin in the absence or presence of other vasoactive medications often stabilizes hemodynamics and improves survival in patients with sepsis. The combined use of vasopressin with other vasoactive medications reduces the overall dose of vasopressin required to maintain arterial pressure, thereby limiting the adverse effects of vasopressin on organ perfusion. In fact, sustained administration of higher doses of vasopressin may produce mesenteric ischemia, peripheral vascular insufficiency, and cardiac arrest because the drug causes pronounced vasoconstriction of cutaneous, skeletal muscle, splanchnic, and coronary vascular beds, concomitant with reduced perfusion of and oxygen delivery to these tissues. Bolus intravenous administration of vasopressin is also used as part of the American Heart

Association Adult Advanced Cardiac Life Support algorithm for cardiac arrest resulting from ventricular fibrillation, pulseless electrical activity, or asystole.

## Nitrovasodilators

Organic nitrates (e.g., nitroglycerin) and nitric oxide (NO) donors (e.g., sodium nitroprusside) are nitrovasodilators that release NO through enzymatic sulfhydryl group reduction or through a spontaneous mechanism that occurs independent of metabolism, respectively. Like endogenous NO produced by vascular endothelium, exogenous NO stimulates guanylate cyclase within the vascular smooth muscle cell to convert guanosine triphosphate to cGMP. The second messenger activates a cGMP-dependent protein kinase (protein kinase G) that dephosphorylates myosin light chains and contributes to relaxation of vascular smooth muscle. NO stimulates  $\text{Ca}^{2+}$  reuptake into the sarcoplasmic reticulum by activating the sarcoplasmic reticulum  $\text{Ca}^{2+}$  ATPase through a cGMP-independent mechanism. This action decreases intracellular  $\text{Ca}^{2+}$  concentration and causes relaxation. NO also stimulates  $\text{K}^{+}$  efflux from the cell by activating the  $\text{K}^{+}$  channel. This shift in  $\text{K}^{+}$  balance produces cellular hyperpolarization, which, in turn, closes the voltage-gated  $\text{Ca}^{2+}$  channel and facilitates relaxation.

Nitrovasodilators are often used to improve hemodynamics and myocardial oxygen supply–demand relations in patients with heart failure. Venodilation reduces venous return, contributing to declines in LV and RV end-diastolic volume, pressure, and wall stress. Arterial vasodilation also reduces systemic and pulmonary arterial pressures, which decreases LV and RV end-systolic wall stress, respectively. These actions combine to decrease myocardial oxygen consumption. Simultaneously, nitrovasodilators increase myocardial oxygen supply through direct dilation of epicardial coronary arteries in the absence of flow-limiting stenoses. The reduction in LV end-diastolic pressure observed during administration of nitrovasodilators coupled with coronary vasodilation substantially enhances subendocardial perfusion. The clinical efficacy of nitrovasodilators may display some initial variability between patients, but the cardiovascular effects of these drugs inevitably diminish with prolonged use. Some patients may be relatively resistant to the effects of organic nitrates in the presence of oxidative stress because superoxide anions scavenge NO, cause reversible oxidation of guanylate cyclase, and inhibit aldehyde dehydrogenase. The latter action prevents the release of NO from organic nitrates. A progressive attenuation of hemodynamic responses to nitrovasodilators may develop in other patients as a result of sympathetic nervous system and renin–angiotensin–aldosterone axis activation. This phenomenon, termed “pseudotolerance,” accounts for the rebound hypertension that may be observed after abrupt discontinuation of

nitrovasodilator therapy. Inhibition of guanylate cyclase activity is most likely responsible for true tolerance to organic nitrates. A daily “drug holiday” is a useful strategy for reversing this effect in patients requiring prolonged treatment. Administration of *N*-acetylcysteine, a sulfhydryl donor, may also be effective for reversing true tolerance. Notably, prolonged use of organic nitrates may also cause methemoglobinemia, interfere with platelet aggregation, and produce heparin resistance. It is important to recognize that organic nitrates should also be used with caution in patients receiving phosphodiesterase type V inhibitors (e.g., sildenafil) because NO-induced vasodilation is enhanced, and profound hypotension, myocardial ischemia or infarction, and death may result.

### **Nitroglycerin**

Nitroglycerin dilates venules to a greater degree than arterioles. At lower doses, the organic nitrate produces venodilation without causing a significant decrease in systemic vascular resistance. Arterial pressure and cardiac output fall in response to the reduction in preload despite a modest baroreceptor reflex-mediated increase in heart rate. Nitroglycerin also decreases pulmonary arterial pressures and vascular resistance. At higher doses, nitroglycerin dilates arterioles and reduces LV afterload. These effects cause more pronounced decreases in arterial pressure and stimulate greater reflex tachycardia. Overshoot hypotension and tachycardia is particularly common in the setting of hypovolemia, such as is often observed in patients with poorly controlled essential hypertension and parturients with pregnancy-induced hypertension.

Nitroglycerin improves the balance of myocardial oxygen supply to demand through its actions as a direct coronary vasodilator (which increase supply) and its systemic hemodynamic effects (which reduce demand). Nitroglycerin dilates both normal and poststenotic epicardial coronary arteries, enhances blood flow through coronary collateral vessels, and preferentially improves subendocardial perfusion. The drug also inhibits coronary vasospasm and dilates arterial conduits (e.g., internal mammary artery, radial artery) used during CABG surgery. Nitroglycerin decreases myocardial oxygen demand by reducing LV preload, and to a lesser extent afterload, thereby producing corresponding reductions in LV end-diastolic and end-systolic wall stress. These effects are particularly important in patients with acutely decompensated heart failure resulting from myocardial ischemia. Thus, nitroglycerin is a very effective first-line drug for the treatment of myocardial ischemia. Nevertheless, caution should be exercised when using nitroglycerin in patients with ischemia who are also hypovolemic because the drug may precipitate life-threatening hypotension by further compromising

coronary perfusion pressure and reducing coronary blood flow despite epicardial vasodilation. These actions may inadvertently worsen myocardial ischemia.

## **Sodium Nitroprusside**

Sodium nitroprusside is an ultra–short-acting direct NO donor. It is a potent venous and arterial vasodilator that rapidly reduces arterial pressure by decreasing LV preload and afterload, respectively. Not surprisingly, sodium nitroprusside is a first-line drug for the treatment of hypertensive emergencies. Sodium nitroprusside is also useful for the treatment of cardiogenic shock because arterial vasodilation improves forward flow by reducing impedance to LV ejection while venodilation decreases LV filling pressures. Unlike nitroglycerin, sodium nitroprusside is relatively contraindicated in patients with acute myocardial ischemia because the drug causes abnormal redistribution of coronary blood flow away from ischemic myocardium (“coronary steal”). This effect occurs because sodium nitroprusside produces greater coronary vasodilation in vessels that perfuse normal myocardium compared with those that supply the ischemic territory, the latter of which are already maximally vasodilated. Baroreceptor reflex-mediated tachycardia is also more pronounced during administration of sodium nitroprusside compared with nitroglycerin because the direct NO donor is a more potent arteriolar vasodilator than the organic nitrate. This reflex tachycardia dramatically increases heart rate and myocardial oxygen consumption, thereby exacerbating acute myocardial ischemia. Sodium nitroprusside is often combined with a  $\beta_1$ -adrenoceptor antagonist such as esmolol to decrease arterial pressure, depress myocardial contractility, and reduce ascending aortic wall stress in patients with acute aortic dissection until direct surgical control of the injury can be achieved. Clinical use of sodium nitroprusside is limited by its toxic metabolites, which predictably accumulate when administration is prolonged or relatively high doses are used. Metabolism of sodium nitroprusside produces cyanide, which binds with cytochrome C to inhibit aerobic metabolism and cause lactic acidosis. Cyanide derived from sodium nitroprusside metabolism also binds with hemoglobin to form methemoglobin and with sulfur to form thiocyanate. The latter metabolite may accumulate in patients with renal insufficiency and produce neurologic complications including delirium and seizures.

## **Hydralazine**

Hydralazine is a direct vasodilator that reduces intracellular  $\text{Ca}^{2+}$  concentration in vascular smooth muscle. Activation of  $\text{K}_{\text{ATP}}$  channels is

partially responsible for this effect, which results in direct relaxation of small arteries and arterioles in coronary, cerebral, splanchnic, and renal vascular beds, declines in systemic vascular resistance, and decreases in arterial pressure. LV preload is relatively preserved because hydralazine does not dilate venous capacitance vessels. The primary reduction in afterload stimulates baroreceptor reflex-mediated tachycardia and increases cardiac output. The magnitude of tachycardia observed with administration of hydralazine is often greater than expected based solely on baroreceptor reflexes alone and may reflect a direct effect of the drug on cardiovascular regulation in the central nervous system. This pronounced tachycardia might produce acute myocardial ischemia in patients with critical coronary stenoses based on increases in myocardial oxygen demand. Hydralazine-induced tachycardia responds appropriately to  $\beta_1$ -adrenoceptor antagonists, but caution should be exercised because further declines in arterial pressure may also occur. Hydralazine is commonly used for management of sustained postoperative hypertension in the absence of tachycardia.

## Calcium Channel Blockers

$\text{Ca}^{2+}$  channels are asymmetric biochemical pores consisting of at least four subunits ( $\alpha_1$ ,  $\alpha_2/\delta$ , and  $\beta$  with or without gamma) that traverse many biologic membranes.<sup>137</sup>  $\text{Ca}^{2+}$  channels are closed under quiescent conditions, but they may open through a voltage-dependent or receptor-operated mechanism to allow  $\text{Ca}^{2+}$  entry into the cell or an organelle (e.g., mitochondria, sarcoplasmic reticulum). Myocardial and vascular smooth muscle cell membranes contain two types of voltage-dependent  $\text{Ca}^{2+}$  channels that are defined on the basis of the duration of opening: T (transient) and L (long). The L-type  $\text{Ca}^{2+}$  channel is the predominant target of  $\text{Ca}^{2+}$  channel blockers in current clinical use. These drugs do not block the T-type  $\text{Ca}^{2+}$  channel.  $\text{Ca}^{2+}$  channel blockers may be divided into four chemical groups including 1,4-dihydropyridines (e.g., nifedipine, nicardipine, nimodipine, clevidipine), benzothiazepines (diltiazem), phenylalkylamines (verapamil), and diarylaminopropylamine ethers (bepridil), the first three of which are used clinically (Table 13-8).

In general,  $\text{Ca}^{2+}$  channel blockers produce varying degrees of **11** vasodilation; direct negative chronotropic, dromotropic, and inotropic effects; and baroreceptor reflex-mediated increases in heart rate, depending on each drug's selectivity for myocardial and vascular smooth muscle L-type  $\text{Ca}^{2+}$  channels. All  $\text{Ca}^{2+}$  channel blockers produce greater relaxation of arterial, compared with venous, vascular smooth muscle. As a result, LV afterload is reduced while preload is relatively preserved.  $\text{Ca}^{2+}$  channel blockers cause coronary arterial vasodilation and inhibit coronary artery

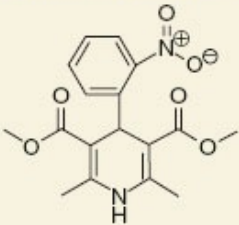

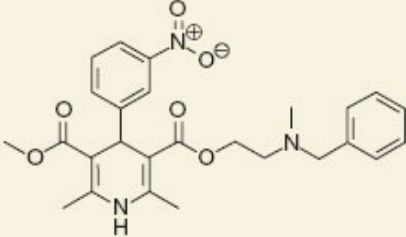

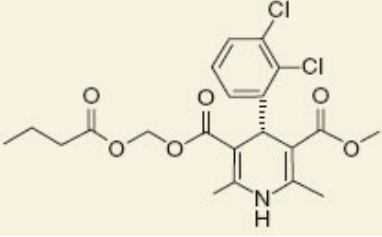

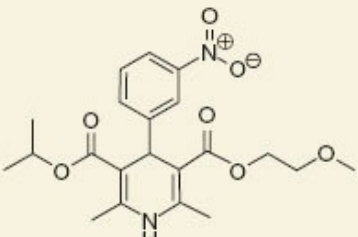

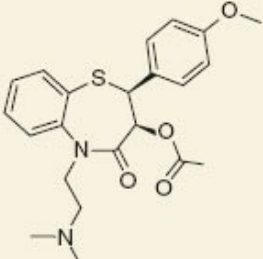

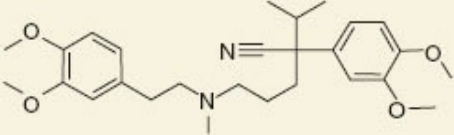

vasospasm. These actions may enhance coronary blood flow assuming that coronary perfusion pressure is not substantially reduced as a result of arterial vasodilation. In addition to causing declines in LV afterload, some Ca<sup>2+</sup> channel blockers (e.g., diltiazem, verapamil) also reduce myocardial oxygen consumption by decreasing heart rate and myocardial contractility. However, other Ca<sup>2+</sup> channel blockers (e.g., dihydropyridines) may increase myocardial oxygen consumption because of baroreceptor reflex-induced tachycardia. As a result, these Ca<sup>2+</sup> channel blockers may not exert anti-ischemic effects in patients with hemodynamically significant coronary artery stenoses.

## **Nifedipine**

Nifedipine and other related dihydropyridine Ca<sup>2+</sup> channel blockers (e.g., amlodipine, felodipine, isradipine) are most often used for chronic treatment of essential hypertension. Like other Ca<sup>2+</sup> channel blockers, nifedipine is a relatively selective arterial vasodilator that does not substantially affect venous vasomotor tone. This effect decreases arterial pressure, but in so doing, activates the sympathetic nervous system and elicits baroreceptor reflex-mediated increases in heart rate. Nifedipine produces direct myocardial depression in vitro, but this negative inotropic effect is not evident when the drug is used clinically because arterial vasodilation occurs at plasma concentrations that are substantially less than those required for reductions in myocardial contractility. Similarly, typical doses of nifedipine only minimally alter SA node automaticity and AV conduction. Maintenance of venous return and contractility state combined with modest tachycardia and a decline in LV afterload result in small increases in cardiac output. Nifedipine is frequently used in patients with coronary artery disease, most often in combination with a  $\beta_1$ -adrenoceptor antagonist to abolish baroreceptor reflex-mediated tachycardia,<sup>138</sup> because the Ca<sup>2+</sup> channel blocker decreases myocardial oxygen consumption via a reduction in LV afterload and is a direct epicardial coronary vasodilator. Another more specific indication for this Ca<sup>2+</sup> channel blocker is variant angina, a disease process in which reductions in coronary blood flow occur as a result of regional coronary vasoconstriction independent of coronary artery stenoses.<sup>138</sup> Nifedipine is probably more effective than nitrates for the treatment of variant angina because the Ca<sup>2+</sup> channel blocker causes more profound, consistent coronary vasodilation. Vasospasm may also occur in patients with unstable angina resulting from atherosclerosis, and nifedipine may also be beneficial in this setting.<sup>139</sup> Despite these salutary effects, nifedipine does not improve and may worsen mortality when used in patients with acute myocardial infarction, in contrast to other Ca<sup>2+</sup> channel blockers such as diltiazem and verapamil.<sup>140</sup> Nifedipine is also used to provide arterial vasodilation in patients with Raynaud's

phenomenon.<sup>141</sup>

**Table 13-8** Comparative Effects of Ca<sup>2+</sup> Channel Blockers

Name	Chemical Structure	Myocardial Depression	Coronary Blood Flow	Suppression of SA Node (Automaticity)	Suppression of AV Node (Conduction)
Nifedipine		+	++++	+	0
Nicardipine		0	++++	+	0
Clevidipine		+	++++	+	0
Nimodipine		+	++++	+	0
Diltiazem		++	+++	++++	++++
Verapamil		++++	++++	++++	++++

## Nicardipine

Nicardipine is another dihydropyridine  $\text{Ca}^{2+}$  channel antagonist that is highly selective for vascular smooth muscle. Nicardipine produces cardiovascular effects that are similar to nifedipine, but has a longer half-life than the latter drug. Nicardipine is a profound vasodilator because of its pronounced inhibition of  $\text{Ca}^{2+}$  influx in vascular smooth muscle. Like other dihydropyridine  $\text{Ca}^{2+}$  channel antagonists, nicardipine preferentially dilates arteriolar vessels; this effect decreases arterial pressure. In contrast to diltiazem and verapamil, nicardipine does not substantially depress myocardial contractility nor does the drug affect the rate of SA node firing. As a result, stroke volume and cardiac output are relatively preserved or may increase. Nicardipine-induced decreases in arterial pressure trigger increases in heart rate through activation of baroreceptor reflexes, but the tachycardia observed during administration of nicardipine is less pronounced than typically occurs with sodium nitroprusside at comparable levels of arterial pressure. Nicardipine is also a highly potent coronary vasodilator and is often used to dilate arterial conduits during coronary artery bypass graft surgery. Because of its relatively long half-life, nicardipine is primarily used for treatment of sustained perioperative hypertension and not for acute, often transient hypertensive episodes that are commonly observed during surgery.

### **Clevidipine**

Clevidipine is an ultra-short-acting dihydropyridine  $\text{Ca}^{2+}$  channel antagonist with a plasma half-life of approximately 2 minutes after intravenous administration.<sup>142,143</sup> Like nicardipine and nifedipine, clevidipine exerts pronounced effects at the less negative resting membrane potentials typically observed in vascular smooth muscle cells, but demonstrates lower potency in cardiac myocytes in which resting membrane potentials are substantially more negative. As a result of these differences in cellular electrophysiology, clevidipine is highly selective for arterial vascular smooth muscle and is nearly devoid of negative chronotropic or inotropic effects. This hemodynamic profile may be especially useful for the treatment of hypertension in patients with compromised LV function in the absence or presence of acute heart failure.<sup>144</sup> Clevidipine causes dose-related arteriolar vasodilation while sparing venous vasomotor tone, thereby reducing systemic vascular resistance and arterial pressure without affecting LV preload. These actions may combine to augment cardiac output. Modest increases in heart rate may also occur during administration of clevidipine as a result of baroreceptor reflex activation. Unlike other short-acting antihypertensive drugs, clevidipine is not associated with the development of tachyphylaxis, and abrupt discontinuation of the drug does not appear to cause rebound hypertension. Because tissue and plasma esterases are responsible for

clevidipine metabolism, little to no accumulation of the drug occurs even in the setting of hepatic or kidney dysfunction. Clevidipine compares favorably with nitroglycerin, sodium nitroprusside, and nicardipine for the treatment of acute hypertension in cardiac surgery patients.<sup>145</sup> Clevidipine has also demonstrated efficacy for treatment of hypertension associated with pheochromocytoma<sup>146</sup> and acute intracerebral hemorrhage.<sup>147</sup> The short-acting  $\text{Ca}^{2+}$  channel blocker is also useful for producing controlled hypotension during spinal surgery.<sup>148</sup>

## *Nimodipine*

The dihydropyridine nimodipine is more lipophilic and more easily crosses the blood–brain barrier than other drugs in this class of  $\text{Ca}^{2+}$  channel blockers. As a result, nimodipine exerts more cerebral arterial vasodilation than other dihydropyridines. Nimodipine is currently the only medication approved by the U.S. Food and Drug Administration for treatment of cerebral vasospasm after aneurysmal subarachnoid hemorrhage.<sup>149,150</sup> Several clinical trials demonstrated that nimodipine significantly reduces the severity of symptoms resulting from cerebral vasospasm, the incidence of cerebral infarction, the occurrence of delayed neurologic deficits, and the risk of mortality while improving long-term neurologic functional status after the initial hemorrhage.<sup>151,152</sup> Nimodipine does not affect the incidence of recurrent hemorrhage or prevent other adverse reactions.<sup>152</sup> Nimodipine also does not reverse angiographic evidence of vasospasm, indicating that the mechanism by which the  $\text{Ca}^{2+}$  channel blocker improves outcome in this setting is most likely not related to dilation of large cerebral arteries. Instead, nimodipine appears to reduce cerebral arteriolar resistance and enhance blood flow through pia mater collateral vessels. In addition, nimodipine may attenuate  $\text{Ca}^{2+}$ -mediated neurotoxicity and thereby exert clinically beneficial neuroprotective effects.<sup>153</sup>

## *Diltiazem*

Diltiazem is the only benzothiazepine  $\text{Ca}^{2+}$  channel blocker in current clinical use.<sup>154</sup> The cardiovascular effects of diltiazem are somewhat different from those produced by the dihydropyridines. Intravenous administration of diltiazem produces arterial vasodilation and decreases arterial pressure. These actions initially stimulate baroreceptor reflex-mediated tachycardia and increase cardiac output, but heart rate subsequently falls because, in contrast to dihydropyridine  $\text{Ca}^{2+}$  channel blockers, diltiazem exerts potent negative chronotropic and dromotropic effects on SA node automaticity and AV node conduction, respectively. Oral administration of diltiazem reduces heart rate,

arterial pressure, and myocardial oxygen consumption. Both routes of administration cause coronary vasodilation and moderate negative inotropic effects. These combined properties make diltiazem a useful alternative medication for the treatment of patients with hypertension and symptomatic coronary artery disease<sup>155</sup> in clinical situations in which  $\beta$ -adrenoceptor antagonists may be relatively contraindicated (e.g., asthma, chronic obstructive pulmonary disease). Similarly, diltiazem may also prevent subsequent myocardial infarction in patients who have already suffered an infarction but cannot receive a  $\beta$ -adrenoceptor antagonist.<sup>138</sup> Because diltiazem prolongs AV node conduction, the drug may be effective for ventricular rate control in patients with chronic atrial fibrillation, atrial flutter, or supraventricular tachycardia.<sup>156,157</sup> However, adenosine or cardioversion (depending on the magnitude of accompanying hypotension) remains the recommended treatment for symptomatic supraventricular tachycardia in the 2015 American Heart Association Advanced Adult Cardiovascular Life Support guidelines.<sup>158</sup>

### *Verapamil*

The phenylalkylamine  $\text{Ca}^{2+}$  channel blocker verapamil produces less arterial vasodilation, but exerts more potent effects on automaticity, conduction, and myocardial contractility than the dihydropyridines. As a result, baroreceptor reflex-mediated increases in heart rate that may be expected because of reductions in arterial vasomotor tone and systemic vascular resistance do not occur. The sympathetic nervous system activation resulting from arterial vasodilation generally compensates for the direct negative inotropic effect of verapamil, and cardiac output is maintained or modestly increased because of the decline in LV afterload in patients with normal LV function. However, verapamil has the potential to markedly worsen pre-existing LV systolic dysfunction in patients with heart failure because of the  $\text{Ca}^{2+}$  channel blocker's myocardial depressant effects. Like diltiazem, verapamil is a coronary vasodilator and decreases myocardial oxygen consumption as a result of its hemodynamic effects. Thus, verapamil may be effective for the treatment of angina pectoris and myocardial infarction in patients who may be unable to tolerate  $\beta_1$ -adrenoceptor antagonists.<sup>159</sup>

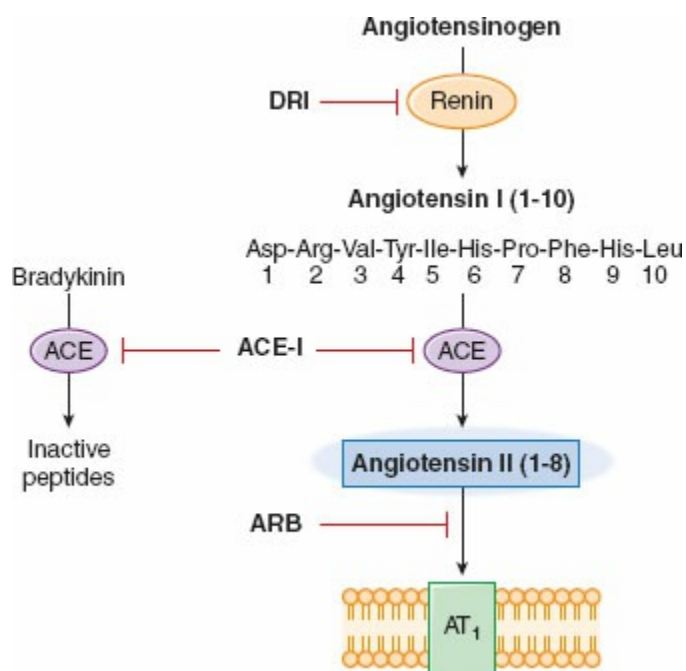

The actions of verapamil on cardiac electrophysiology make the  $\text{Ca}^{2+}$  channel antagonist a useful alternative to adenosine for the treatment of supraventricular tachyarrhythmias.<sup>158</sup> Re-entry through the SA node or AV node is responsible for the vast majority of supraventricular tachyarrhythmias except when an aberrant conduction ("pre-excitation") pathway is present (e.g., the bundle of Kent in Wolff–Parkinson–White syndrome).<sup>160</sup> Similar to but to a greater extent than diltiazem, verapamil reduces the rate of SA node

discharge, markedly decreases AV node conduction velocity, and increases the refractory period of the AV node consistent with a class IV antiarrhythmic. These actions predictably prolong PR interval and increase AV conduction time. For example, verapamil has been shown to significantly reduce the risk of supraventricular tachyarrhythmias in patients undergoing cardiac and noncardiac surgery because of these actions on the proximal cardiac conduction system.<sup>161,162</sup> Verapamil may also be useful for the treatment of atrial fibrillation or flutter with rapid ventricular response because the drug substantially reduces ventricular rate and may occasionally facilitate conversion of the atrial arrhythmia to sinus rhythm. Verapamil is contraindicated in the presence of an aberrant re-entry supraventricular tachyarrhythmia because blockade of AV conduction leaves direct transmission from the atrium to the ventricle through the aberrant pathway unopposed, thereby exposing the patient to the risk of malignant ventricular arrhythmias and sudden cardiac death.<sup>163</sup> Administration of verapamil in the presence of a  $\beta_1$ -adrenoceptor antagonist may cause complete heart block or profound myocardial depression. Verapamil is also contraindicated in patients with sick sinus syndrome or atrioventricular node dysfunction.<sup>164</sup>

## Angiotensin-converting Enzyme Inhibitors

The renin–angiotensin–aldosterone system is another major regulator of cardiovascular homeostasis. Renal cortical juxtaglomerular cells secrete renin in response to decreases in  $\text{Na}^+$  reabsorption by the macula densa, reduced perfusion pressure to preglomerular arterioles, and  $\beta_1$ -adrenoceptor stimulation resulting from sympathetic nervous system activation. Renin cleaves angiotensinogen into the 10 amino acid peptide angiotensin I (Fig. 13-7). Angiotensin-converting enzyme (synthesized in pulmonary vascular endothelium) then excises the C-terminal histidine and leucine residues from the angiotensin I molecule to form the biologically active octapeptide angiotensin II. A potent vasoconstrictor of renal and mesenteric arterioles through its actions at the angiotensin subtype I ( $\text{AT}_1$ ) receptor mediated through  $\text{G}_q$  protein-phospholipase C-inositol triphosphate- $\text{Ca}^{2+}$  signaling,<sup>165</sup> angiotensin II also facilitates the release of norepinephrine from sympathetic postganglionic neurons and augments the actions of the endogenous catecholamine in vascular smooth muscle. In addition, angiotensin II enhances release of norepinephrine and epinephrine from the adrenal medulla and attenuates baroreceptor-mediated reductions in sympathetic nervous system tone that occur in response to compensatory elevations in arterial pressure. Angiotensin II inhibits renal tubular reabsorption of  $\text{Na}^+$ , thereby reducing  $\text{Na}^+$  and water excretion and enhancing  $\text{K}^+$  excretion. Angiotensin II further stimulates the synthesis and release of aldosterone from the zona glomerulosa

of the adrenal cortex. Aldosterone augments the actions of angiotensin II on renal tubular Na<sup>+</sup> retention and K<sup>+</sup> excretion. The net result of these collective effects is elevated arterial pressure and increased intravascular volume.

**Figure 13-7** Schematic illustration of inhibitors of the renin–angiotensin system; abbreviations: DRI, direct renin inhibitor; ACE, angiotensin-converting enzyme; ACE I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; AT<sub>1</sub>, angiotensin subtype 1 receptor. (Adapted with permission from Hilal-Dandan R. Renin and angiotensin. In: Brunton LL, Chabner BA, Knollman BC, eds. *Goodman and Gilman’s The Pharmacological Basis of Therapeutics*. 12th ed. New York, NY: McGraw-Hill Medical; 2011:731.)

ACE inhibitors block the conversion of angiotensin I to angiotensin II. As may be predicted based on the aforementioned effects of angiotensin II, ACE inhibitors are potent antihypertensive medications. There are currently eleven ACE inhibitors in clinical use in the United States, which differ in potency, duration of action, metabolism and clearance, and whether hepatic esterase conversion of a prodrug form to a metabolite is required for activity (e.g., enalapril, quinapril, ramipril). Captopril was the first ACE inhibitor, but its use has diminished to some extent because the drug is associated with a greater number of adverse side effects and possible drug interactions than other ACE inhibitors. Enalapril is the only ACE inhibitor available in an intravenous form (enalaprilat), whereas lisinopril is the only orally administered drug in this class with a prolonged half-life that does not require multiple daily dosing. ACE inhibitors reduce LV afterload and decrease arterial pressure through a reduction in arterial vasomotor tone in patients with essential or renal vascular hypertension, but not in those with primary

aldosteronism. Cardiac output remains unchanged or modestly increases while LV preload is unaffected. Sympathetic nervous system tone does not change despite the decrease in arterial pressure, and baroreceptor-mediated reflexes remain intact. As a result, patients do not develop orthostatic hypotension or limited exercise capacity when treated with an ACE inhibitor unless relative hypovolemia is present because of concomitant diuretic therapy; the ACE inhibitor is administered with another arterial vasodilator (e.g., Ca<sup>2+</sup> channel blocker); or elevated plasma renin concentrations are present.

ACE inhibitors have been shown to be very effective in the treatment of LV systolic dysfunction with or without heart failure. Several large-scale, randomized, controlled double blind clinical trials provided convincing evidence that ACE inhibitors halt or delay the progression of heart failure and improve quality of life in patients resulting from LV systolic or diastolic dysfunction. ACE inhibitors also cause declines in the need for hospitalization, the incidence of myocardial infarction, and the risk of sudden cardiac death. In the presence of LV dysfunction, ACE inhibitors decrease LV afterload, improve arterial compliance, reduce arterial pressure, enhance cardiac output, increase renal blood flow, and facilitate natriuresis. The hemodynamic effects serve to reduce chronically elevated sympathetic nervous system tone because tissue perfusion improves, whereas the renal actions result in beneficial reductions in intravascular volume. ACE inhibitors have well-documented salutary effects in patients with acute myocardial infarction, especially those with diabetes mellitus and hypertension.<sup>166</sup> ACE inhibitors also substantially reduced the incidence of myocardial infarction, cerebrovascular accident, and mortality in patients at high risk for major adverse cardiovascular events.<sup>167</sup> Finally, ACE inhibitors exert renal protective effects in diabetic patients and mitigate the progression of renal dysfunction in other forms of nephropathy as well.<sup>168</sup>

ACE inhibitors produce several side effects, the most common of which is a dry cough that affects as many as 20% of patients treated with these medications. Blockade of ACE-induced degradation of bradykinin exacerbates the pulmonary effects of the inflammatory mediator and contributes to this clinical problem. Nonsteroidal anti-inflammatory drugs attenuate the ability of ACE inhibitors to reduce arterial pressure in patients with hypertension. ACE inhibitors may also cause hyperkalemia in patients with chronic kidney injury and in those with normal renal function who are treated with K<sup>+</sup>-sparing diuretics (e.g., spironolactone, triamterene) or K<sup>+</sup> supplements. Conversely, ACE inhibitors blunt the hypokalemic effects of thiazide and loop diuretics. Acute renal failure, reversible neutropenia, fetal teratogenicity, and dermatitis are other adverse effects of ACE inhibitors. Angioedema is a potentially life-threatening, although rare (0.1% to 0.5% of patients), complication of ACE inhibitors in which rapidly developing edema of the lips,

nose, tongue, mouth, hypopharynx, and glottis occurs that may quickly jeopardize airway integrity.<sup>169</sup> Angioedema resulting from an ACE inhibitor usually occurs with the initial dose of the drug and may require emergent endotracheal intubation or a surgical airway to prevent death from asphyxia. Notably, African-Americans are approximately 4.5-fold more likely to develop this complication than are their Caucasian counterparts.<sup>170</sup> Perhaps of most relevance to the anesthesiologist, chronic treatment with an ACE inhibitor may precipitate profound hypotension in the presence of vasodilating general anesthetics that is refractory to treatment with phenylephrine, ephedrine, or norepinephrine.<sup>171,172</sup> Vasopressinergic V<sub>1</sub> agonists (e.g., terlipressin) are more effective than norepinephrine in treating this form of intraoperative hypotension.<sup>173,174</sup> Discontinuation of ACE inhibitor therapy before elective surgery is recommended to avoid this complication.

## Angiotensin Receptor Blockers

Angiotensin receptor blockers inhibit the AT<sub>1</sub> receptor with high affinity **12** and thereby markedly attenuate the cardiovascular, endocrine, and renal effects of angiotensin II.<sup>175</sup> All ARBs are potent antihypertensive medications that more effectively inhibit the actions of angiotensin II at AT<sub>1</sub> receptors than do ACE inhibitors. In contrast to ACE inhibitors, ARBs do not affect angiotensin II-induced activation of angiotensin subtype 2 (AT<sub>2</sub>) receptors. The clinical implications of these differences in pharmacodynamics between ARBs and ACE inhibitors remain unclear. ARBs and ACE inhibitors reduce arterial pressure to equivalent degrees, but angiotensin receptor blockers produce fewer side effects. Similar to ACE inhibitors, ARBs (e.g., losartan, candesartan, valsartan) improved functional capacity and reduced morbidity and mortality in patients with heart failure<sup>176</sup> and acute myocardial infarction complicated by LV dysfunction.<sup>177</sup> Whether the combination of an ARB and an ACE inhibitor provides any added clinical benefits in these settings has not been resolved.<sup>178</sup> ARBs are most often used in patients with heart failure who are unable to tolerate the side effects of ACE inhibitors, the latter of which continue to be used as first-line medications in heart failure pharmacotherapy. Like ACE inhibitors, ARBs provide renal protection in patients with diabetes mellitus independent of the effects of these drugs on arterial pressure.<sup>179</sup> ARBs also reduce the risk of stroke in patients with hypertension, maintain sinus rhythm after cardioversion in patients with long-term atrial fibrillation, and improve symptoms in patients with hepatic cirrhosis-induced portal hypertension. As predicted by their pharmacologic mechanism of action, ARBs are less likely to cause cough, dermatitis, or angioedema than ACE inhibitors. However, angiotensin receptor blockers exert fetal toxicity and may cause hyperkalemia in patients treated with K<sup>+</sup>-sparing diuretics or those with renal

insufficiency similar to ACE inhibitors.

## **KEY POINTS**

- 1 The autonomic nervous system (ANS) includes that part of the central and peripheral nervous system concerned with involuntary regulation of cardiac muscle, smooth muscle, glandular and visceral functions.
- 2 The sympathetic and parasympathetic nervous systems (SNS, PNS) affect cardiac pump function in three ways: (1) by changing the rate (chronotropism), (2) by changing the strength of contraction

- (inotropism), and (3) by modulating coronary blood flow.
- 3 SNS nerves are by far the most important regulators of the peripheral circulation.
  - 4 The ANS can be pharmacologically subdivided by the neurotransmitter secreted at the effector cell: Acetylcholine (ACh) released by the PNS, and the catecholamines epinephrine (EPI) and norepinephrine (NE), which are the mediators of peripheral SNS activity.
  - 5 An agonist is a substance that interacts with a receptor to evoke a biologic response. An antagonist is a substance that interferes with the triggering of the response at a receptor site by an agonist.
  - 6 The adrenergic receptors are termed adrenergic or noradrenergic, depending on their responsiveness to EPI and NE.
  - 7 The numbers and sensitivity of adrenergic receptors can be influenced by normal, genetic, and developmental factors.
  - 8 The ANS reflex comprises (1) sensors, (2) afferent pathways, (3) CNS integration, and (4) efferent pathways to the receptors and efferent organs.
  - 9 The clinical application of ANS pharmacology is based on the knowledge of ANS anatomy, physiology, and molecular pharmacology.
  - 10 Clinically, anticholinesterase drugs may be divided into two types: the reversible and nonreversible cholinesterase inhibitors.

## Anesthesia and the Autonomic Nervous System

Anesthesiology is the practice of autonomic medicine. Drugs that produce anesthesia may also have potent autonomic side effects. The greater part of our training and practice is spent acquiring skills in utilizing or averting the autonomic nervous system (ANS) side effects of anesthetic drugs under a variety of pathophysiologic conditions. The success of any anesthetic depends upon how well homeostasis is maintained. The anesthetic record reflects ANS function.

**1** The ANS includes that part of the central and peripheral nervous system concerned with involuntary regulation of cardiac muscle, smooth muscle, and glandular and visceral functions. ANS activity refers to visceral reflexes that function below the conscious level. The ANS is also responsive to changes in somatic motor and sensory activities of the body. The physiologic evidence of visceral reflexes as a result of somatic events is abundantly clear. The ANS is therefore not as distinct an entity as the term suggests. Neither somatic nor ANS activity occurs in isolation.<sup>1</sup> The ANS organizes visceral support for somatic behavior and adjusts body states in anticipation of emotional behavior or responses to the stress of disease. In brief, it organizes fight or flight responses.

Afferent fibers from visceral structures are the first link in the reflex arcs of the ANS, and may relay visceral pain or changes in vessel stretch. Most ANS efferent fibers are accompanied by sensory fibers that are now commonly recognized as components of the ANS. However, the afferent components of the ANS cannot be as distinctively divided as can the efferent nerves. ANS visceral sensory nerves are anatomically indistinguishable from somatic sensory nerves. The clinical importance of visceral afferent fibers is closely implicated in the management of chronic pain states.

## Functional Anatomy

The ANS is organized into two divisions based on anatomy, physiology, and pharmacology. Langley divided this nervous system into two parts in 1921. He retained the term *sympathetic* (sympathetic nervous system [SNS]) introduced by Willis in 1665 for the first part, and introduced the term “parasympathetic” (parasympathetic nervous system [PNS]) for the second. The term ANS was adopted as a comprehensive name for both. [Table 14-1](#) lists the complementary effects of SNS (adrenergic, sympathetic) and PNS (cholinergic, parasympathetic) activity of organ systems.

## Central Autonomic Organization

Pure central ANS versus somatic centers are not known. Integration of ANS activity occurs at all levels of the cerebrospinal axis. Efferent ANS activity can be initiated locally and by centers located in the spinal cord, brainstem, and hypothalamus. The cerebral cortex is the highest level of ANS integration. Fainting at the sight of blood is an example of this higher level of somatic and ANS integration. ANS function has also been successfully modulated through conscious, intentional efforts demonstrating that somatic responses are always accompanied by visceral responses and vice versa.

The principal site of ANS organization is the *hypothalamus*. SNS functions are controlled by nuclei in the posterolateral hypothalamus. Stimulation of these nuclei results in a massive discharge of the sympathoadrenal system. PNS functions are governed by nuclei in the midline and some anterior nuclei of the hypothalamus. The anterior hypothalamus is involved with regulation of temperature. The supraoptic hypothalamic nuclei regulate water metabolism and are anatomically and functionally associated with the posterior lobe of the pituitary (see Interaction of Autonomic Nervous System Receptors). This hypothalamic–neurohypophyseal connection represents a central ANS mechanism that affects the kidney by means of antidiuretic hormone (ADH). Long-term blood pressure control, reactions to physical and emotional stress, sleep, and sexual reflexes are regulated by the

hypothalamus.

**Table 14-1** Homeostatic Balance between Adrenergic and Cholinergic Effects

Organ System	Response	
	Adrenergic	Cholinergic
<b>Heart</b>		
Sinoatrial node	Tachycardia	Bradycardia
Atrioventricular node	Increased conduction	Decreased conduction
His-Purkinje	Increased automaticity and conduction velocity	Minimal
Myocardium	Increased contractility, conduction velocity, automaticity	Minimal decrease in contractility
Coronary vessels	Constriction ( $\alpha_1$ ) and dilation ( $\beta_1$ )	Dilation and constriction <sup>a</sup>
<b>Blood Vessels</b>		
Skin and mucosa	Constriction	Dilation
Skeletal muscle	Constriction ( $\alpha_1$ ) > dilation ( $\beta_2$ )	Dilation
Pulmonary	Constriction	Dilation
<b>Bronchial Smooth Muscle</b>		
	Relaxation	Contraction
<b>Gastrointestinal Tract</b>		
Gallbladder and ducts	Relaxation	Contraction
Gut motility	Decreased	Increased
Secretions	Decreased	Increased
Sphincters	Constriction	Relaxation
<b>Bladder</b>

Pupil	Mydriasis	Miosis
Ciliary muscle	Relaxation for far vision	Contraction for near vision

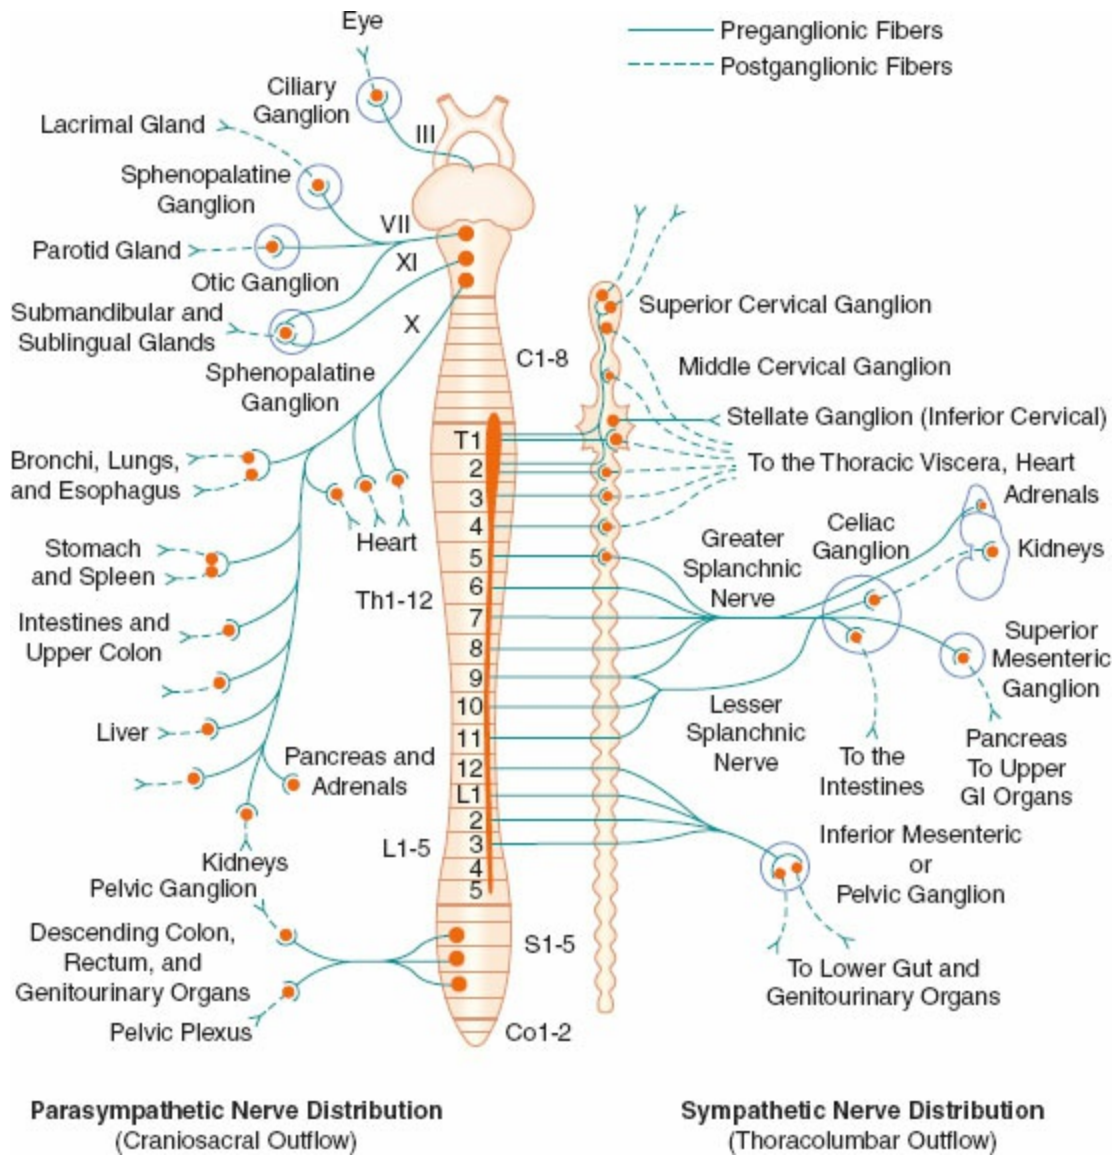

<sup>a</sup>See "Interaction of Autonomic Nervous System Receptors."

The *medulla oblongata* and *pons* are vital centers of acute ANS organization. Together, they integrate momentary hemodynamic adjustments and maintain the sequence and automaticity of ventilation. Integration of afferent and efferent ANS impulses at this central nervous system (CNS) level is responsible for the tonic activity exhibited by the ANS. Tonicity holds visceral organs in a state of intermediate activity that can be either diminished or augmented by altering the rate of nerve firing. The nucleus tractus solitarius, located within the medulla, is the primary area for relay of afferent chemoreceptor and baroreceptor information from the glossopharyngeal and vagus nerves. Increased afferent impulses from these two nerves inhibit peripheral SNS vascular tone, producing vasodilation; it also increases vagal

tone, producing bradycardia. Studies of patients with high spinal cord lesions show that a number of reflex changes are mediated at the spinal or segmental level. ANS hyperreflexia is an example of spinal cord mediation of ANS reflexes without integration of function from higher inhibitory centers.<sup>1</sup>

### **Peripheral Autonomic Nervous System Organization**

The peripheral ANS is the efferent (motor) component of the ANS and consists of the same two complementary parts: The SNS and the PNS. Most organs receive fibers from both divisions (Fig. 14-1). In general, activities of the two systems produce opposite but complementary effects (Table 14-1). A few tissues, such as sweat glands and spleen, are innervated by only SNS fibers. Although the anatomy of the somatic and ANS sensory pathways is identical, the motor pathways are characteristically different. The efferent somatic motor system, like somatic afferents, is composed of a single (unipolar) neuron with its cell body in the ventral gray matter of the spinal cord. Its myelinated axon extends directly to the voluntary striated muscle unit. In contrast, the efferent (motor) ANS is a two-neuron (bipolar) chain from the CNS to the effector organ. The first neuron of both the SNS and PNS originates within the CNS but does not make direct contact with the effector organ. Instead, it relays the impulse to a second station known as an *ANS ganglion*, which contains the cell body of the second ANS (postganglionic) neuron. Its axon contacts the effector organ. Thus, the motor pathways of both divisions of the ANS are schematically a serial two-neuron chain consisting of a preganglionic neuron and a postganglionic effector neuron (Fig. 14-2).

**Figure 14-1** Schematic distribution of the craniosacral (parasympathetic) and thoracolumbar (sympathetic) nervous systems. Parasympathetic preganglionic fibers pass directly to the organ that is innervated. Their postganglionic cell bodies are situated near or within the innervated viscera. This limited distribution of parasympathetic postganglionic fibers is consistent with the discrete and limited effect of parasympathetic function. The postganglionic sympathetic neurons originate in either the paired sympathetic ganglia or one of the unpaired collateral plexuses. One preganglionic fiber influences many postganglionic neurons. Activation of the SNS produces a more diffuse physiologic response rather than a discrete, localized effect. GI, gastrointestinal.

Preganglionic fibers of both subdivisions are myelinated with diameters of less than 3 mm.<sup>1</sup> Impulses are conducted at a speed of 3 to 15 m/s. The postganglionic fibers are unmyelinated and conduct impulses at slower speeds of less than 2 m/s. They are similar to unmyelinated visceral and somatic afferent C fibers (Table 14-2). Compared with the myelinated somatic nerves, the ANS conducts impulses at speeds that preclude its participation in the immediate phase of a somatic response.

**Figure 14-2** Schematic diagram of the efferent ANS. Efferent impulses are integrated centrally and sent reflexly to the adrenergic and cholinergic receptors. Sympathetic fibers ending in the adrenal medulla are preganglionic, and acetylcholine (ACh) is the neurotransmitter. Stimulation of the chromaffin cells, acting as postganglionic neurons, releases epinephrine (EPI) and norepinephrine (NE).

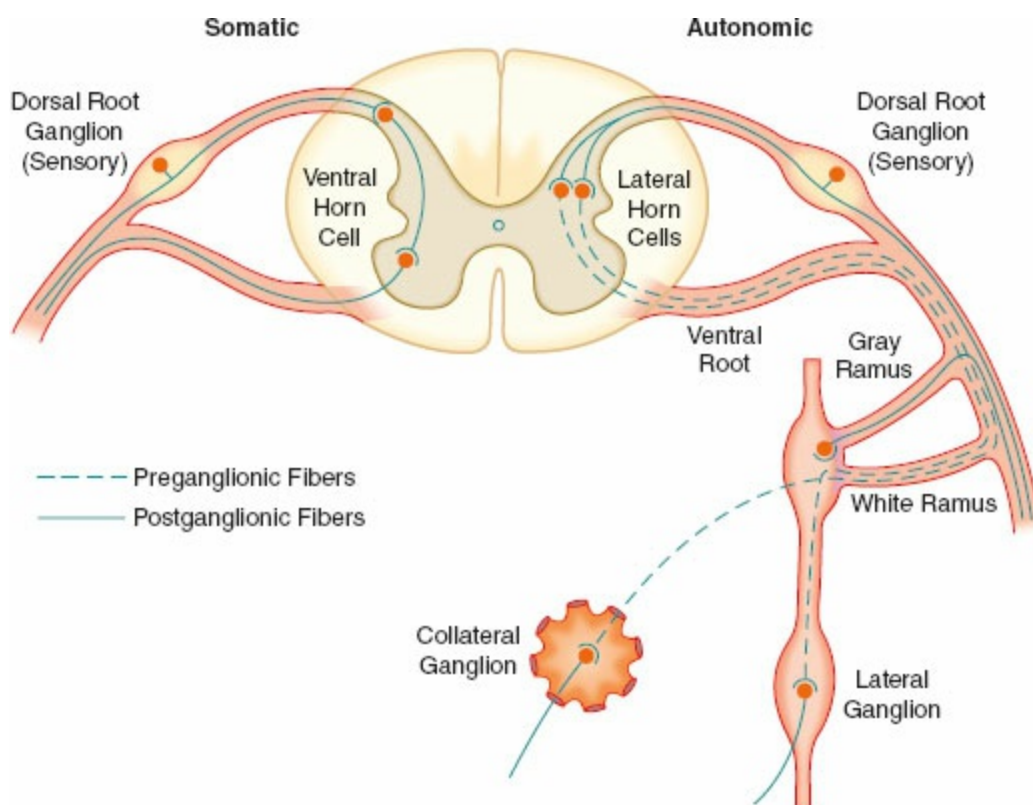

## Sympathetic Nervous System

The efferent SNS is referred to as the thoracolumbar nervous system. [Figure 14-1](#) demonstrates the distribution of the SNS and its innervation of visceral organs. The preganglionic fibers of the SNS (thoracolumbar division) originate in the intermediolateral gray column of the 12 thoracic (T1–T12) and the first three lumbar segments (L1–L3) of the spinal cord. The myelinated axons of these nerve cells leave the spinal cord with the motor fibers to form the white (myelinated) communicating rami ([Fig. 14-3](#)). The rami enter one of the paired 22 sympathetic ganglia at their respective segmental levels. Upon entering the paravertebral ganglia of the lateral sympathetic chain, the preganglionic fiber may follow one of three courses: (1) synapse with postganglionic fibers in ganglia at the level of exit, (2) course upward or downward in the trunk of the SNS chain to synapse in ganglia at other levels, or (3) track for variable distances through the sympathetic chain and exit without synapsing to terminate in an outlying, unpaired, SNS collateral ganglion. The adrenal gland is an exception to the rule. Preganglionic fibers pass directly into the adrenal medulla without

synapsing in a ganglion (Fig. 14-2). The cells of the medulla are derived from neuronal tissue and are analogous to postganglionic neurons.

**Table 14-2** Classification of Nerve Fibers

Description of Nerve Fibers	Group	Diameter ( $\mu\text{m}$ )	Conduction Velocity (m/s)
Myelinated somatic	A	alpha ( $\alpha$ )	120
		beta ( $\beta$ )	5–40 (pain fibers)
		gamma ( $\gamma$ )	5–40 (pain fibers)
		delta ( $\delta$ )	5
		epsilon ( $\epsilon$ )	2
Myelinated visceral (preganglionic autonomic)	B	<3	3–15
Unmyelinated somatic	C	<2	0.5–2.0 (pain fibers)

**Figure 14-3** The spinal reflex arc of the somatic nerves is shown on the left. The different arrangements of neurons in the sympathetic system are shown on the right. Preganglionic fibers coming out through white rami may make synaptic connections following one of three courses: (1) synapse in ganglia at the level of exit, (2) course up or down the sympathetic chain to synapse at another level, or (3) exit the chain without synapsing to an outlying collateral ganglion.

The sympathetic postganglionic neuronal cell bodies are located in ganglia of the paired lateral SNS chain or unpaired collateral ganglia in more peripheral plexuses. Collateral ganglia, such as the celiac and inferior mesenteric ganglia (plexus), are formed by the convergence of preganglionic fibers with many postganglionic neuronal bodies. SNS ganglia are almost always located closer to the spinal cord than to the organs they innervate. The

sympathetic postganglionic neurons can therefore originate in either the paired lateral paravertebral SNS ganglia or one of the unpaired collateral plexuses. The unmyelinated postganglionic fibers then proceed from the ganglia to terminate within the organs they innervate. Many of the postganglionic fibers pass from the lateral SNS chain back into the spinal nerves, forming the gray (unmyelinated) communicating rami at all levels of the spinal cord (Fig. 14-2). They are distributed distally to sweat glands, pilomotor muscle, and blood vessels of the skin and muscle. These nerves are unmyelinated C type fibers (Table 14-2) and are carried within the somatic nerves. Approximately 8% of the fibers in the average somatic nerve are sympathetic.

The first four or five thoracic spinal segments generate preganglionic fibers that ascend in the neck to form three special paired ganglia. These are the superior cervical, middle cervical, and cervicothoracic ganglia. The last is known as the stellate ganglion and is actually formed by the fusion of the inferior cervical and first thoracic SNS ganglia. These ganglia provide sympathetic innervation of the head, neck, upper extremities, heart, and lungs. Afferent pain fibers also travel with these nerves, accounting for chest, neck, or upper extremity pain with myocardial ischemia.

Activation of the SNS produces a diffuse physiologic response (mass reflex) rather than discrete effects. SNS postganglionic neurons outnumber the preganglionic neurons in an average ratio of 20:1 to 30:1.<sup>2</sup> One preganglionic fiber influences a larger number of postganglionic neurons, which are dispersed to many organs.

## Parasympathetic Nervous System

The PNS, like the SNS, has both preganglionic and postganglionic neurons. The preganglionic cell bodies originate in the brainstem and sacral segments of the spinal cord. PNS preganglionic fibers are found in cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus). The sacral outflow originates in the intermediolateral gray horns of the second, third, and fourth sacral nerves. Figure 14-1 shows the distribution of the PNS division and its innervation of visceral organs.

The vagus (cranial nerve X) nerve has the most extensive distribution of all the PNS, accounting for more than 75% of PNS activity. The paired vagus nerves supply PNS innervation to the heart, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, and upper portions of the ureters. The sacral fibers form the pelvic visceral nerves, or *nervi erigentes*. These nerves supply the remainder of the viscera that are not innervated by the vagus. They supply the descending colon, rectum, uterus, bladder, and lower portions of the ureters and are primarily concerned with

emptying. Various sexual reactions are also governed by the sacral PNS. The PNS is responsible for penile erection, but SNS stimulation governs ejaculation.

In contrast to the SNS division, PNS preganglionic fibers pass directly to the organ that is innervated. The postganglionic cell bodies are situated near or within the innervated viscera and generally are not visible. The proximity of PNS ganglia to or within the viscera provides a limited distribution of postganglionic fibers. The ratio of postganglionic to preganglionic fibers in many organs appears to be 1:1 to 3:1 compared with the 20:1 found in the SNS system. The Auerbach plexus in the distal colon is the exception, with a ratio of 8,000:1. The fact that PNS preganglionic fibers synapse with only a few postganglionic neurons is consistent with the discrete and limited effect of PNS function. For example, vagal bradycardia can occur without a concomitant change in intestinal motility or salivation. Mass reflex action is not a characteristic of the PNS. The effects of organ response to PNS stimulation are outlined in [Table 14-1](#).

## Autonomic Innervation

### *Heart*

**2** The heart is well supplied by the SNS and PNS. These nerves affect cardiac pump function in three ways: (1) by changing the rate (chronotropism), (2) by changing the strength of contraction (inotropism), and (3) by modulating coronary blood flow. The PNS cardiac vagal fibers approach the stellate ganglia and then join the efferent cardiac SNS fibers; therefore, the vagus nerve to the heart and lungs is a mixed nerve containing both PNS and SNS efferent fibers. The PNS fibers are distributed mainly to the sinoatrial and atrioventricular (AV) nodes and to a lesser extent to the atria. There is little or no distribution to the ventricles. Therefore, the main effect of vagal cardiac stimulation to the heart is chronotropic. Vagal stimulation decreases the rate of sinoatrial node discharge and decreases excitability of the AV junctional fibers, slowing impulse conduction to the ventricles. A strong vagal discharge can completely arrest sinoatrial node firing and block impulse conduction to the ventricles.<sup>3</sup>

The physiologic importance of the PNS on myocardial contractility is not as well understood as that of the SNS. Cholinergic blockade can double the heart rate (HR) without altering contractility of the left ventricle. Vagal stimulation of the heart can reduce left ventricular maximum rate of tension development (dP/dT) and decrease contractile force by as much as 10% to 20%. However, PNS stimulation is relatively unimportant in this regard compared with its predominant effect on HR. The SNS has the same supraventricular distribution as the PNS, but with stronger representation to

the ventricles. SNS efferents to the myocardium funnel through the paired stellate ganglia. The right stellate ganglion distributes primarily to the anterior epicardial surface and the interventricular septum. Right stellate stimulation decreases systolic duration and increases HR. The left stellate ganglion supplies the posterior and lateral surfaces of both ventricles. Left stellate stimulation increases mean arterial pressure and left ventricular contractility without causing a substantial change in HR. Normal SNS tone maintains contractility approximately 20% above that in the absence of any SNS stimulation.<sup>4</sup> Therefore, the dominant effect of the ANS on myocardial contractility is mediated primarily through the SNS. Intrinsic mechanisms of the myocardium, however, can maintain circulation quite well without the ANS, as evidenced by the success of cardiac transplants (see [Chapter 51](#)). The heart and ANS are in perfect symbiosis. ANS via its components imprints the cardiac electrophysiology by potentially inducing significant dysrhythmias or electrocardiographic abnormalities, which in the end may lead to global cardiac dysfunction. The precise role of the ANS is unknown, specifically if it is an active component or just an accompaniment. Future research interests concern the modification of the autonomic cardiac innervation through pharmacology or using alternative approaches.<sup>5</sup> Early investigations, performed in anesthetized, open-chest animals, demonstrated that cardiac ANS nerves exert only slight effects on the coronary vascular bed; however, more recent studies on chronically instrumented, intact, conscious animals show considerable evidence for a strong SNS regulation of the small coronary resistance and larger conductance vessels<sup>6,7</sup> (see below, Adrenergic Receptors).

Different segments of the coronary arterial tree react differently to various stimuli and drugs. Normally, the large conductance vessels contribute little to overall coronary vascular resistance (see [Chapter 12](#)). Fluctuations in resistance reflect changes in lumen size of the small, precapillary vessels. Blood flow through the resistance vessels is regulated primarily by the local metabolic requirements of the myocardium. The larger conductance vessels, however, can constrict markedly due to neurogenic stimulation. Neurogenic influence also assumes a greater role in the resistance vessels when they become hypoxic and lose autoregulation.

## Peripheral Circulation

**3** The SNS nerves are by far the most important regulators of the peripheral circulation. The PNS nerves play only a minor role in this regard. The PNS dilates vessels, but only in limited areas such as the genitalia. SNS stimulation produces both vasodilation and vasoconstriction, with vasoconstrictor effects predominating. The SNS effect on the vascular bed is determined by the type

of receptors on which the SNS fiber terminates (see below, Adrenergic Receptors). SNS constrictor receptors are distributed to all segments of the circulation. Blood vessels in the skin, kidneys, spleen, and mesentery have an extensive SNS distribution, whereas those in the heart, brain, and muscle have less SNS innervation.

Basal vasomotor tone is maintained by impulses from the lateral portion of the vasomotor center in the medulla oblongata that continually transmits impulses through the SNS, maintaining partial arteriolar and venular constriction. Circulating epinephrine (EPI) from the adrenal medulla has additive effects. This basal ANS tone maintains arteriolar constriction at an intermediate diameter. The arteriole, therefore, has the potential for either further constriction or dilation. If the basal tones were not present, the SNS could only affect vasoconstriction and not vasodilation.<sup>8</sup> The SNS tone in the venules produces little resistance to flow compared with the arterioles and the arteries. The importance of SNS stimulation of veins is to reduce or increase their capacity. By functioning as a reservoir for approximately 80% of the total blood volume, small changes in venous capacitance produce large changes in venous return and, thus, cardiac preload.

## Lungs

The lungs are innervated by both the SNS and PNS. Postganglionic SNS fibers from the upper thoracic ganglia (stellate) pass to the lungs to innervate the smooth muscles of the bronchi and pulmonary blood vessels. PNS innervation of these structures is via the vagus nerve. SNS stimulation produces bronchodilation and pulmonary vasoconstriction.<sup>9</sup> Little else has been proven conclusively about the vasomotor control of the pulmonary vessels other than that they adjust to accommodate the output of the right ventricle. The effect of stimulation of the pulmonary SNS nerves on pulmonary vascular resistance is not ideal but may be important in maintaining hemodynamic stability during stress and exercise by balancing right and left ventricular output. Stimulation of the vagus nerve produces almost no vasodilation of the pulmonary circulation. Hypoxic pulmonary vasoconstriction is a local phenomenon capable of providing a faster adjustment to the requirements of the organism.

Both the SNS and the vagus nerve provide active bronchomotor control. SNS stimulation causes bronchodilation, whereas vagal stimulation produces constriction. PNS stimulation may also increase secretions of the bronchial glands. Vagal receptor endings in the alveolar ducts also play an important role in the reflex regulation of the ventilation cycle. The lung has important nonventilatory activity as well. It serves as a metabolic organ that removes local mediators such as norepinephrine (NE) from the circulation and converts

others, such as angiotensin 1, to active compounds<sup>10</sup> (see below, Interaction with Other Regulatory Systems).

**Figure 14-4** The anatomy and physiology of the terminal postganglionic sympathetic and parasympathetic fibers are similar.

## Autonomic Nervous System Transmission

Transmission of excitation across the terminal junctional sites (synaptic clefts) of the peripheral ANS occurs through the mediation of released chemicals (Fig. 14-4). Transmitters interact with receptors on the end organ to evoke a biologic response.

**4** The ANS can be pharmacologically subdivided by the neurotransmitter secreted at the effector cell. Pharmacologic parlance designates the SNS and PNS as adrenergic and cholinergic, respectively. The terminals of the PNS postganglionic fibers release acetylcholine (ACh). With the exception of sweat glands, NE is the principal neurotransmitter released at the terminals of the sympathetic postganglionic fibers (see Fig. 14-2). Cotransmission of adenosine triphosphate (ATP), neuropeptide Y (NPY), and NE has been demonstrated at vascular sympathetic nerve terminals in a number of different tissues including muscle, intestine, kidney, and skin. The preganglionic neurons of both systems secrete ACh.

The terminations of the postganglionic fibers of both ANS subdivisions are anatomically and physiologically similar. The terminations are characterized by multiple branching called *terminal effector plexuses* or *reticulae*. These filaments surround the elements of the effector unit “like a mesh stocking.”<sup>8</sup> Thus, one SNS postganglionic neuron, for example, can innervate approximately 25,000 effector cells, for example, vascular smooth muscle. The terminal filaments end in presynaptic enlargements called varicosities. Each varicosity contains vesicles, approximately 500 Å in diameter, in which

the neurotransmitters are stored (Fig. 14-4). The rate of synthesis depends on the level of ANS activity and is regulated by local feedback. The distance between the varicosity and the effector cell (synaptic or junctional cleft) varies from 100 Å in ganglia and arterioles to as much as 20,000 Å in large arteries. The time for diffusion is directly proportional to the width of the synaptic gap. Depolarization on the nerve releases the vesicular contents into the synaptic cleft by exocytosis.

## **Parasympathetic Nervous System Transmission**

### *Synthesis*

ACh is considered the primary neurotransmitter of the PNS. ACh is formed in the presynaptic terminal by acetylation of choline with acetyl coenzyme A. This step is catalyzed by choline acetyl transferase (Fig. 14-5). ACh is then stored in a concentrated form in presynaptic vesicles. A continual release of small amounts of ACh, called quanta, occurs during the resting state. Each quantum results in small changes in the electrical potential of the synaptic end plate without producing depolarization. These are known as miniature end-plate potentials. Arrival of an action potential causes a synchronous release of hundreds of quanta, resulting in depolarization of the end plate. Release of ACh from the vesicles is dependent on influx of calcium ( $\text{Ca}^{2+}$ ) from the interstitial space. ACh is not reused like NE; therefore, it must be synthesized constantly.

### *Metabolism*

The ability of a receptor to modulate function of an effector organ is dependent upon rapid recovery to its baseline state after stimulation. For this to occur, the neurotransmitter must be quickly removed from the vicinity of the receptor. ACh removal occurs by rapid hydrolysis by acetylcholinesterase (Fig. 14-5). This enzyme is found in neurons, at the neuromuscular junction, and in various other tissues of the body. A similar enzyme, pseudocholinesterase or plasma cholinesterase is also found throughout the body but only to a limited extent in neural tissue. It does not appear to be physiologically important in termination of the action of ACh. Both acetylcholinesterase and pseudocholinesterase hydrolyze ACh as well as other esters (such as the ester-type local anesthetics), and they may be distinguished by specific biochemical tests.<sup>3</sup>

**Figure 14-5** Synthesis and metabolism of acetylcholine.

## Sympathetic Nervous System Transmission

Traditionally, the catecholamines EPI and NE are considered the main mediators of peripheral SNS activity. NE is released from localized presynaptic vesicles of nearly all postganglionic sympathetic nerves.  Vascular SNS nerve terminals, however, also release ATP. Thus, ATP and NE are co-neurotransmitters. They are released directly to their site of action. Their postjunctional effects appear to be synergistic in tissues.

The SNS fibers ending in the adrenal medulla are preganglionic, and ACh is the neurotransmitter (Fig. 14-2). It interacts with the chromaffin cells in the adrenal medulla, causing release of EPI and NE. The chromaffin cells take the place of the postganglionic neurons. Stimulation of the sympathetic nerves innervating the adrenal medulla, however, causes the release of large quantities of a mixture of EPI and NE into the circulation. The greater portion of this hormonal surge is normally EPI. EPI and NE, when released into the circulation, are classified as hormones in that they are synthesized, stored, and released from the adrenal medulla to act at distant sites.

Hormonal EPI and NE have essentially the same effects on effector cells as those caused by local direct sympathetic stimulation. The hormonal effects, although brief, last about 10 times as long as those caused by direct stimulation. EPI has a greater metabolic effect than NE. It can increase the metabolic rate of the body as much as 100%. It also increases glycogenolysis in the liver and muscle with glucose release into the blood. These functions are all necessary to prepare the body for fight or flight.

### *Catecholamines: The First Messenger*

A catecholamine is any compound with a catechol nucleus (a benzene ring with two adjacent hydroxyl groups) and an amine-containing side chain. The chemical configuration of five of the more common catecholamines in clinical use is demonstrated in Figure 14-6. The endogenous catecholamines in 

humans are dopamine (DA), NE, and EPI. Dopamine is a neurotransmitter present in the CNS, primarily involved in coordinating motor activity in the brain. It is the precursor of NE. NE is synthesized and stored in nerve endings of postganglionic SNS neurons. It is also synthesized in the adrenal medulla and is the chemical precursor of EPI. Stored EPI is located chiefly in chromaffin cells of the adrenal medulla. About 80% to 85% of the catecholamine content of the adrenal medulla is EPI and 15% to 20% is NE. The brain contains both noradrenergic and dopaminergic receptors, but circulating catecholamines do not cross the blood-brain barrier. The catecholamines present in the brain are synthesized there.

**Figure 14-6** The chemical configurations of three endogenous catecholamines are compared with those of three synthetic catecholamines. Sympathomimetic drugs differ in their hemodynamic effects largely because of differences in substitution of the amine group on the catechol nucleus.

Catecholamines are often referred to as adrenergic drugs because their effector actions are mediated through receptors specific for the SNS. Sympathomimetics can activate these same receptors because of their structural similarity. For example, clonidine is an  $\alpha_2$ -receptor agonist that does not possess a catechol nucleus and even has two ring systems that are

aplanar to each other. However, clonidine enjoys a remarkable spatial similarity to NE that allows it to activate the  $\alpha$  receptor. Drugs that produce sympathetic-like effects but lack basic catecholamine structure are defined as sympathomimetics. All clinically useful catecholamines are sympathomimetics, but not all sympathomimetics are catecholamines. The effects of endogenous or synthetic catecholamines on adrenergic receptors can be direct or indirect. Indirect-acting catecholamines (i.e., ephedrine) have little intrinsic effect on adrenergic receptors but produce their effects by stimulating release of the stored neurotransmitter from SNS nerve terminals. Some synthetic and endogenous catecholamines stimulate adrenergic receptor sites directly (e.g., phenylephrine), whereas others have a mixed mode of action. The actions of direct-acting catecholamines are independent of endogenous NE stores; however, the indirect-acting catecholamines are entirely dependent on adequate neuronal stores of endogenous NE.

### *Synthesis*

The main site of NE synthesis is in or near the postganglionic nerve endings. Some synthesis does occur in vesicles near the cell body that pass to the nerve endings. Phenylalanine or tyrosine is taken up into the axoplasm of the nerve terminal and modified into either NE or EPI. [Figure 14-7](#) demonstrates this synthesis cascade. Tyrosine hydroxylase catalyzes the conversion of tyrosine to dihydroxyphenylalanine. This is the rate-limiting step at which NE synthesis is controlled through feedback inhibition. Dopamine (DA) synthesis occurs in the cytoplasm of the neuron. The vesicles of peripheral postganglionic neurons contain the enzyme dopamine- $\beta$ -hydroxylase, which converts dopamine to NE. The adrenal medulla additionally contains phenylethanolamine-N-methyltransferase, which converts NE to EPI. This reaction takes place outside the medullary vesicles, and the newly formed EPI then enters the vesicle for storage ([Fig. 14-8](#)). All the endogenous catecholamines are stored in presynaptic vesicles and released on arrival of an action potential. Excitation–secretion coupling in sympathetic neurons is  $\text{Ca}^{2+}$ -dependent.

**Figure 14-7** Schematic of the synthesis of catecholamines. The conversion of tyrosine to DOPA by tyrosine hydroxylase is inhibited by increased NE synthesis. Epinephrine is shown in these steps but is primarily synthesized in the adrenal medulla. DOPA, dihydroxyphenylalanine.

**Figure 14-8** Schematic of the synthesis and disposition of NE in adrenergic neurotransmission. (1) Synthesis and storage in neuronal vesicles; (2) Action potential permits calcium entry with (3) exocytosis of NE into synaptic gap. (4) Released NE reacts with receptors on effector cell. NE (5) may react with presynaptic α<sub>2</sub> receptor to inhibit further NE release or with presynaptic β-receptor to enhance reuptake of NE (6)

(uptake 1). Extraneuronal uptake (uptake 2) absorbs NE into effector cell (7) with overflow occurring systemically (8). MAO, monoamine oxidase; COMT, catechol-O-methyltransferase; Tyr, tyrosine; DOPA, dihydroxyphenylalanine; NE, norepinephrine.

### *Regulation*

Increased SNS nervous activity, as in congestive heart failure or chronic stress, stimulates the synthesis of catecholamines. Glucocorticoids from the adrenal cortex stimulate an increase in phenylethanolamine-N-methyltransferase that methylates NE to EPI.

The release of NE is dependent upon depolarization of the nerve and an increase in calcium ion permeability. This release is inhibited by colchicine and prostaglandin E<sub>2</sub>, suggesting a contractile mechanism. NE inhibits its own release by stimulating presynaptic (prejunctional)  $\alpha_2$  receptors. Phenoxybenzamine and phentolamine,  $\alpha$ -receptor antagonists, increase the release of NE by blocking inhibitory presynaptic  $\alpha_2$  receptors (Fig. 14-9). Other receptors are also important in NE regulation (see below, Other Receptors).

### *Inactivation*

The catecholamines are removed from the synaptic cleft by three mechanisms (Fig. 14-8). These are reuptake into the presynaptic terminals, extraneuronal uptake, and diffusion. Termination of NE action at the effector site is almost entirely by reuptake of NE into the terminals of the presynaptic neuron. This is an active, energy-requiring, and temperature-dependent process. The reuptake of NE in the presynaptic terminals is also a stereospecific process. Structurally similar compounds (guanethidine, metaraminol) may enter the vesicles and displace the neurotransmitter. Tricyclic antidepressants and cocaine inhibit the reuptake of NE, resulting in high synaptic NE concentrations and accentuated receptor response. In addition, evidence suggests that NE reuptake is mediated by a presynaptic  $\beta$ -adrenergic mechanism because  $\beta$ -blockade causes marked elevations of EPI and NE (Figs. 14-8 and 14-9).<sup>11</sup> Extraneuronal uptake is a minor pathway for inactivating NE. Effector cells and other extraneuronal tissues take up NE. The NE that is taken up by the extraneuronal tissue is metabolized by monoamine oxidase (MAO) and by catechol-O-methyltransferase (COMT) to form vanillylmandelic acid. The minute amount of catecholamine that escapes these two mechanisms diffuses into the circulation, where it is metabolized by the liver and kidney. The same enzymes inactivate EPI. Reuptake is the predominant pathway for inactivation of the endogenous catecholamines, while metabolism by the liver and kidney is the predominant pathway for catecholamines given exogenously. This accounts for the longer duration of

action of the exogenous catecholamines than that noted at the local synapse.

**Figure 14-9** This schematic demonstrates just a few of the presynaptic adrenergic receptors thought to exist. Agonist and antagonist drugs are clinically available for these receptors (Table 14-5). The  $\alpha_2$  receptors serve as a negative feedback mechanism whereby NE stimulation inhibits its own release. Presynaptic  $\beta$ -stimulation increases NE uptake, augmenting its availability. Presynaptic muscarinic (MUSC) receptors respond to ACh diffusing from nearby cholinergic terminals. They inhibit NE release and can be blocked by atropine. NE, norepinephrine.

The final metabolic product of the catecholamines is vanillylmandelic acid. Vanillylmandelic acid constitutes the major metabolite (80% to 90%) of NE found in the urine. Less than 5% of released NE appears unchanged in the urine. The metabolic products excreted in the urine provide a gross estimate of SNS activity and can facilitate the clinical diagnosis of pheochromocytoma (see Chapter 46).

## Receptors

An agonist is a substance that interacts with a receptor to evoke a biologic response. ACh, NE, EPI, DA, and ATP are the major agonists of the ANS. An antagonist is a substance that interferes with the evocation of a response at a receptor site by an agonist. Receptors are therefore target sites that lead to a response by the effector cell when activated by an agonist. Receptors are protein macromolecules and are located in the plasma membrane. Several thousand receptors have been demonstrated in a single cell. The enormity of this network becomes apparent when one considers that

~ 25,000 single cells can be innervated by a single neuron.

## Cholinergic Receptors

ACh is the neurotransmitter for three distinct classes of receptors. These receptors can be differentiated by their anatomic location and their affinity for various agonists and antagonists. ACh mediates the “first messenger” function of transmitting impulses within the PNS, the ganglia of the SNS, and the neuroeffector junction of striated, voluntary muscle (Fig. 14-2). Cholinergic receptors are further subdivided into muscarinic and nicotinic receptors because muscarine and nicotine stimulate them selectively. However, both muscarinic and nicotinic receptors respond to ACh (see below, Cholinergic Drugs). Muscarine activates cholinergic receptors at the postganglionic PNS junctions of cardiac and smooth muscle. Muscarinic stimulation is characterized by bradycardia, decreased inotropism, bronchoconstriction, miosis, salivation, gastrointestinal hypermotility, and increased gastric acid secretion (Table 14-1). Muscarinic receptors can be blocked by atropine without effect on nicotinic receptors (see below, Cholinergic Drugs). Muscarinic receptors are known to exist in sites other than PNS postganglionic junctions. They are found on the presynaptic membrane of sympathetic nerve terminals in the myocardium, coronary vessels, and peripheral vasculature (Fig. 14-9). These are referred to as adrenergic muscarinic receptors because of their location; however, ACh stimulates them also. Stimulation of these receptors inhibits release of NE in a manner similar to  $\alpha_2$ -receptor stimulation. Muscarinic blockade removes the inhibition of NE release, augmenting SNS activity. Atropine, the prototypical muscarinic blocker, may produce sympathomimetic activity in this manner as well as vagal blockade. Neuromuscular blocking drugs that cause tachycardia are thought to have a similar mechanism of action. ACh acting on presynaptic adrenergic muscarinic receptors is a potent inhibitor of NE release.<sup>11</sup> The prejunctional muscarinic receptor may play an important physiologic role because several autonomically innervated tissues (e.g., the heart) possess ANS plexuses in which the SNS and PNS nerve terminals are closely associated. In these plexuses, ACh, released from the nearby PNS nerve terminals (vagus nerve), can inhibit NE release by activation of presynaptic adrenergic muscarinic receptors.

Nicotinic receptors are found at the synaptic junctions of both SNS and PNS ganglia. Because both junctions are cholinergic, ACh or ACh-like substances such as nicotine will excite postganglionic fibers of both systems (Fig. 14-2). Low doses of nicotine produce stimulation of ANS ganglia whereas high doses produce blockade. This dualism is referred to as the nicotinic effect (see below, Ganglionic Drugs). Nicotinic stimulation of the

SNS ganglia produces hypertension and tachycardia by causing the release of EPI and NE from the adrenal medulla. Adrenal hormone release is mediated by ACh in the chromaffin cells, which are analogous to postganglionic neurons. A further increase in nicotine concentration produces hypotension and neuromuscular weakness, as it becomes a ganglionic blocker. The cholinergic neuroeffector junction of skeletal muscle also contains nicotinic receptors, although they are not identical to the nicotinic receptors in ANS ganglia.

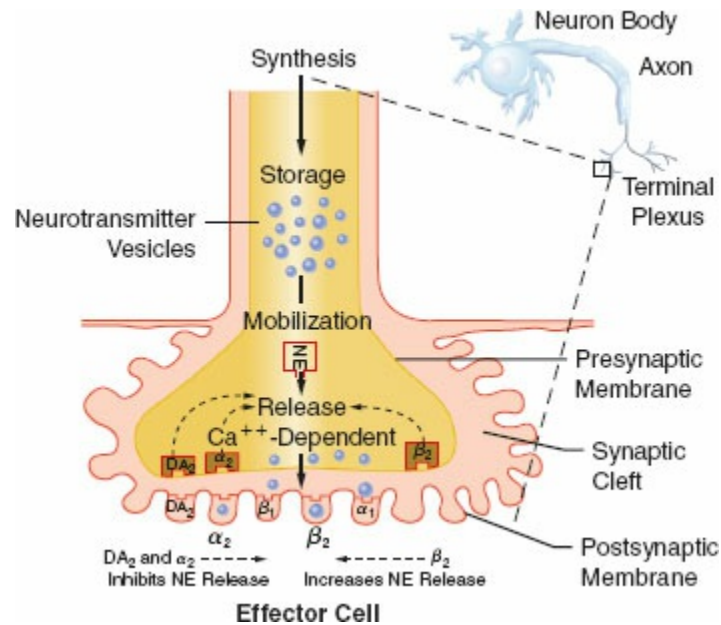

## Adrenergic Receptors

**6** The adrenergic receptors are termed adrenergic or noradrenergic, depending on their responsiveness to EPI or NE. The dissimilarities of these two drugs led Ahlquist in 1948 to propose two types of opposing adrenergic receptors, termed alpha ( $\alpha$ ) and beta ( $\beta$ ). The development of new agonists and antagonists with relatively selective activity allowed subdivision of the  $\beta$ -receptors into  $\beta_1$  and  $\beta_2$ ;  $\alpha$ -receptors were subsequently divided into  $\alpha_1$  and  $\alpha_2$ . These were later further subdivided using molecular cloning. The sympathomimetic adrenergic drugs in current use differ from one another in their effects, largely because of differences in substitution on the amine group, which influences the relative  $\alpha$  or  $\beta$  effect (Fig. 14-6).

Another major peripheral adrenergic receptor specific for dopamine is termed the dopaminergic (DA) receptor. Further studies have revealed not only subsets of the  $\alpha$  and  $\beta$  receptors but also the DA receptor. These DA receptors have been identified in the CNS and in renal, mesenteric, and coronary vessels. The physiologic importance of these receptors is a matter of controversy because there are no identifiable peripheral DA neurons. Dopamine measured in the circulation is assumed to result from spillover from the brain.

The function of dopamine in the CNS has long been known, but the peripheral dopamine receptor has been elucidated only within the past 25 years. The presence of the peripheral DA receptor was obscured because dopamine does not affect the DA receptor exclusively. It also stimulates  $\alpha$  and  $\beta$  receptors in a dose-related manner. However, DA receptors function independently of  $\alpha$  or  $\beta$  blockade and are modified by DA antagonists such as haloperidol, droperidol, and phenothiazines. Thus, there is a necessity for the addition of the DA receptor and its subsets (DA<sub>1</sub> and DA<sub>2</sub>).

**Figure 14-10** Location of several known adrenergic receptors. The presynaptic  $\alpha_2$  and DA receptors serve as a negative feedback mechanism, whereby stimulation of NE inhibits its own release. Presynaptic  $\beta_2$  stimulation increases NE uptake, augmenting its availability. Postsynaptic  $\alpha_2$  and  $\beta_2$  receptors are extrasynaptic and are considered noninnervated hormonal receptors. DA, dopamine; NE, norepinephrine.

The distribution of adrenergic receptors in organs and tissues is not uniform and their function differs not only by their location but also in their numbers and/or distribution. Adrenergic receptors are found in two loci in the sympathetic neuroeffector junction. They are found in both the presynaptic (prejunctional) and postsynaptic (postjunctional) sites as well as extrasynaptic sites (Fig. 14-10). Table 14-3 is a review of the function and synaptic location of some of the clinically important receptors and their subtypes.

### **$\alpha$ -Adrenergic Receptors**

The  $\alpha$ -adrenergic ( $\alpha$ ) receptors have been further subdivided into two clinically important classes,  $\alpha_1$  and  $\alpha_2$ . This classification is based on their response to the  $\alpha$ -antagonists yohimbine and prazosin. Prazosin is a more potent antagonist of  $\alpha_1$  receptors, whereas  $\alpha_2$  receptors are more sensitive to yohimbine. Recently, pharmacologic experiments have demonstrated the existence of two subtypes within the  $\alpha_1$  group, namely  $\alpha_{1A}$  and  $\alpha_{1B}$ , and at least two subtypes within the  $\alpha_2$  group, respectively,  $\alpha_{2A}$  and  $\alpha_{2B}$ . The importance of these subsets is still emerging, with evidence that the spleen and liver contain mainly  $\alpha_{1B}$  receptors, and the heart, neocortex, kidney, vas deferens, and hippocampus contain equal amounts of  $\alpha_{1A}$  and  $\alpha_{1B}$  receptors. The  $\alpha_1$ -adrenergic receptors are found in the smooth muscle cells of the peripheral vasculature, coronary arteries, skin, uterus, intestinal mucosa, and splanchnic beds (Table 14-4).<sup>12</sup> The  $\alpha_1$  receptors serve as postsynaptic

activators of vascular and intestinal smooth muscle as well as of endocrine glands. Their activation results in either decreased or increased tone, depending upon the effector organ. The response in resistance and capacitance vessels is constriction, whereas in the intestinal tract it is relaxation. There is now a large body of evidence documenting the presence of postjunctional  $\alpha_1$  adrenoceptors in the mammalian heart.  $\alpha_1$ -Adrenergic receptors have been shown to have a positive inotropic effect on cardiac tissues in most mammals studied, including humans. Experimental work strongly supports the concept that enhanced myocardial  $\alpha_1$  responsiveness plays a primary role in the genesis of malignant arrhythmias induced by catecholamines during myocardial ischemia and reperfusion. Drugs possessing potent  $\alpha_1$ -antagonist activity such as prazosin and phentolamine provide significant antiarrhythmic activity. The clinical mechanism and significance of these findings are not yet clear. However, there is no doubt that  $\alpha_1$ -adrenergic antagonists prevent catecholamine-induced ventricular arrhythmias.<sup>13</sup> In contrast, studies of the effects of  $\beta$ -antagonists in experimental and clinical myocardial infarction have provided conflicting results.

The discovery of presynaptic  $\alpha$ -adrenoceptors and their role in the modulation of NE transmission provided the stimulus for the subclassification of  $\alpha$  receptors into  $\alpha_1$  and  $\alpha_2$  subtypes. Presynaptic  $\alpha_1$  receptors have not been identified; receptors appear confined only to the postsynaptic membrane. On the other hand,  $\alpha_2$  receptors are found on both presynaptic and postsynaptic membranes of the adrenergic neuroeffector junction. [Table 14-4](#) reviews these sites. Postsynaptic membranes contain a near equal mix of  $\alpha_1$  and  $\alpha_2$  receptors.

The  $\alpha_2$  adrenoceptors may be subdivided even further into as many as four possible subtypes. The postsynaptic  $\alpha_2$  receptors have many actions, which include arterial and venous vasoconstriction, platelet aggregation, inhibition of insulin release, inhibition of bowel motility, stimulation of growth hormone release, and inhibition of ADH release.

**Table 14-3** Adrenergic Receptors: Order of Potency of Agonists and Antagonists

Receptor		Agonists <sup>a</sup>	Antagonists	Location	Action
$\alpha_1$	++++	Norepinephrine	Phenoxybenzamine <sup>b</sup>	Smooth muscle (vascular, iris, radial, ureter, pilomotor, uterus, trigone, gastrointestinal, and bladder sphincters) Brain Smooth muscle (gastrointestinal) Heart Salivary glands  Adipose tissue Sweat glands (localized) Kidney (proximal tubule)	Contraction Vasoconstriction  Neurotransmission Relaxation Glycogenolysis Increased force, <sup>c</sup> glycolysis Secretion (K <sup>+</sup> , H <sub>2</sub> O) Glycogenesis Secretion Gluconeogenesis Na <sup>+</sup> reabsorption

	+	Bromocriptine			

DA, dopamine.

<sup>a</sup>Listed in decreasing order of potency.

<sup>b</sup>Nonselective.

<sup>c</sup> $\beta_1$ -Adrenergic responses are greater.

Pluses indicate strength of potency.

**Table 14-4** Adrenergic Receptors

Receptor	Synaptic Site	Anatomic Site	Action	LV Function and Stroke Volume
$\alpha_1$	Postsynaptic	Peripheral vascular smooth muscle	Constriction	Decreased
		Renal vascular smooth muscle Coronary arteries, epicardial Myocardium	Constriction Constriction Positive inotropism	
$\alpha_2$	Presynaptic	30%–40% of resting tone Renal tubules	Antidiuresis Inhibit NE	Improved
		Peripheral vascular smooth muscle release	Secondary vasodilation	
	Postsynaptic	Coronaries CNS	Inhibition of CNS activity Sedation Decrease MAC Constriction	Decreased
$\beta_1$	Postsynaptic NE sensitive	Coronaries, endocardial CNS	Inhibition of insulin release Decreased bowel motility Inhibition of antidiuretic hormone Analgesia	Improved
		Renal tubule Myocardium	Promotes $\text{Na}^{2+}$ and $\text{H}_2\text{O}$ excretion Positive inotropism and chronotropism	
$\beta_2$	Presynaptic NE sensitive	Sinoatrial (SA) node Ventricular conduction Kidney Coronaries	Renin release Relaxation	Improved
		Myocardium SA node ventricular conduction vessels	Accelerates NE release Opposite action to presynaptic $\alpha_2$ agonism Constriction	
DA <sub>1</sub>	Postsynaptic	Myocardium	Positive inotropism and chronotropism	Improved
		Vascular smooth muscle Bronchial smooth muscle Renal vessels	Relaxation Relaxation Relaxation	
DA <sub>2</sub>	Presynaptic	Blood vessels (renal, mesentery, coronary) Renal tubules	Vasodilation Natriuresis Diuresis	Improved
		Juxtaglomerular cells Sympathetic ganglia	Renin release (modulates diuresis) Minor inhibition	
	Postsynaptic	Postganglionic sympathetic nerves	Inhibit NE release	Improved
	Postsynaptic	Renal and mesenteric vasculature	Secondary vasodilation ? Vasoconstriction	

LV, left ventricular; NE, norepinephrine; MAC, minimum alveolar concentration; EPI, epinephrine; DA, dopamine.

$\alpha_2$  Receptors can be found in cholinergic pathways as well as in adrenergic pathways. They can significantly modulate parasympathetic activity as well. Current research implies that  $\alpha_2$  stimulation of the parasympathetic pathways plays a role in the modulation of the baroreceptor reflex (increased sensitivity), vagal mediation of heart rate (bradycardia), bronchoconstriction, and salivation (dry mouth). However, cholinergic receptors can also be found in adrenergic pathways; thus, muscarinic and nicotinic receptors have been found in presynaptic and postsynaptic locations, where in turn they modulate sympathetic activity (Fig. 14-9). There is speculation that the features that are desirable to the anesthesiologist, such as sedation, anxiolysis, analgesia, and hypnosis, are mediated through this site.

Stimulation of presynaptic  $\alpha_2$  receptors mediates inhibition of NE release into the synaptic cleft, serving as a negative feedback mechanism. The central effects are primarily related to a reduction in sympathetic outflow with a concomitantly enhanced parasympathetic outflow (e.g., enhanced baroreceptor activity). This results in a decreased systemic vascular resistance, decreased cardiac output (CO), decreased inotropic state in the myocardium, and decreased HR. The peripheral presynaptic  $\alpha_2$  effects are similar, and NE release is inhibited in postganglionic neurons. However, stimulation of postsynaptic  $\alpha_2$  receptors, like the  $\alpha_1$  postsynaptic receptor, affects vasoconstriction. NE acts on both  $\alpha_1$  and  $\alpha_2$  receptors. Thus, NE not only activates smooth muscle vasoconstriction (postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors) but also stimulates presynaptic  $\alpha_2$  receptors and inhibits its own release. Selective stimulation of the presynaptic  $\alpha_2$  receptor could produce a beneficial reduction of peripheral vascular resistance. Unfortunately, most known presynaptic  $\alpha_2$  agonists also stimulate the postsynaptic  $\alpha_2$  receptors, causing vasoconstriction. Blockade of  $\alpha_2$  presynaptic receptors, however, ablates normal inhibition of NE, causing vasoconstriction. Vasodilation occurs with the blockade of postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors.

## **$\alpha$ -Adrenergic Receptors in the Cardiovascular System**

Postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors in the mammalian myocardium and coronary arteries mediate a number of responses.

### *Coronary Arteries*

The presence of postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors in mammalian models has been demonstrated. Sympathetic nerves cause coronary vasoconstriction, which is mediated predominately by postsynaptic  $\alpha_2$ , more so than  $\alpha_1$  receptors. The larger epicardial arteries possess mainly  $\alpha_1$  receptors, whereas  $\alpha_2$  receptors and some  $\alpha_1$  receptors are present in the small coronary artery resistance vessels.<sup>14</sup> Epicardial vessels contribute only 5% to the total resistance of the coronary circulation; therefore,  $\alpha_1$  agonists such as phenylephrine have little influence on coronary resistance.<sup>15,16</sup> Myocardial ischemia has been shown to increase  $\alpha_2$  receptor density in the coronary arteries. Ischemia has also been shown to cause a reflex increase in sympathetic activity mediated by  $\alpha$  mechanisms. This cascade may further increase coronary constriction. Postsynaptic  $\alpha_1$  receptors do not rely upon extracellular  $\text{Ca}^{2+}$  to constrict the vessel, whereas the  $\alpha_2$ -constrictor response is highly dependent upon extracellular influx and exquisitely sensitive to calcium channel inhibitors.<sup>17</sup>

### *Myocardium*

The role of  $\beta$  receptors in mediating catecholamine-induced inotropism and arrhythmogenesis is well known (see below,  $\beta$ -Adrenergic Receptors). Studies have shown the presence of postsynaptic myocardial  $\alpha_1$  receptors, which also exert a major, facilitatory, positive inotropic effect on the myocardium of several species of mammals including humans. Their contribution to malignant reperfusion arrhythmogenesis has also been recognized.

Phenylephrine, an  $\alpha_1$  agonist, can increase myocardial contractility two- to threefold compared with a six- to sevenfold increase produced by isoproterenol, a pure  $\beta$  agonist. Myocardial postsynaptic  $\alpha_1$  receptors mediate perhaps as much as 30% to 50% of the basal inotropic tone of the normal heart.

Postsynaptic myocardial  $\alpha_1$  receptors play a more prominent inotropic role in the failing heart by serving as a reserve to the normally predominant  $\beta_1$  receptors. Although the response to both  $\alpha_1$  and  $\beta_1$  agonists is reduced in the failing myocardium, the interaction between the two receptors is more apparent. Chronic heart failure is known to produce a reduced density (downregulation) of myocardial  $\beta_1$  receptors as a result of high levels of circulating catecholamines. However, there is no evidence of downregulation of either  $\alpha_1$  or  $\beta_2$  receptors in cardiac failure. The increase in density of myocardial  $\alpha_1$  adrenoreceptors is more pronounced with failure and myocardial ischemia.<sup>18</sup> Thus, enhanced myocardial  $\alpha_1$ -receptor numbers and sensitivity may contribute to the positive inotropism seen during ischemia as well as to the malignant arrhythmias that occur with reperfusion. Intracellular mobilization of cytosolic  $\text{Ca}^{2+}$  by the activated  $\alpha_1$ -myocardial receptors during ischemia appears to contribute to these arrhythmias. The  $\alpha_1$  receptor also increases the sensitivity of the contractile elements to  $\text{Ca}^{2+}$ . Drugs possessing potent  $\alpha_1$  antagonism such as prazosin and phentolamine have been shown to possess significant antiarrhythmic activity, but are of limited usefulness because of hypotension. Enhanced  $\alpha_1$  activity with myocardial ischemia may explain why the antiarrhythmic benefits of  $\beta$  antagonists in patients with acute myocardial infarction are far from certain. The contribution of  $\beta$  receptors to positive inotropism and arrhythmogenesis during ischemia and reperfusion may be overshadowed by the  $\alpha$  receptors during acute failure and ischemia.

### *Peripheral Vessels*

Activation of the presynaptic  $\alpha_2$ -vascular receptors produces vasodilation, whereas the postsynaptic  $\alpha_1$ - and  $\alpha_2$ -vascular receptors subserve vasoconstriction. Presynaptic vascular  $\alpha_2$  receptors inhibit NE release. This represents a negative feedback mechanism by which NE inhibits its own release via the prejunctional receptor. Presynaptic  $\alpha_2$  agonists, such as clonidine, inhibit NE release at the neurosympathetic junction, producing

vasodilatation. The effect of selective presynaptic  $\alpha_2$ -receptor agonists to ameliorate coronary vasoconstriction in humans is unclear. Excitation of the inhibitory presynaptic  $\alpha_2$  receptors by endogenous or synthetic catecholamines also inhibits NE release. However, most sympathomimetics are nonselective  $\alpha$  agonists that will excite equally presynaptic  $\alpha_2$  vasodilating receptors and vasoconstrictive postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors. Postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors coexist in both the arterial and venous sides of the circulation with the relative distribution of  $\alpha_2$  receptors being greater on the venous side.<sup>12</sup> This may explain why pure  $\alpha_1$  agonists, such as methoxamine, produce little venoconstriction, whereas many nonselective agonists such as phenylephrine produce significant venoconstriction. NE is the most potent venoconstrictor of all the catecholamines. Clinically, venoconstriction would have the effect of preloading by shifting venous capacitance centrally, whereas stimulation of arterial postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors would affect afterloading by increasing arterial resistance.

### **$\alpha$ -Adrenergic Receptors in the Central Nervous System**

All subtypes of the  $\alpha$ ,  $\beta$ , and DA receptors have been found in various regions of the brain and spinal cord. The functional role of the cerebral  $\alpha$  and  $\beta$  receptors suggests a close association with blood pressure and HR control. Cerebral and spinal cord presynaptic  $\alpha_2$  receptors are also involved in inhibition of presynaptic NE release. Although the brain contains adrenergic and dopaminergic receptors, circulating catecholamines do not cross the blood–brain barrier. The catecholamines in the brain are synthesized there. Many actions have been attributed to the cerebral postsynaptic  $\alpha_2$  receptor. This includes inhibition of insulin release, inhibition of bowel motility, stimulation of growth hormone release, and inhibition of ADH release. Central neuraxial injections of  $\alpha_2$  agonists, such as clonidine, induce analgesia, sedation, and cardiovascular depression. The increased duration of epidural or intrathecal anesthesia by the addition of nonselective  $\alpha$  agonists to the local anesthetic may produce additional analgesia through this mechanism.

### **$\alpha$ Receptors in the Kidney**

The kidney has an extensive and exclusive adrenergic innervation of the afferent and efferent glomerular arterioles, proximal and distal renal tubules, ascending loop of Henle, and juxtaglomerular apparatus. The greatest density of innervation is in the thick ascending loop of Henle, followed by the distal convoluted tubules and proximal tube. Both  $\alpha_1$  and  $\alpha_2$  subtypes are found in the kidney with the  $\alpha_2$  receptor dominating. The  $\alpha_1$  receptor is predominant in the renal vasculature and elicits vasoconstriction, which modulates renal

blood flow. Tubular  $\alpha_1$  receptors enhance sodium and water reabsorption, leading to antinatriuresis, whereas tubular  $\alpha_2$  receptors promote sodium and water excretion.

## **$\beta$ -Adrenergic Receptors**

The  $\beta$ -adrenergic receptors, like the  $\alpha$  receptor, have been divided into subtypes. They are designated as the  $\beta_1$  and  $\beta_2$  subtypes. Recently, molecular cloning has demonstrated the existence of a third subtype, namely  $\beta_3$  receptor. Activation of all these receptor subtypes induces the activation of adenylyl cyclase and increased conversion of ATP to cyclic adenosine-3',5'-monophosphate (cAMP).  $\beta_1$  Receptors predominate in the myocardium, the sinoatrial node, and the ventricular conduction system. The  $\beta_1$  receptors also mediate the effects of the catecholamines on the myocardium. These receptors are equally sensitive to EPI and NE, which distinguishes them from the  $\beta_2$  receptors. Effects of  $\beta_1$  stimulation are outlined in [Table 14-4](#), which include their effects specifically on the cardiovascular system.

The  $\beta_2$  receptors are located in the smooth muscles of the blood vessels in the skin, muscle, mesentery, and in bronchial smooth muscle. Stimulation produces vasodilation and bronchial relaxation. The  $\beta_2$  receptors are more sensitive to EPI than NE.  $\beta$  Receptors are found in both presynaptic and postsynaptic membranes of the adrenergic neuroeffector junction.  $\beta_1$  Receptors are distributed to postsynaptic sites and have not been identified on the presynaptic membrane. Presynaptic  $\beta$  receptors are of the  $\beta_2$  subtype. The effects of activation of the presynaptic  $\beta_2$  receptor are diametrically opposed to those of the presynaptic  $\alpha_2$  receptor. The presynaptic  $\beta_2$  receptor accelerates endogenous NE release, whereas blockade of this receptor will inhibit NE release. Antagonism of the presynaptic  $\beta_2$  receptors produces a physiologic result similar to activation of the presynaptic  $\alpha_2$  receptor. The postsynaptic  $\beta_1$  receptors are located on the synaptic membrane and respond primarily to neuronal NE. The postsynaptic  $\beta_2$  receptors, like the postsynaptic  $\alpha_2$  receptor, respond primarily to circulating EPI.

## **$\beta$ Receptors in the Cardiovascular System**

### *Myocardium*

Myocardial  $\beta$  receptors were originally classified as  $\beta_1$  receptors. Those in the vascular and bronchial smooth muscle were called the  $\beta_2$  subtype. However, studies have confirmed the coexistence of  $\beta_1$  and  $\beta_2$  receptors in the myocardium.<sup>19</sup> Both  $\beta_1$  and  $\beta_2$  receptors are functionally coupled to adenylate cyclase, suggesting a similar involvement in the regulation of inotropism and chronotropism. Postsynaptic  $\beta_1$  receptors are distributed predominantly to the

myocardium, the sinoatrial node, and the ventricular conduction system. The  $\beta_2$  receptors have the same distribution but are presynaptic. Activation of the presynaptic  $\beta_2$  receptor accelerates the release of NE into the synaptic cleft. The  $\beta_2$  receptor comprises 20% to 30% of the  $\beta$  receptors in the ventricular myocardium and up to 40% of the  $\beta$  receptors in the atrium.

The effect of NE on inotropism in the normal heart is mediated entirely through the postsynaptic  $\beta_1$  receptor, whereas the inotropic effects of EPI are mediated through both the  $\beta_1$ - and  $\beta_2$ -myocardial receptors. The  $\beta_2$  receptors may also mediate the chronotropic responses to EPI which explains why selective  $\beta_1$  antagonists are less effective in suppressing induced tachycardia than the nonselective  $\beta_1$  antagonist propranolol.

### *Peripheral Vessels*

The postsynaptic vascular  $\beta$  receptors are virtually all of the  $\beta_2$  subtype. The  $\beta_2$  receptors are located in the smooth muscle of the blood vessels of the skin, muscle, mesentery, and bronchi. Stimulation of the postsynaptic  $\beta_2$  receptor produces vasodilation and bronchial relaxation. Modest vasoconstriction occurs when subjected to blockade because the actions of the vascular postsynaptic  $\beta_2$  receptors no longer oppose the actions of the  $\alpha_1$ - and  $\alpha_2$ -postsynaptic receptors.

### **$\beta$ Receptors in the Kidney**

The kidney contains both  $\beta_1$  and  $\beta_2$  receptors, with the  $\beta_1$  being predominant. Renin release from the juxtaglomerular apparatus is enhanced by  $\beta$  stimulation. The  $\beta_1$  receptor evokes renin release in humans. Renal  $\beta_2$  receptors also appear to regulate renal blood flow at the vascular level. They have been identified pharmacologically and mediate a vasodilatory response.

### **Dopaminergic Receptors**

Dopamine, synthesized in 1910, was recognized in 1959 not only as a vasopressor and the precursor of NE and EPI, but also as an important central and peripheral neurotransmitter. Dopamine receptors (DA) are localized in the CNS, on blood vessels and postganglionic sympathetic nerves ([Table 14-4](#)). Two clinically important types of DA receptors have been recognized: DA<sub>1</sub> and DA<sub>2</sub>, while other subtypes such as DA<sub>4</sub> and DA<sub>5</sub> are still being investigated. The DA<sub>1</sub> receptors are postsynaptic, whereas the DA<sub>2</sub> receptors are both presynaptic and postsynaptic. The presynaptic DA<sub>2</sub> receptors, like the presynaptic  $\alpha_2$  receptor, inhibit NE release and can produce vasodilatation. The postsynaptic DA<sub>2</sub> receptor may subserve vasoconstriction similar to that of the postsynaptic  $\alpha_2$  receptor. This effect is opposite to that of the

postsynaptic DA<sub>1</sub> renal vascular receptor. The zona glomerulosa of the adrenal cortex also contains DA<sub>2</sub> receptors, which inhibit the release of aldosterone.

### *Myocardium*

Defining specific dopaminergic receptors has been difficult because dopamine also exerts effects on the  $\alpha$  and  $\beta$  receptors. DA receptors have not been described in the myocardium. Effects of dopamine are those related to activation of  $\beta_1$  receptors, which promote positive inotropism and chronotropism.  $\beta_2$  Activation may produce some systemic vasodilatation.

### *Peripheral Vessels*

The greatest numbers of DA<sub>1</sub>-postsynaptic receptors are found on vascular smooth muscle cells of the kidney and mesentery, but are also found in the other systemic arteries including coronary, cerebral, and cutaneous arteries. The vascular receptors are, like the  $\beta_2$  receptors, linked to adenylate cyclase and mediate smooth muscle relaxation. Activation of these receptors produces vasodilatation, increasing blood flow to these organs. Concurrent activation of vascular presynaptic DA<sub>2</sub> receptors also inhibits NE release at presynaptic  $\alpha_2$  receptors, which may also contribute to peripheral vasodilatation. Higher doses of dopamine can mediate vasoconstriction via the postsynaptic  $\alpha_1$  and  $\alpha_2$  receptors. The constrictive effect is relatively weak in the cardiovascular system, where the action of dopamine on adrenergic receptors is 1/35 and 1/50 as potent as that of EPI and NE, respectively.<sup>20</sup>

### *Central Nervous System*

DA receptors have been identified in the hypothalamus where they are involved in prolactin release. They are also found in the basal ganglia where they coordinate motor function. Degeneration of dopaminergic neurons in the substantia nigra is the cause of Parkinson disease. Another central action of dopamine is to stimulate the chemoreceptor trigger zone of the medulla, producing nausea and vomiting. Dopamine antagonists such as haloperidol and droperidol are clinically effective in countering this action.

### *Kidney and Mesentery*

Apart from their effect on the vessels of the kidney and mesentery, DA receptors on the smooth muscle of the esophagus, stomach, and small intestine enhance secretion production and reduce intestinal motility.<sup>20,21</sup> Metoclopramide, a dopamine antagonist, is useful for aspiration prophylaxis by promoting gastric emptying. The distribution of DA receptors in the renal vasculature is well known, but DA receptors have other functions within the kidney. DA<sub>1</sub> receptors are located on renal tubules, which inhibit sodium

reabsorption with subsequent natriuresis and diuresis. The natriuresis may be the result of a combined renal vasodilatation, improved CO, and tubular action of the DA<sub>1</sub> receptors. Juxtaglomerular cells also contain DA<sub>1</sub> receptors, which increase renin release when activated. This action modulates the diuresis produced by DA<sub>1</sub> activation of the tubules.

Dopamine has unique autonomic effects by activating specific peripheral dopaminergic receptors, which promote natriuresis and reduce afterload via dilatation of the renal and mesenteric arterial beds. Peripheral dopaminergic activity serves as a natural antihypertensive mechanism. Its actions are overshadowed by the opposite effect of its main biologic partner, NE. Plasma NE levels are known to increase with aging, likely the result of reduced clearance, while peripheral dopaminergic activity is known to diminish. Subtle changes in the DA–NE balance with aging may account for the diminished ability of the aged kidney to excrete a salt load.

## **Other Receptors**

### *Adenosine Receptors*

Adenosine produces inhibition of NE release. The effect of adenosine is blocked by caffeine and other methylxanthines. The physiologic function of these receptors may be the reduction of sympathetic tone under hypoxic conditions when adenosine production is enhanced. As a consequence of reduced NE release, cardiac work would be decreased and oxygen demand reduced. Adenosine has been effectively used to produce controlled hypotension.<sup>22</sup>

## **Serotonin**

Serotonin (5-hydroxytryptamine) depresses the response of isolated blood vessels to SNS stimulation and decreases release of labeled NE in these preparations. Raising the external calcium ion concentration antagonizes this inhibitory action of serotonin. Thus, serotonin may inhibit neuronal NE release by a mechanism that limits the availability of calcium ions at the nerve terminal.

### *Prostaglandin E<sub>2</sub>, Histamine, and Opioids*

Prostaglandin E<sub>2</sub>, histamine, and several opioids have been reported to act on prejunctional receptor sites to inhibit NE release in certain sympathetically innervated tissue. However, these inhibitory receptors are unlikely to play a physiologic role in limiting NE release since their direct antagonists, compounds such as inhibitors of cyclooxygenase, histamine antagonists, and naloxone do not increase an NE release.

Histamine acts in a manner similar to the neurotransmitters of the SNS. The cell membrane has specific receptors for histamine, with the individual response being determined by the type of cell being stimulated (see [Chapter 9](#)). Two receptors for histamine have been determined. These have been designated H<sub>1</sub> and H<sub>2</sub>, for which it has been possible to develop specific agonists and antagonists. Stimulation of the H<sub>1</sub> receptors produces bronchoconstriction and intestinal contraction. The major role of the H<sub>2</sub> receptors is related to acid production by the parietal cells of the stomach; however, histamine is also present in relatively high concentrations in the myocardium and cardiac conducting tissue, where it exerts positive inotropic and chronotropic effects while depressing dromotropism. The positive inotropic and chronotropic effects of histamine are H<sub>2</sub> receptor effects that are not blocked by  $\beta$  antagonism. These effects are blocked by H<sub>2</sub> antagonists, such as cimetidine, which accounts for the occasional report of cardiovascular collapse following the use of cimetidine. The negative dromotropic effect and that of coronary spasm caused by histamine are H<sub>1</sub> receptor effects.

### **Adrenergic Receptor Numbers and Sensitivity**

Receptors, once thought to be static entities, are now thought to be dynamically regulated by a variety of conditions and to be in a constant state of flux. Receptors are synthesized in the sarcoplasmic reticulum (SR) of the parent cell, where they may remain extrasynaptic or externalize to the synaptic membranes where they may cluster. Membrane receptors may be removed or internalized to intracellular sites for either dehydration or recycling.

The numbers and sensitivity of adrenergic receptors can be influenced 7 by normal, genetic, and developmental factors. Changes in the number of receptors alter the response to catecholamines. Alteration in the number or density of receptors is referred to as either upregulation or downregulation. As a rule, the number of receptors is inversely proportional to the ambient concentration of the catecholamines. Extended exposure of receptors to their agonists markedly reduces, but does not ablate, the biologic response to catecholamines. For example, increased adrenergic activity occurs in response to reduced perfusion as a result of acute or chronic myocardial dysfunction. Plasma catecholamines are increased. Subsequently, the myocardial postsynaptic  $\beta_1$  receptors are “downregulated” (see [Chapter 11](#)). This is thought to explain the diminished inotropic and chronotropic response to  $\beta_1$  agonists and exercise in patients with chronic heart failure. However, calcium-induced inotropism is not impaired because extrasynaptic  $\beta_2$ -receptor numbers remain relatively intact. The  $\beta_2$  receptors may account for up to 40% of the inotropism of the failing heart compared with 20% in the normal heart.<sup>18,23</sup>

Tachyphylaxis to infused catecholamines is also thought to be the result of acute “downregulation” of receptors. There appears to be a reduction in numbers or sensitivity of  $\beta$  receptors in hypertensive patients who also have elevated plasma catecholamines. Downregulation is the presumptive explanation for the lack of correlation between plasma catecholamine levels and the blood pressure elevation in patients with pheochromocytoma. Chronic use of  $\beta$  agonists such as terbutaline, isoproterenol, or EPI for the treatment of asthma can result in tachyphylaxis because of downregulation. Even short-term use (1 to 6 hours) of  $\beta$  agonists may cause downregulation of receptor numbers. Downregulation is reversible on termination of the agonist. Chronic treatment of animals with nonselective  $\beta$  blockade causes a 100% increase in the number of  $\beta$  receptors. This accounts for the propranolol withdrawal syndrome in which the acute discontinuation of the  $\beta$  antagonist leaves the  $\alpha$  receptors unopposed, in addition to an increased number of  $\beta$  receptors. Clonidine withdrawal can be explained by the same mechanism. Up- or downregulation of receptor numbers may not alter sensitivity of the receptor. Likewise, sensitivity may be increased or decreased in the presence of normal numbers of receptors. The pharmacologic factors affecting up- or downregulation of the  $\alpha$  and  $\beta$  receptors are similar.

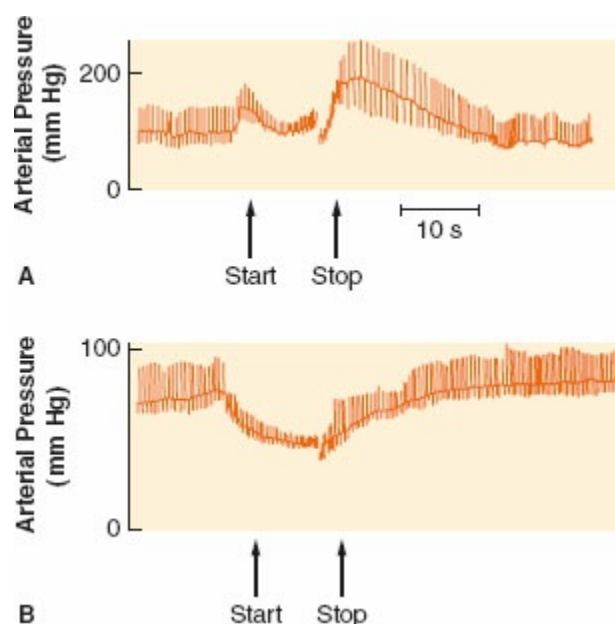

## Autonomic Nervous System Reflexes and Interactions

**8** The ANS reflex has been compared to a computer circuit. This control system, as in all reflex systems, has (1) sensors, (2) afferent pathways, (3) CNS integration, and (4) efferent pathways to the receptors and efferent organs. Fine adjustments are made at the local level through positive and negative feedback mechanisms. The baroreceptor is an example. The variable to be controlled (blood pressure) is sensed (carotid sinus), integrated (medullary vasomotor center), and adjusted through specific effector–receptor sites. Drugs or disease can interrupt this circuit at any point.  $\beta$  Blockers may attenuate the effector response, whereas an  $\alpha$  agonist such as clonidine may alter both the effector and the integrator functions of blood pressure control.

### Baroreceptors

Several reflexes in the cardiovascular system help govern arterial blood pressure, and control cardiac output (CO) and heart rate (HR). The aim of the circulation is to provide blood flow to all the body organs (see [Chapter 12](#)). Yet, the most important controlled variable to which the sensors are attuned is blood pressure, a product of the blood flow and vascular resistance. Étienne Marey noted in 1859 that the pulse rate is inversely proportional to the blood pressure, and this is known as Marey law. Subsequently, Hering, Koch, and

others demonstrated that the alterations in HR evoked by changes in blood pressure are dependent on baroreceptors located in the aortic arch and the carotid sinuses. These pressure sensors react to alterations in stretch caused by blood pressure. Impulses from the carotid sinus and aortic arch reach the medullary vasomotor center by the glossopharyngeal and vagus nerves, respectively. Increased sensory traffic from the baroreceptors, caused by increased blood pressure, inhibits SNS effector traffic. The relative increase in vagal tone produces vasodilation, slowing of the HR, and a lowering of blood pressure. Real increases in vagal tone occur when blood pressure exceeds normal limits. The Valsalva maneuver can best demonstrate the arterial baroreceptor reflex (Fig. 14-11). The Valsalva maneuver raises the intrathoracic pressure by forced expiration against a closed glottis. The arterial blood pressure rises momentarily as the intrathoracic blood is forced into the heart (increased preload). Sustained intrathoracic pressure diminishes venous return, reduces the CO, and drops the blood pressure. Reflex vasoconstriction and tachycardia ensue. Blood pressure returns to normal with release of the forced expiration, but then briefly “overshoots” because of the vasoconstriction and increased venous return. A slowing of the HR accompanies the overshoot in pressure. The cardiovascular responses to the Valsalva maneuver require an intact ANS circuit from peripheral sensor to peripheral adrenergic receptors. The Valsalva maneuver has been used to identify patients at risk for anesthesia due to ANS instability. This was once a major concern in patients receiving drugs that depleted catecholamines, such as reserpine. Dysfunction of the SNS is implicated if exaggerated and prolonged hypotension develops during the forced expiration phase (50% from resting mean arterial pressure). In addition, the overshoot at the end of the Valsalva maneuver is absent. Dysfunction of the PNS can be assumed if the HR does not respond appropriately to the blood pressure changes.

**Figure 14-11 A:** The normal blood pressure response to the Valsalva maneuver is demonstrated. Pulse rate moves in a reciprocal direction according to Marey law of the heart. **B:** An abnormal Valsalva response is shown in a patient with C5 quadriplegia.

Venous baroreceptors may be more dominant in the moment-to-moment regulation of CO. Baroreceptors in the right atrium and great veins produce an increase in HR when stretched by increased right atrial pressure. Reduced venous pressure decreases HR. Unlike the arterial baroreceptors, venous sensors are not thought to alter vascular tone; however, venoconstriction is postulated to occur when atrial pressures decline. Stretch of the venous receptors produces changes in HR opposite to those produced when the arterial pressure sensors are stimulated. The arterial and venous pressure receptors separately monitor two of the four major determinants of CO: afterload and preload, respectively. Venous baroreceptors sample preload by stretch of the atrium. Arterial baroreceptors survey resistance, or afterload, as reflected in the mean arterial pressure. Afterload and preload produce opposite effects on CO; thus, one should not be surprised that the venous and arterial baroreceptors produce opposing effects after a similar stretch stimulus—pressure.

Bainbridge described the venous baroreceptor reflex and demonstrated that it can be abolished by vagal resection. Numerous investigators have confirmed the acceleration of the HR in response to volume. However, the magnitude and direction of the HR response are dependent on the prevailing HR at the time of stimulation. The denervated, transplanted mammalian heart also accelerates in response to volume loading. HR, like CO, can apparently be adjusted to the quantity of blood entering the heart. The Bainbridge reflex relates to the characteristic but paradoxical slowing of the heart seen with spinal anesthesia. Blockade of the SNS levels of T1–T4 ablates the efferent limb of the cardiac accelerator nerves. This source of cardiac deceleration is obvious, as the vagus nerve is unopposed. However, bradycardia during spinal anesthesia is more related to the development of arterial hypotension than to the height of the block. The primary defect in the development of spinal hypotension is a decrease in venous return. Theoretically, the arterial hypotension should reflexly produce a tachycardia through the arterial baroreceptors. Instead, bradycardia is more common. Greene suggests that in the unmedicated person, the venous baroreceptors are dominant over the arterial. A reduced venous pressure, therefore, slows HR.<sup>24</sup> In contrast, humorally mediated tachycardia is the usual response to hypotension or acidosis from other causes. In patients with difficult to control blood pressure, decreasing the sympathetic outflow seems to be beneficial in better regulating the blood pressure. Therefore, surgical interruption of renal efferent sympathetic outflow with radiofrequency ablation through femoral artery

catheterization increases natriuresis and diuresis, and reduces renin production. Also, baroreflex sensitization through an implantable carotid sinus stimulator seems to be extremely promising in patients with refractory hypertension, with more research underway.<sup>25</sup>

### *Denervated Heart*

Reflex modulation of the adrenergic agonists is best seen in the denervated transplant heart, which retains the recipient's innervated sinoatrial node and the donor's denervated sinoatrial node<sup>26</sup> (see [Chapter 51](#)). NE infusion in the transplanted heart produces a slowing of the recipient's atrial rate through vagal feedback as the blood pressure rises. In the unmodulated donor heart, atrial rate increases. The baroreceptors are therefore not operant in the transplanted heart. Isoproterenol, a pure  $\beta$  agonist, increases the discharge rate of both the recipient and donor node by direct action, with the donor rate near doubling that of the recipient node. Atropine accelerates the recipient's atrial rate, whereas no effect is seen on the donor rate, which now controls HR.

$\beta$  blockade produces comparable slowing of the sinoatrial node of both recipient and donor. The exercise capability of the denervated heart is conspicuously reduced by  $\beta$  blockade, presumably because of its reliance on circulating catecholamines. Propranolol has also been demonstrated to reduce the  $\beta$  response to chronotropic effects of NE and isoproterenol in the transplanted heart. The CO of the transplanted heart varies appropriately with changes in preload and afterload.

### *Interaction of Autonomic Nervous System Receptors*

Strong interactions have been noted between SNS and PNS nerves in organs that receive dual, antagonistic innervation. Release of NE at the presynaptic terminal is modified by the PNS. For example, vagal inhibition of left ventricular contractility is accentuated as the level of SNS activity is raised. This interaction is termed "accentuated antagonism" and is mediated by a combination of presynaptic and postsynaptic mechanisms. The coronary arteries present an example of this phenomenon and deserve special attention.

The myocardium and coronary vessels are abundantly supplied with adrenergic and cholinergic fibers. Strong activity of both  $\alpha$  and  $\beta$  receptors has been demonstrated in the coronary vascular bed. Selective stimulation of both the  $\alpha_1$  and postsynaptic  $\alpha_2$  receptors increases coronary vascular resistance, whereas selective  $\alpha$  blockade eliminates this effect. Therefore, both  $\beta_1$  and  $\alpha_1$  adrenoreceptors are present on coronary arteries and accessible to NE released by sympathetic nerves.<sup>6,15</sup>

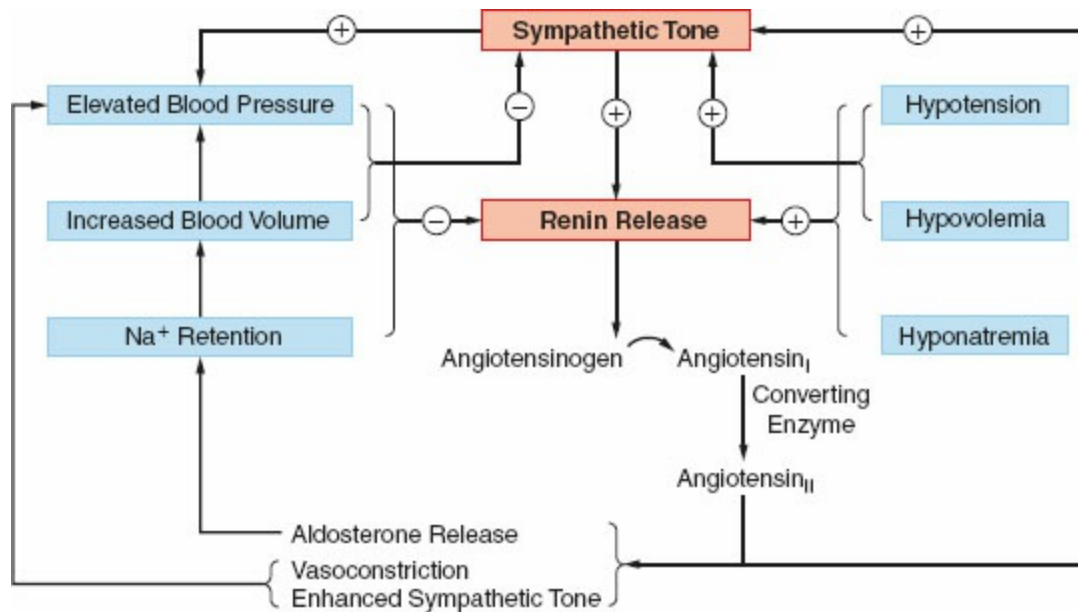

The presynaptic adrenergic terminals of the myocardium and coronary vessels, like all blood vessels studied, contain muscarinic receptors.<sup>11</sup> Recent observations confirm that muscarinic agents and vagal stimulation, acting on the presynaptic, SNS muscarinic receptor, inhibit the release of NE in a manner similar to that of the presynaptic  $\alpha_2$  and DA<sub>2</sub> receptors (Fig. 14-9). Conversely, blockade of the muscarinic receptors with atropine markedly augments the positive inotropic responses to catecholamines.<sup>6</sup> Suppression of NE release explains, in part, vagal-induced attenuation of the inotropic response to strong SNS stimulation (accentuated antagonism) and only a weak negative inotropic effect of vagal stimulation when there is low background SNS activity. This may also explain why vagal activity reduces the vulnerability of the myocardium to fibrillation during infusions of NE.

ACh may cause coronary spasm during periods of high SNS tone.<sup>6</sup> Inhibition of NE release by presynaptic adrenergic muscarinic receptors of the smooth muscle of coronary vessels would lessen the coronary relaxation normally produced by NE on the  $\beta_1$  receptor (Fig. 14-9). In anesthetized dogs, the rate of NE outflow into the coronary sinus blood, evoked by cardiac SNS stimulation, is markedly diminished by simultaneous vagal efferent stimulation.<sup>27</sup> This action is known to be prevented by atropine, which also causes coronary vasodilation.

### *Interaction with Other Regulatory Systems*

The ANS is integrally related to several endocrine systems that ultimately summate to control blood pressure and regulate homeostasis. These include the renin–angiotensin system, ADH, glucocorticoids, and insulin (see Chapter 46). Both  $\alpha$  and  $\beta$  receptors have been found in the endocrine pancreas and modulate insulin release (Table 14-4).  $\beta$  Stimulation increases insulin release, whereas  $\alpha$  stimulation decreases it. The overall importance of this interaction is not entirely clear, but decreased tolerance to glucose and potassium has been noted in subjects taking  $\beta$ -blocking drugs. The renin–angiotensin system is a complex endocrine system that modulates both blood pressure and water–electrolyte homeostasis (Fig. 14-12). Renin is a proteolytic enzyme released by the cells of the juxtaglomerular apparatus of the renal cortex. Renin acts on plasma angiotensinogen to form angiotensin I. Angiotensin I is then converted to angiotensin II by a converting enzyme in the lung. Angiotensin II is a powerful angiotensin direct arterial vasoconstrictor. It also acts on the adrenal cortex to release aldosterone and on the adrenal medulla to release EPI. In addition to its direct effects on vascular smooth muscle, angiotensin II augments NE release via presynaptic receptors, thus enhancing peripheral SNS tone. Captopril, enalapril, and lisinopril inhibit the action of angiotensin-converting enzyme, thus preventing

the conversion of angiotensin I to angiotensin II. Renin is released in response to hyponatremia, decreased renal perfusion pressure, and ANS stimulation via  $\beta$  receptors on juxtaglomerular cells. Changes in sympathetic tone may thus alter renin release and affect homeostasis in a variety of ways. The ANS is also intimately related to adrenocortical function. As outlined above, glucocorticoid release modulates phenylethanolamine-N-methyltransferase formation and thus synthesis of EPI. Glucocorticoids are also important in regulating the response of peripheral tissues to changes in SNS tone. Thus, the ANS is intimately related to other homeostatic mechanisms.

**Figure 14-12** The interactions of the renin–angiotensin and SNS in regulating homeostasis are shown schematically along with the physiologic variables that modulate their function. Arrows with a plus sign (+) represent stimulation, and those with a minus sign (–) represent inhibition.

## Clinical Autonomic Nervous System Pharmacology

**9** The clinical application of ANS pharmacology is based on the knowledge of ANS anatomy, physiology, and molecular pharmacology. Drugs that modify ANS activity can be classified by their site of action, mechanism of action, or the pathology for which they are most commonly used. Antihypertensive drugs are an example of the third category. This classification is a matter of degree because considerable functional overlap occurs. An example of classification by site relates to the ganglionic agonists or blocking agents. ANS drugs can be further categorized as those that act at the presynaptic membrane and those acting postsynaptically. They can then be more specifically classified by the predominant receptor or receptors on which they act.

## Mode of Action

ANS drugs may be broadly classified by mode of action according to their mimetic or lytic actions. This may also be termed agonist or antagonist. A sympathomimetic, such as ephedrine, mimics SNS sympathetic activity by stimulation of adrenergic receptor sites both directly and indirectly. Sympatholytic drugs cause dissolution of SNS activity at these same receptor sites.  $\beta$  Receptor blockers are examples of sympatholytic drugs. Several modes of ANS drug action become evident when one follows the cascade of neurotransmission. Drugs that act on prejunctional membranes may therefore (1) interfere with transmitter synthesis ( $\alpha$ -methyl paratyrosine), (2) interfere with transmitter storage (reserpine), (3) interfere with transmitter release (clonidine), (4) stimulate transmitter release (ephedrine), or (5) interfere with reuptake of transmitter (cocaine). Drugs may also (6) modify metabolism of the neurotransmitter in the synaptic cleft (anticholinesterase). Drugs acting at postjunctional sites may (7) directly stimulate postjunctional receptors and (8) interfere with the transmitter agonist at the postjunctional receptor.

The ultimate response of an effector organ to an agonist or antagonist depends on (1) the drug, (2) its plasma concentration, (3) the number of receptors in the effector organ, (4) binding by the receptor, (5) the concurrent activities of other drugs and hormones, (6) the cellular metabolic status, and (7) reflex adjustments by the organism.

## Ganglionic Drugs

SNS and PNS ganglia are pharmacologically similar in that the transmission through these ANS ganglia is effected by ACh (Fig. 14-2). Most ganglionic agonists and antagonists are not selective and affect SNS and PNS ganglia equally. This nonselective property creates many undesirable and unpredictable side effects, which have limited the clinical usefulness of this category of drug.

### Agonists

There are essentially no clinically useful ganglionic agonists. Nicotine is the prototypical ganglionic agonist. In low doses, it stimulates ANS ganglia and the neuromuscular junction of striated muscle. High doses produce ganglionic and neuromuscular blockade. The protean side effects of nicotinic stimulation render it useful only as an investigative tool.

### Antagonists

Drugs that interfere with neurotransmission at ANS ganglia are known as ganglionic blocking agents. Nicotine, in high doses, is the prototypical ganglionic blocking agent also; however, early stimulatory nicotinic activity can be blocked both at the ganglia and at the muscle end plates with other ganglionic blockers and muscle relaxants, respectively, without blocking muscarinic effects. Ganglionic blockers produce their nicotinic effects by competing, mimicking, or interfering with ACh metabolism. Hexamethonium, trimethaphan, and pentolinium produce a selective nondepolarizing blockade of neurotransmission at ANS ganglia without producing nicotinic neuromuscular blockade. They compete with ACh in the ganglia without stimulating the receptors. The introduction of drugs that produce vasodilation directly or by action on the SNS vasomotor center has made the ganglionic blockers obsolete. D-Tubocurarine (dTC) produces a competitive nondepolarizing block of both motor end plates and ANS ganglia. The action of motor paralysis predominates, but the concomitant ganglionic blockade at higher doses explains part of the hypotensive effect often seen with the use of dTC for muscle relaxation. Anticholinesterase drugs may produce nicotinic type ganglionic blockade by competition with ACh as well as by persistent depolarization via accumulated ACh.

Trimethaphan produces blockade by competition with ACh for receptors, thus stabilizing the postsynaptic membrane. However, side effects and rapid onset tachyphylaxis have markedly reduced its use in anesthesia.<sup>28</sup> The patient's pupils become fixed and dilated during administration, which obscures eye signs, an important consideration for neurosurgery. In this regard, it is distinctly inferior to nitroprusside. The major advantage of trimethaphan is its short duration of action, which is the result of pseudocholinesterase hydrolysis.

## **Cholinergic Drugs**

### **Muscarinic Agonists**

The cholinomimetic muscarinic drugs act at sites in the body where ACh is the neurotransmitter of the nerve impulse. These drugs may be divided into three groups, the first two of which are direct muscarinic agonists. The third group acts indirectly. These groups are choline esters (ACh, methacholine, carbamylcholine, bethanechol), alkaloids (pilocarpine, muscarine), and anticholinesterases (physostigmine, neostigmine, pyridostigmine, edrophonium, echothiophate).

### **Direct Cholinomimetics**

ACh has virtually no therapeutic applications because of its diffuse action and

rapid hydrolysis by cholinesterase (Fig. 14-5). One may encounter the use of topical ACh (1%) drops during cataract extraction when a rapid miosis is desired. Systemic effects are not usually seen because of the rapidity of ACh hydrolysis. Derivatives of ACh, other choline esters, have been synthesized, which possess more selective muscarinic activity than ACh. They differ from ACh in being more resistant to inactivation by cholinesterase and thus having a more prolonged and useful action. They also differ from ACh in their relative muscarinic and nicotinic activities. The best studied of these drugs are methacholine, bethanechol, and carbamylcholine. The chemical structures of ACh and these choline esters are shown in Figure 14-13. Their pharmacologic actions are compared with those of ACh in Table 14-5. These are not important drugs in anesthesiology practice but anesthesiologists may encounter patients who are receiving them. (See Chapter 23.)

ACh is a quaternary ammonium compound that interacts with postsynaptic receptors, causing conformational membrane changes. This results in increased permeability to small ions and, thus, depolarization. All the receptors translate the reversible binding of ACh into openings of discrete channels in excitable membranes, allowing  $\text{Na}^+$  and  $\text{K}^+$  ions to flow along their electrochemical gradients. Structure–activity relationships point to the presence of two important binding sites on the receptor, an esteratic site that binds the ester end of the molecule and an ionic site that binds the quaternary amine portion (Fig. 14-5). Subtle changes in the structure of the compound can markedly alter the responses among different tissue groups. The degree of muscarinic activity falls if the acetyl group is replaced, but this confers a resistance to enzymatic hydrolysis. Bethanechol is resistant to hydrolysis but possesses mainly muscarinic activity.  $\beta$ -Methyl substitution produces methacholine, which is less resistant to hydrolysis and is primarily a muscarinic agonist. Methacholine slows the heart and dilates peripheral blood vessels. It is used to terminate supraventricular tachydysrhythmias, especially paroxysmal tachycardia, when other measures have failed. It also increases intestinal tone. Methacholine should not be given to patients with asthma. Hypertensive patients may also develop marked hypotension. Side effects are those of PNS stimulation such as nausea, vomiting, and flushed sweating. Overdose is treated with atropine. Bethanechol is relatively selective for the gastrointestinal and urinary tracts. In usual doses it does not slow the heart or lower the blood pressure. Bethanechol is of value in treating postoperative abdominal distention (nonobstructive paralytic ileus), gastric atony following bilateral vagotomy, congenital megacolon, nonobstructive urinary retention, and some cases of neurogenic bladder.

+, stimulation; -, inhibition.

Direct-acting cholinomimetic alkaloids include muscarine and pilocarpine. They act at the same sites as ACh, and their effects are similar to those of ACh as described in [Table 14-5](#). There are no uses for these drugs in anesthesiology. Pilocarpine is the only drug of this group used therapeutically in the United States. Its sole use is for the treatment of glaucoma, for which it is the standard. It is used as a topical miotic drug in ophthalmologic practice to reduce intraocular pressure in glaucoma.

Muscarinic agonists are particularly dangerous in patients with myasthenia gravis (who are receiving anticholinesterases), bulbar palsy, cardiac disease, asthma, peptic ulcer, progressive muscular atrophy, or mechanical intestinal obstruction or urinary retention because they intensify these conditions.

## Indirect Cholinomimetics

The indirect-acting cholinomimetic drugs are of greater importance to the anesthesiologist than are the direct-acting drugs. These drugs produce cholinomimetic effects indirectly as a result of inhibition or inactivation of the enzyme acetylcholinesterase, which normally destroys ACh by hydrolysis.

They are referred to as cholinesterase inhibitors or anticholinesterases. Most of these drugs inhibit both acetylcholinesterase and pseudocholinesterase. Inhibition of acetylcholinesterase permits the accumulation of ACh transmitter in the synapse, resulting in intense PNS activity similar to that of the direct cholinomimetic agents. The accumulation of ACh by the anticholinesterases potentially can produce all of the following: (1) stimulation of muscarinic receptors at ANS-effect organs, (2) stimulation followed by depression of all ANS ganglia and skeletal muscle (nicotinic), and (3) stimulation with later depression of cholinergic receptor sites in the CNS. All of these effects may be seen with lethal doses of anticholinesterase drugs, but therapeutic doses only produce the first two.

Actions of therapeutic significance of the anticholinesterase drugs to the anesthesiologist concern the eye, the intestine, and the neuromuscular junction. The effects of anticholinesterases are useful in the treatment of myasthenia gravis, glaucoma, and atony of the gastrointestinal and urinary tracts. Anticholinesterase drugs are used routinely in anesthesia to reverse nondepolarizing neuromuscular block. The most prominent pharmacologic effects of the anticholinesterase drugs are muscarinic. Their most useful actions are their nicotinic effects. Muscarinic activity is evoked by lower concentrations of ACh than are necessary to produce the desired nicotinic effect. For example, the anticholinesterase neostigmine reverses neuromuscular blockade by increasing ACh concentration at the muscle end plate, a nicotinic receptor. Nicotinic reversal of neuromuscular blockade can usually be produced safely only when the patient has been protected by atropine or other muscarinic blockers. This prevents the untoward muscarinic effects of bradycardia, hypotension, bronchospasm, or intestinal spasm. Reversal of neuromuscular blockade in patients who have had bowel anastomosis was at one time a major controversy. (See [Chapter 21](#).) Some thought that the muscarinic effects of anticholinesterase drugs (hypermotility) increased the risk of anastomotic leakage whereas others found no association between their use and subsequent breakdown. National experience has favored the latter opinion.

**10** Clinically, anticholinesterase drugs may be divided into two types: the reversible and nonreversible cholinesterase inhibitors.<sup>28</sup> Reversible cholinesterase inhibitors delay the hydrolysis of ACh from 1 to 8 hours. Nonreversible drugs are so named because their inhibitory effects may last from days to weeks. The differences in duration of various anticholinesterases likely depend on whether they inhibit the anionic or esteratic site of acetylcholinesterase. Therefore, the anticholinesterase drugs have also been pharmacologically subdivided. Drugs that inhibit the anionic site are called competitive inhibitors. Their action is due to competition between the anticholinesterase and ACh for the anionic site. These drugs tend to be short-

acting. Edrophonium is an example of this type. Drugs that inhibit the esteratic site are called acid-transferring inhibitors. These drugs include the longer-acting neostigmine, pyridostigmine, and physostigmine.

Most of the reversible cholinesterase inhibitors are quaternary ammonium compounds and do not cross the blood–brain barrier. Physostigmine is a tertiary amine that readily passes into the CNS (Fig. 14-14). It produces central muscarinic stimulation and, thus, is not used to reverse neuromuscular blockade but can be used to treat atropine poisoning. Conversely, atropine is used to treat physostigmine poisoning. Physostigmine has also been found to be a specific antidote in the treatment of postoperative delirium (see below, Central Anticholinergic Syndrome).<sup>3</sup>

The irreversible cholinesterase inhibitors are mostly organophosphate compounds. The organophosphate compounds are highly lipid-soluble, readily pass into the CNS, and are rapidly absorbed through the skin. They are used as the active ingredient in potent insecticides and chemical warfare agents known as nerve gases (see Chapter 53). The only therapeutic drug of this group is echothiophate, which is available in the form of topical drops for the treatment of glaucoma. Its primary advantage is its prolonged duration of action. Topical absorption is variable but considerable. Echothiophate can remain effective for 2 or 3 weeks following cessation of therapy. A history of use of echothiophate is important in avoiding prolonged action of succinylcholine, which requires pseudocholinesterase for its hydrolysis. Organophosphate poisoning manifests all the signs and symptoms of excess ACh. The antidote cartridges dispensed to troops to counter the effects of anticholinesterase nerve gases contain only atropine, which would effectively counter the muscarinic effects of the gas; however, atropine does little to counter the high-dose nicotinic muscle paralysis or the central ventilation depression that contributes to death from nerve gases. Treatment requires high doses of atropine, 35 to 70 mcg/kg IV every 3 to 10 minutes until muscarinic symptoms abate. Lower doses at less frequent intervals may be required for several days. Central ventilatory depression and weakness require respiratory support and specific therapy of the cholinesterase lesion. Pralidoxime has been reported to reactivate cholinesterase activity by hydrolysis of the phosphate enzyme complex. It is particularly effective with parathion poisoning and is the only cholinesterase reactivator available in the United States.<sup>28</sup>

**Figure 14-14** Structural formulas of clinically useful reversible anticholinesterase drugs. Physostigmine is a tertiary amine and crosses the blood–brain barrier. It is useful in treating the central anticholinergic syndrome.

## Muscarinic Antagonists

*Muscarinic antagonist* refers to a specific drug action for which the term anticholinergic is widely used. Any drug that interferes with the action of ACh as a transmitter can be considered an anticholinergic agent. The term anticholinergic refers to a broader classification that also includes the nicotinic antagonists.

**Figure 14-15** Structural formulas of the clinically useful antimuscarinic drugs.

### Atropine-like Drugs

Atropine, scopolamine, and glycopyrrolate are the most commonly used muscarinic antagonists used in anesthesia (Fig. 14-15). The actions of these drugs include inhibition of salivary, bronchial, pancreatic, and gastrointestinal secretions, and they antagonize the muscarinic side effects of anticholinesterases during reversal of muscle relaxants. Historically, atropine was introduced to anesthesia practice to prevent excessive secretions during ether anesthesia and to prevent vagal bradycardia during the administration of chloroform.<sup>28</sup> Antimuscarinic agents do not inhibit transmission equally, and there are marked variations in sensitivity at different muscarinic sites owing to differences in penetration and affinities of the various receptors. Differences in relative potency between the different antimuscarinics are outlined in Table 14-6. Atropine and scopolamine are tertiary amines (Fig. 14-15) and easily penetrate the blood–brain barrier and placenta. Glycopyrrolate is a quaternary amine that, like the reversible anticholinesterase drugs, does not easily penetrate these barriers. Glycopyrrolate, a synthetic antimuscarinic, has gained popularity because it avoids the central effects of the other two drugs. Clinical observations suggested that bradycardia associated with spinal anesthesia is refractory to the administration of glycopyrrolate, and that atropine and ephedrine are the drugs of choice in order to prevent a possible cardiac arrest. Nevertheless, recent data (69 parturients) demonstrated that prophylactic administration of glycopyrrolate does prevent bradycardia associated with spinal anesthesia for cesarean delivery.<sup>29</sup> Atropine and scopolamine have notable CNS effects that are dissimilar. Scopolamine differs from atropine mainly in its central depressant effects, which produce sedation, amnesia, and euphoria. Such properties are widely used for

premedication for cardiac patients in combination with morphine and a major tranquilizer. Scopolamine also has been used to induce amnesia in patients who have a high risk for intraoperative awareness, such as trauma victims who are hemodynamically unstable and cannot receive adequate anesthesia. Atropine, as a premedication, has slight effects on the CNS, including mild stimulation. Higher doses such as those given for reversal of muscle relaxants (1 to 2 mg) may produce restlessness, disorientation, hallucinations, and delirium (see below, Central Anticholinergic Syndrome).

Atropine is useful in increasing CO when sinus bradycardia due to vagal stimulation is present. Atropine and scopolamine are noted to produce a paradoxical bradycardia when given in low doses. Scopolamine (0.1 to 0.2 mg) usually causes more slowing than atropine but also produces less cardiac acceleration at higher doses. The usual intramuscular premedicant doses of scopolamine cause either a decrease or no change in HR. Atropine may also produce sympathomimetic effects by blocking presynaptic muscarinic receptors found on adrenergic nerve terminals.<sup>30</sup> ACh stimulation of these receptors inhibits NE release, and blockade by atropine releases this inhibition (see Cholinergic Receptors: Muscarinic). Atropine-like drugs that cross the blood–brain barrier also produce dilation of the pupil (mydriasis) and paralysis of accommodation (cycloplegia). Atropine-like drugs are widely used in ophthalmology as mydriatics and cycloplegics. Atropine is contraindicated in patients with narrow-angle glaucoma (see [Chapter 48](#)). Pupillary dilation thickens the peripheral part of the iris, which narrows the iridocorneal angle. This leads to impaired drainage of aqueous humor, and increase of the intraocular pressure. Doses of atropine used for premedication have little effect in this regard, whereas equal doses of scopolamine cause mydriasis. Prudence would dictate avoidance of either agent in patients with narrow-angle glaucoma. The need for antimuscarinic premedication is questionable in this situation.

**Table 14-6** Comparison of Antimuscarinic Drugs

	Duration		CNS	GI Tone	Gastric Acid	Airway Secretions <sup>a</sup>	Heart Rate
	IV	IM (hr)					
Atropine	15–30 min	2–4	++	–	–	–	+++ <sup>c</sup>
Scopolamine	30–60 min	4–6	++ <sup>b</sup>	–	–	–	–0 <sup>f</sup>
Glycopyrrolate	2–4 hr	6–8	0	–	–	–	+0

IV, intravenous; IM, intramuscular; GI, gastrointestinal.

<sup>a</sup>Secretions may be reduced by inspissations.

<sup>b</sup>CNS effect often manifest as sedation before stimulation.

<sup>c</sup>May decelerate initially.

Atropine and scopolamine also possess antiemetic action. Atropine, however, reduces the opening pressure of the lower esophageal sphincter, which theoretically increases the risk of passive regurgitation. The belladonna

alkaloids (atropine and scopolamine) also block ACh transmission to sweat glands, which, although they are cholinergic, are innervated by the SNS. Antimuscarinic agents produce antinicotinic actions at higher doses and result in important actions on CNS transmission that are pharmacologically similar to the postganglionic cholinergic function. Atropine is best avoided where tachycardia would be harmful, as may occur in thyrotoxicosis, pheochromocytoma, or obstructive coronary artery disease. Atropine should be avoided in hyperpyrexial patients because it inhibits sweating.

## Central Anticholinergic Syndrome

 The belladonna alkaloids have long been known to produce undesirable side effects ranging from stupor (scopolamine) to delirium (atropine). This syndrome has been called postoperative delirium, atropine toxicity, and central anticholinergic syndrome. Biochemical studies have demonstrated abundant muscarinic ACh receptors in the brain that can be affected by any drug possessing antimuscarinic activity and capable of crossing the blood–brain barrier. Hundreds of drugs exist that meet these criteria and with which this syndrome has been associated. [Table 14-7](#) lists some of those drugs.<sup>3</sup> High doses of atropinic alkaloids rapidly produce dryness of the mouth, blurred vision with photophobia (mydriasis), hot and dry skin (flushed), and fever. Mental symptoms range from sedation, stupor, and coma to anxiety, restlessness, disorientation, hallucinations, and delirium. Convulsions may occur if lethal poisoning has occurred. Although an alarming reaction may occur, fatalities are rare. Intoxication is usually short-lived and followed by amnesia. These reactions can be controlled by the intravenous injection of physostigmine. Physostigmine is an anticholinesterase that, by virtue of being a tertiary amine, readily passes into the CNS to counter antimuscarinic activity. It should be given slowly in 1 mg doses, not exceeding 3 mg, to avoid producing peripheral cholinergic activity. Neostigmine, pyridostigmine, and edrophonium are not effective because they cannot pass into the CNS. The duration of physostigmine action may be shorter than that of the offending antimuscarinic agent and require repeated injection if symptoms recur. Physostigmine appears safe when used within dose recommendations and when indications are established. Central disorientation alone does not establish a diagnosis. Peripheral signs of antimuscarinic activity should be present in addition to a central anticholinergic syndrome.

Physostigmine has been reported to reverse the CNS effects of many of the drugs listed in [Table 14-7](#), including antihistamines, tricyclic antidepressants, and tranquilizers. Reversal of the sedative effects of opioids and benzodiazepines has also been reported.<sup>31</sup> However, anticholinesterase agents potentiate cholinergic synaptic transmission and increase neuronal activity,

even if no receptor antagonist is present. Thus, arousal may not be a function independent of its cholinesterase activity, and claims that physostigmine is a nonspecific CNS stimulant may not be warranted and could, in fact, be dangerous. These considerations, in association with possible significant bradycardia, made the use of physostigmine fairly scarce in the postanesthesia care units.

## Autonomic Syndromes and Autonomic Regulation

Recent research in different clinical fields seems to connect the autonomic system and its regulation with the course of various diseases, which can prove its importance beyond the classical role of fight or flight.

**Table 14-7** Antimuscarinic Compounds Associated with Central Anticholinergic Syndrome

----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

This type of association between the afferent-pathway-sensing proinflammatory cytokines, which is informing the brain with subsequent vagal feedback from the nucleus tractus solitarius to the periphery and release of ACh, may be a mechanism by which an anti-inflammatory action occurs, with possible vagal regulation of the oncologic processes; it may ultimately lead to extended survival of these patients, which is a promising avenue, especially since vagal activity may be manipulated by behavioral, surgical, and pharmacologic interventions, including the use of  $\beta$ -blockers.<sup>33</sup>

At the onset of temporal seizures, there appears to be a decrease in parasympathetic tone, which returns slowly to normal at the end of the seizure episode. This phenomenon is inversely correlated with patient's age and duration of the seizure episode, and also with postictal hypoxemia, which in extreme cases may increase the risk for patient death.<sup>34</sup>

Even more importantly, cardiac autonomic dysregulation plays a central role in the evolution of several cardiovascular syndromes such as hypertension, arrhythmias, heart failure, and even myocardial infarction.<sup>35</sup> Therefore, addressing the ANS and specifically the upregulation of sympathetic nerve abnormalities in heart failure may have a great impact upon treatment of these conditions.

Explicitly, higher sympathetic tone may precipitate malignant arrhythmias. Therefore, some forms of autonomic testing may be useful to predict which patients are at risk, and subsequently decide on how to proceed with the management. Thus, cardiac autonomic testing includes heart rate variability, baroreflex sensitivity, heart rate turbulence, heart rate deceleration capacity, and T-wave alternans. Of the possible occurring pathology, one can name a few, such as atrial fibrillation, ventricular tachyarrhythmias due to ischemia, cardiomyopathy, heart failure, prolonged QT syndrome, Brugada syndrome, and idiopathic ventricular fibrillation.<sup>35</sup> Implicitly, vagal nerve stimulation is a possible avenue for the management of these arrhythmias as well as heart failure.<sup>36</sup>

Some authors suggest that atrial fibrillation may be due to simultaneous and thus imbalanced discharge of both sympathetic and parasympathetic discharges, with the stellate ganglion and vagus nerve playing an essential part in this process. Renal denervation has been proposed as an adjunct therapy for hypertension, atrial fibrillation, and ventricular arrhythmias, since it appears to lead to a reduction in heart rate, as well as atrioventricular conduction, and therefore it decreases the secretion of NE. Acupuncture has been proposed as a useful, albeit less traditional, tool for atrial fibrillation management. Other possible avenues for further research as well as therapeutic interventions include low-level vagus nerve stimulation, spinal cord stimulation, left cardiac sympathetic denervation, ganglionated plexus ablation, and cutaneous stimulation, which may prove to be a better alternative in patients who cannot tolerate pharmacologic treatment; some of these techniques can be utilized as well for patients with chronic heart failure.<sup>37-40</sup> Explicitly, patients with resistant hypertension may benefit from bilateral renal nerve ablation by catheters delivering high-frequency ultrasound, as well as bilateral, and more recently unilateral carotid baroreceptor stimulation via an implanted stimulator. However, some negative results have been found as well, with no significant difference between tested subjects, which leads to the need for more randomized studies

to elucidate this important clinical issue.<sup>41</sup> There are still some unanswered questions regarding the use of  $\beta$  blockers in patients with heart failure, especially since central inhibition of SNS seems to be associated with increase in mortality; therefore it appears that a better approach remains with receptor inhibition, and that the  $\beta$  blockers' beneficial effects reside in counteracting the effects of tachycardia.<sup>42</sup>

Even beyond our ability to manipulate the ANS, it appears that just by observing a cohort of patients admitted to the Emergency Department, one can predict their short-term mortality by determining their deceleration capacity, a factor assessed using heart rate and R-R interval, which ultimately appear to be significantly lower in nonsurvivors rather than in survivors.<sup>43</sup> In addition, autonomic impairment in patients with traumatic brain injury, which is measured by heart rate variability and baroreflex sensitivity, appears to worsen the risk of death in these patients.<sup>44</sup> The ANS seems to be implicated as a cause of sudden cardiac death in epilepsy by several possible mechanisms, such as long or short QT interval, Brugada syndrome, Dravet syndrome, decreased heart rate variability, chronic autonomic changes, ventricular arrhythmias, bradycardia, asystole, and antiepileptic medications.<sup>45</sup> Also, obese patients with insulin resistance may benefit from sympathetic blockade, either with pharmacologic methods or through renal denervation, but more studies are needed in the future for complete elucidation of these mechanisms.<sup>46</sup>

## **Horner Syndrome**

Horner syndrome, also known as oculosympathetic paresis, classically manifests as miosis, ptosis, and anhidrosis (Fig. 14-16). Its occurrence is the result of a lesion alongside a three-neuron adrenergic pathway from the hypothalamus, through the brachial plexus to the superior cervical ganglion, and then through the cavernous sinus within the adventitia of the internal carotid artery toward the eye. There it converges with the ophthalmic division of the trigeminal nerve, and it ends up innervating the iris dilator muscle, Muller's muscle, which induces a lower lid retraction as well as minor portion of upper lid elevation.

The causes of Horner syndrome are stroke, tumor, trauma, demyelinating diseases, dissections, or aneurysms of the internal carotid artery, as well as idiopathic events.

**Figure 14-16** Horner Syndrome (left eye). Note miosis and ptosis. Loss of sweating not shown.

It is essential to differentiate more precisely the location of the injury along the sympathetic tract, such as first-, second-, or third-order neuron in order to facilitate more specific testing, which will lead to a more accurate diagnosis. For example, injuries along the first-order neuron include commonly lateral medullary infarction, as well as strokes, tumors, and demyelinating afflictions, and usually are associated with other neurologic signs such as weakness, sensory deficits, hoarseness, and possible vertigo. Second-order neuron injuries include apical pulmonary tumors and thyroid malignancies. Several regional anesthesia procedures such as epidural nerve blocks may produce Horner syndrome symptoms due to the effect of local anesthetics on the preganglionic neuron. Finally, third-order syndrome includes disease of the carotid artery, such as aneurysm, dissection, thrombosis, and even carotid endarterectomy. In these cases, common symptoms are face and neck pain.<sup>47</sup>

If the diagnosis can be done clinically, the next step is localizing the culprit; otherwise confirmation is performed by utilizing either a few drops of cocaine, which block the reuptake of NE and induce pupillary dilatation more in the normal eye than in the affected pupil, or apraclonidine, a direct  $\alpha$ -adrenergic receptor agonist that reverses the anisocoria.

In order to determine the location of the lesion along the sympathetic tract, one can utilize a few drops of hydroxyl amphetamine, or its derivative pholedrine, which release NE, and in cases of first- or second-order Horner's the pupils will dilate, while in third-order Horner's the pupils will not dilate. Clearly, neuroimaging with CT scanning, and even MRI, are required for a more precise diagnosis.

Treatment is mainly supportive, and based on the cause, that is why clear identification of the location of the lesion is of utmost importance.<sup>48,49</sup>

## **Diabetic Neuropathy**

Diabetic neuropathy is probably the best-known affliction associated with ANS dysfunctions. There is a progression of the symptoms with sensory loss initially and, as the disease progresses, with motor weakness as well. The first symptoms relate to a deficiency in vibratory sensation, as well as impairment of sensation to pain, light touch, and temperature, classically characterized as stocking-glove sensorial deficit. These symptoms are associated with depressed ankle reflexes, with a gradual evolution toward a more generalized motor weakness and loss of reflexes. This is not an uncommon occurrence in adult-onset diabetes, with a prevalence of approximately 41.9% to 26.4%, in a more recent study.<sup>50,51</sup> The most significant reason why it is important to follow this particular development is due to the fact that it can lead to foot ulcers, either acute and chronic, as well as muscle and joint pathology, with muscle atrophy, arthropathies, and stress fractures.

There are several methods of assessing the severity of the neuropathy, which can be normal, mild, moderate, or severe, by evaluating both symptoms and clinical signs.

Electrodiagnostic testing is necessary for atypical presentations, as well as for classification in clinical and epidemiologic studies.<sup>52,53</sup>

Monitoring of patients should be done at diagnosis and at regular intervals, to prevent development of complications associated with the diabetic foot.

### *Orthostatic Hypotension*

Orthostatic hypotension is characterized by a decrease in blood pressure after standing or eating, and can be manifested by dizziness and syncope, which may progress to angina and, in rare cases, even to death.

In normal circumstances, upon standing, a certain volume of blood is pooled by gravity toward the splanchnic vessels and lower extremities, which leads to a decrease in venous return and subsequently a drop in blood pressure. The normal response is a compensatory mechanism that involves the central and peripheral nervous system, and consists of an increase in sympathetic outflow that instead raises the peripheral vascular resistance, venous return, and cardiac output and maintains blood pressure within normal limits, ultimately allowing standing upright.

The main conditions that lead to orthostatic hypotension are autonomic dysfunction and significant hypovolemia, and they appear to be more common in the elderly population.

These conditions are different from short-lived reflex syncope, which includes vasovagal, situational, and carotid sinus syncope; reflex syncope manifests with vasodilation and bradycardia instead of expected tachycardia, which subsequently determines hypotension followed by cerebral

hypoperfusion, and thus causes the main symptom of temporary loss of consciousness.<sup>54</sup>

This condition may be due to neurodegenerative diseases whose common denominator is inappropriately low release of NE from the postganglionic sympathetic neurons, followed by inadequate vasoconstriction, reduced intravascular volume, and orthostatic hypotension. These disease include Parkinson disease, dementia with Lewy bodies, multiple system atrophy, and pure autonomic failure. In addition, there are peripheral neuropathies, as well as autoimmune blockade of ganglionic transmission, that produce the same manifestations, and here we can include diabetes mellitus, Guillain–Barré, paraneoplastic autonomic neuropathy, and familial dysautonomia. Orthostatic hypotension is among the side effects of several medications including alcohol,  $\alpha$ -blockers, antidepressants, sympathetic nervous system blockers, antiparkinsonism drugs,  $\beta$ -blockers, diuretics, muscle relaxants, morphine, phosphodiesterase inhibitors, sedatives, and vasodilators. Aging contributes to a decrease in baroreceptor sensitivity, and it may be related to milder forms of orthostatic hypotension.

Symptoms, which vary in intensity, consist of dizziness, lightheadedness, weakness, blurred vision, and in severe cases syncope, angina, or even stroke. Less specific symptoms may include generalized weakness, fatigue, cognitive slowing, neck pain, and localized headache in the posterior cervical and shoulder region, also called coat hanger headache.

Diagnosis is made when there is at least a 20 mmHg drop in systolic blood pressure and/or 10 mmHg decrease in diastolic blood pressure, associated commonly with increase in heart rate within 2 to 5 minutes after changing posture from supine to standing.<sup>55–57</sup>

Treatment is symptomatic, starting with removal of medications that may possibly induce this pathology, lifestyle modification, avoiding dehydration, exercise, physical maneuvers such as crossing legs when standing, increasing the salt and water intake, avoiding large meals, and drinking water with meals. Medications that can be used to alleviate symptoms include fludrocortisone, sympathetic agents such as ephedrine, phenylephrine, midodrine, other supplements such as pyridostigmine, nonsteroidal agents, caffeine, and erythropoietin. Other experimental agents including vasopressin analogues, yohimbine, somatostatin, dihydroergotamine, dihydroxyphenylserine, dopamine antagonists such as metoclopramide, atomoxetine, and even ambulatory NE infusion have been attempted with some positive results.<sup>58</sup>

### ***Monoamine Oxidase Inhibitors***

Monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants are used

to treat psychotic depression.<sup>61–63</sup> These drugs are not used in the practice of anesthesia but are a source of potentially serious anesthetic interactions in patients who take them chronically (see [Chapter 22](#)). Their use is rapidly declining, as the nontricyclic antidepressants such as fluoxetine (Prozac) are more efficacious and produce fewer side effects. Few of the MAOIs or tricyclic antidepressants will be encountered in an anesthesia practice today, with the exceptions of phenelzine (Nardil) and amitriptyline (Amitril, Elavil). Their pharmacologic actions and side effects are the direct result of their effect on the cascade of catecholamine metabolism. MAOIs block the oxidative deamination of endogenous catecholamines into inactive vanillylmandelic acid. They do not inhibit synthesis. Thus, blockade of MAO would produce an accumulation of NE, EPI, dopamine, and 5-hydroxytryptamine in adrenergically active tissues, including the brain. The action of sympathomimetic amines is potentiated in patients taking MAOIs. Indirect acting sympathomimetics (ephedrine, tyramine) produce an exaggerated response as they trigger the release of accumulated catecholamines. Foods containing a high tyramine content such as cheese, red Italian wine, and pickled herring can also precipitate hypertensive crises.<sup>28</sup> Meperidine has been reported to produce hypertensive crisis, convulsions, and coma with MAO inhibitors. Hepatotoxicity has been reported that does not seem to be related to dosage or duration of treatment. Its incidence is low but remains a factor in selecting anesthesia.

The anesthetic management of patients taking MAOIs remains controversial. Currently, recommendations for management include discontinuation of the drugs for at least 2 weeks before surgery; however, this recommendation is not based on controlled studies but rather is the result of limited case reports that suggest potent drug interactions.

### ***Tricyclic Antidepressants***

On the basis of their chemical structure, this group of antidepressant drugs is referred to as tricyclic antidepressants. These drugs have almost replaced MAOIs, since they have fewer side effects.<sup>62,63</sup> All of these agents block uptake of NE into adrenergic nerve endings. Just as with MAOIs, high doses of tricyclic antidepressants can induce seizure activity that is responsive to diazepam. Neuroleptic drugs may potentiate the effects of tricyclic antidepressants by competition with metabolism in the liver. Chronic barbiturate use increases metabolism of tricyclic antidepressants by microsomal enzyme induction. Other sedatives, however, potentiate the tricyclic antidepressants in a manner similar to that occurring with MAOIs. Atropine also has an exaggerated effect because of the anticholinergic effect of tricyclic antidepressants. Prolonged sedation from thiopental has been

reported. Ketamine may also be dangerous in patients taking tricyclic antidepressants by producing acute hypertension and cardiac dysrhythmia. Despite these serious interactions, discontinuation of these drugs before surgery is probably not necessary. The latency of onset of these drugs is from 2 to 5 weeks; however, the excretion of tricyclic antidepressants is rapid, with approximately 70% of a dose appearing in the urine during the first 72 hours. The long latency period for resumption of treatment militates against interrupted treatment. A thorough knowledge of the possible drug interactions and autonomic countermeasures now available obviates postponement.

### ***Selective Serotonin Reuptake Inhibitors***

Mechanism of action of SSRIs appears to be the selective inhibition of neuronal uptake of serotonin. This potentiates the behavioral changes induced by the serotonin precursor 5-hydroxytryptophan.<sup>62,63</sup> The availability of sympathetic antagonists for treatment of possible side effects during anesthesia weighs in favor of continuation of therapy versus the risk of exacerbation of a severe depression. Prozac (fluoxetine) is a popular oral nontricyclic antidepressant. The elimination half-life of Prozac is 1 to 3 days and can lead to significant accumulation of the drug. Prozac's metabolism, like that of other compounds, including tricyclic antidepressants, phenobarbital, ethanol, and pentothal, involves the P450 II D6 system; concomitant therapy with drugs also metabolized by this enzyme system may lead to drug interactions and prolongation of effect of the benzodiazepines. Bupropion hydrochloride is available in both a regular (Wellbutrin) and sustained-release (Zyban) form. Wellbutrin is used as an antidepressant, whereas Zyban is marketed as a nonnicotine aid to smoking cessation. The neurochemical mechanism of the antidepressant effect of bupropion is not known. It does not inhibit MAO and is a weak blocker of the neuronal uptake of serotonin and NE. It also inhibits the neuronal uptake of dopamine to some extent. No systematic data have been collected on the interactions of bupropion and other drugs. Patients with heart disease have emerged as a special category due to the finding that depression significantly affects cardiovascular health. Several studies support the safety of SSRIs in these patients due to their association with a decrease in morbidity and mortality, and the need for continuous treatment, especially in the elderly. Nevertheless, there is some evidence, although small, that these drugs may increase the risk of bleeding. Since these patients may use concomitantly other antiplatelet/anticoagulation therapies, increased vigilance is mandatory.<sup>61-63</sup>

## KEY POINTS

- 1 In a person with normal lungs, breathing can be performed exclusively by the diaphragm.
- 2 In the adult, the tip of an orotracheal tube moves an average of 3.8 cm with flexion/extension of the neck, but can travel as much as 6.4 cm. In infants and children, displacement of even 1 cm can move the tube above the vocal cords or below the carina.
- 3 The following anatomy should be considered when contemplating use of a double-lumen tube. The adult right main stem bronchus is about 2.5 cm long before it branches into lobar bronchi. In 10% of adults, the right upper lobe bronchus departs from the right main stem bronchus less than 2.5 cm below the carina. In 2% to 3% of adults, the right upper lobe bronchus opens directly into the trachea, above the carina.
- 4 When lung compliance is reduced, larger changes in pleural pressure are needed to create the same tidal volume ( $V_t$ ). Patients with low lung compliance breathe with smaller  $V_t$  and more rapidly, making spontaneous respiratory rate the most sensitive clinical index of lung compliance.
- 5 Carotid and aortic bodies are stimulated by  $PaO_2$  values less than 60 to 65 mmHg. Thus, patients who depend on hypoxic ventilatory drive must have  $PaO_2$  values below 65 mmHg. The response of the peripheral receptors will not reliably increase ventilatory rate or minute ventilation to herald the onset of hypoxemia during general anesthesia or recovery.
- 6 There are three etiologies of hyperventilation: arterial hypoxemia, metabolic acidemia, and central etiologies (e.g., intracranial hypertension, hepatic cirrhosis, anxiety, pharmacologic agents).
- 7 Increases in dead space ventilation primarily affect  $CO_2$  elimination (with minimal influence on arterial oxygenation), whereas increases in physiologic shunt primarily affect arterial oxygenation (with minimal influence on  $CO_2$  elimination).
- 8 During spontaneous ventilation, the ratio of alveolar ventilation to dead space ventilation is 2:1. The alveolar-to-dead space ventilation ratio during positive-pressure ventilation is 1:1. Thus, minute ventilation during mechanical ventilatory support must be greater than that during spontaneous ventilation to achieve the same  $PaCO_2$ .
- 9  $PaCO_2 \geq PETCO_2$  unless the patient inspires or receives exogenous  $CO_2$ . The difference between  $PaCO_2$  and  $PETCO_2$  is due to dead space ventilation. The most common reason for an acute increase in dead space ventilation is decreased cardiac output.
- 10 Calculation of the shunt fraction is the best tool for evaluating the lungs' efficiency in oxygenating the arterial blood. It is the only index of

oxygenation that takes into account the contribution of mixed venous blood to arterial oxygenation.

- 11 When functional residual capacity (FRC) is reduced, lung compliance falls (causing tachypnea) and venous admixture increases, creating arterial hypoxemia.
- 12 There is no compelling evidence that defines rules for ordering preoperative pulmonary function tests. Rather, they should only be obtained to ascertain the presence of reversible pulmonary dysfunction (bronchospasm) or to define the severity of advanced pulmonary disease.
- 13 Patients who smoke should be advised to *stop* smoking at least 2 months prior to an elective operation to decrease the risk of postoperative pulmonary complications (PPCs).
- 14 The operative site is one of the most important determinants of the risk of PPC. The highest risk for PPC is associated with nonlaparoscopic upper abdominal operations, followed by lower abdominal and intrathoracic operations.
- 15 The single most important aspect of postoperative pulmonary care and prevention of PPC is early ambulation. Patients should be encouraged to get out of bed and walk.

Anesthesiologists directly manipulate pulmonary function. Thus, a sound and thorough working knowledge of applied pulmonary physiology is essential to the safe conduct of anesthesia. This chapter discusses pulmonary anatomy, the control of ventilation, oxygen and carbon dioxide transport, ventilation–perfusion relationships, lung volumes and pulmonary function testing, abnormal physiology and anesthesia, the effect of smoking on pulmonary function, and risk assessment for postoperative pulmonary complications (PPCs).

## Functional Anatomy of the Lungs

This section emphasizes functional lung anatomy, with structure described as it applies to the mechanical and physiologic function of the lungs.

### Thorax

The thoracic cage is shaped like a truncated cone, with a small superior aperture and a larger inferior opening to which the diaphragm is attached. The sternal angle is located in the horizontal plane that passes through the vertebral column at the T4 or T5 level. This plane separates the superior from the inferior mediastinum. During ventilation, the predominant changes in thoracic diameter occur in the anteroposterior direction in the upper thoracic

region and in the lateral or transverse direction in the lower thorax.

## *Muscles of Ventilation*

Work of breathing is the energy expenditure of ventilatory muscles. Similar to other skeletal muscles, the ventilatory muscles are endurance muscles subject to fatigue from inadequate oxygen delivery, poor nutrition, and increased work secondary to chronic obstructive pulmonary disease (COPD) with gas trapping or increased airway resistance. The ventilatory muscles include the diaphragm, intercostal muscles, abdominal muscles, cervical strap muscles, sternocleidomastoid muscles, and the large back and intervertebral muscles of the shoulder girdle. During nonstrenuous breathing, the diaphragm performs **1** most of the muscle work. Work contribution from the intercostal muscles in nonstrenuous breathing is minor. Normally, at rest, inspiration requires work while exhalation is passive. As work of breathing increases, abdominal muscles assist with rib depression and increase intra-abdominal pressure to facilitate forced exhalation causing the “stitch,” or rib pain athletes experience when they actively exhale. When a further increase in work is required, the cervical strap muscles are recruited to help elevate the sternum and upper portions of the chest to optimize the dimensions of the thoracic cavity. Finally, during periods of maximal work, recruitment of large back and paravertebral muscles of the shoulder girdle contribute to ventilatory effort. The muscles of the abdominal wall, the most powerful muscles of expiration, are important for expulsive efforts such as coughing.<sup>1</sup> However, with normal lungs, breathing can be performed solely by the diaphragm.

Breathing is an endurance phenomenon involving fatigue-resistant muscle fibers, characterized by a slow-twitch response to electrical stimulation that must create sufficient force to lift the ribs and generate subatmospheric pressure in the intrapleural space. These fatigue-resistant fibers comprise approximately 50% of the total diaphragmatic muscle fibers. The high oxidative capacity of these fibers creates endurance units.<sup>2</sup> Fast-twitch muscle fibers, more susceptible to fatigue, have rapid responses to electrical stimulation, imparting strength and allowing greater force over less time. The combination of fast-twitch fibers useful during brief periods of maximal ventilatory effort (coughing, sneezing) and slow-twitch fibers providing endurance (breathing without rest) underscores the unique dual function of the diaphragm as a muscle.<sup>3</sup>

A working muscle like the diaphragm must be firmly anchored at both its origin and insertion. However, its unique insertion is mobile—a central tendon originates from fibers attached to the vertebral bodies, as well as the lower ribs and sternum. Diaphragmatic contraction results in descent of the diaphragmatic dome and expansion of the thoracic base, creating decreases in

intrathoracic and intrapleural pressure and an increase in intra-abdominal pressure.

The cervical strap muscles, active even during restful breathing, are the most important inspiratory accessory muscles. When diaphragm function is impaired, as in patients with cervical spinal cord transection, they can become the primary inspiratory muscles.

## *Lung Structures*

In an intact respiratory system, the expandable lung tissue fills the pleural cavity. The visceral and parietal pleurae oppose each other, creating a potential intrapleural space where pressure decreases when the diaphragm descends and the rib cage expands. At the end of inspiration, the resultant subatmospheric intrapleural pressure is a reflection of the opposing and equal forces between the natural tendency of the lungs to collapse and the chest wall musculature to remain expanded. These equal and opposing forces at end-inspiration result in the functional residual capacity (FRC), the volume of gas remaining in the lungs at passive end-expiration. At FRC, the intrapleural space normally has a slightly subambient pressure (−2 to −3 mmHg). Major divisions of the right and left lung are listed in [Table 15-1](#). Knowledge of the bronchopulmonary segments is important for localizing lung pathology, interpreting lung radiographs, identifying lung regions during bronchoscopy, and operating on the lung. Each bronchopulmonary segment is separated from its adjacent segments by well-defined connective tissue planes that often anatomically confine initial lung pathologies.

**Table 15-1** Major Divisions of the Lung

Lung Side/Lobe	Bronchopulmonary Segment
<b>Right</b>	
Upper	Apical Anterior Posterior
Middle	Medial Lateral
Lower	Superior Medial basal Lateral basal Anterior basal Posterior basal
<b>Left</b>	
Upper	Apical posterior Anterior
Lingula	Superior Inferior
Lower	Superior Posterior basal Anteromedial basal Lateral basal

The lung parenchyma can be subdivided into three airway categories based on functional lung anatomy (Table 15-2). The conductive airways allow basic gas transport without gas exchange. The next group of airways, which have smaller diameters, are transitional airways. Transitional airways are not only conduits for gas movement, but also allow limited gas diffusion and exchange. Finally, the primary function of the smallest respiratory airways is gas exchange.

Conventionally, large airways with diameters more than 2 mm create 90% of total airway resistance. The number of alveoli increases progressively with age, from approximately 24 million at birth, and reaches its final adult count of 300 million by the age of 8 or 9 years. These alveoli are associated with about 250 million precapillaries and 280 billion capillary segments, resulting in a surface area of approximately 70 m<sup>2</sup> for gas exchange.

### Conductive Airways

In the adult, the trachea is a fibromuscular tube about 10 to 12 cm long with an outer diameter of approximately 20 mm. Structural support is provided by 20 U-shaped structures composed of hyaline cartilage, with the opening of the U facing posteriorly. The cricoid membrane tethers the trachea to the cricoid cartilage at the level of the sixth cervical vertebral body. The trachea enters the superior mediastinum and bifurcates at the sternal angle (the lower border of the fourth thoracic vertebral body). Normally, half of the trachea is intrathoracic and half is extrathoracic. Because both ends of the trachea are

attached to mobile structures, the adult carina can move superiorly as much as 5 cm from its normal resting position. Awareness of airway “motion” is essential to proper care of the intubated patient. In the adult, the tip of an orotracheal tube moves an average of 3.8 cm with flexion and extension of the neck, but can travel as far as 6.4 cm.<sup>4</sup> In infants and children, tracheal tube movement with respect to the trachea is even more critical: displacement of even 1 cm can result in unintentional extubation or bronchial intubation.

**Table 15-2** Functional Airway Divisions

Type	Function	Structure
Conductive	Bulk gas movement	Trachea to terminal bronchioles
Transitional	Bulk gas movement	Respiratory bronchioles
	Limited gas exchange	Alveolar ducts
Respiratory	Gas exchange	Alveoli Alveolar sacs

The next airway generation below the carina is composed of the right and left main stem bronchi. The diameter of the right bronchus is generally greater than that of the left. In the adult, the right bronchus leaves the trachea at approximately 25 degrees from the vertical tracheal axis, whereas the angle of the left bronchus is about 45 degrees. Thus, unintentional endobronchial intubation or aspiration of foreign material is more likely to occur on the right than the left. Furthermore, the right upper lobe bronchus dives almost directly posterior at approximately 90 degrees from the right main bronchus, facilitating aspiration of foreign bodies and fluid into the right upper lobe in the supine patient. In children younger than 3 years of age, the angles created by the right and left main stem bronchi are approximately equal, with takeoff angles of about 55 degrees.

The adult right main bronchus is about 2.5 cm long before it initially branches into lobar bronchi. However, in 10% of adults, the right upper lobe bronchus departs from the right main stem bronchus less than 2.5 cm from the carina. Furthermore, in 2% to 3% of adults, the right upper lobe bronchus opens into the trachea, superior to the carina. Patients with these anomalies require special consideration when placing double-lumen tracheal tubes, especially if one contemplates inserting a right-sided endobronchial tube. After the right upper and middle lobe bronchi divide from the right main bronchus, the main channel becomes the right lower lobe bronchus.

The left main bronchus is about 5 cm long before its initial branching point to the left upper lobe and the lingula; it then continues as the left lower lobe bronchus.

The bronchioles, typically 1 mm in diameter, are devoid of cartilaginous support and have the highest proportion of smooth muscle in their walls. Of the three to four bronchiolar generations, the final generation is the terminal bronchiole, which is the last airway component incapable of gas exchange.

## **Transitional Airways**

The respiratory bronchiole, which follows the terminal bronchiole, is the first site in the tracheobronchial tree where gas exchange occurs. In adults, two or three generations of respiratory bronchioles lead to alveolar ducts, of which there are four to five generations, each with multiple openings into alveolar sacs. The final divisions of alveolar ducts terminate in alveolar sacs that open into alveolar clusters.

## **Respiratory Airways and the Alveolar–capillary Membrane**

The alveolar-capillary membrane has two primary functions: transport of respiratory gases (oxygen and carbon dioxide), and the production of a wide variety of local and humoral substances. Gas transport is facilitated by the pulmonary capillary beds that are the densest capillary networks in the body. This extensive vascular branching system starts with pulmonary arterioles in the region of the respiratory bronchioles. Each alveolus is closely associated with some 1,000 short capillary segments.

The alveolar–capillary interface is complicated, but well designed to facilitate gas exchange. Viewed with electron microscopy, the alveolar wall consists of a thin capillary epithelial cell, a basement membrane, a pulmonary capillary endothelial cell, and a surfactant lining layer. The flattened, squamous type I alveolar cells cover about 80% of the alveolar surface. Type I cells contain flattened nuclei and extremely thin cytoplasmic extensions that provide the surface suitable for gas exchange. Type I cells are highly differentiated and metabolically limited, which makes them highly susceptible to injury. When type I cells are damaged severely (during acute lung injury or adult respiratory distress syndrome), type II cells replicate and modify to form new type I cells.<sup>5</sup>

Type II alveolar cells are interspersed among type I cells, primarily at alveolar–septal junctions. These polygonal cells have vast metabolic and enzymatic activity, and manufacture surfactant. The enzymatic activity required to produce surfactant is only 50% of the total enzymatic activity present in type II alveolar cells.<sup>6</sup> The remaining enzymatic activity modulates local electrolyte balance, as well as endothelial and lymphatic cell functions. Both type I and type II alveolar cells have tight intracellular junctions, providing a relatively impermeable barrier to fluids.

Type III alveolar cells, alveolar macrophages, are an important element of

immunologic lung defense. Their migratory and phagocytic activities permit ingestion of foreign materials within alveolar spaces.<sup>7</sup> Although functional pulmonary macrophages reduce the incidence of lung infection,<sup>8</sup> they also play an integral role in the organ-wide pulmonary inflammatory response. Thus, it is highly controversial whether the presence of these cells is beneficial (reducing the sequelae of infection) or harmful (contributing to the inflammatory response).<sup>9</sup>

## *Pulmonary Vascular Systems*

Two major circulatory systems supply blood to the lungs: the pulmonary and bronchial vascular networks. The pulmonary vascular system delivers mixed-venous blood from the right ventricle to the pulmonary capillary bed via two pulmonary arteries. After gas exchange occurs in the pulmonary capillary bed, blood is returned to the left atrium via four pulmonary veins. The pulmonary veins run independently along the intralobar connective tissue planes. The pulmonary capillary system adequately provides the metabolic and oxygen needs of the alveolar parenchyma. The bronchial arterial system provides oxygen to the conductive airways and pulmonary vessels. Anatomic connections between the bronchial and pulmonary venous circulations create an absolute shunt of about 2% to 5% of the total cardiac output, and represent “normal” shunt.

## **Lung Mechanics**

Lung movement occurs secondary to forces external to the lungs. During spontaneous ventilation, the external forces are produced by ventilatory muscles. The response of the lungs to these external forces is governed by two main characteristics: ease of elastic recoil of the chest wall and resistance to gas flow within airways.

### *Elastic Work*

The natural tendency of the lungs is to collapse because of elastic recoil; thus, expiration at rest is normally passive as gas flows out of the lungs. The thoracic cage exerts an outward-directed force, and the lungs exert an inward-directed force. Because the outward force of the thoracic cage exceeds the inward force of the lung, the overall tendency of the lung within the thoracic cage is to remain inflated. FRC represents the gas volume in the lungs when the outward and inward forces on the lung are equal. Gravitational forces create a more subatmospheric pressure in nondependent areas of the lung than in dependent areas. In the upright adult, the difference in intrapleural

pressure from the top to the bottom of the lung is about 7 cm H<sub>2</sub>O.

Surface tension at an air–fluid interface produces forces that tend to further reduce the area of interface. For a bubble to remain inflated, the gas pressure within the bubble is contained by surface tension and must be higher than the surrounding gas pressure. Alveoli resemble bubbles in this respect, but unlike a bubble, alveolar gas communicates with the atmosphere via the airways. The Laplace equation describes this phenomenon:  $P = 2T/R$ , where  $P$  is the pressure within the bubble ( $\text{dyn} \times \text{cm}^{-2}$ ),  $T$  is the surface tension of the liquid ( $\text{dyn} \times \text{cm}^{-1}$ ), and  $R$  is the radius of the bubble (cm).

During inspiration, the surface tension of the liquid in the lung increases to 40 mN/m, a value close to that of plasma. During expiration, this surface tension falls to 19 mN/m, a value lower than that of most other fluids. This change in surface tension creates hysteresis of the alveoli, the phenomenon of different pressure–volume relationships of the alveoli during inspiration versus expiration. Unlike a bubble, the pressure within an alveolus decreases as the radius of curvature decreases, creating gas flow from larger to smaller alveoli that maintains structural stability and prevents lung collapse.

The alveolar transmural pressure gradient, or transpulmonary pressure, is the difference between intrapleural and alveolar pressure, and is directly proportional to lung volume. Intrapleural pressure can be safely measured with a percutaneously inserted catheter<sup>10</sup>; however, clinicians rarely perform this technique. When measured with an esophageal balloon in the midesophagus, esophageal pressure can be used as a reflection of intrapleural pressure.<sup>11</sup> Commercially available esophageal pressure monitors increase the ease and accuracy of measuring esophageal pressure as a reflection of intrapleural pressure.<sup>12</sup> These monitors are useful for estimating the elastic work performed by the patient during spontaneous ventilation, mechanical ventilation, or a combination of spontaneous and mechanical ventilation. By estimating intrapleural pressure on a real-time basis, it is possible to quantitate the patient's work of breathing. For example, low levels of inspiratory pressure support can compensate for the work of breathing imposed by the endotracheal tube.<sup>13</sup>

Physiologic work of breathing includes elastic work (inspiratory work required to overcome the elastic recoil of the pulmonary system) and resistive work (work to overcome resistance to gas flow in the airway). For a patient in whom breathing apparatus is employed—such as an endotracheal tube or a ventilator demand valve—the concept of total work of breathing encompasses physiologic work plus equipment-imposed ventilatory work to overcome the resistance imposed by the breathing apparatus.

If the lungs are slowly inflated and deflated, the pressure–volume curve during inflation differs from that obtained during deflation. The two curves

form a hysteresis loop that becomes progressively broader as the tidal volume is increased (Fig. 15-1). To inflate the lungs, pressure greater than the recoil pressure of deflation is needed. This means that the lung accepts deformation poorly and, once deformed, reforms to its original shape slowly. Elastic hysteresis is important for the maintenance of normal lung compliance, but is not clinically significant.

**Figure 15-1** Dynamic pressure–volume loop of resting tidal volume. Quiet, normal breathing is characterized by hysteresis of the pressure–volume loop. The lung is more resistant to deformation than expected and returns to its original configuration less easily than expected. The slope of the line connecting the zenith and nadir lung volumes is lung compliance, about  $500 \text{ mL}/3 \text{ cm H}_2\text{O} = 167 \text{ mL}/\text{cm H}_2\text{O}$ .

**2** The sum of the pressure–volume relationships of the thorax and lung results in a sigmoidal curve (Fig. 15-2). The vertical line drawn at end-expiration coincides with FRC. Normally, humans breathe on the steepest part of the sigmoidal curve, where compliance ( $\Delta V/\Delta P$ ) or slope is highest. In restrictive pulmonary diseases, the compliance curve shifts to the right, has decreased slope ( $\Delta V/\Delta P$ ), or both. This decreased lung compliance results in smaller FRCs. When lung compliance is reduced, larger changes in intrapleural pressure are required to create the same tidal volume; that is, the thorax has to work harder to move the same volume of gas into the lungs. The body, being an energy conserving organism, prefers to move less gas with each breath rather than working harder to achieve the same tidal volume. Thus, patients with restrictive lung disease typically breathe **4** with smaller tidal volumes at more rapid rates, making spontaneous ventilatory rate one of the most sensitive indices of lung compliance. When lung compliance is decreased, the benefit of therapeutic continuous positive airway pressure (CPAP) is its ability to shift the vertical FRC line to the right, allowing the patient to breathe on a steeper, more efficient portion of the volume–pressure curve. In other words, CPAP can increase the FRC, which

allows for a slower ventilatory rate with a larger tidal volume.

**Figure 15-2** Pulmonary pressure–volume relationships at different values of total lung capacity (TLC), ignoring hysteresis. The *blue* depicts the normal pulmonary pressure–volume relationships. Humans normally breathe on the linear, steep part of this sigmoidal curve, where the slope (equal to compliance) is greatest. The *black vertical line* at zero defines functional residual capacity (FRC), regardless of the position of the curve on the graph. Mild restrictive lung disease, indicated by the *green line*, shifts the curve to the right with little change in slope. However, with restrictive disease, the patient breathes on a lower FRC, at a point on the curve where the slope is less. Severe restrictive pulmonary disease profoundly depresses the FRC and diminishes the slope of the entire curve (*red line*). Obstructive disease (*orange line*) elevates both FRC and compliance.

At the other end of the spectrum, patients with diseases that increase lung compliance expend less elastic work to inspire, but have decreased elastic recoil, resulting in larger than normal FRC (gas trapping). In such cases, their volume–pressure curves shift to the left and steepen. Chronic obstructive lung disease and acute asthma are the most common examples of diseases with high lung compliance. If lung compliance and FRC are sufficiently high that elastic recoil is minimal, the patient must use ventilatory muscles to actively exhale. The difficulty these patients experience in emptying the lungs is compounded by increased airway resistance.

Both compliance and inspiratory elastic work can be measured for a single breath by measuring airway pressure ( $P_{aw}$ ), intrapleural ( $P_{pl}$ ) pressure, and tidal volume. If esophageal pressure is measured correctly, the esophageal pressure values can be substituted for  $P_{pl}$  values. Lung compliance ( $C_L$ ) is the slope of the volume–pressure curve, and calculated by the equation

$$C_L = \frac{\Delta V}{\Delta P_L} + \frac{V_t}{P_{L_i} - P_{L_e}} = \frac{V_t}{(P_{aw_i} - P_{pl_i}) - (P_{aw_e} - P_{pl_e})} \quad (15-1)$$

where  $P_L$  is transpulmonary pressure,  $P_{L_i}$  and  $P_{L_e}$  are transpulmonary pressures at end-inspiration and end-expiration,  $V_t$  is tidal volume,  $P_{aw_e}$  and  $P_{aw_i}$  are expiratory and inspiratory airway pressures, and  $P_{pl_e}$  and  $P_{pl_i}$  are expiratory and inspiratory intrapleural pressures.

Elastic work ( $W_{el}$ ) is performed during inspiration only because expiration is passive during normal breathing. The area within the triangle in [Figure 15-2](#) describes the work required to inspire. The equation that yields elastic work (and the area of the triangle) is

$$\begin{aligned} W_{el} &= \frac{1}{2}(V_t)(P_{L_i} - P_{L_e}) \\ &= \frac{1}{2}(V_t)[(P_{aw_i} - P_{pl_i}) - (P_{aw_e} - P_{pl_e})] \end{aligned} \quad (15-2)$$

### **Resistance to Gas Flow**

Both laminar and turbulent flows exist within the respiratory tract, usually in mixed patterns. The physics of each, however, is significantly different.

#### **Laminar Flow**

Below critical flow rates that create turbulent flow, gas proceeds through a straight tube as a series of concentric cylinders that slide over one another. Fully developed flow has a parabolic profile with a velocity of zero at the cylinder wall and a maximum velocity at the center of the advancing “cone.” This type of streamlined flow is usually inaudible. The advancing conical front means that some fresh gas reaches the end of the tube before the tube has been completely filled with fresh gas. Thus, laminar flow in the airways results in alveolar ventilation that can occur even when the tidal volume ( $V_t$ ) is less than anatomic dead space. This phenomenon has significant clinical implications. As noted by Rohrer<sup>14</sup> in 1915, it allows high-frequency ventilation to achieve adequate alveolar ventilation.

Resistance ( $R$ ) to laminar gas flows in a straight, unbranched cylinder can be calculated by the following equation of Poiseuille:

$$R = \frac{8 \times \text{length} \times \text{viscosity}}{\pi \times (\text{radius})^4} = \frac{P_B - P_A}{\text{flow}} \quad (15-3)$$

where  $P_B$  and  $P_A$  are barometric and alveolar pressures. It is essential to note that as radius decreases in narrowed airways, resistance will increase by a power of four. Viscosity is the only physical gas property that is relevant under conditions of laminar flow. Helium has a low density, but its viscosity

is close to that of air. Therefore, helium will not improve gas flow if the flow is laminar. However, if flow is turbulent due to critical airway narrowing or abnormally high airway resistance, low-density helium is potentially useful therapy (see next section).

## **Turbulent Flow**

High flow rates, particularly through branched or irregularly shaped tubes, disrupt the orderly flow of laminar gas. When resistance to gas flow is significant, turbulent flow occurs and is usually audible. Turbulent flow usually presents with a square front; fresh gas will not reach the end of the tube until the amount of gas entering the tube is almost equal to the volume of the tube. Thus, turbulent flow effectively purges the contents of a tube. Four conditions that will change laminar flow to turbulent flow are high gas flows, sharp angles within the tube, branching in the tube, and a decrease in the diameter of the tube. During laminar flow, resistance is inversely proportional to gas flow rate. Conversely, during turbulent flow, resistance increases significantly in proportion to the flow rate. A detailed description of these phenomena is beyond the scope of this chapter, but the reader is referred to descriptions by Nunn.<sup>15</sup>

## **Increased Airway Resistance**

Bronchiolar smooth muscle hyperreactivity (true bronchospasm), mucosal edema, mucous plugging, epithelial desquamation, tumors, and foreign bodies all increase airway resistance. The conscious subject can detect small increases in inspiratory resistance.<sup>16</sup> The normal response to increased inspiratory resistance is increased inspiratory muscle effort, with little change in FRC.<sup>17</sup> Emphysematous patients retain remarkable ability to preserve an adequate alveolar ventilation, even with gross airway obstruction. In patients with preoperative FEV<sub>1</sub> values lower than 1 L, PaCO<sub>2</sub> is normal in most patients. Furthermore, asthmatic patients compensate well for increased airway resistance and also keep the mean PaCO<sub>2</sub> in the lower end of normal range.<sup>18</sup> Thus, an increased PaCO<sub>2</sub> in the setting of increased airway resistance warrants serious attention as it suggests that the patient's compensatory mechanisms are nearly exhausted. Mild expiratory resistance does not result in muscle use for active exhalation in conscious or anesthetized subjects. Instead, the initial work to overcome expiratory resistance is performed by augmenting inspiratory force until a sufficiently high lung volume is achieved that allows elastic recoil to overcome expiratory resistance.<sup>19</sup> Only when expiratory resistance becomes excessive are accessory muscles recruited to expel gas from the lungs. During acute increases in expiratory resistance, this response is well tolerated by most patients. However, chronic use of

accessory muscles to exhale significantly increases the risk of ventilatory failure as the work of breathing is further increased. Work of breathing that exceeds physiologic reserves becomes detrimental to physiologic homeostasis, and increases the risk of ventilatory failure. Acute ventilatory failure secondary to muscle fatigue is evidenced by an acute increase in arterial carbon dioxide. Commonly, this is precipitated by pneumonia or heart failure.

### **Physiologic Changes in Respiratory Function Associated with Aging**

Physiologic aging of the lung is associated with dilation of the alveoli, enlargement of the airspaces, decrease in exchange surface area, and loss of supporting tissue. Changes in the aging lung and chest wall result in decreased lung recoil (elastance) creating an increased residual volume and FRC. In addition, compliance of the chest wall diminishes, thereby increasing the work of breathing compared with younger subjects. Respiratory muscle strength decreases with aging and is strongly correlated with nutritional status and cardiac index. Expiratory flow rates decrease with a flow–volume curve suggestive of small airway resistance. Despite these changes, the respiratory system is normally able to maintain adequate gas exchange at rest and during exertion throughout life, with only modest decrements in PaO<sub>2</sub> and no change in PaCO<sub>2</sub>. With aging, respiratory centers in the nervous system demonstrate decreased sensitivity to hypoxemia and hypercapnia resulting in a blunted ventilatory response when challenged by heart failure, airway obstruction, or pneumonia.<sup>20</sup>

### **Control of Ventilation**

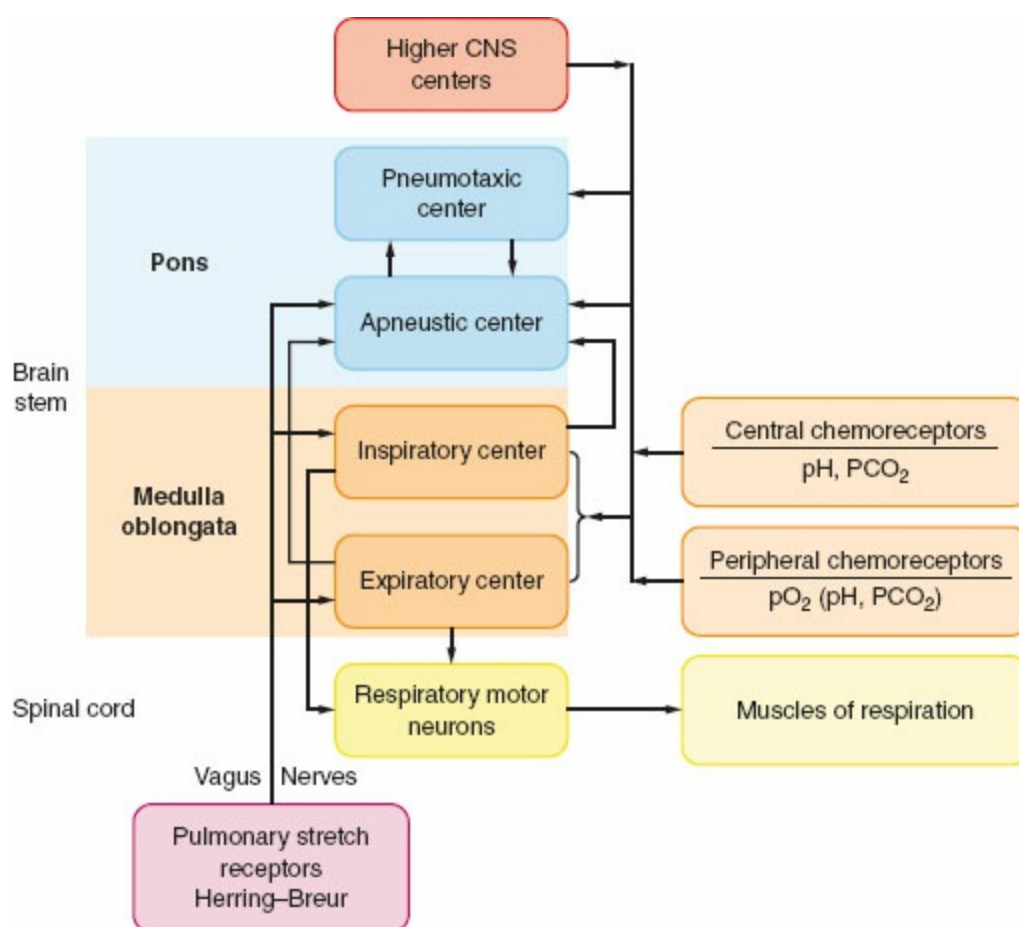

Mechanisms that control ventilation are extremely complex, requiring integration with many parts of the central and peripheral nervous systems (Fig. 15-3). LeGallois, who localized the respiratory centers in the brainstem in 1812, demonstrated that breathing does not depend on an intact cerebrum. Rather, breathing depends on a small region of the medulla near the origin of the vagus nerves.<sup>21</sup> Countless studies in the past two centuries have greatly increased our knowledge and understanding of the anatomic components of ventilatory control. However, experimental work performed in animals is difficult to apply to humans because of interspecies variation.

### **Terminology**

The terms breathing, ventilation, and respiration are often used interchangeably; however, these terms have distinct meanings. *Breathing* refers to the act of inspiring and exhaling that requires energy utilization for

muscle work; therefore, it is limited by energy reserves. *Ventilation*, on the other hand, is the movement of gas in and out of the lungs. When spontaneous, ventilation requires energy for muscle work and is thus, breathing. *Respiration* occurs when energy is released from organic molecules. Such energy release is dependent on the movement of gas molecules such as carbon dioxide and oxygen across membranes, whether alveolar or mitochondrial. Thus, humans breathe to ventilate and ventilate to respire. Despite what appears to be clear distinctions in terminology, vernacular use of these terms is often confused in daily dialogue. For example: *respirators* are used to treat those who have succumbed to *respiratory* arrest and do not have a *respiratory* rate, and residents are sometimes advised to *breathe* down a patient using a potent anesthetic agent.

**Figure 15-3** Classic central nervous system (CNS) respiratory centers. Diagram illustrates major respiratory centers, neurofeedback circuits, primary neurohumoral sensory inputs, and mechanical outputs.

### Generation of Ventilatory Pattern

Refer to [Table 15-3](#) for definitions of terms used in this section. A *respiratory center* is a specific area in the brain that integrates neural traffic to produce spontaneous ventilation. Within the pontine and medullary reticular

formations, there are several discrete respiratory centers that function as the control system (Fig. 15-3).

Initial descriptions of brainstem respiratory functions are based on classic ablation and electrical stimulation studies. Another method for localizing respiratory centers entails the recording of action potentials from different areas of the brainstem with microelectrodes. This method is based on the assumption that local brain activity that occurs in phase with respiratory activity identifies “respiratory neurons.”<sup>22</sup> These techniques are imperfect for precisely localizing discrete respiratory centers.

**Table 15-3** Definition of Respiratory Pattern Terminology

Word	Definition
Eupnea	“Good breathing”: continuous inspiratory and expiratory movement without interruption
Apnea	“No breathing”: cessation of ventilatory effort at passive end-expiration (lung volume = FRC)
Apneusis	Cessation of ventilatory effort with lungs filled at TLC
Apneustic ventilation	Apneusis with periodic expiratory spasms
Biot	Ventilatory gasps interposed between periods of ventilation apnea; <i>also</i> “agonal ventilation”

FRC, functional residual capacity; TLC, total lung capacity.

## Medullary Centers

The medulla oblongata contains the most basic ventilatory control centers in the brain. Specific medullary areas are primarily active during inspiration or during expiration, with many neural inspiratory or expiratory interconnections. The inspiratory centers that reside in the dorsal respiratory group (DRG) are located in the dorsal medullary reticular formation. The DRG is the source of elementary ventilatory rhythmicity<sup>23,24</sup> and serves as the “pacemaker” for the respiratory system.<sup>25</sup> Whereas resting lung volume occurs at end-expiration, the electrical activity of the ventilatory centers is at rest at end-inspiration. The rhythmic activity of the DRG persists even when all incoming peripheral and interconnecting nerves are sectioned or blocked completely. Isolating the DRG in this manner results in ataxic, gasping ventilation with frequent maximum inspiratory efforts (apneustic breathing).

The ventral respiratory group (VRG) is located in the ventral medullary reticular formation and serves as the expiratory coordinating center. The inspiratory and expiratory neurons function by a system of reciprocal innervation, or negative feedback.<sup>22</sup> When the DRG creates an impulse to

inspire, inspiration occurs and the DRG impulse is quenched by a reciprocating VRG impulse. This VRG transmission prohibits further use of the inspiratory muscles, thus allowing passive expiration to occur.

## *Pontine Centers*

The pontine centers process information that originates in the medulla. The apneustic center is located in the middle or lower pons. With activation, this center sends impulses to inspiratory DRG neurons to sustain inspiration. Electrical stimulation of this area results in inspiratory spasm.<sup>26</sup> The middle and lower pons contain specific areas for phase-spanning neurons<sup>27</sup> that assist with the transition between inspiration and expiration, but do not exert direct control over ventilatory muscles.

The pneumotaxic respiratory center is in the rostral pons. A simple transection through the brainstem that isolates this portion of the pons from the upper brainstem decreases ventilatory rate and increases tidal volume. If both vagus nerves are additionally transected, apneusis results.<sup>28</sup> Thus, the primary function of the pneumotaxic center is to limit the depth of inspiration. When maximally activated, the pneumotaxic center secondarily increases ventilatory frequency. However, the pneumotaxic center performs no pacemaking function and has no intrinsic rhythmicity.

## *Higher Respiratory Centers*

Many higher brain structures can affect ventilatory control processes. In the midbrain, stimulation of the reticular activating system increases the rate and amplitude of ventilation.<sup>29</sup> The cerebral cortex also affects breathing pattern, although precise neural pathways are not known. Occasionally, the ventilatory control process becomes subservient to other regulatory centers. For example, the respiratory system plays an important role in the control of body temperature because it supplies a large surface area for heat exchange. This is especially important in animals in which panting is a primary means of dissipating heat. Thus, the ventilatory pattern is influenced by neural input from descending pathways from the anterior and posterior hypothalamus to the pneumotaxic center of the upper pons.

Vasomotor control and certain respiratory responses are closely linked. Stimulation of the carotid sinus not only decreases vasomotor tone, but also inhibits ventilation. Alternatively, stimulation of the carotid body chemoreceptors (see Chemical Control of Ventilation section) results in an increase in both ventilatory activity and vasomotor tone.

## Reflex Control of Ventilation

Reflexes that directly influence ventilatory pattern usually do so to prevent airway obstruction. *Deglutition*, or swallowing, involves the glossopharyngeal and vagus nerves. Stimulation of the anterior and posterior pharyngeal pillars of the posterior pharynx induces swallowing. During swallowing, inspiration ceases momentarily, is usually followed by a single large breath, and briefly increases ventilation.

*Vomiting* significantly modifies normal ventilatory activity.<sup>30</sup> Swallowing, salivation, gastrointestinal reflexes, rhythmic spasmodic ventilatory movements, and significant diaphragmatic and abdominal muscular activity must be coordinated over a very brief interval. Because of the obvious risk of aspirating gastric contents, it is advantageous to inhibit inspiration during vomiting. Input into the respiratory centers occurs from both cranial and spinal cord nerves.

*Coughing* results from stimulation of the tracheal subepithelium, especially along the posterior tracheal wall and carina.<sup>31</sup> Coughing also requires coordination of both airway and ventilatory muscle activity. An effective cough requires deep inspiration and then forced exhalation against a momentarily closed glottis to increase intrathoracic pressure, thus allowing an expulsive expiratory maneuver.

*Proprioception* in the pulmonary system, the qualitative knowledge of the gas volume within the lungs, probably arises from smooth muscle spindle receptors. These proprioceptors, which are located within the smooth muscle of all airways, are sensitive to pressure changes. Airway stretch reflexes can be demonstrated during distention of isolated airways. Airway pressure, rather than volume distention, appears to be the primary stimulation.<sup>32</sup> Clinical conditions in which pulmonary airway stretch receptors are stimulated include pulmonary edema and atelectasis.

*Golgi tendon organs* (tendon spindles), which are arranged in series within ventilatory muscles, facilitate proprioception. The intercostal muscles are rich in tendon spindles, whereas the diaphragm has a limited number. Thus, the pulmonary stretch reflex primarily involves the intercostal muscles, but not the diaphragm. When the lungs are full and the chest wall is stretched, these receptors send signals to the brainstem that inhibit further inspiration.

In 1868, Hering and Breuer reported that lightly anesthetized, spontaneously breathing animals would cease or decrease ventilatory effort during sustained lung distention.<sup>33</sup> This response was blocked by bilateral vagotomy. The *Hering–Breuer reflex* is prominent in lower-order mammals and sufficiently active that even 5 cm H<sub>2</sub>O CPAP will induce apnea. In humans, however, the reflex is only weakly present, such that humans will continue to breathe spontaneously with CPAP in excess of 40 cm H<sub>2</sub>O.

## Chemical Control of Ventilation

### Peripheral Chemoreceptors

In a simplistic view of chemical ventilatory control, the peripheral chemoreceptors respond primarily to lack of oxygen, and the central nervous system (CNS) receptors respond primarily to changes in  $\text{PCO}_2$ , pH, and acid–base disturbances.

The peripheral chemoreceptors are composed of the carotid and aortic bodies. The carotid bodies, located at the bifurcation of the common carotid artery, have predominantly ventilatory effects. The aortic bodies are scattered about the aortic arch and its branches, and have predominantly circulatory effects. The neural output from the carotid body reaches the central respiratory centers via the afferent glossopharyngeal nerves. Output from the aortic bodies travels to the medullary centers via the vagus nerve. Both carotid and aortic bodies are stimulated by decreased  $\text{PaO}_2$ , but not by decreased  $\text{SaO}_2$  or  $\text{CaO}_2$ . When  $\text{PaO}_2$  falls to less than 100 mmHg, neural activity from these receptors begins to increase. However, it is not until the  $\text{PaO}_2$  reaches 60 to 65 mmHg that neural activity increases sufficiently to substantially augment minute ventilation. Thus, patients who depend on hypoxic ventilatory drive have  $\text{PaO}_2$  values in the mid-60s. Once these patients'  $\text{PaO}_2$  values exceed 60 to 65 mmHg, ventilatory drive diminishes and  $\text{PaO}_2$  falls until ventilation is again stimulated by arterial hypoxemia. Thus, during withdrawal of mechanical ventilatory support in the patient who depends on hypoxic ventilatory drive, the  $\text{PaO}_2$  must fall to less than 65 mmHg for spontaneous ventilation to resume.

The carotid bodies are also sensitive to decreased  $\text{pH}_a$ , but this response is minor. Similarly, changes in  $\text{PaCO}_2$  do not stimulate these receptors sufficiently to alter minute ventilation. Increases in blood temperature, hypoperfusion of the carotid bodies themselves, and some chemicals will stimulate these receptors. Sympathetic ganglion stimulation by nicotine or acetylcholine will stimulate the carotid and aortic bodies; this effect is blocked by hexamethonium. Blockade of the cytochrome electron transport system by cyanide will prevent oxidative metabolism and will also stimulate these receptors.

Increased ventilatory rate and tidal volume result from stimulation of these receptors. Hemodynamic changes resulting from stimulation of these receptors include bradycardia, hypertension, increases in bronchiolar tone, and increases in adrenal secretion. The carotid body chemical receptors have been termed *ultimum moriens* (“last to die”). Although the response of peripheral receptors to hypoxemia was formerly believed to be resistant to the influences of anesthesia, potent inhaled anesthetics appear to depress hypoxic ventilatory response by depressing carotid body response to

hypoxemia.<sup>34</sup> The response of the peripheral receptors during general anesthesia or recovery from anesthesia is not sufficiently robust to reliably increase ventilatory rate or minute ventilation to herald the onset of arterial hypoxemia. Furthermore, flumazenil only partially reversed the diazepam-induced depression of hypoxic ventilatory drive,<sup>35</sup> and suggests that humans may develop tolerance to respiratory depressant effects of diazepam.

## Central Chemoreceptors

Approximately 80% of the ventilatory response to inhaled carbon dioxide originates in the central medullary centers. Acid–base regulation involving carbon dioxide,  $H^+$ , and bicarbonate is related primarily to chemosensitive receptors located in the medulla close to or in contact with the cerebrospinal fluid (CSF). The chemosensitive areas of the brainstem are in the inferolateral aspects of the medulla near the origin of the glossopharyngeal and vagus nerves. The area just beneath the surface of the ventral medulla is exquisitely sensitive to the extracellular fluid  $H^+$  concentration.<sup>36</sup> Although this central response is the major regulator of breathing, carbon dioxide has little direct stimulating effect on these chemosensitive areas. These receptors are primarily sensitive to changes in  $H^+$  concentration. Carbon dioxide has a potent but indirect effect by reacting with water to form carbonic acid, which dissociates into hydrogen and bicarbonate ions.<sup>37</sup>

An acute increase in  $PaCO_2$  is a more potent ventilatory stimulus than an acute increase in arterial  $H^+$  concentration from a metabolic source. Carbon dioxide, but not  $H^+$ , passes readily through the blood–brain and blood–CSF barriers. Although local buffering systems in arterial blood and body fluids immediately neutralize  $H^+$ , the CSF has minimal buffering capacity. Thus, once carbon dioxide crosses into the CSF,  $H^+$  are created and trapped in the CSF, resulting in a CSF  $H^+$  concentration considerably greater than that found in the blood. Because carbon dioxide crosses the blood–brain barrier readily, the  $PCO_2$  values in the CSF, cerebral tissue, and jugular venous blood rise quickly and to the same degree as the  $PaCO_2$ , although the central values are about 10 mmHg higher than those measured in arterial blood.

The ventilatory response to changes in  $PaCO_2$  (increased  $V_t$ , increased respiratory rate) is rapid and peaks within 1 to 2 minutes after an acute change in  $PaCO_2$ . With persistent levels of carbon dioxide stimulation, however, the resultant increase in ventilation declines over a period of several hours. This is probably the result of bicarbonate ions that are actively transported from the blood into the CSF through the arachnoid villi that increase CSF pH toward the normal range.<sup>38</sup>

With chronic carbon dioxide retention, CSF pH is renormalized, which then determines ventilatory response to subsequent changes in arterial carbon

dioxide tension. This phenomenon explains the differing effects of acute versus chronic hypercapnia on the CNS-mediated ventilatory response. Because of this difference, the goals of mechanical ventilatory support in a patient with chronic CO<sub>2</sub> retention are different from a normal patient. Providing mechanical support that allows a PaCO<sub>2</sub> range to generate a pH that is normal for a specific patient is referred to as “eucapnic ventilation.” Attempting to achieve a normal PaCO<sub>2</sub> (normocarbica) in a patient with chronic carbon dioxide retention will iatrogenically result in alkalemia, further increasing CSF pH and raising the apneic threshold.<sup>39</sup> Finally, central medullary chemoreceptors also respond to temperature change. Cold CSF (with normal pH) or local anesthetic applied to the medullary surface will depress ventilation.

### **Ventilatory Response to Altitude**

Ventilatory response and adaptation to high altitude are good examples of how peripheral and central chemoreceptors integrate in the control of ventilation. The following mechanism of acclimatization was proposed by Severinghaus et al.<sup>40</sup> in 1963 and has since been confirmed.

Following ascent from sea level to 4,000 m, acute exposure to high altitude and low P<sub>IO<sub>2</sub></sub> results in arterial hypoxemia. This decrease in PaO<sub>2</sub> activates the peripheral hypoxemic ventilatory drive by stimulating the carotid and aortic bodies, and causes increased minute ventilation. As minute ventilation increases, PaCO<sub>2</sub> and CSF PCO<sub>2</sub> decrease, causing concomitant increases in p<sub>H<sub>a</sub></sub> and CSF pH. The alkaline shift of the CSF decreases ventilatory drive via medullary chemoreceptors, partially offsetting hypoxemic drive. A temporary equilibrium is attained within minutes, with PaCO<sub>2</sub> only 2 to 5 mmHg less than normal and PaO<sub>2</sub> approximately 45 mmHg. This initially profound hypoxemia probably causes the acute respiratory distress and other associated symptoms (headache, diarrhea) associated with rapid ascent. However, the CNS is able to restore CSF pH to normal (7.326) by pumping bicarbonate ions out of the CSF over 2 to 3 days. In 2 to 3 days, CSF bicarbonate concentration decreases approximately 5 mEq/L and restores CSF pH to within 0.01 pH unit of values at sea level. Then, centrally mediated ventilatory drive returns to normal, and hypoxic drive and stimulation of peripheral receptors can proceed unopposed. Thus, after 3 days' exposure to 4,000 m altitude, ventilatory adaptation would result in a new equilibrium, with PaCO<sub>2</sub> approximately 30 mmHg and PaO<sub>2</sub> approximately 55 mmHg. Following descent to sea level, the low CSF bicarbonate concentration persists for several days, and the climber “overbreathes” until CSF bicarbonate and pH values return to normal.

## Breath-holding

Most adults with normal lungs and gas exchange can hold their breath for about 1 minute when breathing room air without previously hyperventilating. After 1 minute of breath-holding under these circumstances, PaO<sub>2</sub> decreases to approximately 65 to 70 mmHg and PaCO<sub>2</sub> increases by about 12 mmHg. In the absence of supplemental oxygen and hyperventilation, the “breakpoint” at which normal people are compelled to breathe is remarkably constant at a PaCO<sub>2</sub> of 50 mmHg.<sup>41,42</sup> However, if the individual breathes 100% oxygen prior to breath-holding, he or she should be able to hold his or her breath for 2 to 3 minutes, or until PaCO<sub>2</sub> rises to 60 mmHg. Hyperventilation prior to breath-holding reducing PaCO<sub>2</sub> to 20 mmHg can lengthen the period of breath-holding to 3 to 4 minutes.<sup>43</sup> Hyperventilation with 100% oxygen prior to breath-holding should extend the apneic period to 6 to 10 minutes. The rate of PaCO<sub>2</sub> rise in awake, preoxygenated adults with normal lungs who hold their breath without previous hyperventilation is 7 mmHg/min in the first 10 seconds, 2 mmHg/min in the next 10 seconds, and 6 mmHg/min thereafter.<sup>42</sup>

The duration of voluntary breath-holding is directly proportional to lung volume at onset, and is probably related both to oxygen stores in the alveoli and to the rate at which PaCO<sub>2</sub> rises. With smaller lung volumes, the same amount of carbon dioxide is emptied into a smaller volume during the apneic period, thus increasing the carbon dioxide concentration more rapidly than occurs with larger lung volumes. Of note, apneic patients during general anesthesia actually “breath-hold” at FRC rather than at vital capacity, which tends to accelerate the rate of PaCO<sub>2</sub> rise. Despite this difference in lung volume, the rate of rise of PaCO<sub>2</sub> in apneic anesthetized patients is 12 mmHg during the first minute and 3.5 mmHg/min thereafter, significantly lower than in the awake state.<sup>43,44</sup> During anesthesia, metabolic rate and carbon dioxide production are significantly less than during ambulatory wakefulness, which likely accounts for the lower rate of PaCO<sub>2</sub> rise under anesthesia.

Hyperventilation with room air prior to prolonged breath-holding during exercise is inadvisable. During underwater swimming after poolside hyperventilation, the urge to breathe is first stimulated by a rising PaCO<sub>2</sub>. Swimmers who hyperventilate with room air prior to swimming long distances frequently lose consciousness from arterial hypoxemia before the PaCO<sub>2</sub> is sufficiently increased to stimulate the “need” to breathe.

Hyperventilation is rarely followed by an apneic period in awake humans, despite a markedly depressed PaCO<sub>2</sub>. However, minute ventilation may decrease significantly. Aggressive intermittent positive-pressure breathing treatments for patients with COPD who continue to have a carbon dioxide-based ventilatory drive can depress minute ventilation sufficiently to create arterial hypoxemia if they breathe room air after cessation of therapy.<sup>45</sup> In contrast, even mild hyperventilation during general anesthesia will produce

prolonged apneic periods.<sup>46</sup>

## Quantitative Aspects of Chemical Control of Breathing

The ventilatory responses to oxygen and carbon dioxide can be assessed quantitatively. Unfortunately, the quantitative indices of hypoxemic sensitivity are not clinically useful because the normal range is wide and confounded by many environmental factors. The reader is referred to a classical discussion of the quantitative indices of hypoxemic sensitivity.<sup>47</sup>

Ventilatory responses to PaCO<sub>2</sub> changes are measured in several ways, provided that carbon dioxide production remains constant. When subjects voluntarily increase minute ventilation to a prescribed level, the PaCO<sub>2</sub> decreases nonlinearly. The plot of minute ventilation (independent variable) and PaCO<sub>2</sub> (dependent variable) is the metabolic hyperbola (Fig. 15-4). This curve is cumbersome to evaluate and difficult to use clinically.

The curve more commonly used is the PaCO<sub>2</sub> ventilatory response curve (Fig. 15-4) that describes the effect of changing PaCO<sub>2</sub> on minute ventilation. Usually, subjects inspire carbon dioxide to raise PaCO<sub>2</sub>, and the effect on minute ventilation is measured. The carbon dioxide response curve can be generated more rapidly by increasing the fraction of inspired carbon dioxide (FICO<sub>2</sub>) and requiring the subject to rebreathe exhaled gas. However, the results obtained with this technique are less pure because the FICO<sub>2</sub> is not controlled.

Creating these curves and observing how they change in various circumstances allows quantitative study of factors that affect carbon dioxide control of ventilation. The carbon dioxide response curve approaches linearity in the range most often encountered in life: at PaCO<sub>2</sub> values between 20 and 80 mmHg. Once the PaCO<sub>2</sub> exceeds 80 mmHg, the curve becomes parabolic, with its peak ventilatory response at a PaCO<sub>2</sub> between 100 and 120 mmHg. Increasing the PaCO<sub>2</sub> to higher than 100 mmHg allows carbon dioxide to act as a ventilatory and CNS depressant, the origin of the term “carbon dioxide narcosis,” with 1 minimum alveolar concentration (MAC) being approximately 200 mmHg.

**Figure 15-4** Carbon dioxide–ventilatory response curve. The metabolic hyperbola, curve A, is generated by varying minute ventilation ( $V_E$ ) and measuring changes in carbon dioxide concentration. The hyperbolic configuration makes it cumbersome for clinical use. The carbon dioxide–ventilatory response curve, B, is linear between approximately 20 and 80 mmHg. It is generated by varying  $PaCO_2$  (usually by controlling inspired carbon dioxide concentration) and measuring the resultant  $V_E$ . This is the most commonly used test of ventilatory response. The slope defines “sensitivity”; the setpoint, or resting  $PaCO_2$ , occurs at the intersection of the metabolic hyperbola and the carbon dioxide–ventilatory response curve; and the apneic threshold can be obtained by extrapolating the carbon dioxide–ventilatory response curve to the x-intercept. In the absence of surgical stimulation, increasing doses of potent inhaled anesthesia or opioids will shift the curve to the right and eventually depress the slope (*green, red, and brown lines*). Painful stimulation will reverse these changes to varying and unpredictable degrees.

The slope of the carbon dioxide response curve represents carbon dioxide sensitivity. When  $PaCO_2$  reaches 100 mmHg, carbon dioxide sensitivity is at its peak. The *setpoint*—the intersection of the carbon dioxide response curve and the metabolic hyperbola—defines normal resting  $PaCO_2$ . Extrapolation of the carbon dioxide response curve to the x-intercept (where minute ventilation is 0) defines the apneic threshold. In awake, normal adults, the apneic threshold normally occurs at a  $PaCO_2$  of around 32 mmHg, although awake adults usually continue to breathe when they achieve the apneic threshold because the sensation of apnea is disturbing. The slope of the curve is a measure of the response of the entire ventilatory mechanism to carbon dioxide stimulation.

Once  $PaO_2$  exceeds 100 mmHg, it no longer influences the carbon dioxide response curve. When the  $PaO_2$  is between 65 and 100 mmHg, its effect on the carbon dioxide response curve is small. However, when  $PaO_2$  falls to less than 65 mmHg, the carbon dioxide response curve shifts to the left and its slope increases, probably as a result of increased ventilatory drive stimulated

by the peripheral chemoreceptors. Thus, during measurements of carbon dioxide ventilatory response, the subject should breathe supplemental oxygen to prevent hypoxic ventilatory drive interference. Three clinical states result in a left shift and/or a steepened slope of the carbon dioxide response curve, and are the only causes of true hyperventilation, that is, an increase in minute ventilation such that the decreased PaCO<sub>2</sub> creates either primary or **6** compensatory respiratory alkalosis. These three causes of hyperventilation are arterial hypoxemia, metabolic acidemia, and CNS etiologies. Examples of central etiologies include drug administration, intracranial hypertension, hepatic cirrhosis, and nonspecific arousal states such as anxiety and fear. Aminophylline, doxapram, salicylates, and norepinephrine stimulate ventilation independent of peripheral chemoreceptors. Opioid antagonists given in the absence of opioids do not stimulate ventilation. However, when given after opiate administration, they do reverse the effects of opioids on the carbon dioxide response curve.

Conversely, ventilatory depressants either shift the carbon dioxide response curve to the right, decrease its slope, or both. Changes in physiology that depress ventilation include metabolic alkalemia, denervation of peripheral chemoreceptors, normal sleep, and drugs. During normal sleep, the carbon dioxide response curve is displaced to the right, with the degree of displacement depending on the depth of sleep. Usually, PaCO<sub>2</sub> increases up to 10 mmHg during deep sleep. Hypoxemic responses are not impaired by sleep, which is convenient for continued survival at high altitude while sleeping.

Opioids displace the carbon dioxide response curve to the right with little change in slope at sedative doses. With higher, “anesthetic” doses, the curve shifts farther to the right and its slope is depressed, simulating the effect of potent inhalation agents on the carbon dioxide response curve (Fig. 15-4). In the absence of other ventilatory depressant drugs, opioids induce pathognomonic changes in ventilatory patterns: a decreased ventilatory rate with an increased tidal volume. Not until opioids nearly induce apnea is tidal volume decreased. Large narcotic doses usually result in apnea responsive to verbal encouragement before consciousness is lost.

Barbiturates in sedative or light hypnotic doses have little effect on the carbon dioxide response curve. However, in doses adequate to allow skin incision, barbiturates shift the carbon dioxide response curve to the right. The ventilatory pattern resulting from barbiturate administration is characterized by decreased tidal volume and increased ventilatory rate. Potent inhaled anesthetics displace the carbon dioxide response curve to the right and decrease the slope to a degree dependent on both the anesthetic dose and the level of surgical stimulation. Like barbiturates, the ventilatory pattern following administration of potent inhaled anesthetics is initially represented by a decreased tidal volume and increased ventilatory rate. As more potent

anesthetic agent is administered, however, ventilatory rate decreases toward an apneic end point. This clinical response occurs when the carbon dioxide response curve eventually becomes horizontal (slope = 0), resulting in essentially no ventilatory response to PaCO<sub>2</sub> changes.

Potent inhaled anesthetics and opioids displace the setpoint to the right, implying that the resting, steady-state PaCO<sub>2</sub> is higher and minute ventilation lower. Furthermore, when the carbon dioxide response curve shifts to the right, the apneic threshold also increases (Fig. 15-4). Surgical stimulation reverses the ventilatory response changes induced by inhaled anesthetics and opioids, but the degree of reversal is not predictable.

## Oxygen and Carbon Dioxide Transport

This chapter discusses only external respiration, in which oxygen moves from the ambient environment into the pulmonary capillaries, and carbon dioxide leaves the pulmonary capillaries to enter the atmosphere. The movement of gas across the alveolar–capillary membrane depends on the integrity of the pulmonary and cardiac systems. Unless otherwise stated, the reader should assume the ventilation and perfusion of alveolar–capillary units are normal. Abnormal distribution of ventilation or perfusion of the lungs is discussed later (see Ventilation–Perfusion Relationships section).

### *Bulk Flow of Gas (Convection)*

Convection, in which all gas molecules move in the same direction, is the primary mechanism responsible for gas flow in large and most small airways, from the bronchi down to the bronchiolar airways of the fourteenth or fifteenth generation. Resistance can be defined with Poiseuille law (Equation 15-2), and increases rapidly as the radius or cross-sectional area of a tube decreases. Although a single isolated fourteenth-generation bronchiolar airway may have greater resistance to air flow compared to a bronchus, the overall total resistance in a system is also dependent on the number of parallel pathways present. The overall total resistance of the system will be less than any individual tube's resistance, as illustrated by the equation:

$$1/R_{\text{total}} = 1/R_1 + 1/R_2 + 1/R_3 + \text{etc.} \quad (15-4)$$

The anatomy of the tracheobronchial tree is organized in such a way that there is an increase in total parallel pathways and total cross-sectional area with each generation toward the periphery. Therefore, total airway resistance to gas flow is lower at the periphery compared to the large bronchi.

The exponential increase in total cross-sectional area of parallel airways

toward the lung periphery also affects airflow velocity. Similar to airflow resistance, velocity is inversely proportional to a system's overall total cross-sectional area. Therefore, airflow velocity at the lower generations of the tracheobronchial tree is lower than that of the bronchi. In other words, the velocity of airflow decreases from the trachea down to the peripheral distal airways. During normal quiet ventilation, gas flow within convective airways is mainly laminar.

## Gas Diffusion

Diffusion within a gas-filled space is random molecular motion that results in complete mixing of all gases. In the distal airways of the lung beginning with the terminal bronchioles (sixteenth airway generation), diffusion becomes the predominant mode of gas transport. Once gas reaches the small alveolar ducts, alveolar sacs, and alveoli, both diffusion and regional  $V/Q$  relationships influence gas transport. Historically, clinicians assumed defects in gas diffusion were responsible for arterial hypoxemia. However, the most frequent cause of arterial hypoxemia is shunt effect (see Ventilation–Perfusion Relationships section).<sup>48</sup>

The other usage of “diffusion” refers to the passive movement of molecules across a membrane that is governed primarily by concentration gradient. In this sense, carbon dioxide is 20 times more diffusible across human membranes than is oxygen; therefore, carbon dioxide crosses alveoli easily. As a result, hypercapnia is *never* the result of defective diffusion; rather, it is the result of inadequate alveolar ventilation relative to carbon dioxide production.

True diffusion defects that create arterial hypoxemia are rare. The most common reason for a measured decrease in diffusing capacity (see Pulmonary Function Testing section) is mismatched ventilation and perfusion, which functionally results in a decreased surface area available for diffusion.

## Distribution of Ventilation and Perfusion

The efficiency with which oxygen and carbon dioxide exchange at the alveolar–capillary level highly depends on the matching of capillary perfusion and alveolar ventilation. At this level, the marriage between the lung and the circulatory system must be well matched and intimate.

## Distribution of Blood Flow

Blood flow within the lung is mainly gravity dependent. Because the alveolar–capillary beds are not composed of rigid vessels, the pressure of the

surrounding tissues can influence the resistance to flow through the individual capillaries. Thus, blood flow depends on the relationship between pulmonary artery pressure ( $P_{pa}$ ), alveolar pressure ( $P_A$ ), and pulmonary venous pressure ( $P_{pv}$ ) (Fig. 15-5). West created a lung model that divides the lung into three zones.<sup>48,49</sup> Zone 1 conditions occur in the most gravity-independent part of the lung (lung apex). In this region, alveolar pressure is approximately equal to atmospheric pressure. Pulmonary artery pressure always exceeds pulmonary venous pressure, which is subatmospheric in Zone 1. Therefore, Zone 1 can be described by the following relationship:  $P_A > P_{pa} > P_{pv}$ . In Zone 1, alveolar pressure transmitted to the pulmonary capillaries promotes their collapse, with a consequent theoretical blood flow of zero to this lung region. Thus, Zone 1 receives ventilation in the absence of perfusion. This relationship is referred to as alveolar dead space ventilation. Normally, Zone 1 areas exist only to a limited extent. However, in conditions of decreased pulmonary artery pressure, such as hypovolemic shock, Zone 1 enlarges, thus increasing alveolar dead space ventilation.

Zone 2 occurs from the lower limit of Zone 1 to the upper limit of Zone 3, where  $P_{pa} > P_A > P_{pv}$ . The pressure difference between pulmonary artery and alveolar pressure determines blood flow in Zone 2. Pulmonary venous pressure has little influence. Well-matched ventilation and perfusion occur in Zone 2, which contains the majority of alveoli.

Finally, Zone 3 occurs in the most gravity-dependent areas of the lung where  $P_{pa} > P_{pv} > P_A$  and blood flow is primarily governed by the pulmonary arterial to venous pressure difference. Because gravity also increases pulmonary venous pressure, the pulmonary capillaries become distended. Thus, perfusion in Zone 3 is lush, resulting in capillary perfusion in excess of ventilation, or physiologic shunt.

## Distribution of Ventilation

Alveolar pressure is the same throughout the lung; therefore, the more negative intrapleural pressure at the apex (or the least gravity-dependent area) results in larger, more distended apical alveoli than in other areas of the lung. The transpulmonary pressure ( $P_{aw} - P_{pl}$ ), or distending pressure of the lung, is greater at the top and lower at the bottom, where intrapleural pressure is less negative. Despite the smaller alveolar size, more ventilation is delivered to dependent pulmonary areas. The decrease in intrapleural pressure at the base of the lungs during inspiration is greater than at the apex because of diaphragmatic proximity. Thus, because the dependent area of the lung generates the greatest change in transpulmonary pressure, more gas is sucked into dependent areas of the lung.

## Ventilation–Perfusion Relationships

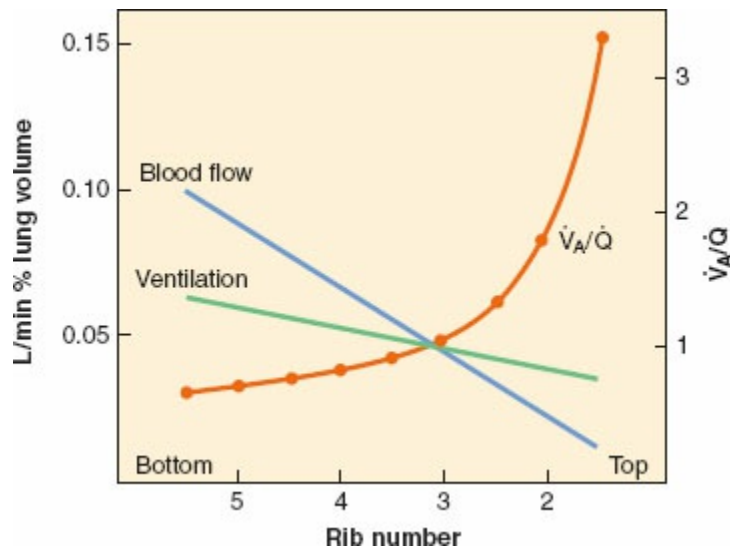

As discussed previously, the majority of blood flow is distributed to the gravity-dependent part of the lung. During a spontaneous breath, the largest portion of the tidal volume also reaches the gravity-dependent part of the lung. Thus, the nondependent area of the lung receives a lower proportion of both ventilation ( $V_A$ ) and perfusion ( $Q$ ), and dependent lung receives greater proportions of ventilation and perfusion. Nevertheless, ventilation and perfusion are not matched perfectly, and various  $V/Q$  ratios result throughout the lung. The ideal  $V/Q$  ratio of 1 is believed to occur at approximately the level of the third rib. Above this level, ventilation occurs slightly in excess of perfusion, whereas below the third rib the  $V/Q$  ratio becomes less than 1 (Fig. 15-6).

In a simplified model, gas exchange units can be divided into normal ( $V/Q$  1:1), dead space ( $V/Q = 1:0$ ), shunt ( $V/Q = 0:1$ ), or a silent unit ( $V/Q = 0:0$ ) (Fig. 15-7). Although this model is helpful in understanding  $V/Q$  relationships and their influences on gas exchange,  $V/Q$  really occurs as a continuum. In the lungs of a healthy, upright, spontaneously breathing individual, the majority of alveolar–capillary units are normal gas exchange units. The  $V/Q$  ratio varies between absolute shunt (in which  $V/Q = 0$ ) to absolute dead space (in which  $V/Q = \infty$ ). Rather than absolute shunt, most units with low  $V/Q$  mismatch receive a small amount of ventilation relative to blood flow. Similarly, most dead space units are not absolute, but rather are characterized by low blood flow relative to ventilation. During acute lung injury and adult respiratory distress syndrome, areas of low  $V/Q$  matching commonly lie adjacent to areas of high  $V/Q$  matching.<sup>50</sup> Thus, the West lung zone model should be used to aid the understanding of pulmonary physiology and not be regarded as an incontrovertible anatomic truism.

**Figure 15-5** Distribution of blood flow in the isolated lung. In Zone 1, alveolar pressure ( $P_A$ ) exceeds pulmonary artery pressure ( $P_{pa}$ ), and no flow occurs because the vessels are collapsed. In Zone 2, arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds pulmonary venous pressure ( $P_{pv}$ ). Flow in Zone 2 is determined by

the arterial–alveolar pressure difference ( $P_{pa} - P_A$ ), which steadily increases down the zone. In Zone 3, pulmonary venous pressure exceeds alveolar pressure, and flow is determined by the arterial–venous pressure difference ( $P_{pa} - P_{pv}$ ), which is constant down this pulmonary zone. However, the pressure across the vessel walls increases down the zone so their caliber increases, as does flow. (Adapted from West JB, Dollery CT, Naimark A. Distribution of blood flow in isolated lung: Relation to vascular and alveolar pressures. *J Appl Physiol*. 1964;19:713–724.)

**Figure 15-6** Distribution of ventilation, blood flow, and ventilation–perfusion ratio in the normal, upright lung. Straight lines have been drawn through the ventilation and blood flow data. Because blood flow falls more rapidly than ventilation with distance up the lung, ventilation—perfusion ratio rises, slowly at first, then rapidly. (Reprinted with permission from West JB. *Ventilation/Blood Flow and Gas Exchange*, 4th ed. Oxford, England, Blackwell Scientific, 1985.)

Hypoxic pulmonary vasoconstriction and bronchoconstriction allow the lungs to maintain optimal  $V/Q$  matching. Hypoxic pulmonary vasoconstriction, stimulated by alveolar hypoxia, severely decreases blood flow. Thus, poorly ventilated alveoli also receive minuscule blood flow. Furthermore, decreased regional pulmonary blood flow results in bronchiolar constriction and diminishes the degree of dead space ventilation.<sup>51,52</sup> When either phenomenon occurs, the shunt or dead space units effectively become silent units in which little ventilation or perfusion occurs.

Many pulmonary diseases result in both physiologic shunt and dead space abnormalities. However, most disease processes can be characterized as producing either primarily shunt or dead space in their early stages. Increases in dead space ventilation primarily affect carbon dioxide elimination and have little influence on arterial oxygenation until dead space ventilation exceeds 80% to 90% of minute ventilation ( $\dot{V}_E$ ). Similarly, physiologic shunt primarily affects arterial oxygenation with little effect on carbon dioxide elimination until the physiologic shunt fraction exceeds 75% to 80% of the cardiac

7

output. Defective to absent gas exchange can be the net effect of either abnormality in the extreme.

### Physiologic Dead Space

Each inspired breath is composed of gas that contributes to alveolar ventilation ( $V_A$ ) and gas that becomes dead space ventilation ( $V_D$ ). Thus, tidal volume ( $V_t$ ) =  $V_A + V_D$ . In the normal, spontaneously breathing person, the ratio of alveolar-to-dead space ventilation ( $V_A/V_D$ ) for each breath is 2:1. Conveniently, the rule of “1, 2, 3” applies to normal, spontaneously breathing persons. For each breath, 1 mL/lb (lean body weight) becomes  $V_D$ , 2 mL  $\times$  lb<sup>-1</sup> becomes  $V_L$ , and 3 mL  $\times$  lb<sup>-1</sup> constitutes the  $V_t$ .

**Figure 15-7** Continuum of ventilation–perfusion relationships. Gas exchange is maximally effective in normal lung units and only partially effective in shunt and dead space effect units. It is totally absent in silent units, absolute shunt, and dead space units.

Physiologic dead space consists of anatomic and alveolar dead space. Anatomic dead space ventilation, approximately 2 mL/kg ideal body weight, accounts for the majority of physiologic dead space. It arises from ventilation of structures that do not exchange respiratory gases: the oronasopharynx to the terminal and respiratory bronchioles. Clinical conditions that modify anatomic dead space include tracheal intubation, tracheostomy, and large lengths of ventilator tubing between the tracheal tube and the ventilator Y-piece. It is important to note that ventilation occurs because gas flows into

and out of the alveoli. In contrast, the inspiratory or expiratory limb of the anesthesia circle system has unidirectional flow, and therefore, is not a component of anatomic dead space ventilation.

Alveolar dead space ventilation arises from ventilation of alveoli with inadequate or no perfusion. Since disease produces little change in anatomic dead space, physiologic dead space is primarily influenced by changes in alveolar dead space. Rapid changes in physiologic dead space ventilation most often arise from changes in pulmonary blood flow, resulting in decreased perfusion to ventilated alveoli. The most common etiology of acutely increased physiologic dead space is an abrupt decrease in cardiac output. Another pathologic condition that interferes with pulmonary blood flow, and thereby creates dead space, is pulmonary embolism, whether due to thrombus, fat, air, or amniotic fluid. Although there may be obstruction to blood flow with some types of pulmonary emboli, the greatest decrease in pulmonary blood flow is due to vasoconstriction induced by locally released vasoactive substances such as leukotrienes.

Chronic pulmonary diseases create dead space ventilation by irreversibly changing the relationship between alveolar ventilation and blood flow; this alteration is especially prominent in patients with COPD. In general, individuals with acute exacerbations of COPD will have a greater degree of ventilation defect than perfusion defect due to obstruction caused by inflammation, mucous plugging, or bronchospasm. However, individuals with chronic COPD may develop decreased perfusion in areas of poor ventilation from hypoxic vasoconstriction, and collateral ventilation can occur, leading to a smaller than expected  $V/Q$  mismatch. Similar to acute exacerbations of COPD, acute diseases such as adult respiratory distress syndrome can cause an increase in dead space ventilation owing to intense pulmonary vasoconstriction. Finally, therapeutic or supportive manipulations such as positive-pressure ventilation or positive airway pressure therapy can increase alveolar dead space because depressed venous return to the right heart will decrease cardiac output and blood flow through the pulmonary vasculature, leading to decreased perfusion of the alveoli despite improved ventilation with positive-pressure therapy. However, this can usually be overcome by intravenous fluid administration. Occasionally, therapeutics which create intrapulmonary positive pressure may increase physiologic shunt, when blood flow to a previously silent area of  $V/Q$  matching now receives blood redistributed by positive pressure from more compliant areas of the lung.

### ***Assessment of Physiologic Dead Space***

As the lung receives nearly 100% of the cardiac output, assessment of physiologic dead space ventilation in the acute setting yields valuable

information about pulmonary blood flow and, ultimately, about cardiac output. If pulmonary blood flow decreases, the most likely cause is a decreased cardiac output. Thus, it is clinically useful to be able to readily assess the degree of physiologic dead space ventilation.

There are two easy and several difficult ways to assess dead space ventilation. A comparison of minute ventilation and  $\text{PaCO}_2$  allows a gross qualitative assessment of physiologic dead space ventilation. The  $\text{PaCO}_2$  is determined only by alveolar ventilation and carbon dioxide production ( $\text{VCO}_2$ ). If  $\text{VCO}_2$  remains constant,  $\text{PaCO}_2$  will also remain constant as long as minute ventilation supplies the same degree of alveolar ventilation. If the spontaneously breathing individual must increase minute ventilation to maintain the same  $\text{PaCO}_2$ , he or she will experience an increase in dead space ventilation because less of the minute ventilation is contributing to alveolar ventilation. Alternatively, a mechanically ventilated patient with a fixed minute ventilation and no increases in  $\text{VCO}_2$  also experiences an increased dead space ventilation if the  $\text{PaCO}_2$  rises. Hence, when  $\text{PaCO}_2$  in a mechanically ventilated patient increases, it is necessary to determine if the cause is increased dead space ventilation or an increased  $\text{VCO}_2$ .

Because positive-pressure ventilation increases alveolar pressure, the mechanically ventilated patient with normal lungs has a dead space to alveolar ventilation ratio ( $\text{V}_\text{D}/\text{V}_\text{A}$ ) of 1:1 (more West Zone 1) rather than 1:2, as during spontaneous ventilation. If mechanical  $\text{V}_\text{t}$  is 1,000 mL, 500 mL contributes to  $\text{V}_\text{A}$ , and 500 mL contributes to  $\text{V}_\text{D}$ . At rest, the required  $\text{V}_\text{A}$  with normal  $\text{VCO}_2$  is approximately 60 mL/kg/min. A 70-kg man would then require a  $\text{V}_\text{A}$  of 4,200 mL/min. During spontaneous breathing, the required  $\text{V}_\text{E}$  would be 6,300 mL/min, but during mechanical ventilation  $\text{V}_\text{E}$  would have **8** to be 8,400 mL/min. Using this calculation, if a 70-kg resting patient requires  $\text{V}_\text{E}$  much in excess of 8,400 mL/min, either  $\text{V}_\text{D}$  or  $\text{VCO}_2$  is increased. A rule of thumb for mechanically ventilated patients is that doubling baseline minute ventilation decreases  $\text{PaCO}_2$  from 40 to 30 mmHg, and quadrupling minute ventilation decreases  $\text{PaCO}_2$  from 40 to 20 mmHg.

The  $\text{PaCO}_2$  will be greater than or equal to end-tidal  $\text{PaCO}_2$  ( $\text{PETCO}_2$ ) unless the patient inspires or receives exogenous carbon dioxide (e.g., from peritoneal insufflation). The difference between  $\text{PETCO}_2$  and  $\text{PaCO}_2$  is due to dead space ventilation. The most common reason for an acute increase in **9** dead space ventilation is decreased cardiac output. Measurement of this difference—which is simple, readily obtainable, and fairly inexpensive—yields reliable information relative to the degree of dead space ventilation. Clinical situations that change pulmonary blood flow sufficiently to increase dead space ventilation can be detected by comparing  $\text{PETCO}_2$  with temperature-corrected  $\text{PaCO}_2$ . Yamanaka and Sue<sup>53</sup> found that the  $\text{PETCO}_2$  in ventilated patients varied linearly with the dead space to tidal volume ratio

( $V_D/V_t$ ) and that  $PETCO_2$  correlated poorly with  $PaCO_2$ . Thus, in the critically ill, mechanically ventilated patient, and in anesthetized patients, monitoring  $PETCO_2$  gives far more information about ventilatory efficiency or dead space ventilation than it does about the absolute value of  $PaCO_2$ .

Anesthesiologists commonly measure  $PETCO_2$  to detect venous air embolism during anesthesia. A lowered cardiac output alone, in the absence of venous air embolism, may sufficiently decrease pulmonary perfusion, so dead space ventilation increases and  $PETCO_2$  falls. Thus, a depressed  $PETCO_2$  is sensitive for decreased cardiac output but not specific for pulmonary embolism. Air in the pulmonary arteries mechanically interferes with blood flow and also causes pulmonary arterial constriction, further decreasing pulmonary blood flow. A decreased  $PETCO_2$  suggests that a physiologically significant air embolism has occurred. The same physiologic considerations apply to detecting pulmonary thromboembolism.

Some clinicians use the divergence of  $PETCO_2$  from  $PaCO_2$  as a reflection of pulmonary blood flow for other applications. During intentional pharmacologic or surgical manipulation of pulmonary blood flow, the difference between  $PaCO_2$  and  $PETCO_2$  serves as a useful physiologic monitor for the effectiveness of these interventions. Furthermore,  $PETCO_2$  reflects pulmonary perfusion, is a useful tool for studying and monitoring the effectiveness of resuscitation efforts, and may provide a marker for survival after resuscitation.<sup>54</sup>

The most quantitative technique used to measure physiologic dead space uses a modification of the Bohr equation:

$$\frac{V_D}{V_t} = \frac{PaCO_2 - \bar{P}_{ECO_2}}{PaCO_2} \quad (15-5)$$

where  $\bar{P}_{ECO_2}$  is the  $PCO_2$  from the mixture of all expired gases over the period of time during which measurements are made. This calculation estimates the fraction of each breath that does not contribute to gas exchange. In spontaneously breathing patients, normal  $V_D/V_t$  is between 0.2 and 0.4, or approximately 0.33. In patients receiving positive-pressure ventilation,  $V_D/V_t$  becomes about 0.5. The major limitation of performing this calculation is the difficulty in collecting exhaled gas for  $\bar{P}_{ECO_2}$  measurement. Exhaled gases, collected in cumbersome Douglas bags, can be easily contaminated with inspired air or supplemental oxygen. The measurement will also be inaccurate if the patient does not maintain a steady ventilatory pattern. Therefore, extreme care must be taken to ensure all measurements are performed accurately. In practice, this measurement is rarely performed.

## Physiologic Shunt

Whereas physiologic dead space ventilation applies to areas of the lung that are ventilated but poorly perfused, physiologic shunt occurs in lung that is perfused but poorly ventilated. The physiologic shunt ( $Q'_{SP}$ ) is that portion of the total cardiac output ( $Q'_T$ ) that returns to the left heart and systemic circulation without receiving oxygen in the lung. When pulmonary blood is not exposed to alveoli or when those alveoli are devoid of ventilation, the result is *absolute or true shunt*, in which  $V_A/Q' = 0$ . *Shunt effect*, or *venous admixture*, is the more common clinical phenomenon and occurs in areas where alveolar ventilation is deficient compared with the degree of perfusion:  $0 < V_A/Q' < 1$ .

Because blood passing through areas of absolute shunt receives no oxygen, arterial hypoxemia resulting from absolute shunt is minimally reversed with supplemental oxygen. Alternatively, supplemental oxygen supplied to patients with arterial hypoxemia due to venous admixture will increase the  $PaO_2$ . Although ventilation to these alveoli is deficient, they do carry a small amount of oxygen to the capillary bed. Thus, assessment of arterial oxygen responsiveness to supplemental oxygen administration is a helpful diagnostic tool.

A small percentage of venous blood normally bypasses the right ventricle and empties directly into the left atrium. This anatomic, absolute, or true shunt arises from the venous return of the pleural, bronchiolar, and thebesian veins. This venous admixture accounts for 2% to 5% of total cardiac output and represents the small shunt that normally occurs. Anatomic shunts of greatest magnitude are usually associated with congenital heart diseases that cause right-to-left shunt. Intrapulmonary anatomic shunts can also cause anatomic shunt. For example, the arterial hypoxemia associated with advanced hepatic failure (hepatopulmonary syndrome) is due, in part, to arteriovenous malformations.<sup>55,56</sup> Diseases that may cause absolute or true shunt include acute lobar atelectasis, extensive acute lung injury, advanced pulmonary edema, and consolidated pneumonia. Disease entities that tend to produce venous admixture include mild pulmonary edema, postoperative atelectasis, and COPD.

### **Assessment of Arterial Oxygenation and Physiologic Shunt**

The simplest assessment of oxygenation is qualitative comparison of the patient's  $F_{IO_2}$  and  $PaO_2$ . The highest possible  $PaO_2$  for any given  $F_{IO_2}$  (and  $PaCO_2$ ) can be calculated from the alveolar gas equation:

$$PaO_2 = F_{IO_2} (P_b - P_{H_2O}) - \frac{PaCO_2}{R} \quad (15-6)$$

where  $P_{aO_2}$  and  $P_{aCO_2}$  are alveolar  $PO_2$  and  $PCO_2$ ,  $P_{H_2O}$  is water vapor pressure at 100% saturation and  $37^\circ C$ ,  $P_b$  is barometric pressure, and  $R$  is respiratory quotient. Assuming one makes the calculation for a well-perfused alveolus, the alveolar and arterial  $PCO_2$  are equal. Therefore,  $P_{aCO_2}$  can be substituted for  $P_{aCO_2}$ . Respiratory quotient ( $R$ ) is the ratio of  $O_2$  consumed ( $V_{O_2}$ ) to  $CO_2$  produced ( $V_{CO_2}$ ):

$$\frac{V_{CO_2}}{V_{O_2}} = \frac{200 \text{ mL/min}}{250 \text{ mL/min}} = 0.8 \quad (15-7)$$

Oxygen tension–based indices do not reflect mixed venous contribution to arterial oxygenation and can be misleading.<sup>57</sup> Even if venous admixture is small, mixed venous blood with very low oxygen content will magnify the effect of a small shunt. Oxygen tension–based indices, for example,  $P_{aO_2}/F_{IO_2}$ , alveolar to arterial  $PO_2$  difference ( $P[A-a]O_2$ ), and ratio  $P_{aO_2}/P_{aCO_2}$ , do not take into account the influence of mixed venous oxygen content ( $C_{v-O_2}$ ) on arterial oxygenation. Therefore, in critically ill patients who are hypoxemic, the insertion of a pulmonary artery catheter to assess shunt and to measure cardiac output may be essential to understanding the influence of cardiac function on arterial oxygenation.

The alveolar gas equation has important clinical utility in recognizing alveolar hypoventilation due to its effect on arterial oxygenation. Dalton’s law refers to the fact that each gas in a mixture will exert its own partial pressure, and in sum will equal the total pressure of the mixture.<sup>58</sup> The first term in the equation describes the partial pressure of oxygen in the alveolus, while the second represents carbon dioxide. In the event of significant alveolar hypoventilation, carbon dioxide accumulates in arterial blood and subsequently the alveolus. While inspiring room air the concentration of oxygen is reduced and arterial hypoxemia will occur. Using a  $P_{aCO_2}$  value of 80 mmHg, the alveolar gas equation will calculate the  $P_{aO_2}$  as approximately 50 mmHg. Assuming a normal  $P_{50}$  for hemoglobin and normal  $A-a$  gradient, this arterial oxygen tension will correspond to an arterial saturation value in the 80% range, modestly above the value for mixed venous saturation.<sup>39</sup> In response to hypoxemia, alveolar hyperventilation produces a decrease in  $P_{aCO_2}$  and  $P_{aCO_2}$ . While inspiring room air, if the  $P_{aCO_2}$  were to decrease, a concomitant increase in the partial pressure of oxygen must occur to preserve the total pressure in the alveolus. For example, if the  $P_{aCO_2}$  were to decrease to 20 mmHg, the resulting  $P_{aO_2}$  would increase by approximately 25 mmHg, thereby increasing arterial oxygen saturation, oxygen content, and oxygen delivery.

The assessment of arterial oxygenation requires, at least, knowledge of  $F_{IO_2}$  and either  $P_{aO_2}$  or  $SaO_2$ . Oxygen tension–based indices of oxygenation

are useful, but they do not take into account the contribution of mixed venous blood to arterial oxygenation. Mixed venous blood can become extremely desaturated in the critically ill patient owing to inadequate cardiac output, anemia, arterial hypoxemia, increased  $\dot{V}O_2$ , or abnormal hemoglobin moieties. The best knowledge of the efficiency with which the lungs oxygenate the arterial blood can be obtained only by calculating shunt fraction.

### Physiologic Shunt Calculation

The clinical reference standard for the calculation of physiologic shunt fraction is derived from a two-compartment pulmonary blood flow model. One compartment performs ideal gas exchange and contains perfectly married alveolar–capillary units while the other is the shunt compartment and contains pulmonary capillaries that have no exposure to ventilated alveoli. Using the Fick relationship, the following equation can be derived:

$$\frac{Q_{SP}}{Q_T} = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - C\bar{v}O_2} \quad (15-8)$$

where  $Q_{SP}/Q_T$  is the shunt fraction ( $Q_{SP}$  is blood flow through the physiologic shunt compartment,  $Q_T$  is total cardiac output), and  $Cc'O_2$ ,  $CaO_2$ , and  $C\bar{v}O_2$  are end-capillary, arterial, and mixed-venous oxygen contents, respectively. Normal intrapulmonary shunt is approximately 5%. Because this equation is based on an artificial two-compartment model, the absolute value is physically meaningless. A calculated  $Q_{SP}/Q_T$  of 25% means that if the lung existed in two compartments, 25% of the cardiac output would travel through the shunt compartment. Since the lung does not truly exist in two compartments, this equation grossly estimates pulmonary oxygen exchange defects. Nevertheless, it remains our best tool for clinically evaluating the lungs' efficiency in oxygenating arterial blood. Observing changes in shunt fraction corresponding to therapeutic intervention or disease progression is more valuable than knowing the absolute value per se.

Since hemoglobin concentration is uniform throughout the vascular system, the oxygen contents in the shunt equation are determined primarily by oxyhemoglobin saturation. Thus, the shunt equation can be approximated by substituting saturation values for each term; the new value, called *ventilation–perfusion ratio* (VQI),<sup>56</sup> is determined as follows:

$$VQI = \frac{Sc'O_2 - SaO_2}{Sc'O_2 - S\bar{v}O_2} \cong \frac{1 - SaO_2}{1 - S\bar{v}O_2} \quad (15-9)$$

If the patient is neither breathing a hypoxic gas mixture nor has a

methemoglobin or carboxyhemoglobin value in excess of 5% to 6%,  $S_c'O_2$  must equal 1 because the model requires a perfect alveolar–capillary interface. This substitution results in the final expression in the previous equation. The absolute values of VQI are meaningless, although “normal” should be 0% to 4%. Like  $Q'_{SP}/Q'_T$ , the importance of these values lies in their trend as disease and treatment progress.

10  $SaO_2$  and  $S_{\bar{v}}O_2$  can be estimated continuously with pulse oximetry and by using a pulmonary artery catheter with oximetry capability. By interfacing the outputs of these two devices with a computer, VQI can be calculated continuously. The greatest advantage of calculating  $Q'_{SP}/Q'_T$  or VQI to assess arterial oxygenation efficiency is that these values include the contribution of mixed venous blood.

## Pulmonary Function Testing

Because anesthesiologists frequently care for patients with significant pulmonary dysfunction, they must be able to interpret tests of pulmonary function (and dysfunction) intelligently. This section discusses lung volumes, tests of pulmonary mechanics, and diffusing capacity.

### Lung Volumes and Capacities

Known, reproducible pulmonary gas volumes and capacities provide a reliable basis for comparison between normal and abnormal measurements.<sup>59</sup> Because normal measurements vary with size, height is most frequently used to define “normal.” Lung capacities are composed of two or more lung volumes. Lung volumes and capacities are schematically illustrated in [Figure 15-8](#).

*Tidal volume* is the volume of gas that moves in and out of the lungs during quiet breathing and is about 6 to 8 mL/kg. Tidal volume falls with decreased lung compliance or when the patient has reduced ventilatory muscle strength.

*Vital capacity* is usually around 60 mL/kg but may vary as much as 20% from normal in healthy individuals. Vital capacity correlates well with deep breathing and effective coughing. It is decreased by restrictive pulmonary disease such as pulmonary edema or atelectasis. Vital capacity may also be reduced by mechanically induced, extrapulmonary restriction seen in pleural effusion, pneumothorax, pregnancy, large ascites, or ventilatory muscle weakness.

The *inspiratory capacity* is the largest volume of gas that can be inspired from the resting expiratory level and is frequently decreased in the presence of significant extrathoracic airway obstruction. This measurement is one of the few simple tests that can detect extrathoracic airway obstruction. Most

routine pulmonary function tests measure only exhaled flows and volumes, which may be relatively unaffected by extrathoracic obstruction until it is severe. Changes in the absolute volume of inspiratory capacity usually parallel changes in vital capacity. *Expiratory reserve volume* is not of great diagnostic value.

FRC is the volume of gas remaining in the lungs at passive end-expiration. *Residual volume* is the gas remaining within the lungs at the end of forced maximal expiration. The FRC serves two primary physiologic functions. First, it determines the point on the pulmonary volume–pressure curve for resting ventilation (Fig. 15-2). The tangent defined by the midportion pulmonary volume–pressure curve at FRC defines lung compliance. Thus, FRC determines the elastic pressure–volume relationships within the lung. Furthermore, FRC is the resting expiratory volume of the lung and is the primary determinant of oxygen reserve in humans when apnea occurs. As such, it greatly influences ventilation–perfusion relationships within the lung. When FRC is **11** reduced, venous admixture (low  $V_A/Q$ ) increases and results in arterial hypoxemia (see Oxygen and Carbon Dioxide Transport and Lung Mechanics sections).

**Figure 15-8** Lung volumes and capacities. The *darkest shaded bar* on the far right depicts the four basic lung volumes that sum to create TLC. Other lung capacities are composed of two or more lung volumes. The overlying spirometric tracing orients the reader to the relationship between the lung volumes and capacities and the spirogram. ERV, expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; IRV, inspiratory reserve volume; RV, residual volume; TLC, total lung capacity; VC, vital capacity; Vt, tidal volume.

Further, the FRC may be used to quantify the degree of pulmonary restriction. Disease processes that reduce FRC and lung compliance include

acute lung injury, pulmonary edema, pulmonary fibrotic processes, and atelectasis. Mechanical factors also reduce FRC, for example, pregnancy, obesity, pleural effusion, and posture. The FRC decreases 10% when a healthy subject lies supine. Ventilatory muscle weakness or paralysis will also decrease FRC. In contrast, patients with COPD have excessively compliant lungs that recoil less forcibly. Their lungs retain an abnormally large volume at the end of passive expiration, a phenomenon called *gas trapping*.

## FRC Measurement

The FRC and residual volume must be measured indirectly because residual volume cannot be removed from the lung. The multiple-breath nitrogen washout test is performed by having the subject breathe 100% oxygen for several minutes to enable alveolar nitrogen to gradually “wash out.” With each breath, the volume of gas and the concentration of nitrogen in the exhaled gas are measured. A rapid nitrogen analyzer coupled to a spirometer or pneumotachometer provides a breath-by-breath analysis of nitrogen washout. Electronic signals proportional to nitrogen concentrations and exhaled volumes (or flow, if a pneumotachometer is used) are integrated to derive the exhaled volume of nitrogen for each breath. Then, the values for all breaths are summed to provide a total volume of nitrogen washed out of the lungs. The test proceeds until the alveolar nitrogen concentration is reduced to less than 7%, usually requiring 7 to 10 minutes. FRC is calculated using the equation:

$$\text{FRC} = \text{N}_2 \text{ volume} \times \frac{[\text{N}_2]_f}{[\text{N}_2]_i} \quad (15-10)$$

where  $[\text{N}_2]_i$  and  $[\text{N}_2]_f$  are the fractional concentrations of alveolar nitrogen at the beginning and end of the test, respectively.

## Pulmonary Function Tests

### Forced Vital Capacity

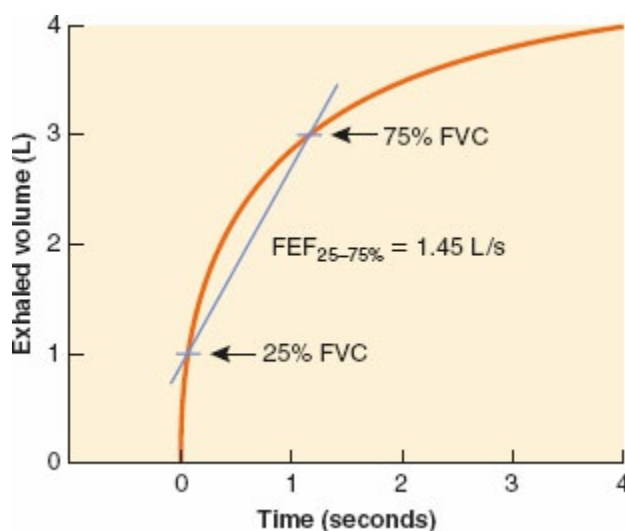

The forced vital capacity (FVC) is the volume of gas that can be expired as forcefully and rapidly as possible after maximal inspiration. Normally, FVC is equal to vital capacity. Although forced expiration significantly increases intrapleural pressures yet changes airway pressure minimally, bronchiolar collapse, obstructive lesions, and gas trapping are exaggerated. Thus, FVC may be reduced in chronic obstructive diseases even when the vital capacity appears near normal. FVC is nearly always decreased by restrictive diseases. FVC values lower than 15 mL/kg are associated with an increased incidence

of PPCs, probably because these patients cough ineffectively.<sup>60</sup> FVC reduced to this level represents a profound defect, most commonly seen in quadriplegics or severe neuromuscular disease. Finally, FVC is largely dependent on patient effort and cooperation.

## Forced Expiratory Volume

FEV<sub>T</sub> is the forced expiratory volume of gas over a given time interval during the FVC maneuver. The interval, described by the subscript T, is the time elapsed in seconds from the onset of expiration. Because FEV<sub>T</sub> records a volume of gas expired over time, it is actually a measure of flow. By measuring expiratory flow at specific intervals, the severity of airway obstruction can be ascertained. Decreased FEV<sub>T</sub> values are common in both obstructive and restrictive disease patterns. The most important application of FEV<sub>T</sub> is its comparison with the patient's FVC. Normal subjects can expire at least three-fourths of FVC within the first second of the forced expiratory maneuver. The FEV<sub>1</sub>, the most frequently employed value, is normally greater than or equal to 75% of the FVC, or  $FEV_1/FVC \geq 0.75$ .

Normally, an individual can expire 50% to 60% of FVC in 0.5 second, 75% to 85% in 1 second, 94% in 2 seconds, and 97% in 3 seconds. Cooperative patients with obstructive disease will exhibit a reduced FEV<sub>1</sub>/FVC in most cases. However, patients with restrictive disease usually have normal FEV<sub>1</sub>/FVC ratios. The validity of the evaluation of the FEV<sub>1</sub>/FVC is highly dependent on patient cooperation and effort. It is possible to deliberately produce an artificially low FEV<sub>1</sub>/FVC.

**Figure 15-9** FEF<sub>25%-75%</sub>. The spirogram depicts a 4 L FVC on which the points representing 25% and 75% FVC are marked. The slope of the line connecting these points is the FEF<sub>25%-75%</sub>.

## Forced Expiratory Flow

FEF<sub>25%–75%</sub> is the average forced expiratory flow during the middle half of the FEV maneuver. This test is also called maximum mid-expiratory flow rate. The length of time required for a subject to expire the middle half of the FVC is divided into 50% of the FVC. The spirogram in [Figure 15-9](#) marks the place from 25% to 75% of FVC, constituting the middle 50% of FVC. The straight line connecting the 25% and 75% volumes has a slope approximately equal to average flow. A normal value for a healthy 70-kg man is approximately 4.7 L/sec (or 280 L/min). Normally, both the absolute value and the percentage of predicted value for the individual being studied are recorded. A normal value is  $100 \pm 25\%$  of predicted. Decreased flow rates from this middle 50% of FVC are indicative of obstructive disease of medium size airways. This value is typically normal in restrictive diseases. This test is fairly sensitive in the early stages of obstructive airway disease. Decreased FEF<sub>25%–75%</sub> frequently will be observed before other obstructive manifestations occur. Although somewhat effort dependent, the test is much more reliable and reproducible than FEV<sub>1</sub>/FVC.

### **Maximum Voluntary Ventilation**

Maximum voluntary ventilation (MVV) is the largest volume of gas that can be breathed in 1 minute by voluntary effort. The MVV is measured by having the subject breathe as deeply and as rapidly as possible for 10, 12, or 15 seconds. The results are extrapolated to 1 minute. The subject is instructed to set his or her own ventilatory rate and move more than tidal volume but less than vital capacity in each breath.

MVV measures the endurance of the ventilatory muscles and indirectly reflects lung–thorax compliance and airway resistance. MVV is the best ventilatory endurance test that can be performed in the laboratory. Values that vary by as much as 30% from predicted values may be normal, so only large reductions in MVV are significant. Healthy, young adults average about 170 L/min. Values are lower in women and decrease with age in both sexes. Because this maneuver exaggerates air trapping and exerts the ventilatory muscles, MVV is decreased greatly in patients with moderate to severe obstructive disease. MVV is usually normal in patients with restrictive disease.

**Figure 15-10** Flow–volume loop. The figure depicts a normally configured adult flow–volume loop. The slope of the loop after the subject reaches peak expiratory flow is nearly linear.

## Flow–Volume Loops

The flow–volume loop graphically demonstrates the flow generated during a forced expiratory maneuver followed by a forced inspiratory maneuver, plotted against the volume of gas expired (Fig. 15-10). The subject forcefully exhales completely, then immediately forcefully inhales to vital capacity. The expired and inspired volumes are plotted on the abscissa and flow is plotted on the ordinate. Although various numbers can be generated from the flow–volume loop, the configuration of the loop itself is probably the most informative part of the test.

Flow–volume loops were formerly useful in the diagnosis of large airway and extrathoracic airway obstruction prior to the availability of precise imaging techniques. Imaging techniques such as MRI give more precise and useful information in the diagnosis of upper airway and extrathoracic obstruction and superseded the use of flow–volume loops for diagnosis of these conditions. Therefore, it is rare that flow–volume loops are useful for preoperative pulmonary evaluation in the modern era of imaging.

## Carbon Monoxide Diffusing Capacity

Since  $PO_2$  in the pulmonary capillary blood varies with time as it moves through the pulmonary microvasculature, oxygen cannot be used to assess diffusing capacity. Instead, a gas mixture containing carbon monoxide is traditionally used to measure diffusing capacity. The partial pressure of carbon monoxide in the blood is nearly zero, and its affinity for hemoglobin is 200 times that of oxygen.<sup>61</sup> Carbon monoxide diffusing capacity (DLCO)

collectively measures all the factors that affect diffusion across the alveolar–capillary membrane. The DLCO is recorded in mL CO/min/mmHg at STPD. In persons with normal hemoglobin concentrations and normal V/Q matching, the main factor limiting diffusion is the alveolar–capillary membrane. There are several methods for determining DLCO, but all measure diffusing capacity according to the equation

$$DL_{CO} = VA \times (60/t) \times [1/(PB-47)] \times \ln (FACO_0/FACOt) \quad (15-11)$$

The average value for resting subjects when the single-breath method is used is 25 mL CO/min/mmHg. DLCO values can increase to two or three times normal during exercise.

The DLO<sub>2</sub> may be estimated from the DLCO by multiplying DLCO by 1.23, although the DLCO is usually the reported value. DLCO can be divided by the lung volume at which the measurement was made to obtain an expression of diffusing capacity per unit lung volume.

Some of the other factors that can influence DLCO are as follows:

1. Hemoglobin concentration: decreased hemoglobin concentration decreases the DLCO
2. Alveolar PCO<sub>2</sub>: an increased PaCO<sub>2</sub> raises DLCO
3. Body position: the supine position increases DLCO
4. Pulmonary capillary blood volume

Diffusing capacity is decreased in alveolar fibrosis associated with sarcoidosis, asbestosis, berylliosis, oxygen toxicity, and pulmonary edema. These states are frequently categorized as diffusion defects, but low DLCO is probably more closely related to loss of lung volume or capillary bed perfusion. DLCO is decreased in obstructive disease because of the decreased alveolar surface area, loss of capillary bed, the increased distance from the terminal bronchiole to the alveolar–capillary membrane, and V/Q mismatching. In short, few disease states truly inhibit oxygen diffusion across the alveolar–capillary membrane.

### ***Practical Application of Pulmonary Function Tests***

Of the many pulmonary function tests, spirometry is the most useful, cost-effective, and commonly used test.<sup>62</sup> Screening spirometry yields VC, FVC, and FEV<sub>1</sub>. From these values, two basic types of pulmonary dysfunction can be identified and quantitated: obstructive defects and restrictive defects. The primary criterion for airflow obstruction is decreased FEV<sub>1</sub>/FVC ratio. Other measurements, such as FEF<sub>25%–75%</sub>, can be used to support the diagnosis of an obstructive defect or to assist in management (e.g., use of bronchodilators). A

restrictive defect is a proportional decrease in all lung volumes (VC, FVC, and FEV<sub>1</sub>), but FEV<sub>1</sub>/FVC remains normal. When there is a question about whether a decreased VC is due to restriction, TLC should be measured. Reduced TLC defines a restrictive defect, but is not necessary unless VC on screening spirometry is reduced. The American Thoracic Society published an experts' consensus concerning interpretation of lung function tests.<sup>63</sup> Table 15-4 summarizes the distinctions between results from those with restrictive versus obstructive defects.

## **Preoperative Pulmonary Assessment**

Markedly impaired pulmonary function is likely in patients who have the following:

1. Any chronic disease that involves the lung
2. Smoking history, persistent cough, and/or wheezing
3. Chest wall and spinal deformities
4. Morbid obesity
5. Surgical need for single-lung anesthesia or lung resection
6. Severe neuromuscular disease

Preoperative pulmonary evaluation must include history and physical examination, and may include chest radiograph, arterial blood gas analysis, and screening spirometry, depending on the patient's history. A history of sputum production, wheezing or dyspnea, exercise intolerance, or limited daily activities may yield more practical information than does formal testing. Arterial blood analysis while the patient breathes room air adds information regarding gas exchange and acid–base balance. It is most useful if the patient's history suggests chronic hypoxemia or carbon dioxide retention, and can guide perioperative ventilatory management. Blood gas results should be interpreted in the context of measured bicarbonate levels, which are frequently elevated in those with chronic acidemia.

**Table 15-4** Pulmonary Function Tests in Restrictive and Obstructive Lung Disease

Value	Restrictive Disease	Obstructive Disease
Definition	Proportional decreases in all lung volumes	Small airway obstruction to expiratory flow
FVC	↓↓↓	Normal or slightly ↑
FEV <sub>1</sub>	↓↓↓	Normal or slightly ↓
FEV <sub>1</sub> /FVC	Normal	↓↓↓
FEF <sub>25-75%</sub>	Normal	↓↓↓
FRC	↓↓↓	Normal or ↑ if gas trapping
TLC	↓↓↓	Normal or ↑ if gas trapping

FEV, forced expiratory volume; FRC, functional residual capacity; FVC, forced vital capacity; TLC, total lung capacity; ↓↓↓, ↑↑↑ = large decrease or increase, respectively; ↓, ↑ = small/moderate decrease or increase, respectively.

The goals of preoperative pulmonary function testing are to predict the likelihood of pulmonary complications, obtain quantitative baseline information to guide perioperative management, and identify patients who may benefit from preoperative therapy to improve pulmonary function. For patients undergoing lung resections, pulmonary function testing provides some predictive benefit.<sup>64</sup> For all other patients, however, evidence suggests that preoperative pulmonary function testing does not predict or assign risk for PPCs.<sup>65,66</sup>

In 2012, the American Society of Anesthesiologists' Taskforce on Preanesthetic Evaluation published an updated practice advisory<sup>67</sup> stating that "there is insufficient evidence to identify explicit decision parameters or rules for ordering preoperative tests on the basis of specific clinical characteristics." The literature<sup>68</sup> also reveals that specific measurements of lung function do **12** not predict PPCs. Rather, testing should be performed to identify reversible pulmonary disease (bronchospasm) or to define the severity of advanced pulmonary disease, because the clinician obtains valuable information from the patient's history. In a series of 272 adults undergoing nonthoracic surgery, McAlister et al.<sup>69</sup> reported the following historical factors to independently increase the risk of PPC: age above 65 years, smoking more than 40 pack-years, COPD, asthma, productive cough, and exercise tolerance of less than one flight of stairs.

The need to obtain baseline pulmonary function data should be reserved for those patients with severely impaired preoperative pulmonary function, such as quadriplegics or myasthenics, so that liberation from mechanical ventilation and/or tracheal extubation can be based on objective baseline pulmonary function.

Arterial blood gases are not indicated unless the patient's history suggests arterial hypoxemia or severe COPD. Then, the arterial blood gas should be

used in a similar manner as preoperative pulmonary function testing—to identify reversible disease or to define the severity of the disease at baseline. Defining baseline PaO<sub>2</sub> and PaCO<sub>2</sub> is particularly important if one anticipates postoperative ventilation of a patient with severe COPD.

## Anesthesia and Obstructive Pulmonary Disease

Patients with marked obstructive pulmonary disease are at increased risk for both intraoperative and postoperative pulmonary complications. For example, patients with reduced FEV<sub>1</sub>/FVC or reduced mid-expiratory flow exhibit both small airway obstruction and increased airway reactivity. Because of the hazard of provoking reflex bronchoconstriction during laryngoscopy and tracheal intubation, patients with COPD or asthma should receive aggressive bronchodilator therapy prior to instrumentation of the airway. Adjunctive intravenous administration of opioids and lidocaine prior to airway instrumentation will decrease airway reactivity by deepening anesthesia. High alveolar concentrations of most potent inhalational anesthetics will blunt reflex bronchoconstriction. Furthermore, a single dose of corticosteroids may help prevent postoperative increases in airway resistance.

In patients with severe obstructive disease, spontaneous ventilation during general anesthesia is more likely to result in hypercapnia than in patients with normal pulmonary function.<sup>70</sup> Preoperative FEV<sub>1</sub> reduction correlates with the PaCO<sub>2</sub> increase during anesthesia. Slower rates of mechanical ventilation (8 to 10 breaths min<sup>-1</sup>) should be used to allow sufficient time for exhalation. Low ventilatory rates necessitate a larger V<sub>t</sub> to maintain a normal PaCO<sub>2</sub>; however, the larger V<sub>t</sub> may predispose the patient to pulmonary barotrauma due to higher peak airway pressure. Tidal volume and inspiratory flows should be adjusted to keep peak airway pressure less than 40 cm H<sub>2</sub>O,<sup>71,72</sup> if possible. Higher inspiratory flows produce a shorter inspiratory time and, usually a higher peak airway pressure. Thus, a balance that avoids high peak airway pressure and excessively large V<sub>t</sub>, yet allows a long expiratory time should be sought.

In most cases, one would extubate the patient's trachea at the end of surgery because the endotracheal tube increases both airway resistance and reflex bronchoconstriction, limits the ability of the patient to clear secretions effectively, and increases the risk of iatrogenic infection. Because endotracheal tubes can trigger reflex bronchospasm during emergence from general anesthesia, in some patients with obstructive disease (e.g., the young asthmatic), tracheal extubation is performed during deep levels of anesthesia at the conclusion of the operation.

## Anesthesia and Restrictive Pulmonary Disease

Restrictive disease is characterized by proportional decreases in all lung volumes. The decreased FRC produces low lung compliance and also results in arterial hypoxemia because of low  $V/Q$  conditions. These patients typically breathe rapidly and shallowly.

Positive-pressure ventilation of patients with restrictive disease is fraught with high peak airway pressures because more pressure is required to expand stiff lungs. Use of a lower  $V_t$  at more rapid rates can reduce the risk of barotrauma, but may increase the chances of developing atelectasis. Large  $V_t$  should be avoided because of the increased risks of both barotrauma<sup>73</sup> and volutrauma.<sup>50</sup> Various lung protective strategies have been developed to ventilate patients with profound restrictive lung disease (see [Chapters 36](#) and [56](#)).

Patients with severe restrictive diseases tolerate apnea poorly because the FRC is reduced, and a lower oxygen store is available during apneic periods. Even preoxygenation with an  $FIO_2$  of 1.0 can result in arterial hypoxemia within seconds after the cessation of breathing or disconnection from a ventilator circuit. Because arterial hypoxemia develops so rapidly, transportation of these patients within the hospital should be performed with a pulse oximeter.

Even healthy individuals develop mild restrictive defects during anesthesia. FRC decreases 10% to 15% when healthy, spontaneously breathing individuals lie supine. Tracheal intubation also minimally reduces FRC. General anesthesia decreases FRC by an additional 5% to 10%,<sup>74</sup> which usually results in decreased lung compliance.<sup>75</sup> The FRC reaches its nadir within the first 10 minutes of anesthesia,<sup>74,76,77</sup> independent of whether ventilation is spontaneous or controlled. The diminished FRC persists into the postoperative period, but is improved with positive end-expiratory pressure or CPAP.<sup>74,78,79</sup> However, once positive airway pressure is removed, FRC falls to previously diminished levels, and reaches a postoperative nadir 12 hours after operation.<sup>80</sup>

## Effects of Cigarette Smoking on Pulmonary Function

Smoking affects pulmonary function in many ways. The irritant smoke decreases ciliary motility and increases sputum production. Thus, these patients have a high volume of sputum and decreased ability to clear it effectively. In addition, airway reactivity and the development of obstructive disease become problematic. Studies of the pathogenesis of COPD suggest that smoking results in an excess of pulmonary proteolytic enzymes that directly damage the lung parenchyma.<sup>81</sup> Exposure to smoke increases synthesis and release of elastolytic enzymes from alveolar macrophages—cells instrumental in the genesis of COPD due to smoking. Further damage to the

lung tissue is likely caused by reactive metabolites of oxygen (hydroxyl radicals and hydrogen peroxide) that macrophages use to kill microorganisms. The immunoregulatory function of the macrophages is also changed by cigarette smoking, including presentation of antigens and interaction with T lymphocytes.<sup>82</sup> Other adverse effects of smoking on lung tissue include increased epithelial permeability<sup>83</sup> and changed pulmonary surfactant.<sup>84</sup> The airway irritation or small airway reactivity evoked by inhaling cigarette smoke results from nicotine-mediated activation of sensory endings located in the central airways.<sup>85</sup>

Early in the disease, mild V/Q mismatch, bronchitis, and airway hyperreactivity are present, and with time progress to the hallmarks of COPD: gas trapping, flattened diaphragmatic configuration (decreasing the diaphragm's efficiency), and barrel chest deformity. Lung compliance increases significantly and limited elastic recoil prevents complete passive exhalation. As a result, many COPD patients exhale forcibly to reduce gas trapping.

With gas trapping, V/Q mismatch increases, resulting in large areas of dead space ventilation and venous admixture. Carbon dioxide elimination is inefficient because of increased dead space ventilation. The typical minute ventilation for patients with advanced obstructive lung disease can be up to twice normal. In addition, venous admixture produces arterial hypoxemia that is exquisitely sensitive to low concentrations of supplemental oxygen. Gas exchange is further impaired by the increased carboxyhemoglobin concentration from inspired smoke. Normal carboxyhemoglobin concentration in nonsmokers is approximately 1%; in smokers, however, it can be as high as 8% to 10%. Cessation of smoking, even for 12 to 24 hours preoperatively, can decrease carbon monoxide concentration to near normal.

Smoking is one of the main and most prevalent risk factors associated with postoperative morbidity.<sup>86</sup> COPD patients who smoke have a two-fold to six-fold<sup>87</sup> risk of developing postoperative pneumonia compared with nonsmokers. Furthermore, smokers' relative risk of PPCs is doubled, even if they do not have evidence of clinical pulmonary disease or abnormal pulmonary function.<sup>88</sup> The incidence of PPCs in smokers can be reduced by abstinence from smoking, although there is no consensus on the minimal or optimal duration of preoperative smoking abstinence.<sup>89–91</sup> Warner et al.<sup>86</sup> studied 200 patients undergoing coronary artery bypass grafting and found that patients who continued to smoke or stopped less than 8 weeks before the operation had a complication rate nearly four times that of patients who had quit smoking more than 8 weeks preoperatively. Normalization of mucociliary function requires 2 to 3 weeks of abstinence from smoking, during which time sputum production increases. Several months of smoking abstinence is required to return sputum clearance to normal.<sup>92</sup> In a study of

bupropion-assisted smoking cessation, Hurt et al.<sup>93</sup> demonstrated a decreased risk of postoperative complications even after 4 weeks of abstinence from smoking.

Nonetheless, Public Health Service guidelines published in 2000 emphasize the responsibility of health-care facilities to coordinate interventions aimed at tobacco dependence treatment. The guidelines note that tobacco dependence often necessitates repeated interventions, although “every patient who uses tobacco should be offered at least brief treatment” as brief tobacco dependence therapy has been shown to be effective. These guidelines recognize five first-line pharmacologic adjuncts that increase smoking cessation success: bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray, and nicotine patch. In addition, clonidine and nortriptyline were identified as second-line pharmacologic adjuncts.<sup>94</sup>

Following publication of these 2000 guidelines, a randomized controlled trial utilizing the partial nicotinic acetylcholine agonist, varenicline, showed improved smoking abstinence rates compared to bupropion SR treatment.<sup>95</sup> Based on this information, the utilization of varenicline in a smoking cessation program should be considered.

Smokers who decrease, but do not stop cigarette consumption without the aid of nicotine replacement therapy, continue to acquire equal amounts of nicotine from fewer cigarettes by changing their technique of smoking to maximize nicotine intake.<sup>96</sup> Levels of serum nicotine and cotinine and urinary mutagenesis levels remain unchanged. Thus, *reduction* in the number of cigarettes smoked will likely have little effect on the risk of developing PPCs.<sup>87</sup> Smoking patients should be advised to *stop* smoking 2 months **13** prior to elective operations to maximize their benefit,<sup>86</sup> or for at least 4 weeks to benefit from improved mucociliary function and some reduction in PPC rate. If patients cannot stop smoking for 4 to 8 weeks preoperatively, it is controversial whether they should be advised to stop smoking 24 hours preoperatively. A 24-hour smoking abstinence would allow carboxyhemoglobin levels to fall to normal, but may increase the risk of PPC.

## Postoperative Pulmonary Function

The changes in pulmonary function that occur postoperatively are primarily restrictive, with proportional decreases in all lung volumes and no change in airway resistance. The decrease in FRC, however, is the yardstick by which the severity of the restrictive defect is gauged. This defect is generated by abdominal contents that impinge on and prevent normal movement of the diaphragm, and by an abnormal respiratory pattern devoid of sighs and characterized by shallow, rapid respirations. The normal resting respiratory rate for adults is 12 breaths per minute, whereas the postoperative patient

usually breathes approximately 20 breaths per minute. Furthermore, most (but not all) factors that tend to make the restrictive defect worse are also associated with a higher risk of PPCs.

The operative site is the single most important determinant of postoperative pulmonary dysfunction and the risk of PPCs. **14** Nonlaparoscopic upper abdominal operations cause the most profound restrictive defect, precipitating a 40% to 50% decrease in FRC compared with preoperative levels, when conventional postoperative analgesia is employed. Lower abdominal and thoracic operations cause the next most severe change in pulmonary function, with decreases in FRC to 30% of preoperative levels. Most other operative sites—intracranial, peripheral vascular, otolaryngologic—have approximately the same effect on FRC, with reductions of 15% to 20% of preoperative levels.

### *Postoperative Pulmonary Complications*

 Two problems confound interpretation of the literature examining PPCs. First, there is no clear definition of what constitutes a PPC. For example, some clinical studies include only pneumonia, whereas others add atelectasis and/or ventilatory failure. Thus it is important to discern what complications are specifically being addressed. Second, the criteria by which diagnoses of postoperative pneumonia or atelectasis is made varies from study to study. For this discussion, PPCs include atelectasis and pneumonia only. Reasonable, well-accepted diagnostic criteria for pneumonia include change in the color and quantity of sputum, oral temperature exceeding 38.5°C, and a new infiltrate on chest radiograph.

The operative site is an important risk factor for the development of PPCs. Nonlaparoscopic upper abdominal operations increase PPC risk at least two-fold,<sup>90</sup> with rates of occurrence varying from 20% to 70%.<sup>96</sup> Lower abdominal and intrathoracic operations are associated with slightly less risk, but still higher risk than extremity, intracranial, and head/neck operations.

Patients with COPD are at high risk for PPC. This risk can be minimized by ensuring they do not have an active pulmonary infection, and that any increased airway resistance is minimized by the use of bronchodilator therapy. Interestingly, those with asthma are not at increased risk for atelectasis or pneumonia. However, exacerbation of asthma in the postoperative period can be problematic. Careful attention must be given to ensuring the bronchodilating regimens and steroid administration (either inhaled or systemic) are continued throughout the perioperative period.

There are several strategies to reduce risk of PPC: the use of postoperative lung-expanding therapies, choice of analgesia,<sup>97</sup> and cessation of smoking. After upper abdominal operations, FRC typically recovers over 3 to 7 days.

However, with the use of intermittent CPAP by mask, FRC will recover within 72 hours.<sup>97</sup> Patients correctly use incentive spirometers only 10% of the time unless therapy is supervised.<sup>98</sup> Combinations of deep breathing cough, mobilization, and pain management are as effective as incentive spirometry at preventing PPCs,<sup>99</sup> and they are less expensive than supervised incentive spirometry; thus, they are preferred over incentive spirometry therapy.

After median sternotomy for cardiac operations, FRC does not return to normal for several weeks, regardless of postoperative pulmonary therapy.<sup>100</sup> The persistently low FRC in this population is probably due to mechanical factors such as a widened mediastinum, intrapleural fluid, and altered chest wall compliance. The single most important aspect of postoperative pulmonary care is getting the patient out of bed, preferably walking. **15**

The choice of anesthetic technique for intraoperative anesthesia does not change the risk for PPCs independent of the operative site or duration of the operation. Operations exceeding 3 hours are associated with a higher rate of PPCs. Choice of postoperative analgesia strongly influences the risk of PPCs.<sup>90</sup> The use of postoperative epidural analgesia, particularly for abdominal and thoracic operations, markedly decreases the risk of PPCs, and may decrease length of hospital stay.

Although obesity is associated with marked restrictive defects, it is controversial whether obesity independently increases the risk of PPCs.<sup>101</sup> However, data support<sup>101</sup> advanced age as an independent risk factor for PPCs.

Several authors have attempted to assess the influence of overall health on PPC risk. Indices that weigh and score various aspects of physiology and health demonstrate that patients who are in a poor state of health preoperatively tend to be at higher risk of PPCs.<sup>91</sup>

Patients with obstructive airway disease and decreased expiratory flows may benefit from preoperative bronchodilator therapy and formal pulmonary toilet.<sup>102</sup> High-risk patients with COPD who receive bronchodilation, chest physical therapy, deep breathing, forced oral fluids (>3 L/day), and preoperative instruction in postoperative respiratory techniques, as well as those who stop smoking for more than 2 months preoperatively, experience a PPC rate approximately equal to that observed in normal patients.<sup>103</sup> Interestingly, although such a regimen significantly reduces the incidence of PPCs,<sup>104</sup> airway obstruction and arterial hypoxemia are not measurably reversed during the 48 to 72 hours of preoperative therapy.<sup>105</sup> It is possible that the reduced PPC rate results from the additional attention that these patients receive, rather than from the specific regimen employed.

## KEY POINTS

- 1 The Henderson–Hasselbalch equation describes the relationship between pH, PaCO<sub>2</sub>, and serum bicarbonate. The Henderson equation defines the previous relationship but substitutes calculated hydrogen ion concentration for pH.
- 2 The pathophysiology of metabolic alkalosis is divided into generating and maintenance factors. A particularly important maintenance factor is the renal response to hypovolemia.
- 3 The addition of iatrogenic respiratory alkalosis to metabolic alkalosis can produce severe alkalemia.

- 4 Metabolic acidosis occurs as a consequence of the use of bicarbonate to buffer endogenous organic acids or as a consequence of external bicarbonate loss. The former causes an increase in the anion gap, calculated as  $[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$ .
- 5 When substituting mechanical ventilation for spontaneous ventilation in a patient with severe metabolic acidosis, appropriate ventilatory compensation should be maintained, pending effective treatment of the primary cause for the metabolic acidosis.
- 6 Sodium bicarbonate, never proved to alter outcome in acidemic patients, should be reserved for those patients with severe acidemia.
- 7 Control of blood glucose in critically ill surgical patients has been associated with improvements in clinical outcomes. However, a blood glucose target of 180 mg/dL or less is associated with a lower mortality than a target of 81 to 108 mg/dL.
- 8 In patients undergoing moderate surgical procedures, generous administration of fluids is associated with fewer minor complications, such as nausea, vomiting, and drowsiness.
- 9 In patients undergoing colon surgery, careful perioperative fluid restriction has been associated with lower mortality and better wound healing.
- 10 Homeostatic mechanisms are usually adequate for the maintenance of electrolyte balance. However, critical illnesses and their treatment strategies can cause significant perturbations in electrolyte status, possibly leading to worsened patient outcome.
- 11 Disorders of the concentration of sodium, the principal extracellular cation, depend on the total body water (TBW) concentration and can lead to neurologic dysfunction. Disorders of potassium, the principal intracellular cation, are influenced primarily by insults that result in increased total body losses of potassium or changes in the distribution between extracellular and intracellular compartments.
- 12 Calcium, phosphorus, and magnesium are all essential for maintenance and function of the cardiovascular system. In addition, they also provide the milieu that ensures neuromuscular transmission. Disorders affecting any one of these electrolytes may lead to significant dysfunction and possibly result in cardiopulmonary arrest.

As a consequence of underlying diseases and of therapeutic manipulations, surgical patients develop potentially harmful disorders of acid–base equilibrium, intravascular and extravascular volume, and serum electrolytes. Precise perioperative management of acid–base status, fluids, and electrolytes may limit perioperative morbidity and mortality.

## Acid–Base Interpretation and Treatment

Management of perioperative acid–base disturbances requires an understanding of the four simple acid–base disorders—metabolic alkalosis, metabolic acidosis, respiratory alkalosis, and respiratory acidosis—as well as more complex combinations of disturbances. This section will review the pathogenesis, major complications, physiologic compensatory mechanisms, and treatment of common perioperative acid–base abnormalities.

### Overview of Acid–Base Equilibrium

Conventionally, acid–base equilibrium is described using the Henderson–  
**1** Hasselbalch equation:

$$\text{pH} = 6.1 + \log \frac{[\text{HCO}_3^-]}{0.03 \times \text{PaCO}_2} \quad (16-1)$$

where 6.1 = the pK<sub>a</sub> of carbonic acid and 0.03 is the solubility coefficient in blood of carbon dioxide (CO<sub>2</sub>).<sup>1</sup> Within this context, pH is the dependent variable, while the bicarbonate concentration ([HCO<sub>3</sub><sup>−</sup>]) and PaCO<sub>2</sub> are independent variables; therefore, metabolic alkalosis and acidosis are defined as disturbances in which [HCO<sub>3</sub><sup>−</sup>] is primarily increased or decreased, and respiratory alkalosis and acidosis are defined as disturbances in which PaCO<sub>2</sub> is primarily decreased or increased. pH, the negative logarithm of the hydrogen ion concentration ([H<sup>+</sup>]), defines the acidity or alkalinity of solutions or blood. The simpler Henderson equation, after calculation of [H<sup>+</sup>] from pH, also describes the relationship between the three major variables measured or calculated in blood gas samples:

$$[\text{H}^+] = \frac{24 \times \text{PaCO}_2}{[\text{HCO}_3^-]} \quad (16-2)$$

To approximate the logarithmic relationship of pH to [H<sup>+</sup>], assume that [H<sup>+</sup>] is 40 mmol/L at a pH of 7.4; that an increase in pH of 0.10 pH units reduces [H<sup>+</sup>] to 0.8 × the starting [H<sup>+</sup>] concentration; that a decrease in pH of 0.10 pH units increases the [H<sup>+</sup>] by a factor of 1.25; and that small changes (i.e., <0.05 pH units) produce reciprocal increases or decreases of 1 mmol/L in [H<sup>+</sup>] for each 0.01 decrease or increase in pH units.

The alternative “Stewart” approach to acid–base interpretation distinguishes between the independent variables and dependent variables that determine pH.<sup>2,3</sup> The independent variables are PaCO<sub>2</sub>, the strong (i.e., highly dissociated) ion difference, and the concentration of proteins, which usually are not strong ions. The strong ions include sodium (Na<sup>+</sup>), potassium (K<sup>+</sup>),

chloride ( $\text{Cl}^-$ ), and lactate. The strong ion difference, calculated as  $(\text{Na}^+ + \text{K}^+ - \text{Cl}^-)$ , is approximately 42 mEq/L. Although the Stewart approach provides more insight into the mechanisms underlying acid–base disturbances than does the more descriptive Henderson–Hasselbalch approach, the clinical interpretation or treatment of common acid–base disturbances is rarely handicapped by the simpler constructs of the conventional Henderson–Hasselbalch or Henderson equations.<sup>4</sup>

## Metabolic Alkalosis

Metabolic alkalosis, characterized by hyperbicarbonatemia ( $> 27$  mEq/L) and usually by an alkalemic pH ( $> 7.45$ ), occurs frequently in postoperative and critically ill patients. Factors that generate metabolic alkalosis include vomiting and diuretic administration (Table 16-1).<sup>5</sup> Maintenance of metabolic alkalosis depends on a continued stimulus, such as renal hypoperfusion, hypokalemia, hypochloremia, or hypovolemia, for distal tubular reabsorption of  $[\text{HCO}_3^-]$  (Table 16-2).<sup>5</sup>

Metabolic alkalosis is associated with hypokalemia, ionized hypocalcemia, secondary ventricular arrhythmias, increased digoxin toxicity, and compensatory hypoventilation (hypercarbia), although compensation rarely results in  $\text{PaCO}_2$  above 55 mmHg (Table 16-3). Alkalemia may reduce tissue oxygen availability by shifting the oxyhemoglobin dissociation curve to the left and by decreasing cardiac output.<sup>5</sup> During anesthetic management, inadvertent addition of iatrogenic respiratory alkalosis to pre-existing metabolic alkalosis may produce severe alkalemia and precipitate cardiovascular depression, dysrhythmias, and hypokalemia.

In patients in whom arterial blood gases have not yet been obtained, serum electrolytes and a history of major risk factors, such as vomiting, nasogastric suction, or chronic diuretic use, can suggest metabolic alkalosis. Estimates of  $[\text{HCO}_3^-]$  on serum electrolyte results (often abbreviated as total  $\text{CO}_2$ ) should be about 1 mEq/L greater than  $[\text{HCO}_3^-]$  on simultaneously obtained arterial blood gases. If either calculated  $[\text{HCO}_3^-]$  on the arterial blood gases or “ $\text{CO}_2$ ” on the serum electrolytes exceeds normal (24 and 25 mEq/L, respectively) by more than 4 mEq/L, the patient either has a primary metabolic alkalosis or has conserved bicarbonate in response to chronic hypercarbia. Recognition of hyperbicarbonatemia on the preoperative serum electrolytes justifies arterial blood gas analysis and should alert the anesthesiologist to the likelihood of factors that generate or maintain metabolic alkalosis (Tables 16-1 and 16-2).

**Table 16-1** Generation of Metabolic Alkalosis

Generation	Examples
I. Loss of acid from extracellular space	Vomiting
A. Loss of gastric fluid (HCl)	Primary aldosteronism plus diuretic
B. Acid loss in the urine: Increased distal Na delivery in presence of hyperaldosteronism	Potassium deficiency
C. Acid shifts into cells	Congenital chloride-losing diarrhea
D. Loss of acid into stool	Milk-alkali syndrome
II. Excessive HCO <sub>3</sub> <sup>-</sup> loads	Lactate, acetate, or citrate administration
A. Absolute	NaHCO <sub>3</sub> dialysis
1. Oral or parenteral HCO <sub>3</sub> <sup>-</sup>	Correction (e.g., by mechanical ventilatory support) of chronic hypercapnia
2. Metabolic conversion of the salts of organic acids to HCO <sub>3</sub> <sup>-</sup>	
B. Relative	
III. Posthypercapnic states	

Modified from Khanna A, Kurtzman NA. Metabolic alkalosis. *J Nephrol.* 2006;19(Suppl 9):S86–S96.

**Table 16-2** Factors That Maintain Metabolic Alkalosis

Factor	Proposed Mechanism
Decreased GFR	Increases fractional HCO <sub>3</sub> <sup>-</sup> reabsorption and prevents the elevated plasma [HCO <sub>3</sub> <sup>-</sup> ] from exceeding T <sub>m</sub>
Volume contraction	Stimulates proximal tubular HCO <sub>3</sub> <sup>-</sup> reabsorption
Hypokalemia	Decreases GFR and increases proximal tubular HCO <sub>3</sub> <sup>-</sup> reabsorption; stimulates Na-independent/ K-dependent (low) secretion in CCT
Hypochloremia <sup>a</sup>	Increases renin, decreases GFR, and decreases distal chloride delivery (↑ proton secretion in MCT)
Passive backflux of HCO <sub>3</sub> <sup>-</sup>	Creates a favorable concentration gradient for passive HCO <sub>3</sub> <sup>-</sup> movement from proximal tubular lumen to blood
Aldosterone	Increases Na-dependent proton secretion in CCT and Na-independent proton secretion in CCT and MCT

All factors decrease urinary HCO<sub>3</sub> excretion in vivo.

<sup>a</sup>Animal models are associated with hypokalemia; thus, the precise role of chloride in humans is not clearly understood.

GFR, glomerular filtration rate; CCT, cortical collecting tubule; MCT, medullary collecting tubule. TM, transport maximum for HCO<sub>3</sub><sup>-</sup>.

Modified from Khanna A, Kurtzman NA. Metabolic alkalosis. *J Nephrol.* 2006;19(Suppl 9):S86–S96.

Treatment of metabolic alkalosis consists of etiologic and nonetiologic therapies. Etiologic therapy consists of measures such as expansion of intravascular volume or the administration of potassium. Infusion of 0.9% saline will dose-dependently increase serum [Cl<sup>-</sup>] and decrease serum [HCO<sub>3</sub><sup>-</sup>].<sup>6</sup> Nonetiologic therapy includes administration of acetazolamide (a carbonic anhydrase inhibitor that causes renal bicarbonate wasting), dialysis against a high-chloride/low bicarbonate dialysate or infusion of [H<sup>+</sup>] in the form of ammonium chloride, arginine hydrochloride, or 0.1 N hydrochloric acid (100 mmol/L).<sup>5</sup> Of the previously mentioned factors, 0.1 N hydrochloric

acid most rapidly corrects life-threatening metabolic alkalosis but must be infused into a central vein; peripheral infusion will cause severe tissue damage.

**Table 16-3** Respiratory Compensation in Response to Metabolic Alkalosis and Metabolic Acidosis

## Metabolic Acidosis

Metabolic acidosis, characterized by hypobicarbonatemia (<21 mEq/L) and usually by an acidemic pH (<7.35), can be innocuous or reflect a life-threatening emergency. Metabolic acidosis occurs as a consequence of buffering by bicarbonate of endogenous or exogenous acid loads or as a consequence of abnormal external loss of bicarbonate.<sup>7-9</sup> Approximately 70 mmol of acid metabolites are produced, buffered, and excreted daily; these include about 25 mmol of sulfuric acid from amino acid metabolism, 40 mmol of organic acids, and phosphoric and other acids. Extracellular volume (ECV) in a 70-kg adult contains 336 mmol of bicarbonate buffer (24 mEq/L × 14 L of ECV). Glomerular filtration of plasma volume (PV) necessitates reabsorption of 4,500 mmol of bicarbonate daily, of which 85% is reabsorbed in the proximal tubule and 10% in the thick ascending limb, and the remainder is titrated by proton secretion in the collecting duct.

Calculation of the anion gap [AG; [Na<sup>+</sup>] - ([Cl<sup>-</sup>] + [HCO<sub>3</sub><sup>-</sup>])] distinguishes between two types of metabolic acidosis (Table 16-4).<sup>10</sup> The AG is normal (<13 mEq/L) in situations such as diarrhea, biliary drainage, and renal tubular acidosis, in which bicarbonate is lost externally, and is also normal or reduced in hyperchloremic acidosis associated with perioperative infusion of substantial quantities of 0.9% saline.<sup>6,11</sup> Metabolic acidosis associated with a high AG (>13 mEq/L) occurs because of excess production or decreased excretion of organic acids or ingestion of one of several toxic compounds (Table 16-4). In metabolic acidosis associated with a high AG, bicarbonate ions are consumed in buffering hydrogen ions, while the associated anion replaces bicarbonate in serum. Three quarters of the normal

AG consists of albumin; to correct the calculated AG for hypoalbuminemia, add to the calculated AG the difference between measured serum albumin and normal albumin concentration (4 g/dL) multiplied by 2 to 2.5.<sup>12</sup> The albumin-corrected AG should exceed the normal anion gap by an amount ( $\Delta$ AG) approximately equal to the decrease below normal of serum  $[\text{HCO}_3^-]$  ( $\Delta\text{HCO}_3^-$ ).<sup>13</sup> A ratio of  $\Delta\text{AG}:\Delta\text{HCO}_3^-$  that is below 0.8 or above 1.2 should prompt consideration of a mixed acid–base disturbance.

**Table 16-4** Differential Diagnosis of Metabolic Acidosis

<b>Elevated Anion Gap<sup>a</sup></b>	
<b>Three diseases</b>	
•	Uremia
•	Ketoacidosis
•	Lactic acidosis
<b>Toxins</b>	
•	Methanol
•	Ethylene glycol
•	Salicylates
•	Paraldehyde
<b>Normal Anion Gap<sup>b</sup></b>	
•	Renal tubular acidosis
•	Diarrhea
•	Carbonic anhydrase inhibition
•	Ureteral diversions
•	Early renal failure
•	Hydronephrosis
•	HCl administration
•	Saline administration

<sup>a</sup>Correction of the anion gap for hypoalbuminemia is essential for effective perioperative use.

<sup>b</sup>To correct the anion gap for hypoalbuminemia, add to the calculated anion gap twice the difference between normal serum albumin (4 g/L) and actual serum albumin.

**Table 16-5** Failure to Maintain Appropriate Ventilatory Compensation for Metabolic Acidosis<sup>a</sup>

		Spontaneous Ventilation		Mechanical Hypoventilation
Arterial	pH	7.29		7.13
blood gases	PaCO <sub>2</sub> (mmHg)	29	→ → → → → → →	49
	[HCO <sub>3</sub> <sup>-</sup> ] (mEq/L)	14		16

<sup>a</sup>In the presence of metabolic acidosis, an otherwise modest increase in PaCO<sub>2</sub> may create a life-threatening decrease in pH.

Sufficient reductions in pH may reduce myocardial contractility, increase pulmonary vascular resistance, and decrease systemic vascular resistance. It is particularly important to note that failure of a patient to appropriately hyperventilate in response to metabolic acidosis is physiologically equivalent to respiratory acidosis<sup>7</sup> and suggests clinical deterioration. If a patient with metabolic acidosis requires mechanical ventilation, for example, during general anesthesia, every attempt should be made to maintain an

appropriate level of ventilatory compensation (Table 16-3) until the primary process can be corrected. Table 16-5 illustrates failure to maintain compensatory hyperventilation.

The anesthetic risk associated with metabolic acidosis is proportional to the severity of the underlying process that produces the metabolic acidosis. Although a patient with hyperchloremic metabolic acidosis may be relatively healthy, those with lactic acidosis, ketoacidosis, uremia, or toxic ingestions will be chronically or acutely ill. Preoperative assessment should emphasize volume status and renal function. If shock has caused metabolic acidosis, direct arterial pressure monitoring may be necessary, and preload may require assessment via echocardiography or pulmonary arterial catheterization. Intraoperatively, one should be concerned about the possibility of exaggerated hypotensive responses to drugs and positive pressure ventilation. In planning intravenous fluid therapy, consider that balanced salt solutions tend to increase pH and  $[\text{HCO}_3^-]$  (i.e., by metabolism of lactate to bicarbonate) and 0.9% saline tends to decrease pH and  $[\text{HCO}_3^-]$ .

The treatment of metabolic acidosis consists of treatment of the primary pathophysiologic process, for example, hypoperfusion or hypoxia, and if pH is severely decreased, administration of  $\text{NaHCO}_3^-$ . Hyperventilation, although an important compensatory response to metabolic acidosis, is not a definitive therapy for metabolic acidosis. The initial dose of  $\text{NaHCO}_3$  can be calculated as:

$$\text{NaHCO}_3 (\text{mEq/L}) = \frac{\text{Wt}(\text{kg}) \times 0.3(24 \text{ mEq/L} - \text{Actual } \text{HCO}_3^-)}{2} \quad (16-3)$$

where 0.3 = the assumed distribution space for bicarbonate and 24 mEq/L is the normal value for  $[\text{HCO}_3^-]$  on arterial blood gas determination. The calculation markedly underestimates dosage in severe metabolic acidosis. In infants and children, a customary initial dose is 1 to 2 mEq/kg of body weight.

Both evidence and opinion suggest that  $\text{NaHCO}_3$  should rarely be used to treat acidemia induced by metabolic acidosis.<sup>7,8,14</sup> In critically ill patients with lactic acidosis, there were no important differences between the physiologic effects (other than changes in pH) of 0.9 M  $\text{NaHCO}_3$  and 0.9 M sodium chloride.<sup>15</sup> Importantly,  $\text{NaHCO}_3$  did not improve the cardiovascular response to catecholamines and actually reduced plasma ionized calcium.<sup>15</sup> Although many clinicians choose to administer  $\text{NaHCO}_3$  to patients with persistent lactic acidosis and ongoing deterioration, there are no clinical trials that demonstrate improved outcome. In contrast to  $\text{NaHCO}_3$ , the buffer *tris*-hydroxymethyl aminomethane (THAM) effectively reduces  $[\text{H}^+]$ , does not increase plasma  $[\text{Na}^+]$ , does not generate  $\text{CO}_2$  as a byproduct of buffering,

and does not decrease plasma  $[K^+]$ <sup>16</sup>; however, there is no generally accepted indication for THAM.

## *Respiratory Alkalosis*

Respiratory alkalosis, always characterized by hypocarbia ( $PaCO_2 \leq 35$  mmHg) and usually characterized by an alkalemic pH ( $>7.45$ ), results from an increase in minute alveolar ventilation ( $V_A$ ) that is greater than that required to excrete metabolic  $CO_2$  production. Because respiratory alkalosis may be a sign of pain, anxiety, hypoxemia, central nervous system disease, or systemic sepsis, the development of spontaneous respiratory alkalosis in a previously normocarbic patient requires prompt evaluation. The hyperventilation syndrome, a diagnosis of exclusion, is most often encountered in the emergency department.<sup>17</sup>

Respiratory alkalosis may produce hypokalemia, hypocalcemia, cardiac dysrhythmias, bronchoconstriction, and hypotension, and may potentiate the toxicity of digoxin. In addition, both brain pH and cerebral blood flow are tightly regulated and respond rapidly to changes in  $PaCO_2$ .<sup>18</sup> Doubling  $V_A$  reduces  $PaCO_2$  to 20 mmHg and halves cerebral blood flow; conversely, halving minute ventilation doubles  $PaCO_2$  and doubles cerebral blood flow. Therefore, acute hyperventilation may be useful in neurosurgical procedures to reduce brain bulk and to control intracranial pressure (ICP) during emergent surgery for noncranial injuries associated with acute closed head trauma. In those situations, intraoperative monitoring of arterial blood gases, correlated with capnography, will document adequate reduction of  $PaCO_2$ . Acute profound hypocapnia ( $<20$  mmHg) may produce electroencephalographic evidence of cerebral ischemia. If  $PaCO_2$  is maintained at abnormally high or low levels for 8 to 24 hours, cerebral blood flow will return toward previous levels, associated with a return of cerebrospinal fluid  $[HCO_3^-]$  toward normal.

Treatment of respiratory alkalosis per se is often not required. The most important steps are recognition and treatment of the underlying cause.<sup>17</sup> For instance, correction of hypoxemia or effective management of sepsis should result in resolution of the associated increases in respiratory drive. Preoperative recognition of chronic hyperventilation necessitates intraoperative maintenance of a similar  $PaCO_2$ .

## *Respiratory Acidosis*

Respiratory acidosis, always characterized by hypercarbia ( $PaCO_2 >45$  mmHg) and usually characterized by a low pH ( $<7.35$ ), occurs because of a decrease in  $V_A$ , an increase in production of carbon dioxide ( $VCO_2$ ) or both,

from the equation:

$$P_{aCO_2} = K \frac{V_{CO_2}}{V_A} \quad (16-4)$$

where  $K$  = constant (rebreathing of exhaled, carbon dioxide-containing gas may also increase  $P_{aCO_2}$ ). Respiratory acidosis may be either acute, without compensation by renal  $[HCO_3^-]$  retention, or chronic, with  $[HCO_3^-]$  retention, offsetting the decrease in pH (Table 16-6). A reduction in  $V_A$  may be due to an overall decrease in total minute ventilation ( $V_E$ ) or to an increase in the amount of wasted ventilation ( $V_D$ ), according to the equation:

$$V_A = V_E - V_D \quad (16-5)$$

Decreases in  $V_E$  may occur because of central ventilatory depression by drugs or central nervous system injury, because of increased work of breathing, or because of airway obstruction or neuromuscular dysfunction. Increases in  $V_D$  occur with chronic obstructive pulmonary disease, pulmonary embolism, decreased cardiac output, and most forms of respiratory failure.  $V_{CO_2}$  may be increased by sepsis, high-glucose parenteral feeding, or fever.

Patients with chronic hypercarbia due to intrinsic pulmonary disease require careful preoperative evaluation. The ventilatory restriction imposed by upper abdominal or thoracic surgery may aggravate ventilatory insufficiency after surgery. Administration of narcotics and sedatives, even in small doses, may cause hazardous ventilatory depression. Preoperative evaluation should consider direct arterial pressure monitoring and frequent intraoperative blood gas determinations, as well as strategies to manage postoperative pain with minimal doses of systemic opioids. Intraoperatively, a patient with chronically compensated hypercarbia should be ventilated to maintain a normal pH. Inadvertent restoration of normal  $V_A$  may result in profound alkalemia. Postoperatively, prophylactic ventilatory support may be required for selected patients with chronic hypercarbia.

The treatment of respiratory acidosis depends on whether the process is acute or chronic. Acute respiratory acidosis may require mechanical ventilation unless a simple etiologic factor (i.e., narcotic overdose or residual muscular blockade) can be treated quickly. Bicarbonate administration is never indicated unless severe metabolic acidosis is also present or unless mechanical ventilation is ineffective in reducing acute hypercarbia. In contrast, chronic respiratory acidosis is rarely managed with ventilation but rather with efforts to improve pulmonary function. In patients requiring mechanical ventilation for acute respiratory failure, ventilation with a lung-protective strategy may result in hypercapnia, which occasionally may require administration of buffers to avoid excessive acidemia.<sup>19</sup>

**Table 16-6** Changes of  $[\text{HCO}_3^-]$  and pH in Response to Acute and Chronic Changes in  $\text{PaCO}_2$

<sup>a</sup>Hospitalized patients rarely develop chronic compensation for hypocarbia because of stimuli that enhance distal tubular reabsorption of sodium.

## Practical Approach to Acid–Base Interpretation

Rapid interpretation of a patient's acid–base status involves the integration of three sets of data: arterial blood gases, electrolytes, and history. A systematic approach facilitates interpretation (Table 16-7). Acid–base assessment usually can be completed before initiating therapy; however, the first step should be to determine whether there are life-threatening pH disturbances (e.g., respiratory acidosis or metabolic acidosis with  $\text{pH} < 7.1$ ) that require immediate attention.

The second step is to determine whether a patient is acidemic ( $\text{pH} < 7.35$ ) or alkalemic ( $\text{pH} > 7.45$ ). The pH status will usually indicate the predominant primary process, that is, acidosis produces acidemia and alkalosis produces alkalemia. Note that the suffix “-osis” indicates a primary process that, if unopposed, will produce the corresponding pH change. The suffix “-emia” refers to the pH. A compensatory process is not considered an “-osis.” Of course, a patient may have mixed “-oses,” that is, more than one primary process.

The third step is to determine whether the entire arterial blood gas picture is consistent with a simple acute respiratory alkalosis or acidosis (Table 16-6). For example, a patient with acute hypocarbia ( $\text{PaCO}_2$  30 mmHg) would have a pH increase of 0.10 units to a pH of 7.50 and a decrease of calculated  $[\text{HCO}_3^-]$  to 22 mEq/L.

As the fourth step, recognition that changes in  $\text{PaCO}_2$ , pH, and  $[\text{HCO}_3^-]$  which are not consistent with a simple acute respiratory disturbance should prompt consideration of chronic respiratory acidosis ( $\geq 24$  hours) or metabolic acidosis or alkalosis. In chronic respiratory acidosis, pH returns to nearly normal as bicarbonate is retained by the kidneys (Table 16-6), usually

at a ratio of 4 to 5 mEq/L per 10 mmHg chronic increase in PaCO<sub>2</sub>.<sup>20</sup> For example, chronic hypoventilation at a PaCO<sub>2</sub> of 60 mmHg would be associated with an increase in [HCO<sub>3</sub><sup>-</sup>] of 8 to 10 mEq/L so that [HCO<sub>3</sub><sup>-</sup>] would be expected to range from 32 to 34 mEq/L and pH would be expected to be within the low normal range (7.35 to 7.38). If neither an acute nor chronic respiratory change appears to explain the arterial blood gas data, then a metabolic disturbance must also be present.

**Table 16-7** Sequential Approach to Acid–Base Interpretation

1. Is the pH life-threatening, requiring immediate intervention?
2. Is the pH acidemic or alkalemic?
3. Could the entire arterial blood gas picture represent only an acute increase or decrease in PaCO<sub>2</sub>?
4. If the answer to question 3 is “No,” is there evidence of a chronic respiratory disturbance or of an acute metabolic disturbance?
5. If an acute metabolic disturbance is present, is it accompanied by appropriate respiratory compensatory changes?
6. Is an anion gap present?
7. Are the clinical data consistent with the proposed interpretation?

The fifth question addresses respiratory compensation for metabolic disturbances, which occurs more rapidly than renal compensation for respiratory disturbances (Table 16-3). Several general rules describe compensation. First, overcompensation is rare. Second, inadequate or excessive compensation suggests an additional primary disturbance. Third, hypobicarbonatemia associated with an increased anion gap is never compensatory.

The sixth question, whether an anion gap is present, should be assessed even if the arterial blood gases appear straightforward. The simultaneous occurrence of metabolic alkalosis and metabolic acidosis may result in an unremarkable pH and [HCO<sub>3</sub><sup>-</sup>]; therefore, the combined abnormality may only be appreciated by examining the anion gap (if the cause of the metabolic acidosis is associated with a high anion gap). As noted previously, correct assessment of the anion gap requires correction for hypoalbuminemia.<sup>12</sup> Metabolic acidoses associated with increased anion gaps require specific treatments, thus necessitating a correct diagnosis and differentiation from hyperchloremic metabolic acidosis. For instance, if metabolic acidosis results from administration of large volumes of 0.9% saline, no specific treatment of metabolic acidosis would usually be necessary.

The seventh and final question is whether the clinical data are consistent with the proposed acid–base interpretation. Failure to integrate clinical findings with arterial blood gas and plasma electrolyte data may lead to serious errors in interpretation and management.

## Examples

The following two hypothetical cases illustrate the use of the algorithm and rules of thumb previously discussed.

### Example 1

A 65-year-old woman has undergone 12 hours of an expected 16-hour radical neck dissection and flap construction. Estimated blood loss is 1,000 mL. She has received three units of packed red blood cells and 6 L of 0.9% saline. Her blood pressure and heart rate have remained stable while anesthetized with 0.5% to 1% isoflurane in 70:30 nitrous oxide and oxygen. Urinary output is adequate. Arterial blood gas levels are shown in [Table 16-8](#).

The step-by-step interpretation is as follows:

1. The pH requires no immediate treatment.
2. The pH is normal.
3. The arterial blood gases cannot be adequately explained by acute hypocarbia. The predicted pH would be 7.48 and the predicted  $[\text{HCO}_3^-]$  would be 22 mEq/L ([Table 16-6](#)).
4. A metabolic acidosis appears to be present.
5. Patients under general anesthesia with controlled mechanical ventilation cannot compensate for metabolic acidosis. However, spontaneous hypocarbia of this magnitude would represent slight overcompensation for metabolic acidosis ([Table 16-3](#)) and would suggest the presence of a primary respiratory alkalosis.
6. Metabolic acidosis occurring during prolonged anesthesia and surgery could suggest lactic acidosis and prompt additional fluid therapy or other attempts to improve perfusion. However, serum electrolytes reveal an AG that is slightly less than normal ([Table 16-8](#)), suggesting that the metabolic acidosis is probably the result of dilution of the ECV with a high-chloride fluid. Correction of the AG for the serum albumin of 3 g/dL only increases the anion gap to 10 to 11 mEq/L, again consistent with hyperchloremic metabolic acidosis. After differentiation from high-AG metabolic acidoses, hyperchloremic acidosis secondary to infusion of high-chloride fluid usually requires no treatment. The arterial blood gases and serum electrolytes are compatible with the clinical picture.

**Table 16-8** Hyperchloremic Metabolic Acidosis during Prolonged Surgery

Parameter	Value
Arterial blood gases	
pH	7.40
PaCO <sub>2</sub>	32 mmHg
[HCO <sub>3</sub> <sup>-</sup> ]	19 mEq/L
Electrolytes	
[Na <sup>+</sup> ]	140 mEq/L
[Cl <sup>-</sup> ]	114 mEq/L
CO <sub>2</sub>	20 mEq/L
Anion gap	8 mEq/L
Serum albumin	3 g/dL

**Example 2**

A 35-year-old man, 3 days after appendectomy, develops nausea with recurrent emesis persisting for 48 hours. An arterial blood gas reveals the results shown in the third column of [Table 16-9](#).

1. The pH of 7.50 requires no immediate intervention.
2. The pH is alkalemic, suggesting a primary alkalosis.
3. An acute PaCO<sub>2</sub> of 46 mmHg would yield a pH of approximately 7.37; therefore, this is not simply an acute ventilatory disturbance.
4. The patient has a primary metabolic alkalosis as suggested by the [HCO<sub>3</sub><sup>-</sup>] of 35 mEq/L.
5. The limits of respiratory compensation for metabolic alkalosis are wide and difficult to predict for individual patients. The rules of thumb, summarized in [Table 16-3](#), suggest that [HCO<sub>3</sub><sup>-</sup>] + 15 should equal the last two digits of the pH and that the PaCO<sub>2</sub> should increase 5 to 6 mmHg for every 10 mEq/L change in serum [HCO<sub>3</sub><sup>-</sup>]; that is, a pH of 7.50 and a PaCO<sub>2</sub> of 46 mmHg are within the expected range.

**Table 16-9** Metabolic Alkalosis Secondary to Nausea and Vomiting with Subsequent Lactic Acidosis Secondary to Hypovolemia

Parameter	Normal	Metabolic Alkalosis	Metabolic Acidosis
<b>Blood Gases</b>			
pH	7.40	7.50	7.40
PaCO <sub>2</sub> (mmHg)	40	46	40
[HCO <sub>3</sub> <sup>-</sup> ] (mEq/L)	24	35	24
<b>Serum Electrolytes</b>			
[Na <sup>+</sup> ] (mEq/L)	140	140	140
[Cl <sup>-</sup> ] (mEq/L)	105	94	94
CO <sub>2</sub> (mEq/L)	25	36	25
Anion gap (mEq/L)	10	10	21

6. The anion gap is 10 mEq/L.

7. The diagnosis of a primary metabolic alkalosis with compensatory hypoventilation is consistent with the history of recurrent vomiting. Consider how the arterial blood gases could change if vomiting were sufficiently severe to produce hypovolemic shock and lactic acidosis (fourth column of [Table 16-9](#)).

This sequence illustrates the important concept that the final pH, PaCO<sub>2</sub>, and [HCO<sub>3</sub><sup>-</sup>] represent the result of all of the vectors operating on acid–base status. Complex or “triple disturbances” can only be interpreted using a thorough, stepwise approach.

## Fluid Management

### Physiology

#### Body Fluid Compartments

Accurate replacement of fluid deficits necessitates an understanding of the expected volumes of distribution spaces for water, sodium, and colloid. The sum of intracellular volume (ICV; 40% of total body weight), ECV (20% of body weight), equals total body water (TBW), which therefore approximates 60% of total body weight. Plasma volume equals about 3 L, one-fifth of ECV, the remainder of which is interstitial fluid volume (IFV). Red cell volume, approximately 2 L, is part of ICV.

The volume of distribution of sodium-free water is TBW while the distribution volume of infused sodium is ECV. The sodium concentrations ([Na<sup>+</sup>]) in PV and IFV, the two components of the ECV, are approximately 140 mEq/L. The predominant intracellular cation, potassium, has an intracellular concentration ([K<sup>+</sup>]) approximating 150 mEq/L. The volume of distribution for colloid solutions is the ECV. Albumin, the most important oncologically active colloid in the ECV, is unequally distributed in PV (~4 g/dL) and IFV (~1 g/dL). However, the IFV concentration of albumin varies greatly among tissues.

#### Distribution of Infused Fluids

Conventionally, clinical prediction of PV expansion after fluid infusion assumes that body fluid spaces are static. Kinetic analysis of PV expansion replaces the static assumption with a dynamic description. As an example of the static approach, assume that a 70-kg patient has suffered an acute blood loss of 2,000 mL, approximately 40% of the predicted 5 L blood volume. The formula describing the effects of replacement with 5% dextrose in water (D<sub>5</sub>W), lactated Ringer solution, or 5% or 25% human serum albumin is as follows:

$$\text{Expected PV increment} = \frac{\text{volume infused} \times \text{normal PV}}{\text{distribution volume}} \quad (16-6)$$

Calculating the volume of a given fluid required to produce a certain PV increment requires the following rearrangement of the equation:

$$\text{Volume infused} = \frac{\text{expected PV increment} \times \text{distribution volume}}{\text{normal PV}} \quad (16-7)$$

To restore blood volume using D<sub>5</sub>W, assuming a distribution volume for sodium-free water of TBW, requires 28 L:

$$28 \text{ L} = 2 \text{ L} \times 42 \text{ L} / 3 \text{ L} \quad (16-8)$$

where 2 L is the desired PV increment, 42 L = TBW in a 70-kg person, and 3 L is the normal estimated PV.

To restore blood volume using lactated Ringer solution requires 9.1 L:

$$9.1 \text{ L} = 2 \text{ L} \times 14 \text{ L} / 3 \text{ L} \quad (16-9)$$

where 14 L = ECV in a 70-kg person.

If 5% albumin, which exerts colloid osmotic pressure similar to plasma, were infused, the infused volume initially would remain in the PV, perhaps attracting additional interstitial fluid intravascularly. Twenty-five percent human serum albumin, a concentrated colloid, expands PV by approximately 400 mL for each 100 mL infused.

However, these static analyses are simplistic. Infused fluid does not simply equilibrate throughout an assumed distribution volume but is added to a complex system that regulates intravascular, interstitial, and ICV. A more comprehensive kinetic model was proposed by Svensén and Hahn.<sup>21</sup> Kinetic models of intravenous fluid therapy allow clinicians to predict more accurately the time course of volume changes produced by infusions of fluids of various compositions. Kinetic analysis permits estimation of peak volume expansion and rates of clearance of infused fluid and complements analysis of “pharmacodynamic” effects, such as changes in cardiac output or cardiac filling pressures.<sup>22</sup>

Using a kinetic approach to fluid therapy permits analysis of the effects of common physiologic and pharmacologic influences on fluid distribution in experimental animals or humans. For example, in chronically instrumented sheep, fluid infusion during isoflurane anesthesia was associated with greater expansion of extravascular volume than in the conscious state.<sup>23</sup> The kinetics of PV expansion after fluid infusion were similar in conscious and anesthetized sheep, but reduced urinary output under anesthesia was associated with greater expansion of extravascular volume; this effect was attributable to isoflurane and not to mechanical ventilation.<sup>23</sup> Similar studies

in volunteers suggested that the influence of anesthesia on fluid kinetics could be related to lower mean arterial pressures and activation of the renin/angiotensin/aldosterone system.<sup>24</sup> In subsequent studies in sheep, administration of catecholamine infusions before and during fluid infusions profoundly altered intravascular fluid retention, with phenylephrine diminishing and isoproterenol enhancing intravascular fluid retention (Fig. 16-1).<sup>25</sup>

The influence of rapid fluid infusion on the integrity of the endothelial glycocalyx potentially confounds volume kinetic assessment of PV. Rapid infusion of crystalloid fluids can potentially release noncirculating fluid volume that is trapped within the endothelial glycocalyx,<sup>26</sup> resulting in apparent rather than actual plasma dilution.

### **Regulation of Osmolarity and Effective Circulating Volume**

TBW content is the net result of intake and output of water. Water intake includes ingested liquids plus an average of 750 mL ingested in solid food and 350 mL that is generated metabolically. Water output consists of insensible losses (~1,000 mL/day), gastrointestinal losses (100 to 150 mL/day), and urinary output, the volume of which is regulated to maintain TBW. Thirst, the primary mechanism of controlling water intake, is triggered by an increase in body fluid tonicity or by a decrease in effective circulating volume.

**Figure 16-1 A:** Blood hemoglobin (mean  $\pm$  SEM) sampled at three baseline periods during a 30-minute catecholamine infusion and for 3 hours after starting a 20-minute 0.9% NaCl bolus of 24 mL/kg. Catecholamine protocols are dopamine (Dopa, *open diamonds*), isoproterenol (Iso, closed circles), phenylephrine (Phen, open triangles), and no-drug control (Control, closed squares). The 0.9% NaCl bolus decreased hemoglobin in all protocols at the end of the 20-minute 0.9% NaCl infusion and in all protocols except the Phen protocol thereafter. Postinfusion protocol differences were Phen > Dopa = Control > Iso. **B:** Calculated blood volume (mean  $\pm$  SEM) at three baseline periods during a catecholamine infusion and for 3 hours after starting a 20-minute 0.9% NaCl bolus of 24 mL/kg. The 0.9% NaCl bolus increased blood volume in all protocols at T<sub>20</sub> and in all protocols except the Phen protocol thereafter. Postinfusion protocol differences were Iso > Dopa = Control > Phen. NS, normal saline bolus. (Adapted with permission from Vane LA, Prough DS, Kinsky MA, et al. Effects of different catecholamines on the dynamics of volume expansion of crystalloid infusion. *Anesthesiology*. 2004;101:1136–1144.)

Renal reabsorption of filtered water and sodium is regulated by the renin/angiotensin/aldosterone system, antidiuretic hormone (ADH), and natriuretic peptides.<sup>27</sup> Renal water handling has three important components: (1) delivery of tubular fluid to the diluting segments of the nephron, (2)

separation of solute and water in the diluting segment, and (3) variable reabsorption of water in the collecting ducts. In the descending loop of Henle,  water is reabsorbed while solute is retained to achieve a final osmolality of tubular fluid of approximately 1,200 mOsm/kg (Fig. 16-2). This concentrated fluid is then diluted by the active reabsorption of sodium via the NaKCl<sub>2</sub> transporter in the ascending limb of the loop of Henle<sup>28</sup> and via the Na/Cl transporter in the distal tubule, both of which are relatively impermeable to water. Within the collecting duct, water reabsorption is modulated by ADH (also called *vasopressin*).<sup>29</sup> Vasopressin binds to V<sub>2</sub> receptors (G-protein coupled receptors) along the basolateral membrane of the collecting duct cells; the resulting increased cAMP levels then stimulate the synthesis and insertion of the aquaporin-2 water channel into the apical membrane of collecting duct cells.<sup>30,31</sup>

Plasma hypotonicity suppresses ADH release, resulting in excretion of dilute urine. Hypertonicity stimulates ADH secretion, which increases the permeability of the collecting duct to water and enhances water reabsorption. In response to changing plasma [Na<sup>+</sup>], changing secretion of ADH can vary urinary osmolality from 50 to 1,200 mOsm/kg and urinary volume from 0.4 to 20 L/day (Fig. 16-3).<sup>32</sup> Nonosmotic modulators of ADH secretion include hemodynamic (hypotension, hypovolemia, congestive heart failure, cirrhosis, nephrotic syndrome, and adrenal insufficiency) and nonhemodynamic stimuli (nausea, pain, and medications, including opiates).<sup>33</sup>

Two powerful hormonal systems regulate total body sodium. The natriuretic peptides, ANP, brain natriuretic peptide, and C-type natriuretic peptide, defend against sodium overload<sup>34,35</sup> and the renin–angiotensin–aldosterone axis defends against sodium depletion and hypovolemia. ANP, released from the cardiac atria in response to increased atrial stretch, exerts vasodilatory effects and increases the renal excretion of sodium and water. ANP secretion is decreased during hypovolemia. Even in patients with chronic (nonoliguric) renal insufficiency, infusion of ANP in low, nonhypotensive doses increased sodium excretion and augmented urinary losses of retained solutes.<sup>34</sup>

Aldosterone is the final common pathway in a complex response to decreased effective arterial volume, whether decreased effective arterial volume is absolute or relative, as in edematous states or hypoalbuminemia. In this pathway, decreased stretch in the baroreceptors of the aortic arch and carotid body and stretch receptors in the great veins, pulmonary vasculature, and atria result in increased sympathetic tone. Increased sympathetic tone, in combination with decreased renal perfusion, leads to renin release and formation of angiotensin I from angiotensinogen. Subsequently, in the lungs, angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II, which stimulates the adrenal cortex to synthesize and release aldosterone.<sup>36</sup>

Acting primarily in the distal tubules, high concentrations of aldosterone cause sodium reabsorption and may reduce urinary excretion of sodium nearly to zero. Intrarenal physical factors are also important in regulating sodium balance. Sodium loading decreases colloid osmotic pressure, thereby increasing the glomerular filtration rate (GFR), decreasing net sodium reabsorption, and increasing distal sodium delivery, which, in turn, suppresses renin secretion.

## Fluid Replacement Therapy

### Maintenance Requirements for Water, Sodium, and Potassium

Calculation of maintenance fluid requirements is of limited value in determining intraoperative fluid requirements. However, calculation of maintenance fluid requirements (Table 16-10) is useful for estimating water and electrolyte deficits that result from preoperative restriction of oral food and fluids and for estimating the ongoing requirements for patients with prolonged postoperative bowel dysfunction. In healthy adults, sufficient water is required to balance gastrointestinal losses (100 to 200 mL/day), insensible losses (500 to 1,000 mL/day), and urinary losses of 1,000 mL/day. Urinary losses exceeding 1,000 mL/day may represent an appropriate physiologic response to ECV expansion or pathophysiologic inability to conserve salt or water.

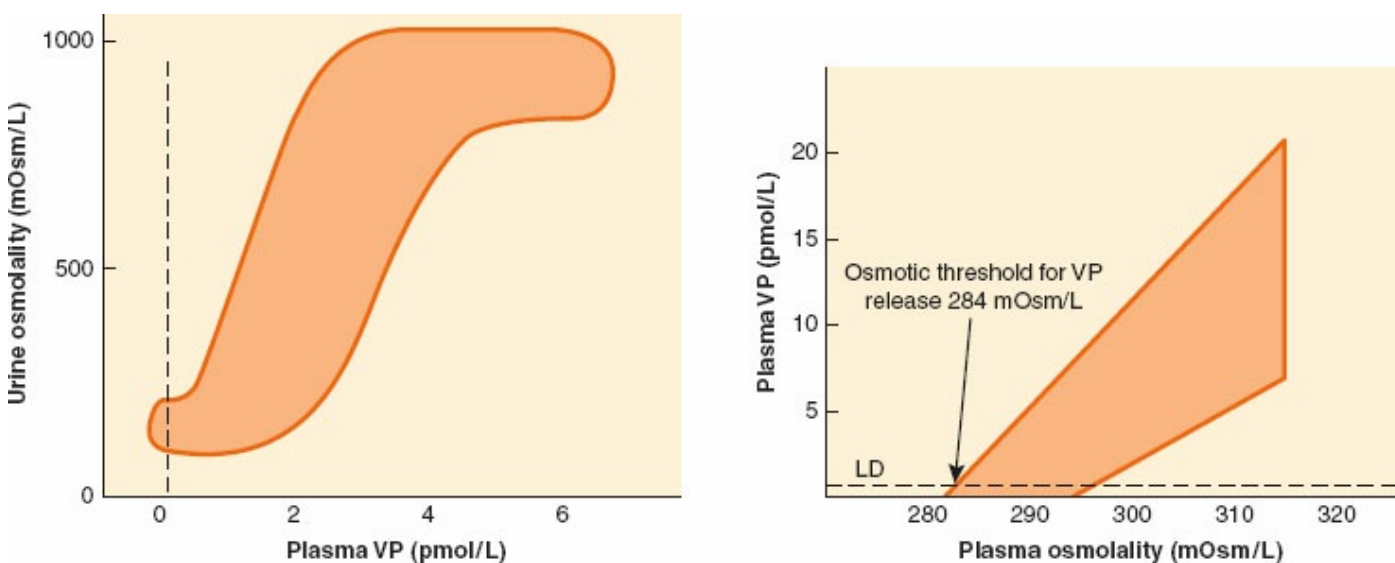

**Figure 16-2** Renal filtration, reabsorption, and excretion of water. *Open arrows* represent water and *solid arrows* represent electrolytes. Water and electrolytes are filtered by the glomerulus. In the proximal tubule (1), water and electrolytes are absorbed isototically. In the descending loop of Henle (2), water is absorbed to achieve osmotic equilibrium with the interstitium while electrolytes are retained. The numbers (300, 600, 900, and 1,200) between the descending and ascending limbs represent the osmolality of the interstitium in milliosmoles per kilogram. The delivery of solute and fluid to the distal nephron is a function of proximal tubular reabsorption; as proximal tubular

reabsorption increases, delivery of solute to the medullary (3a) and cortical (3b) diluting sites decreases. In the diluting sites, electrolyte-free water is generated through selective reabsorption of electrolytes while water is retained in the tubular lumen, generating a dilute tubular fluid. In the absence of vasopressin, the collecting duct (4a) remains relatively impermeable to water and diluted urine is excreted. When vasopressin acts on the collecting ducts (4b), water is reabsorbed from these vasopressin-responsive nephron segments, allowing the excretion of concentrated urine. (Adapted with permission from Fried LF, Palevsky PM. Hyponatremia and hypernatremia. *Med Clin North Am.* 1997;585–609.)

Daily adult requirements for sodium and potassium are approximately 75 and 40 mEq respectively, although wider ranges of sodium intake than potassium intake are physiologically tolerated because renal sodium conservation and excretion are more efficient than potassium conservation and excretion. Therefore, healthy, 70-kg adults require 2,500 mL/day of water containing  $[\text{Na}^+]$  of 30 mEq/L and  $[\text{K}^+]$  of 15 to 20 mEq/L. Intraoperatively, fluids containing sodium-free water (i.e.,  $[\text{Na}^+] < 130$  mEq/L) are rarely used in adults because of the necessity for replacing isotonic losses and the risk of postoperative hyponatremia.<sup>37–40</sup>

**Figure 16-3 Left:** The sigmoid relationship between plasma vasopressin (VP) and urinary osmolality. Data were obtained during water loading and fluid restriction in a group of healthy adults. Maximum urinary concentration is achieved by plasma VP values of 3 to 4 pmol/L. **Right:** The linear relationship between plasma osmolality and plasma VP. Increases in VP in response to hypertonicity induced by infusion of 855 mmol/L saline in a group of healthy adults. The *shaded area* represents the reference range response. LD represents the limit of detection of the VP assay, 0.3 pmol/L. (Adapted with permission from Ball SG. Vasopressin and disorders of water balance: the physiology and pathophysiology of vasopressin. *Ann Clin Biochem.* 2007;44:417–431.)

## Dextrose

Traditionally, glucose-containing intravenous fluids have been given in an effort to prevent hypoglycemia and limit protein catabolism. However, because of the hyperglycemic response associated with surgical stress, only infants and patients receiving insulin or drugs that interfere with glucose synthesis are at risk for hypoglycemia. Iatrogenic hyperglycemia can limit the effectiveness of fluid resuscitation by inducing an osmotic diuresis and, in animals, may aggravate ischemic neurologic injury.<sup>41</sup> Although associated with worsened clinical outcome after subarachnoid hemorrhage<sup>42</sup> and traumatic brain injury,<sup>43</sup> hyperglycemia may also constitute a hormonally mediated response to more severe injury. In a meta-analysis of studies **7** performed in critically ill patients, targeted blood glucose management, at a target of 180 mg/dL or less, was associated with reduced mortality and morbidity in comparison with a tighter control target of 81 to 108 mg/dL.<sup>44</sup>

**Table 16-10** Hourly and Daily Maintenance Water Requirements

Weight (kg)	Water (mL/kg/hr)	Water (mL/kg/day)
1–10	4	100
11–20	2	50
21–n†	1	20

## Surgical Fluid Requirements

### Water and Electrolyte Composition of Fluid Losses

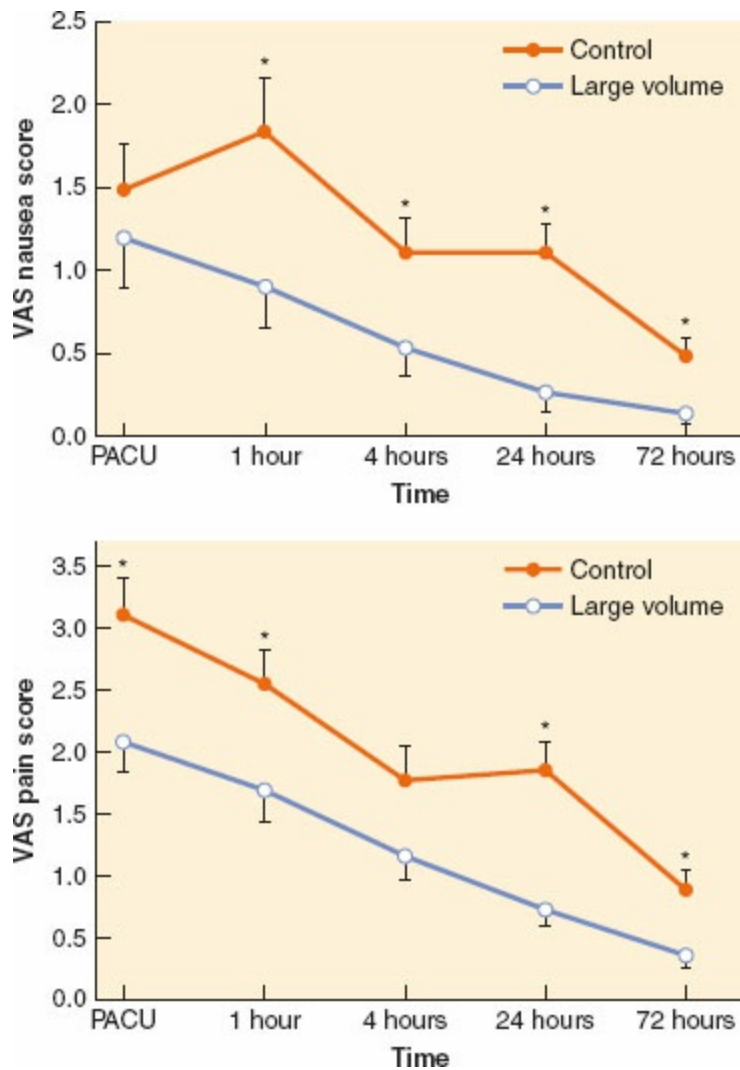

Surgical patients require replacement of PV and ECV losses secondary to wound or burn edema, ascites, and gastrointestinal secretions. The fluid composition of wound and burn edema and ascitic fluid is protein-rich, with electrolyte concentrations similar to those of plasma. Although gastrointestinal secretions vary greatly in composition, the composition of replacement fluid need not be closely matched if ECV is adequate and renal and cardiovascular functions are normal. Substantial loss of gastrointestinal fluids requires more accurate replacement of electrolytes (i.e., potassium, magnesium, phosphate). Chronic gastric losses may produce hypochloremic metabolic alkalosis that can be corrected with 0.9% saline; chronic diarrhea may produce hyperchloremic metabolic acidosis that may be prevented or corrected by infusion of fluid containing bicarbonate or bicarbonate substrate (e.g., lactate). If cardiovascular or renal function is impaired, more precise replacement may require frequent assessment of serum electrolytes.

### Influence of Perioperative Fluid Infusion Rates on Clinical Outcomes

Conventionally, intraoperative fluid management included replacement of fluid (“third space fluid”) that was assumed to accumulate extravascularly in **8** surgically manipulated tissue.<sup>45</sup> Until recently, perioperative clinical practice included, in addition to replacement of estimated blood loss, 4 to 6 mL/kg/hr for procedures involving minimal tissue trauma, 6 to 8 mL/kg/hr for those involving moderate trauma, and 8 to 12 mL/kg/hr for those involving severe trauma.

However, clinical trials strongly link perioperative fluid management to both minor and major morbidities. Moreover, the influence of fluid volume **9** and composition appear to be specific to the type of surgery used .

Maharaj et al.<sup>46</sup> randomized 80 ASA I–II patients scheduled for gynecologic laparoscopy to either large volume, defined as 2 mL/kg/hr of fasting over 20 minutes preoperatively (e.g., 1,440 mL/60 kg in a patient who had been fasting for 12 hours) or small volume, defined as total fluid of 3 mL/kg over 20 minutes preoperatively. In patients receiving the higher dose, postoperative nausea and vomiting and pain were significantly reduced (Fig. 16-4).<sup>46</sup> Holte et al.<sup>47</sup> randomized 48 ASA I–II patients undergoing laparoscopic cholecystectomy to receive either 15 or 40 mL/kg of lactated Ringer solution intraoperatively; the higher dose of fluid was associated with improved postoperative pulmonary function and exercise capacity, reduced neurohumoral stress response, and improvements in nausea, general sense of well-being, thirst, dizziness, drowsiness, fatigue, and balance function. Holte et al.<sup>48</sup> randomized 48 ASA I–III patients undergoing fast-track elective knee arthroplasty under intraoperative epidural/spinal anesthesia and postoperative epidural analgesia to either liberal or restricted fluids. Median intravenous fluid administered intraoperatively and in the postanesthesia care unit in the restrictive group was 1,740 mL (range, 1,100–2,165 mL) of lactated Ringer solution and in the liberal group was 3,275 mL (range, 2,400–4,000 mL). Restrictive fluid administration was associated with a higher incidence of vomiting but less hypercoagulability and no difference in short-term postoperative mobility or ileus. Therefore, in patients undergoing surgery of limited scope, fluid restriction appears to be less well tolerated than more liberal fluid therapy, but perhaps at the expense of hypercoagulability.

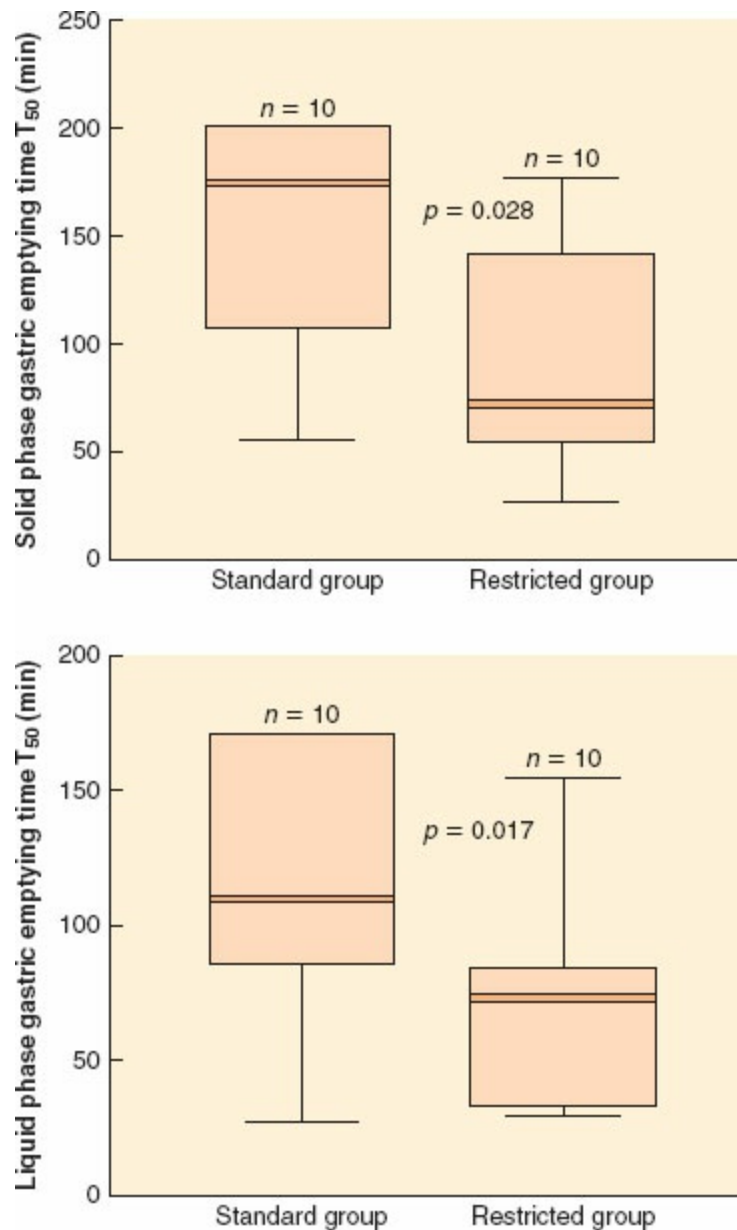

**Figure 16-4 Top:** Mean postoperative verbal analogue scale (VAS) nausea scores in each group over the first 72 postoperative hours. Mean VAS nausea scores were significantly lower in the group that received the large-volume intravenous fluid infusion compared with the control group at 1, 4, 24, and 72 hours postoperatively. **Bottom:** Mean postoperative VAS pain scores in each group over the first 72 postoperative hours. Mean VAS pain scores were significantly lower in the group that received the large-volume intravenous fluid infusion compared with the control group at 0, 1, 24, and 72 hours postoperatively. \*Significantly higher ( $p < 0.05$ ,  $t$ -test postanalysis of variance) VAS score compared with the large volume group. PACU, postanesthesia care unit. (Adapted with permission from Maharaj CH, Kallam SR, Malik A, et al. Preoperative intravenous fluid therapy decreases postoperative nausea and pain in high risk patients. *Anesth Analg.* 2005;100:675–682.)

In patients undergoing major intra-abdominal surgery, recent randomized controlled trials also suggest that restrictive fluid administration is associated with a combination of positive and negative effects. Brandstrup et al.<sup>49</sup> randomized 172 elective colon surgery patients to either restrictive perioperative fluid management or standard perioperative fluid management, with the primary goal of maintaining preoperative body weight in the fluid-restricted group. By design, the fluid-restricted group received less

perioperative fluid and gained less than 1 kg (the weight of 1 L of fluid), in contrast to more than 3 kg in the standard therapy group. More importantly, cardiopulmonary complications, tissue-healing complications, and total postoperative complications were significantly fewer in the fluid-restricted group. In 152 patients undergoing intra-abdominal surgery, including colon surgery, Nisanevich et al.<sup>50</sup> reported less prompt return of gastrointestinal function and longer hospital stays in patients receiving conventional fluid therapy (10 mL/kg/hr of lactated Ringer solution) than in patients receiving restricted fluid therapy (4 mL/kg/hr). In a small clinical trial comparing gastric emptying in patients randomized to receive postoperative fluids at a restricted ( $\leq 2$  L/day of water;  $\leq 77$  mEq/day of  $\text{Na}^+$ ) or liberal regimen ( $\geq 3$  L/day;  $\geq 154$  mEq/day), gastric emptying time for both liquids and solids was significantly reduced in patients receiving restricted fluids (Fig. 16-5).<sup>51</sup> Khoo et al.<sup>52</sup> randomized 70 ASA I–III patients undergoing elective colorectal surgery to conventional perioperative management, including intraoperative fluid management at the discretion of the anesthesiologist, or to multimodal perioperative management, including intraoperative fluid restriction, unrestricted postoperative oral intake, prokinetic agents, early ambulation, and postoperative epidural analgesia. Multimodal perioperative management was associated with a reduced median stay (5 vs. 7 days) and fewer cardiorespiratory and anastomotic complications, but more hospital readmissions. Holte et al.<sup>53</sup> randomized 32 ASA I–III patients undergoing “fast-track” colon resection under combined epidural/general anesthesia to intraoperative fluid administration using either a restrictive (median: 1,640 mL; range: 935 to 2,250 mL) or liberal (median: 5,050 mL; range: 3,563 to 8,050 mL) regimen. Fluid-restricted patients had significantly improved postoperative forced vital capacity and fewer, less severe episodes of oxygen desaturation, but at the expense of increased stress responses (aldosterone, ADH, and angiotensin II measurements), and a statistically insignificantly increased number of complications. In a recent meta-analysis, Corcoran et al.<sup>54</sup> reviewed 23 randomized trials involving 3,861 patients assigned to liberal or goal-directed therapy during major surgery. Patients in both the liberal and goal-directed therapy groups received more fluid during surgery than their respective comparative groups (restrictive fluid administration). However, the patients in the liberal groups had a higher risk of pneumonia (risk ratio 2.2), pulmonary edema (risk ratio 3.8), and longer hospital stay (mean difference 2 days) than their comparative groups. The patients in the goal-directed therapy groups had a lower risk of pneumonia and renal complications (risk ratio 0.7), and shorter hospital stay (mean difference 2 days) compared to the patients in the non-goal-directed therapy group. These authors concluded that goal-directed fluid therapy was associated with fewer adverse outcomes than non-goal-directed, liberal fluid administration.

However, they also concluded that the data do not establish whether goal-directed fluid therapy is superior to non-goal-directed restrictive fluid therapy.

**Figure 16-5** Solid and liquid phase gastric emptying times ( $T_{50}$ ) after 4 days of standard or restricted intravenous postoperative fluid therapy. *Solid lines* are medians, *shaded areas* interquartile ranges, and *whiskers* represent extreme values. Differences between medians for solid and liquid phase  $T_{50}$  were 56 minutes (95% confidence interval: 12 to 132 minutes) and 52 minutes (9 to 95 minutes), respectively. (Adapted with permission from Lobo DN, Bostock KA, Neal KR, et al. Effect of salt and water balance on recovery of gastrointestinal function after elective colonic resection: a randomised controlled trial. *Lancet*. 2002;359:1812.)

Critically ill patients with acute lung injury represent an important group that may benefit from careful regulation of fluid intake. The ARDS Clinical Trials Network<sup>55</sup> randomized 1,000 patients with acute lung injury to a 7-day

trial comparing a conservative fluid strategy with a liberal fluid strategy. Over the course of the trial the conservative strategy group had a cumulative net fluid balance that was slightly negative in comparison to a mean net cumulative fluid balance in the liberal group of nearly 7 L. Although overall mortality was no different in the two groups, the conservative fluid group had improved oxygenation and required fewer days of mechanical ventilation and intensive care. Despite achieving a negative fluid balance, the conservative strategy group had no greater incidence of acute renal failure.

## Colloids, Crystalloids, and Hypertonic Solutions

### Physiology and Pharmacology

Osmotically active particles attract water across semipermeable membranes until equilibrium is attained. *Osmolarity* is defined as the number of osmotically active particles per *liter* of solvent; *osmolality*, defined as the number of osmotically active particles per *kilogram*, can be estimated as follows:

$$\text{Osmolality} = ([\text{Na}^+] \times 2) + (\text{Glucose}/18) + (\text{BUN}/2.8) \quad (16-10)$$

where osmolality is expressed in mmol/kg,  $[\text{Na}^+]$  is expressed in mEq/L, serum glucose is expressed in mg/dL, and BUN is blood urea nitrogen expressed in mg/dL. Sugars, alcohols, and radiographic dyes increase measured osmolality, generating an increased “osmolal gap” between the measured and calculated values.

High concentrations of osmotically active particles lead to hyperosmolar states. Both uremia (increased BUN) and hypernatremia (increased serum sodium) increase serum osmolality. However, because urea distributes throughout TBW, an increase in BUN does not cause *hypertonicity*. Sodium, largely restricted to the ECV, causes hypertonicity, that is, osmotically mediated redistribution of water from ICV to ECV. The term *tonicity* is also used colloquially to compare the osmotic pressure of a parenteral solution to that of plasma.

Although only a small proportion of the osmotically active particles in blood consist of plasma proteins, those particles are essential in determining the equilibrium of fluid between the interstitial and plasma compartments of ECV. The reflection coefficient ( $\sigma$ ) describes the permeability of capillary membranes to individual solutes, with 0 representing free permeability and 1 representing complete impermeability. The reflection coefficient for albumin ranges from 0.6 to 0.9 in various capillary beds. Because capillary protein concentrations exceed interstitial concentrations, the osmotic pressure exerted by plasma proteins (termed *colloid osmotic pressure* or *oncotic pressure*) is

higher than interstitial oncotic pressure and tends to preserve PV. The filtration rate of fluid from the capillaries into the interstitial space is the net result of a combination of forces, including the gradient from intravascular to interstitial colloid osmotic pressures and the hydrostatic gradient between intravascular and interstitial pressures. The net fluid filtration at any point within a systemic or pulmonary capillary is approximated by Starling law of capillary filtration, as expressed in the equation:

$$Q = kA [(P_c - P_i) + \sigma(\pi_i - \pi_c)] \quad (16-11)$$

where  $Q$  = fluid filtration,  $k$  = capillary filtration coefficient (conductivity of water),  $A$  = area of the capillary membrane,  $P_c$  = capillary hydrostatic pressure,  $P_i$  = interstitial hydrostatic pressure,  $\sigma$  = the reflection coefficient for albumin,  $\pi_i$  = interstitial colloid osmotic pressure, and  $\pi_c$  = capillary colloid osmotic pressure. However, it is important to note that the Starling law does not account for the influence on fluid filtration of the capillary glycocalyx, which is strongly influenced by disease processes and fluid administration.<sup>56</sup> Attachment of albumin to the endothelial glycocalyx results in the colloid osmotic pressure gradient actually being the difference between  $\pi_c$  and the colloid osmotic pressure in the space between the endothelial glycocalyx and the capillary wall.<sup>57</sup>

The IFV is determined by the relative rates of capillary filtration and lymphatic drainage.  $P_c$ , the most powerful factor promoting fluid filtration, is determined by capillary flow, arterial resistance, venous resistance, and venous pressure. If capillary filtration increases, the rates of water and sodium filtration usually exceed protein filtration, resulting in preservation of  $\pi_c$ , dilution of  $\pi_i$ , and preservation of the oncotic pressure gradient, the most powerful factor opposing fluid filtration. When coupled with increased lymphatic drainage, preservation of the oncotic pressure gradient limits the accumulation of IF. If  $P_c$  increases at a time when lymphatic drainage is maximal, then IFV accumulates, forming edema. However, because of the influence of the glycocalyx, theoretical rates of fluid filtration usually substantially exceed actual filtration rates, a phenomenon termed the “low lymph flow paradox.”<sup>57</sup>

### **Clinical Implications of Choices between Alternative Fluids**

If membrane permeability is intact, colloids such as albumin or hydroxyethyl starch (HES) preferentially expand PV rather than IFV. Concentrated colloid-containing solutions (e.g., 25% albumin) exert sufficient oncotic pressure to translocate substantial volumes of IFV into the PV, thereby increasing PV by a volume that exceeds the original infused volume. PV expansion unaccompanied by IFV expansion offers apparent advantages: Lower fluid

requirements, less peripheral and pulmonary edema accumulation, and reduced concern about the cardiopulmonary consequences of later fluid mobilization (Table 16-11). However, exhaustive research has failed to establish the superiority of either colloid-containing or crystalloid-containing fluids for either intraoperative or postoperative use.

Despite the lack of conclusive evidence of efficacy, albumin has been used in critically ill patients for decades.<sup>58</sup> In patients with sepsis or septic shock, the Early Albumin Resuscitation during Septic Shock (EARSS) study<sup>59</sup> and the Albumin Italian Outcome Sepsis (ALBIOS) trial<sup>60</sup> failed to find any overall difference in mortality. However, in the ALBIOS trial, time to discontinue vasoactive agents was shorter in the albumin group and, in a post hoc analysis, the subgroup of patients presenting with septic shock had a significantly reduced 90-day mortality if they received albumin. This benefit remained after adjustment of confounding variables.<sup>61</sup>

Meta-analyses have generated conflicting information regarding the influence of albumin administration on outcome. In burn patients who received albumin, mortality and the incidence of abdominal compartment syndrome were reduced.<sup>62</sup> In hypoalbuminemic patients who were resistant to diuretics, coadministration of albumin and furosemide transiently improved urinary output and sodium excretion.<sup>63</sup> In a meta-analysis of clinical trials in patients with acute respiratory distress syndrome (ARDS), albumin administration was associated with improved oxygenation but no increase in survival.<sup>64</sup> Overall, the findings of these reviews are confounded by heterogeneity and by the paucity of available clinical data, thus making it more difficult to elucidate the benefit of albumin resuscitation in critically ill patients.

HES, once a commonly used synthetic colloid, has been linked in critically ill patients to increased mortality and morbidity such as coagulopathy, pruritus, nephrotoxicity, and acute renal failure.<sup>65</sup> In the “6S Trial,” HES was associated with an increased risk of death and end-stage renal failure in comparison to Ringer acetate.<sup>66</sup> As a consequence, the Surviving Sepsis Campaign recommended that HES be eliminated from treatment of septic patients.<sup>67</sup> Subsequently, the US Food and Drug Administration banned all marketing of HES due to lack of evidence of clinical benefit in any patient population, with abundant evidence of harm, especially kidney failure. Eventually, HES was recalled from the US market.

**Table 16-11** Claimed Advantages and Disadvantages of Colloid Versus Crystalloid Intravenous Fluids

Solution	Advantages	Disadvantages
Colloid	Smaller infused volume Prolonged increase in plasma volume Less peripheral edema	Greater cost Coagulopathy (dextran > HES) Pulmonary edema (capillary leak states) Decreased GFR Osmotic diuresis (low-molecular-weight dextran) Greater duration of excessive volume expansion
Crystalloid	Lower cost Greater urinary flow Interstitial fluid replacement	Transient increase in intravascular volume Transient hemodynamic improvement Peripheral edema (protein dilution) Pulmonary edema (protein dilution plus high PAOP)

HES, hydroxyethyl starch; GFR, glomerular filtration rate; PAOP, pulmonary arterial occlusion pressure.

### *Colloids and Traumatic Brain Injury*

Two-year follow-up of a subset of 460 patients with traumatic brain injury (Glasgow Coma Scale score  $\leq 13$ ) demonstrated a nearly twofold increased risk of death in patients receiving colloid fluid management.<sup>68</sup> A subsequent secondary analysis suggested that patients receiving 4% albumin had a higher incidence of refractory intracranial hypertension.<sup>69</sup> Van Aken et al.<sup>70</sup> offered a plausible explanation, in that the 4% albumin solution used in the SAFE trial was suspended in a hypo-osmolar carrier solution, so that the adverse effects of the infusion could have been due to reduced osmolality, independent of the colloid content.

Cirrhotic patients may represent a specific subset of patients in whom albumin infusion could be beneficial. In patients with decompensated cirrhosis, infusion of albumin reduced prostaglandin E<sub>2</sub> and improved macrophage function.<sup>71</sup> In rodents with cirrhosis and ascites, albumin improved cardiac function, apparently by reducing production of TNF $\alpha$  and nitric oxide.<sup>72</sup> Clinical trials will be needed to confirm the therapeutic value of albumin in cirrhosis.

### **Implications of Crystalloid and Colloid Infusions on Intracranial Pressure**

Because the cerebral capillary membrane, the blood–brain barrier, is highly impermeable to sodium, abrupt changes in serum osmolality produced by changes in serum sodium produce reciprocal changes in brain water. The effects of acute changes in colloid osmotic pressure are less clear. In anesthetized rabbits, reducing plasma osmolality from 295 to 282 mOsm/kg (which decreases plasma osmotic pressure by  $\sim 250$  mmHg) increased cortical water content and ICP; in contrast, reducing colloid osmotic pressure from 20 to 7 mmHg produced no significant change in either variable.<sup>73</sup> In anesthetized rats subjected to fluid percussion TBI followed by hemorrhage of 20 mL/kg, resuscitation with 90 mL/kg of isotonic lactated Ringer solution was associated with equivalent blood volume expansion to 20 mL/kg of 5%

albumin, but at the expense of higher brain water. Resuscitation with only 50 mL/kg of isotonic lactated Ringer solution did not increase brain water, but also failed to restore blood volume.<sup>74</sup> In this experimental study, the 5% albumin was suspended in a slightly hyperosmolar solution in contrast to the hypo-osmolar 4% solution used in the SAFE clinical trial.<sup>70</sup> Although the role of colloid in resuscitation of brain-injured patients remains unclear, it is appropriate to avoid large volumes of hypo-oncotic fluids such as lactated Ringer solution.<sup>75</sup>

## Clinical Implications of Hypertonic Fluid Administration

An ideal alternative to conventional crystalloid and colloid fluids would be inexpensive, would produce minimal peripheral or pulmonary edema, would generate sustained hemodynamic effects, and would be effective even if administered in small volumes. Hypertonic, hypernatremic solutions, with or without added colloid, appear to fulfill some of these criteria (Table 16-12).

Hypertonic solutions exert favorable effects on cerebral hemodynamics, in part because of the reciprocal relationship between plasma osmolality and brain water.<sup>73</sup> ICP increased during resuscitation from hemorrhagic shock with lactated Ringer solution but remained unchanged if 7.5% saline was infused in a sufficient volume to comparably improve systemic hemodynamics.<sup>76</sup> However, a delayed increase in ICP was reported after hypertonic resuscitation from hypovolemic shock accompanied by an intracranial mass lesion.<sup>77</sup>

Despite concerns about central nervous system dysfunction due to hypertonicity and hypernatremia associated with hypertonic saline, acute increases in serum sodium to 155 to 160 mEq/L produced no apparent harm in hypovolemic trauma patients resuscitated with hypertonic saline.<sup>78</sup> Central pontine myelinolysis, which follows rapid correction of severe, chronic hyponatremia, has not been observed in clinical trials of hypertonic resuscitation. Despite theoretical considerations favoring the use of hypertonic saline in resuscitation of patients with traumatic brain injury, a subsequent randomized trial failed to demonstrate an improvement in outcome.<sup>79</sup>

Will clinicians routinely use hypertonic, or a combination of hypertonic/hyperoncotic, fluids for resuscitation in the future? Pending further preclinical work, the theoretical advantages of such fluids appear most attractive in the acute resuscitation of hypovolemic patients who have decreased intracranial compliance.<sup>80</sup>

Hypertonic solutions are also used to reduce brain water and intracranial volume during neurosurgery and in critical care. Although this goal is conventionally accomplished with mannitol, some clinicians prefer hypertonic

saline solutions.<sup>81,82</sup> Hypertonic saline solutions and mannitol solutions of similar osmolality have similar effects on brain water, intracranial volume, and ICP. However, infusion of hypertonic saline increases intravascular volume, while diuresis secondary to mannitol decreases intravascular volume.<sup>83</sup> While few complications relate specifically to osmotic therapy, acute severe hyperosmolality could, theoretically, precipitate BBB opening. Clinical use of hypertonic saline is associated, as is 0.9% saline, with hyperchloremic acidosis, which usually requires no treatment, but must be differentiated from other causes of metabolic acidosis.

**Table 16-12** Hypertonic Resuscitation Fluids: Advantages and Disadvantages

Solution	Advantages	Disadvantages
Hypertonic crystalloid	Inexpensive Promotes urinary flow Small initial volume Arteriolar dilation Reduced peripheral edema Lower intracranial pressure	Hypertonicity Subdural hemorrhage Transient effect Potential rebound intracranial hypertension
Hypertonic crystalloid plus colloid (in comparison to hypertonic crystalloid alone)	Sustained hemodynamic response Reduced subsequent volume requirements	Added expense Osmotic diuresis Hypertonicity

## Fluid Status: Assessment and Monitoring

For most surgical patients, conventional clinical assessment of the adequacy of intravascular volume is appropriate. For high-risk patients, goal-directed hemodynamic management may be superior.

### Conventional Clinical Assessment

Assessment of blood volume and ECV begins with identification of predisposing factors such as bowel obstruction, preoperative bowel preparation, chronic diuretic use, sepsis, burns, and trauma. Assessment of hypovolemia is mainly based in physical signs that include oliguria, supine hypotension, and a positive tilt test. In general, oliguria implies hypovolemia, keeping in mind that hypovolemic patients can have adequate urinary output and that urinary output can be misleadingly high. Supine hypotension suggests a blood volume deficit greater than 30%, although in elderly or chronic hypertensive patients, an arterial blood pressure within the normal range could represent relative hypotension.

A positive tilt test, defined as an increase in heart rate of at least 20 beats per minute and a decrease in systolic blood pressure of 20 mmHg or more when the subject assumes the upright position, can be falsely negative.

Young, healthy subjects can withstand acute loss of 20% of blood volume while exhibiting only postural tachycardia and variable postural hypotension. In contrast, orthostasis may occur in 20% to 30% of elderly patients despite normal blood volume. In volunteers, withdrawal of 500 mL of blood<sup>84</sup> was associated with a greater increase in heart rate on standing than before blood withdrawal, but with no significant difference in the response of blood pressure or cardiac index.

Laboratory markers of hypovolemia or ECV depletion include azotemia, low urinary sodium, metabolic alkalosis (if hypovolemia is mild), and metabolic acidosis (if hypovolemia is severe). In acute hemorrhage, hematocrit decreases slowly as fluid shifts from the interstitial to the intravascular space and more rapidly during administration of fluids. The sensitivities and specificities of measurements of blood and urinary variables to hypovolemia are poor. Conditions other than hypovolemia that increase BUN include high-protein intake, gastrointestinal bleeding, or accelerated catabolism. Severe liver dysfunction is associated with a low BUN. Serum creatinine (SCr), a product of muscle catabolism, may be misleadingly low in elderly adults, females, and debilitated or malnourished patients. In contrast, in muscular or acutely catabolic patients, SCr may exceed the normal range (0.5 to 1.5 mg/dL) because of greater muscle protein metabolism. SCr is a late marker of acute kidney injury and an insensitive indicator of chronic kidney dysfunction, because 40% to 50% of nephrons must become dysfunctional before SCr exceeds the normal range. A ratio of BUN to SCr exceeding normal (10 to 20) suggests dehydration. In prerenal oliguria, enhanced sodium reabsorption should reduce urinary  $[Na^+]$  to 20 mEq/L or less and enhanced water reabsorption should increase urinary concentration (i.e., urinary osmolality  $>400$  mOsm/kg, urine/plasma creatinine ratio  $>40:1$ ). Although hypovolemia does not generate metabolic alkalosis, ECV depletion is a potent stimulus for the maintenance of metabolic alkalosis. Severe hypovolemia may result in systemic hypoperfusion and lactic acidosis.

### **Intraoperative Clinical Assessment**

Both surgeons and anesthesiologists tend to underestimate blood loss, based on assessment of blood on surgical gauze pads, pooled on the floor, and accumulated in the surgical field and suction containers. Assessment of the adequacy of intraoperative fluid resuscitation integrates multiple clinical variables, including heart rate, blood pressure, urinary output, arterial oxygenation, and pH. In patients receiving potent inhalational agents, maintenance of blood pressure within the normal range implies adequate intravascular volume. When measured, a central venous pressure of 6 to 12 mmHg suggests adequate blood volume. Tachycardia is an insensitive and

nonspecific indicator of hypovolemia that is also altered by anesthetic drugs. In severe hypovolemia, the accuracy of indirect measurements of blood pressure diminishes. Under those circumstances, direct arterial pressure measurements are more accurate than indirect techniques. Arterial cannulation also provides convenient access for obtaining blood samples and assessing pulse pressure variation (PPV) accompanying positive pressure ventilation in the presence of hypovolemia.<sup>85,86</sup>

Urinary output usually declines precipitously during moderate to severe hypovolemia. Therefore, in the absence of glycosuria or diuretic administration, a urinary output of 0.5 to 1.0 mL/kg/hr during anesthesia suggests adequate renal perfusion. Lactic acidosis and acidemia occur only when tissue hypoperfusion becomes severe. Cardiac output can be normal despite severely reduced regional blood flow. Mixed venous hemoglobin desaturation, a specific indicator of poor systemic perfusion, reflects average perfusion in multiple organs and cannot supplant regional monitors such as urinary output.

Assessing the adequacy of intravascular volume and targeting a goal related to intravascular volume are common components of Enhanced Recovery After Surgery (ERAS).<sup>87</sup> Assessing physiologic responses to fluid administration can indicate the adequacy of cardiac preload and facilitate management of hemodynamics. Assessment increasingly depends on dynamic physiologic variables rather than static variables such as central venous pressure. Common physiologic variables that have been developed include PPV, passive leg raising (PLR), the 250-L bolus challenge test,<sup>88</sup> and assessment of corrected flow time (FTc) and descending aortic stroke volume using the esophageal Doppler.<sup>87</sup>

Several clinical studies have shown that goal-directed hemodynamic therapy during high-risk surgery, including cardiac, hip, and major bowel surgery, is associated with improved postoperative outcome.<sup>87,89-91</sup> In general, monitoring techniques are used to estimate whether additional fluid administration will improve cardiac output, hopefully while avoiding excessive fluid administration. If, after PLR or a bolus challenge (250 mL), cardiac output increases over 15%, or a PPV of over 13% decreases below that threshold, an increase in cardiac preload will be associated with an increase in cardiac output. PLR cannot be used in patients with abdominal hypertension or in patients with traumatic brain injury because PLR may increase ICP. PPV requires direct arterial pressure monitoring, full mechanical ventilation with tidal volumes above 8 mL/kg without dyssynchrony, and absence of cardiac arrhythmias.

Esophageal Doppler assessment of blood flow in the descending aorta is another promising technique in measuring adequacy of cardiac preload during high-risk surgical procedures.<sup>92,93</sup> In general, a corrected flow time less than

0.35 second suggests that volume expansion should improve cardiac output, while a corrected flow time greater than 0.4 second suggests that further volume expansion will be ineffective. Using the esophageal Doppler to guide administration of colloid boluses, Venn et al.<sup>94</sup> and Gan et al.<sup>91</sup> have reported shortened length of hospital stay after hip surgery and major surgery, respectively. Of note, Horowitz and Kumar<sup>95</sup> speculated that the infusion of colloid rather than the monitor-driven algorithm was responsible for the improved results. Large multicenter trials are needed in order to ascertain the benefits of the described novel techniques in perioperative outcomes of patients undergoing high-risk surgery.

## Oxygen Delivery as a Goal of Management

Because of the assumption that tissue hypoperfusion could be subclinical, the concept arose that maintenance of systemic oxygen delivery ( $DO_2$ ) above a somewhat arbitrary threshold could limit the frequency and severity of clinically inapparent tissue hypoperfusion. In high-risk surgical patients, a  $DO_2$  index ( $DO_2I$ ) of at least 600 mL  $O_2/m^2/min$  (equivalent to a cardiac index of 3 L/ $m^2/min$ , a [Hgb] of 14 g/dL, and 98% oxyhemoglobin saturation) has been associated with improved outcome.<sup>96</sup> However, there is no apparent benefit for patients other than surgical patients and patients undergoing initial resuscitation from septic shock in the emergency department.<sup>97</sup> In addition, outcome may be strongly influenced by the choice of methods to increase  $DO_2$ , that is, the choice of fluid administration or various inotropic agents. Lobo et al.<sup>98</sup> randomized 50 high-risk patients, defined as elderly patients with coexistent pathologies who were undergoing major elective surgery, to goal-directed hemodynamic therapy ( $DO_2I > 600$  mL  $O_2/m^2/min$ ) intraoperatively and for the first 24 hours postoperatively either with fluids alone or with fluids plus dobutamine. Postoperative cardiovascular complications occurred significantly more frequently in the group receiving fluids alone (13/25, 52%, vs. 4/25, 16%; relative risk, 3.25; 95% CI, 1.22–8.60;  $p < 0.05$ ); in addition, mortality was greater, but not statistically significantly greater in the group receiving fluids alone. Another specific risk associated with use of fluids to achieve goal-oriented resuscitation is an increased incidence of abdominal compartment syndrome in trauma patients.<sup>99</sup>

## Electrolytes

### Sodium

#### Physiologic Role

Sodium, the principal extracellular cation and solute, is essential for generation of action potentials in neurologic and cardiac tissues. **10** Disorders (pathologic increases or decreases) of *total body sodium* are associated with corresponding increases or decreases of ECV and PV. Disorders of sodium *concentration*, that is, hyponatremia and hypernatremia, usually result from relative excesses or deficits, respectively, of water. Regulation of total body sodium and  $[\text{Na}^+]$  is accomplished primarily by the endocrine and renal systems (Table 16-13). Secretion of aldosterone and ANP control *total body sodium*. ADH, which is secreted in response to increased osmolality or decreased blood pressure, primarily regulates  $[\text{Na}^+]$ . Therefore, primary hyperaldosteronism is associated with hypervolemia and with hypertension, but not with abnormal  $[\text{Na}^+]$ .<sup>100,101</sup>

**Table 16-13** Regulation of Total Body Electrolyte Mass and Plasma Concentrations

Electrolyte	Regulated by
Sodium	Total body sodium regulated by aldosterone, ANP, $[\text{Na}^+]$ altered by ADH
Potassium	Total body potassium regulated by aldosterone, intrinsic renal mechanisms; $[\text{K}^+]$ regulated by epinephrine, insulin
Calcium	Both total body calcium and $[\text{Ca}^{++}]$ regulated by PTH, vitamin D
Phosphate	Both total body phosphate and $[\text{HPO}_4^-]$ regulated primarily by renal mechanisms with a minor contribution from PTH
Magnesium	Both total body magnesium and $[\text{Mg}^{++}]$ regulated primarily by renal mechanisms with a minor contribution from PTH and vitamin D

ANP, atrial natriuretic peptide;  $[\text{Na}^+]$ , sodium concentration; ADH, antidiuretic hormone; PTH, parathyroid hormone.

## Hyponatremia

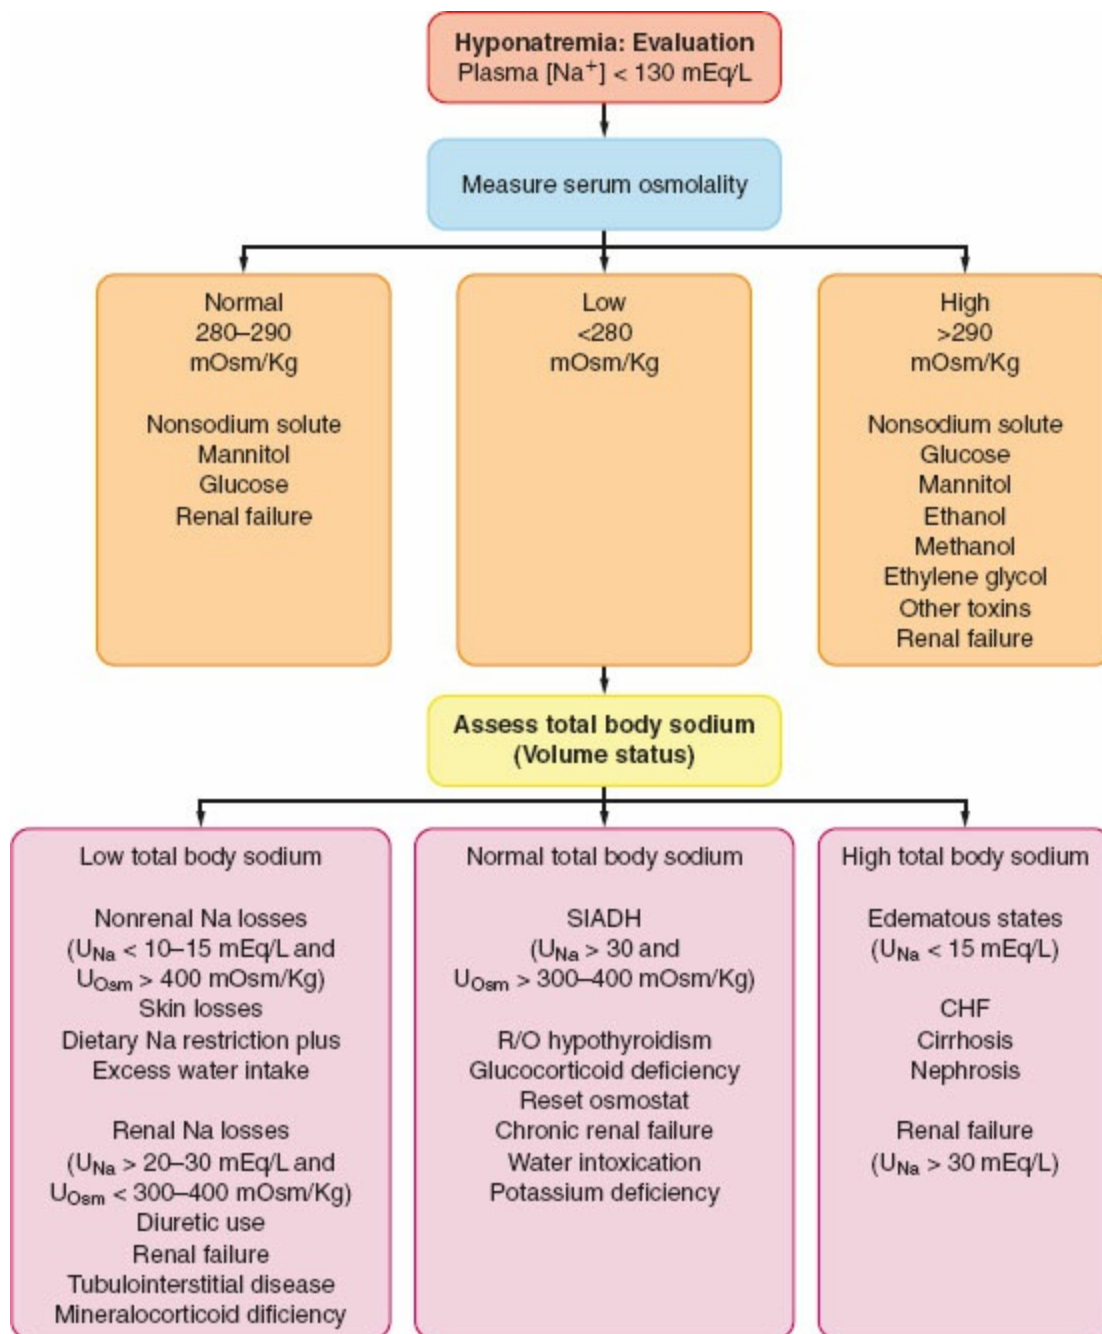

Hyponatremia, defined as  $[\text{Na}^+]$  below 130 mEq/L, is the most common electrolyte disturbance in hospitalized patients.<sup>102</sup> In the majority of hyponatremic patients, total body sodium is normal or increased. The most common clinical scenarios associated with hyponatremia include the postoperative state, acute intracranial disease, malignant disease, medications, and acute pulmonary disease. Recently, hyponatremia, as well as hypokalemia and hypophosphatemia, have been recognized as complications of immunologic treatment of cancers such as hepatocellular carcinoma and melanoma.<sup>103,104</sup> Hyponatremia is associated with increased mortality, both as a direct effect of hyponatremia and because of the association between hyponatremia and severe systemic disease, and with prolonged hospital stay, increased frequency of readmission and increased costs of care.<sup>102</sup>

The signs and symptoms of hyponatremia depend on both the rate and severity of the decrease in plasma  $[\text{Na}^+]$ . Symptoms that can accompany severe hyponatremia ( $[\text{Na}^+] < 120 \text{ mEq/L}$ ) include loss of appetite, nausea, vomiting, cramps, weakness, altered level of consciousness, coma, and seizures.<sup>105</sup>

Acute central nervous system manifestations of hyponatremia result from brain overhydration. Because the blood–brain barrier is poorly permeable to sodium but freely permeable to water, a rapid decrease in plasma  $[\text{Na}^+]$  promptly increases both extracellular and intracellular brain water. Because the brain does not rapidly compensate for changes in osmolality,<sup>106</sup> acute hyponatremia produces more severe symptoms than chronic hyponatremia. The symptoms of chronic hyponatremia probably relate to depletion of brain electrolytes. Once brain volume has compensated for hyponatremia, rapid increases in  $[\text{Na}^+]$  may lead to abrupt brain dehydration.

In hyponatremic patients, serum osmolality may be normal, high, or low (Fig. 16-6). Hyponatremia with a normal or high serum osmolality results from the presence of a nonsodium solute, such as glucose or mannitol, which holds water within the extracellular space and results in dilutional hyponatremia. The presence of a nonsodium solute may be inferred if measured osmolality exceeds calculated osmolality by over 10 mOsm/kg. For example, plasma  $[\text{Na}^+]$  decreases approximately 2.4 mEq/L for each 100 mg/dL rise in glucose concentration, with perhaps even greater decreases at glucose concentration above 400 mg/dL.<sup>107</sup> In anesthesia practice, a common cause of hyponatremia associated with a normal osmolality is the absorption of large volumes of sodium-free irrigating solutions (containing mannitol, glycerin, or sorbitol as the solute) during transurethral resection of the prostate.<sup>108</sup>

**Figure 16-6** Algorithm by which hyponatremia can be evaluated. SIADH, syndrome of inappropriate antidiuretic hormone secretion; R/O, rule out; CHF, congestive heart failure.

Hyposmolality is more important in generating symptoms than is hyponatremia per se.<sup>108</sup> Neurologic symptoms are minimal if mannitol is the unmeasured osmole because mannitol does not cross the blood–brain barrier and is excreted with water in the urine. In contrast, as glycine or sorbitol is metabolized, hyposmolality will gradually develop, and cerebral edema may appear as a late complication. Hyponatremia with a normal or elevated serum osmolality also may accompany renal insufficiency. BUN, included in the calculation of total osmolality, distributes throughout both ECV and ICV. Calculation of *effective* osmolality ( $2[\text{Na}^+] + \text{glucose}/18$ ) excludes the contribution of urea to osmolality and demonstrates true hypotonicity.

Hyponatremia with low serum osmolality may be associated with a high, low, or normal total body sodium and PV. Therefore, hyponatremia with hyposmolality (Fig. 16-6) is evaluated by assessing total body sodium content (volume status), BUN, SCr, urinary osmolality, and urinary  $[\text{Na}^+]$ . Hyponatremia with increased total body sodium is characteristic of edematous states, that is, congestive heart failure, cirrhosis, nephrosis, and renal failure. Aquaporin 2, the vasopressin-regulated water channel, is upregulated in experimental congestive heart failure<sup>109</sup> and cirrhosis<sup>110</sup> and decreased by chronic vasopressin stimulation. In patients with renal insufficiency, reduced urinary diluting capacity can lead to hyponatremia if excess free water is given. In general, diseases that prompt hospitalization generate numerous stimuli for secretion of arginine vasopressin (AVP), suggesting that hyponatremic fluids are rarely indicated for hospitalized patients.<sup>37</sup>

The underlying mechanism of hypovolemic hyponatremia is secretion of AVP (synonymous with ADH) in response to volume contraction in association with ongoing oral or intravenous intake of hypotonic fluid.<sup>111</sup> In patients with hyponatremia, plasma copeptin levels are elevated in both sodium-depleted and sodium-expanded patients but are normal in patients with SIADH.<sup>112,113</sup> Angiotensin II also decreases renal free water clearance. Thiazide diuretics, unlike loop diuretics, promote hypovolemic hyponatremia by interfering with urinary dilution in the distal tubule.<sup>111</sup> Hypovolemic hyponatremia associated with a urinary  $[\text{Na}^+]$  above 20 mmol/L suggests mineralocorticoid deficiency, especially if serum  $[\text{K}^+]$ , BUN, and SCr are increased.<sup>111</sup>

The cerebral salt-wasting syndrome is an often severe, symptomatic salt-losing diathesis that appears to be mediated by brain natriuretic peptide and in which, in contrast to the syndrome of inappropriate antidiuretic hormone secretion (SIADH), secretion of AVP is *appropriate*<sup>111</sup>; patients at risk for the cerebral salt-wasting syndrome include those with cerebral lesions due to trauma, subarachnoid hemorrhage, tumors, and infection. In patients after subarachnoid hemorrhage, administration of hydrocortisone 1,200 mg/day prevented the cerebral salt-wasting syndrome.<sup>114</sup>

 Euvolemic hyponatremia is most commonly associated with nonosmotic vasopressin secretion, for example, glucocorticoid deficiency, hypothyroidism, thiazide-induced hyponatremia, SIADH, and the reset osmostat syndrome.<sup>111</sup> Total body sodium and ECV are relatively normal and edema is rarely evident. SIADH may be idiopathic but also is associated with diseases of the central nervous system and with pulmonary disease (Table 16-14). Euvolemic hyponatremia is usually associated with exogenous AVP administration, pharmacologic potentiation of AVP action, drugs that mimic the action of AVP in the renal tubules, or excessive ectopic AVP secretion. Tissues from some small cell lung cancers, duodenal cancers, and pancreatic cancers increase AVP production in response to osmotic

stimulation.<sup>111</sup>

At least 4% of postoperative patients experience plasma  $[\text{Na}^+]$  below 130 mEq/L. Although neurologic manifestations usually do not accompany mild postoperative hyponatremia, signs of hypervolemia are occasionally present. Much less frequently, postoperative hyponatremia is accompanied by mental status changes, seizures, and transtentorial herniation,<sup>115</sup> attributable in part to intravenous administration of hypotonic fluids, secretion of AVP, and other factors, including drugs and altered renal function that influence perioperative water balance. Women appear to be more vulnerable than men, and premenopausal women appear to be more vulnerable than postmenopausal women to brain damage secondary to postoperative hyponatremia.<sup>105</sup> If AVP is persistently increased, postoperative hyponatremia can develop even with infusion of isotonic fluids.

**Table 16-14** Common Associations with the Syndrome of Inappropriate Antidiuretic Hormone Secretion

<b>Neoplastic Disease</b>
Carcinoma (e.g., lung)
Thymoma
Mesothelioma
Lymphoma, leukemia

If both  $[\text{Na}^+]$  and measured osmolality are below the normal range, hyponatremia is further evaluated by first assessing volume status using physical findings and laboratory data. In hypovolemic patients or edematous patients, the ratio of BUN to SCr should be above 20:1. Urinary  $[\text{Na}^+]$  is generally below 15 mEq/L in edematous states and volume depletion and above 20 mEq/L in hyponatremia secondary to renal salt wasting or renal failure with water retention.

The criteria for the diagnosis of SIADH are listed in [Table 16-15](#). Urinary  $[\text{Na}^+]$  should be above 20 mEq/L unless fluids have been restricted. Arieff<sup>116</sup>

has argued that the diagnosis of SIADH may be inaccurately applied to functionally hypovolemic postoperative patients, in whom, by definition, AVP secretion would be “appropriate.” In addition, the definition of SIADH is changing due to identification of distinctive molecular characteristics that differentiate among patients with SIADH.<sup>117,118</sup>

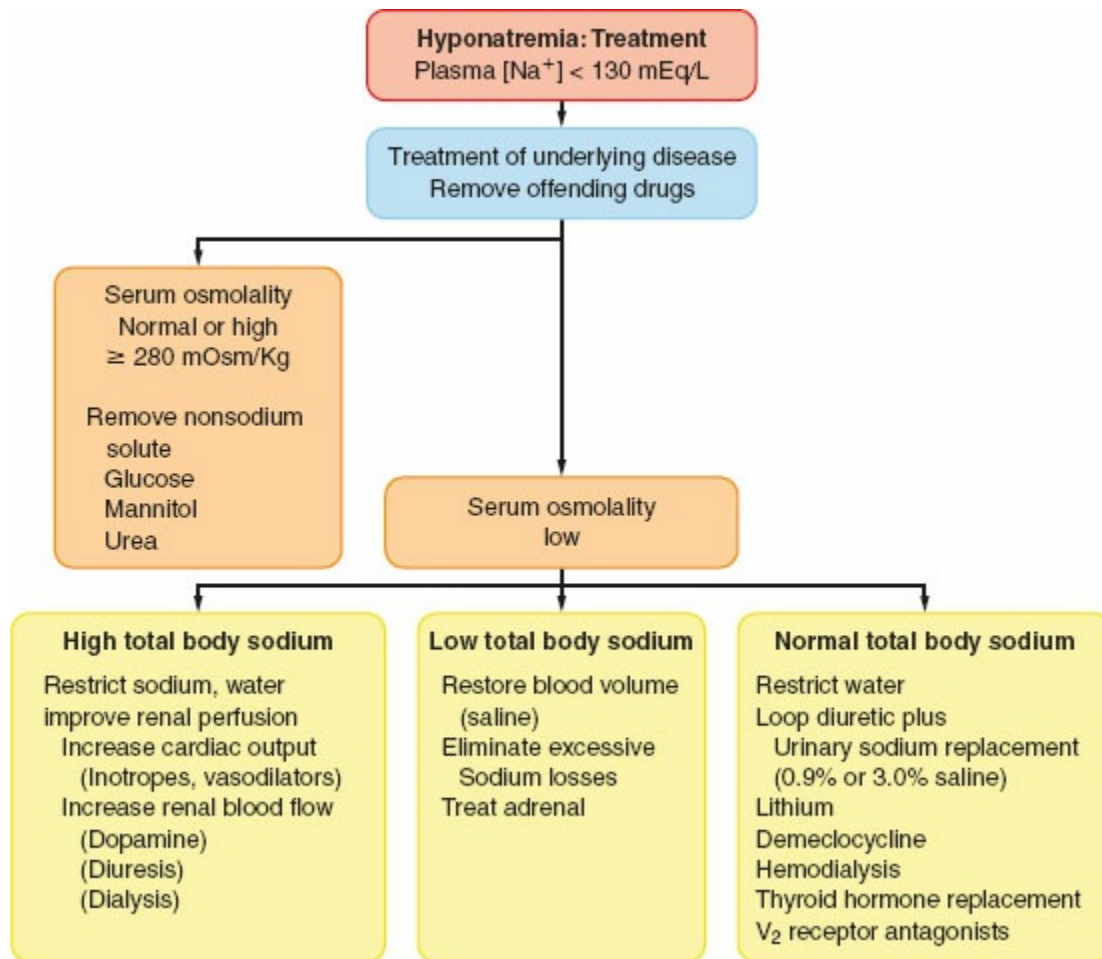

Treatment of hyponatremia associated with a normal or high serum osmolality requires reduction of the elevated concentrations of the responsible solute, for example, urea or mannitol. Uremic patients are treated by free water restriction or dialysis. Treatment of edematous (hypervolemic) patients necessitates restriction of both sodium and water, usually accompanied by efforts to improve cardiac output and renal perfusion and to use diuretics to inhibit sodium reabsorption (Fig. 16-7). In hypovolemic, hyponatremic patients, blood volume must be restored, usually by infusion of 0.9% saline, and excessive sodium losses must be curtailed. Correction of hypovolemia usually results in removal of the stimulus for AVP release, accompanied by a rapid water diuresis.

**Table 16-15** Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone Secretion

Hyponatremia with appropriately low plasma osmolality  
Urinary osmolality greater than plasma osmolality  
Renal sodium excretion >20 mmol/L  
Absence of hypotension, hypovolemia, and edematous states  
Normal renal and adrenal functions  
Absence of drugs that directly influence renal water and sodium handling

Modified from Ball SG. Vasopressin and disorders of water balance: the physiology and pathophysiology of vasopressin. *Ann Clin Biochem.* 2007;44:417–431.

The cornerstone of SIADH management is free water restriction and elimination of precipitating causes. Water restriction, sufficient to decrease TBW by 0.5 to 1 L/day, decreases ECV even if excessive AVP secretion continues. The resultant reduction in GFR enhances proximal tubular reabsorption of salt and water, thereby decreasing free water generation, and stimulates aldosterone secretion. As long as free water losses (i.e., renal, skin, gastrointestinal) exceed free water intake, plasma  $[Na^+]$  will increase. During treatment of hyponatremia, increases in plasma  $[Na^+]$  are determined both by the composition of the infused fluid and by the rate of renal free water excretion. Free water excretion can be increased by administering furosemide.

**Figure 16-7** Hyponatremia is treated according to the etiology of the disturbance, the level of serum osmolality, and a clinical estimation of total body sodium.

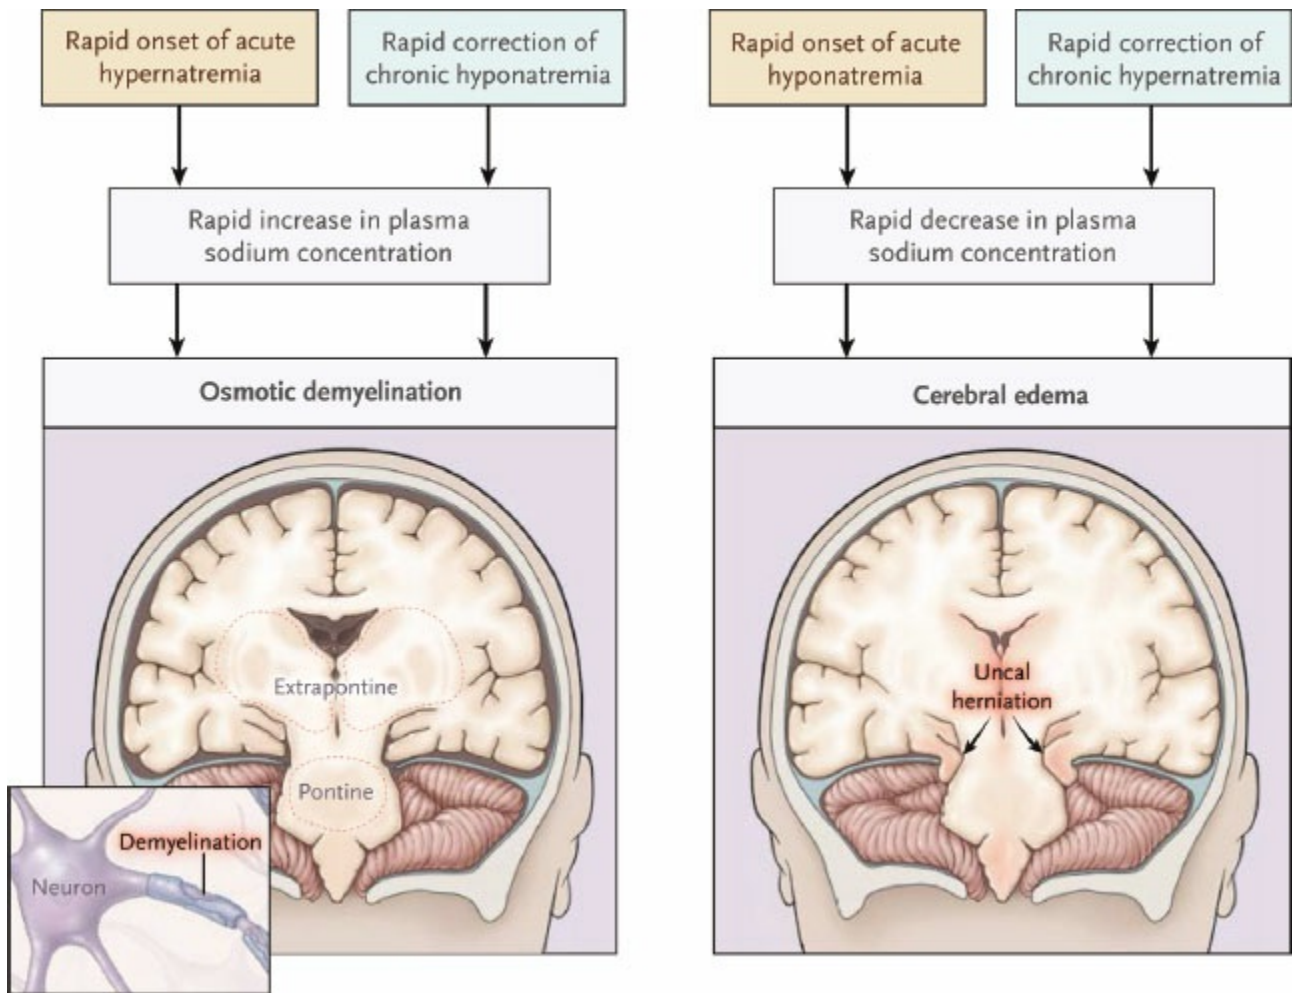

Vasopressin receptor blocking agents inhibit the action of AVP on the renal collecting ducts.<sup>119–122</sup> These agents have proven to be safe and efficacious in hyponatremic patients, appearing to have particular value in patients with hypervolemic hyponatremia secondary to congestive heart failure.<sup>119</sup> Conivaptan, which inhibits both V<sub>1a</sub> and V<sub>2</sub> receptors, has been approved for the treatment of normovolemic and hypervolemic, hyponatremic patients.<sup>121</sup> However, potential decreases in blood pressure associated with V<sub>1a</sub> receptor blockade necessitate caution in patients with borderline low blood pressure.<sup>122</sup> Tolvaptan, a selective V<sub>2</sub> receptor antagonist, also has proven effective in clinical trials.<sup>123</sup> Vaptans are rapidly becoming a mainstay of therapy for normovolemic and hypervolemic hyponatremia.<sup>122,124</sup>

Neurologic symptoms or profound hyponatremia ( $[Na^+] < 115$  to  $120$  mEq/L) require more aggressive therapy. Hypertonic (3%) saline is most clearly indicated in patients who have seizures or who acutely develop symptoms of water intoxication secondary to intravenous fluid administration. In such patients, acute hyponatremia is associated with severe brain swelling that can lead to herniation.<sup>125</sup> In patients with severe neurologic symptoms, 3% saline may be administered at a rate of 1 to 2 mL/kg/hr, to increase plasma  $[Na^+]$  by 1 to 2 mEq/L/hr; however, this

treatment should not continue for more than a few hours with the goal being to increase  $[Na^+]$  by no more than 4 to 8 mEq/L/day.<sup>125</sup> An increase in  $[Na^+]$  of 4 mEq/L is usually sufficient to markedly reduce acute symptoms.<sup>118</sup> Three percent saline may only transiently increase plasma  $[Na^+]$  because ECV expansion results in increased urinary sodium excretion. Intravenous furosemide, combined with quantitative replacement of urinary sodium losses with 0.9% or 3% saline, can rapidly increase plasma  $[Na^+]$ , in part by increasing free water clearance.

The rate of treatment of hyponatremia continues to generate controversy, extending from “too fast, too soon” to “too slow, too late.” Although delayed correction may result in neurologic injury, inappropriately rapid correction may result in abrupt brain dehydration (Fig. 16-8) or permanent neurologic sequelae (i.e., osmotic demyelination syndrome),<sup>126</sup> cerebral hemorrhage, or congestive heart failure. The symptoms of the osmotic demyelination syndrome vary from mild (transient behavioral disturbances or seizures) to severe (including pseudobulbar palsy and quadriparesis). The principal determinants of neurologic injury appear to be the severity and chronicity of hyponatremia and the rate of correction. The osmotic demyelination syndrome is more likely when hyponatremia has persisted for longer than 48 hours. Most patients in whom the osmotic demyelination syndrome is fatal have undergone correction of plasma  $[Na^+]$  of more than 20 mEq/L/day. Other risk factors for the development of osmotic demyelination syndrome include alcoholism, poor nutritional status, liver disease, burns, and hypokalemia.<sup>127</sup>

**Figure 16-8** Rapid correction of either hypernatremia or hyponatremia can cause severe brain injury. Rapid increases in plasma sodium concentration, especially when those increases occur with overzealous correction of chronic hyponatremia, may cause the osmotic demyelination syndrome (also termed central pontine myelinolysis). Rapid reduction of plasma sodium is associated with cerebral edema, which in severe cases may progress to brain herniation, because water crosses the blood–brain barrier freely while sodium crosses minimally. (Reprinted with permission from Sterns RH. Disorders of plasma sodium—causes, consequences, and correction. *N Engl J Med.* 2015;372:55–65.)

The clinician faces formidable difficulties in predicting the rate at which plasma  $[Na^+]$  will increase because increases in plasma  $[Na^+]$  are determined both by the composition of the infused fluid and by the rate of renal free water excretion. The expected change in plasma  $[Na^+]$  resulting from 1 L of selected infusate can be estimated using the following equation<sup>128</sup>:

$$\Delta[Na^+]_s = \frac{[Na^+]_{inf} - [Na^+]_s}{TBW + 1} \quad (16-12)$$

where  $\Delta[Na^+]_s$  = the change in the patient's serum  $[Na^+]$ ,  $[Na^+]_{inf}$  = the  $[Na^+]$  of the infusate,  $[Na^+]_s$  = serum  $[Na^+]$ , TBW = estimated total body water in liters, and 1 is a factor added to take into account the volume of

infusate.

Treatment should be interrupted or slowed when symptoms improve. Frequent determinations of  $[\text{Na}^+]$  are important to prevent correction at a rate above 1 to 2 mEq/L in any 1 hour and above 8 mEq/L in 24 hours.<sup>127</sup> Initially, plasma  $[\text{Na}^+]$  may be increased by 1 to 2 mEq/L/hr; however, the rate of correction should then be slowed to avoid excessively rapid correction. Hypernatremia should be avoided. Once plasma  $[\text{Na}^+]$  exceeds 120 to 125 mEq/L, water restriction alone is usually sufficient to normalize  $[\text{Na}^+]$ . As acute hyponatremia is corrected, central nervous system signs and symptoms usually improve within 24 hours, although 96 hours may be necessary for maximal recovery.

For patients who require long-term pharmacologic therapy of hyponatremia, vasopressin receptor antagonists are the current most promising therapies.<sup>129</sup> Hemodialysis is occasionally necessary in severely hyponatremic patients who cannot be adequately managed with drugs or hypertonic saline. Once hyponatremia has improved, careful fluid restriction is necessary to avoid recurrence of hyponatremia.

## Hypernatremia

Hypernatremia ( $[\text{Na}^+] > 150$  mEq/L) indicates an absolute or relative water deficit.<sup>126</sup> Normally, slight increases in tonicity or  $[\text{Na}^+]$  stimulate thirst and AVP secretion. Therefore, severe, persistent hypernatremia occurs only in patients who cannot respond to thirst by voluntary ingestion of fluid, that is, obtunded patients, anesthetized patients, and infants.

Hypernatremia produces neurologic symptoms (including stupor, coma, and seizures), hypovolemia, renal insufficiency (occasionally progressing to renal failure), and decreased urinary concentrating ability. Because hypernatremia frequently results from diabetes insipidus (DI) or osmotically induced losses of sodium and water, many patients are hypovolemic or bear the stigmata of renal disease. Postoperative neurosurgical patients who have undergone pituitary surgery are at particular risk of developing transient or prolonged DI. Polyuria may be present for only a few days within the first week of surgery, may be permanent, or may demonstrate a triphasic sequence: early DI, return of urinary concentrating ability, then recurrent DI.<sup>130</sup>

The clinical consequences of hypernatremia are most serious at the extremes of age and when hypernatremia develops abruptly. Geriatric patients are at increased risk of hypernatremia because of decreased renal concentrating ability and decreased thirst. Brain shrinkage secondary to rapidly developing hypernatremia may damage delicate cerebral vessels, leading to subdural hematoma, subcortical parenchymal hemorrhage,

subarachnoid hemorrhage, and venous thrombosis. Polyuria may cause bladder distention, hydronephrosis, and permanent renal damage. Although the mortality of patients with hypernatremia is 40% to 55%, it is unclear whether hypernatremia contributes to mortality or is simply a marker of severe associated disease.

Surprisingly, if plasma  $[\text{Na}^+]$  is initially normal, moderate acute increases in plasma  $[\text{Na}^+]$  do not appear to precipitate central pontine myelinolysis. However, larger accidental increases in plasma  $[\text{Na}^+]$  have produced severe consequences in children. In experimental animals, acute severe hypernatremia (acute increase from 146 mEq/L to 170 mEq/L) caused neuronal damage at 24 hours, suggestive of early central pontine myelinolysis.<sup>131</sup>

By definition, hypernatremia indicates an absolute or relative water deficit and is always associated with hypertonicity. Hypernatremia can be generated by hypotonic fluid loss, as in burns, gastrointestinal losses, diuretic therapy, osmotic diuresis, renal disease, mineralocorticoid excess or deficiency, and iatrogenic causes or can be generated by isolated water loss, as in central or nephrogenic DI. The acquired form of nephrogenic DI is more common and usually less severe than the congenital form. As chronic renal failure advances, most patients have defective concentrating ability, resulting in resistance to AVP associated with hypotonic urine. Because hypovolemia accompanies most pathologic water loss, signs of hypoperfusion also may be present. In many patients, before the development of hypernatremia, an increased volume of hypotonic urine suggests an abnormality in water balance. Although uncommon as a cause of hypernatremia, isolated sodium gain occasionally occurs in patients who receive large quantities of sodium, such as treatment of metabolic acidosis with 8.4% sodium bicarbonate, in which  $[\text{Na}^+]$  is approximately 1,000 mEq/L, or perioperative or prehospital treatment with hypertonic saline resuscitation solutions.

Hypernatremic patients can be separated into three groups—hypovolemic, normovolemic, and hypervolemic—based on clinical assessment of ECV (Fig. 16-9). Note that plasma  $[\text{Na}^+]$  does not reflect total body sodium, which must be estimated separately based on signs of the adequacy of ECV. Polyuric, hypernatremic patients may be undergoing solute diuresis or may have DI. Measurement of urinary sodium and osmolality can help to differentiate the various causes. Hypotonic urine (osmolality < 150 mOsm/kg) in the setting of hypertonicity and polyuria is diagnostic of DI.

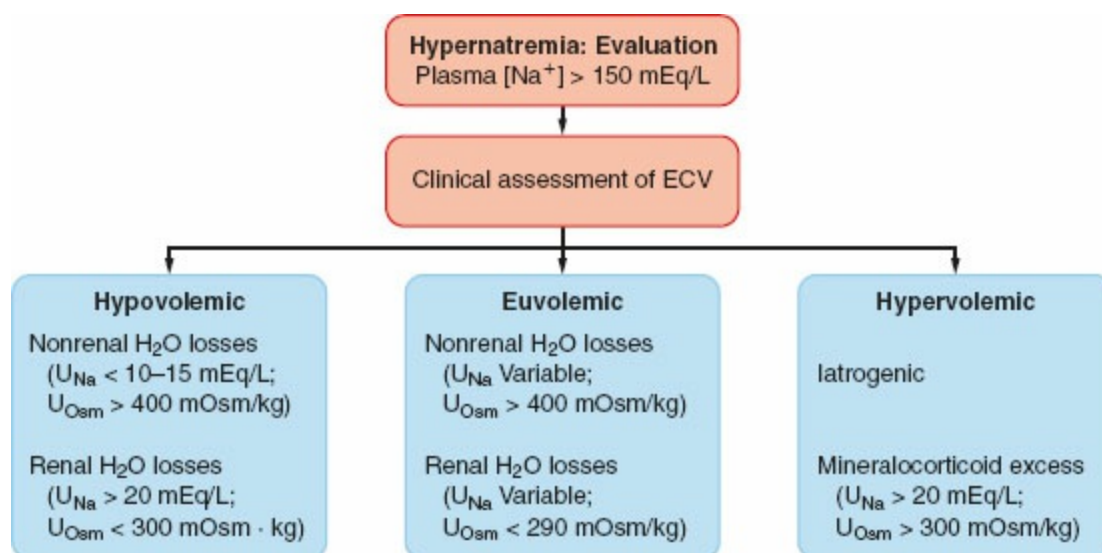

Treatment of hypernatremia produced by water loss requires repletion of water as well of associated deficits in total body sodium and other electrolytes (Table 16-16). Common errors in treating hypernatremia include excessively rapid correction as well as failing to appreciate the magnitude of the water deficit and failing to account for ongoing maintenance requirements

and continued fluid losses in planning therapy.<sup>132–134</sup>

**Table 16-16** Hyponatremia: Acute Treatment

<p><b>Sodium Depletion (Hypovolemia)</b>  Hypovolemia correction (0.9% saline)  Hypernatremia correction (hypotonic fluids)</p> <p><b>Sodium Overload (Hypervolemia)</b>  Enhance sodium removal (loop diuretics, dialysis)  Replace water deficit (hypotonic fluids)</p> <p><b>Normal Total Body Sodium (Euvolemia)</b>  Replace water deficit (hypotonic fluids)  Control diabetes insipidus  Central diabetes insipidus:  DDAVP, 10–20 µg intranasally; 2–4 µg SC  Aqueous vasopressin, 5 U q2–4h IM or SC  Nephrogenic diabetes insipidus:  Restrict sodium, water intake  Thiazide diuretics</p>

DDAVP, desmopressin.

**Figure 16-9** Severe hyponatremia is evaluated by first separating patients into hypovolemic, euvolemic, and hypervolemic groups based on assessment of extracellular volume (ECV). Next, potential etiologic factors are diagnostically assessed. [Na<sup>+</sup>], serum sodium concentration; U<sub>Na</sub>, urinary sodium concentration; U<sub>Osm</sub>, urinary osmolality.

The first step in treating hyponatremia is to estimate the TBW deficit, which can be accomplished by inserting the measured plasma [Na<sup>+</sup>] into the equation:

$$\text{TBW deficit} = 0.6 \times \text{body weight (kg)} \times \left[ \frac{[\text{Na}^+] - 140}{140} \right] \quad (16-13)$$

where 140 is the middle of the normal range for [Na<sup>+</sup>]. Adrogue and

Madias<sup>132</sup> proposed a useful equation (Eq. 16-12) to predict the expected change in serum  $[\text{Na}^+]$  produced by infusion of 1 L of infusate.

Hypernatremia must be corrected slowly because of the risk of neurologic sequelae such as seizures or cerebral edema (Fig. 16-8). At the cellular level, restoration of cell volume occurs quickly after tonicity is altered; as a consequence, acute treatment of hypertonicity may result in overshooting the original, normotonic cell volume. The water deficit should be replaced over 24 to 48 hours, and the plasma  $[\text{Na}^+]$  should not be reduced by more than 1 to 2 mEq/L/hr for the first few hours and, if the hypernatremia has been present for more than 2 days, no more than 10 mEq/L/day.<sup>126,132</sup> Reversible underlying causes should be treated. Hypovolemia should be corrected promptly with 0.9% saline. Although the  $[\text{Na}^+]$  of 0.9% saline is 154 mEq/L, the solution is effective in treating volume deficits and will reduce  $[\text{Na}^+]$  that exceeds 154 mEq/L in hypovolemic, hypernatremic patients. Once hypovolemia is corrected, water can be replaced orally or with intravenous hypotonic fluids, depending on the ability of the patient to tolerate oral hydration. In the occasional sodium-overloaded patient, sodium excretion can be accelerated using loop diuretics or dialysis. In acute, severe hypernatremia, treatment with venovenous hemofiltration was associated with lower mortality than was calculation of water deficit and infusion of hypotonic fluids.<sup>134,135</sup>

The management of hypernatremia secondary to DI varies according to whether the cause is central or nephrogenic (Table 16-16). The two most suitable agents for correcting central DI (an AVP deficiency syndrome) are desmopressin (DDAVP) and aqueous vasopressin. DDAVP, given subcutaneously in a dose of 1 to 4  $\mu\text{g}$  or intranasally in a dose of 5 to 20  $\mu\text{g}$  every 12 to 24 hours, is effective in most patients. DDAVP is preferred because it has a longer duration of action than AVP and lacks vasoconstrictor effects.<sup>135</sup> Incomplete AVP deficits (partial DI) often are effectively managed with pharmacologic agents that stimulate AVP release or enhance the renal response to AVP. Chlorpropamide, which potentiates the renal effects of vasopressin, and carbamazepine, which enhances vasopressin secretion, have been used to treat partial central DI, but are associated with clinically important side effects. In nephrogenic DI, salt and water restriction or thiazide diuretics induce contraction of ECV, thereby enhancing fluid reabsorption in the proximal tubules. If less filtrate passes through into the collecting ducts, less water will be excreted. However, thiazide diuretics exert limited therapeutic effects.<sup>134</sup>

## Potassium

### Physiologic Role

Potassium plays an important role in cell membrane physiology, especially in maintaining resting membrane potentials and in generating action potentials in the central nervous system and heart. Potassium is actively transported into cells by a Na/K adenosine triphosphatase (ATPase) pump, which maintains an intracellular  $[K^+]$  that is at least 30-fold greater than extracellular  $[K^+]$ . Intracellular potassium concentration ( $[K^+]$ ) is normally 150 mEq/L, while the extracellular concentration is only 3.5 to 5 mEq/L. Serum  $[K^+]$  measures about 0.5 mEq/L higher than plasma  $[K^+]$  because of cell lysis during clotting. Total body potassium in a 70-kg adult is approximately 4,256 mEq, of which 4,200 mEq is intracellular; of the 56 mEq in the ECV, only 12 mEq is located in the PV. The ratio of intracellular to extracellular potassium contributes to the resting potential difference across cell membranes and therefore to the integrity of cardiac and neuromuscular transmissions. The primary mechanism that maintains potassium inside cells is the negative voltage created by the transport of three sodium ions out of the cell for every two potassium ions transported in. Both insulin and  $\beta$ -agonists promote potassium entry into cells.<sup>136,137</sup> Metabolic and respiratory acidoses tend to shift potassium out of cells, while metabolic and respiratory alkaloses favor movement into cells.

Usual potassium intake varies between 50 and 150 mEq/day. Freely filtered at the glomerulus, most potassium excretion is urinary, with some fecal elimination. Most filtered potassium is reabsorbed; usually, excretion is approximately equal to daily intake. As long as GFR is above 8 mL/min, dietary potassium intake, unless greater than normal, can be excreted. Assuming a plasma  $[K^+]$  of 4 mEq/L and a normal GFR of 180 L/day, 720 mEq of potassium are filtered daily, of which 85% to 90% is reabsorbed in the proximal convoluted tubule and loop of Henle. The remaining 10% to 15% reaches the distal convoluted tubule, which is the major site at which potassium excretion is regulated. Excretion of potassium ions is a function of open potassium channels and the electrical driving force in the cortical collecting duct.

The two most important regulators of potassium excretion are plasma  $[K^+]$  and aldosterone. Potassium secretion into the distal convoluted tubules and cortical collecting ducts is increased by hyperkalemia, aldosterone, alkalemia, increased delivery of  $Na^+$  to the distal tubule and collecting duct, high urinary flow rates, and the presence in luminal fluid of nonreabsorbable anions such as carbenicillin, phosphates, and sulfates. As sodium reabsorption increases, the electrical driving force opposing reabsorption of potassium is increased. Aldosterone increases sodium reabsorption by inducing a more open configuration of the epithelial sodium channel; potassium-sparing diuretics (amiloride and triamterene) and trimethoprim block the epithelial sodium channel, thereby increasing potassium reabsorption. Magnesium

depletion contributes to renal potassium wasting.

## Hypokalemia

Uncommon among healthy persons, hypokalemia ( $[K^+] < 3.5$  mEq/L) is a frequent complication of treatment with diuretic drugs and occasionally complicates other diseases and treatment regimens (Table 16-17). Plasma  $[K^+]$  poorly reflects total body potassium; hypokalemia may occur with normal, low, or high total body potassium. However, as a general rule, a chronic decrement of 1 mEq/L in the plasma  $[K^+]$  corresponds to a total body deficit of approximately 200 to 300 mEq. In uncomplicated hypokalemia, the total body potassium deficit exceeds 300 mEq if plasma  $[K^+]$  is below 3 mEq/L and 700 mEq if plasma  $[K^+]$  is below 2 mEq/L.

Gitelman syndrome

Modified from Weiner ID, Wingo CS. Hypokalemia: consequences, causes, and correction. *J Am Soc Nephrol.* 1997;8:1179–1188.

The symptoms and signs of hypokalemia primarily relate to neuromuscular and cardiovascular functions. Hypokalemia causes muscle weakness and, when severe, may even cause paralysis. With chronic potassium loss, the ratio of intracellular to extracellular  $[K^+]$  remains relatively stable; in contrast, acute redistribution of potassium from the extracellular to the intracellular

space substantially changes resting membrane potentials. Cardiac rhythm disturbances are among the most dangerous complications of potassium deficiency. Acute hypokalemia causes hyperpolarization of the cardiac cell and may lead to ventricular escape activity, re-entrant phenomena, ectopic tachycardias, and delayed conduction. In patients treated with digoxin, hypokalemia increases toxicity by increasing myocardial digoxin binding and pharmacologic effectiveness. Hypokalemia contributes to systemic hypertension, especially when combined with a high-sodium diet. In diabetic patients, hypokalemia impairs insulin secretion and end-organ sensitivity to insulin. Although no clear threshold has been defined for a level of hypokalemia below which safe conduct of anesthesia is compromised,  $[K^+]$  below 3.5 mEq/L in cardiac surgical patients has been associated with an increased incidence of perioperative dysrhythmias, especially atrial fibrillation/flutter.<sup>138</sup>

Potassium depletion also induces defects in renal concentrating ability, resulting in polyuria and a reduction in GFR. Potassium replacement improves GFR, although the concentrating deficit may not improve for several months after treatment. If hypokalemia is sufficiently prolonged, chronic renal interstitial damage may occur. In experimental animals, hypokalemia was associated with intrarenal vasoconstriction and a pattern of renal injury similar to that produced by ischemia.<sup>139</sup>

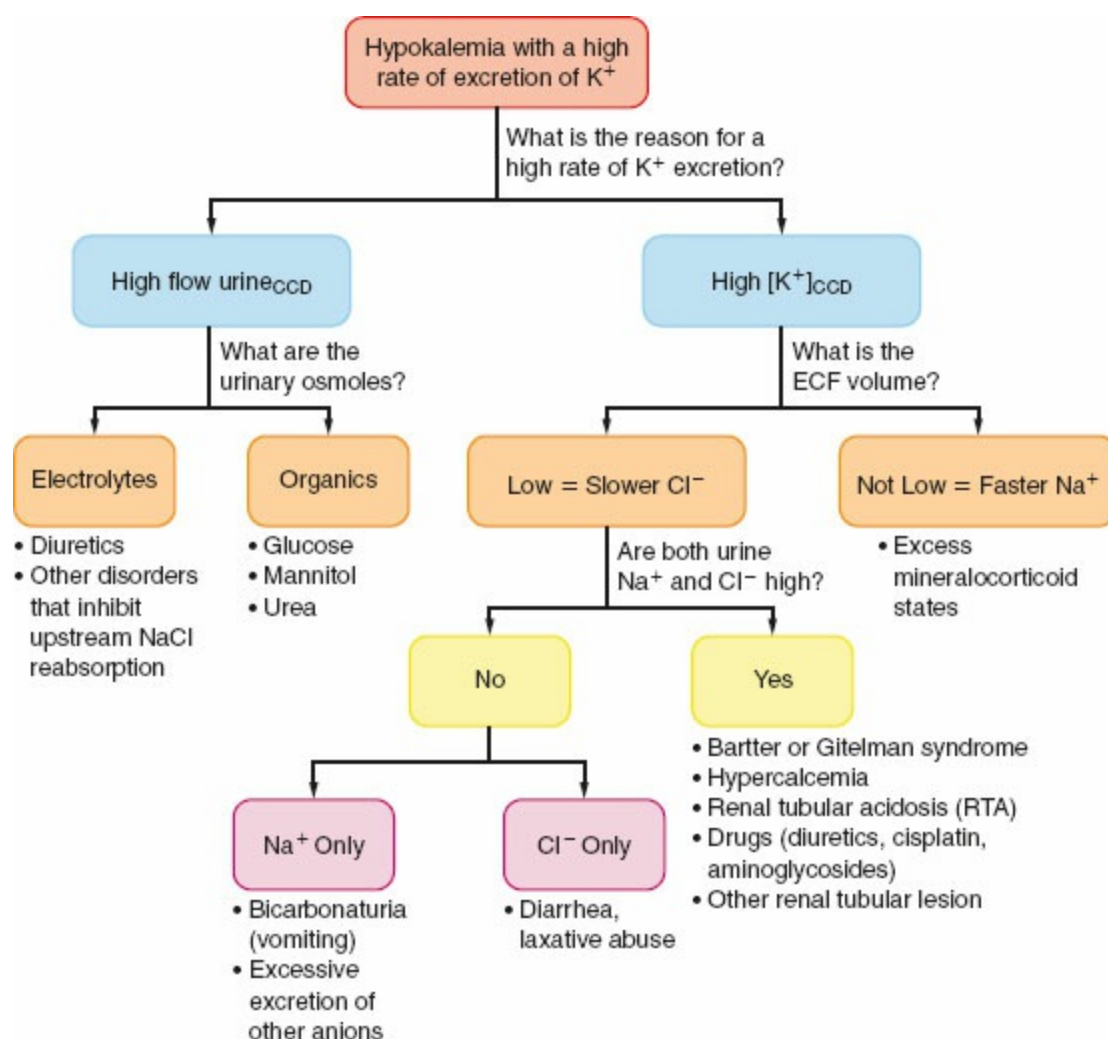

Hypokalemia may result from chronic depletion of total body potassium or from acute redistribution of potassium from the ECV to the ICV. Redistribution of potassium into cells occurs when the activity of the sodium-potassium ATPase pump is acutely increased by extracellular hyperkalemia or increased intracellular concentrations of sodium, as well as by insulin, carbohydrate loading (which stimulates release of endogenous insulin),  $\beta_2$ -agonists, and aldosterone. Both metabolic and respiratory alkaloses lead to decreases in plasma  $[K^+]$ .

Causes of chronic hypokalemia include those etiologies associated with renal potassium conservation (extrarenal potassium losses; low urinary  $[K^+]$ ) and those with renal potassium wasting (Fig. 16-10).<sup>140</sup> A low urinary  $[K^+]$  suggests inadequate dietary intake or extrarenal depletion (in the absence of recent diuretic use). Diuretic-induced urinary potassium losses are frequently associated with hypokalemia, secondary to increased aldosterone secretion, alkalemia, and increased renal tubular flow. Aldosterone does not cause renal potassium wasting unless sodium ions are present; that is, aldosterone primarily controls sodium reabsorption, not potassium excretion. Renal tubular damage due to nephrotoxins such as aminoglycosides or amphotericin B may also cause renal potassium wasting.

Initial evaluation of hypokalemia includes a medical history (e.g., diarrhea, vomiting, diuretic, or laxative use), physical examination (e.g.,

hypertension, cushingoid features, edema), measurement of serum electrolytes (e.g., magnesium), arterial pH assessment, and evaluation of the electrocardiogram (ECG). Measurement of 24-hour urinary excretion of sodium and potassium may distinguish extrarenal from renal causes. Magnesium deficiency, associated with aminoglycoside and cisplatin therapy, can generate hypokalemia that is resistant to potassium replacement therapy. Plasma renin and aldosterone levels may be helpful in the differential diagnosis of hypokalemia of unclear origin, especially if primary hyperaldosteronism is suspected.<sup>141</sup> Characteristic electrocardiographic changes associated with hypokalemia include flat or inverted T waves, prominent U waves, and ST segment depression.

**Figure 16-10** A diagnostic flow chart for hypokalemia with a high rate of  $K^+$  excretion. ECF, extracellular fluid; CCD, cortical collecting duct. (Adapted from Lin SH, Halperin ML. Hypokalemia: a practical approach to diagnosis and its genetic basis. *Curr Med Chem.* 2007;14:1551–1565.)

The treatment of hypokalemia consists of potassium repletion, correction of alkalemia, and removal of offending drugs (Table 16-18). Hypokalemia secondary only to acute redistribution (e.g., secondary to acute alkalemia)

may not require treatment. There is no urgent need for potassium replacement therapy in mild-to-moderate hypokalemia (3 to 3.5 mEq/L) in patients who have no symptoms or signs. If total body potassium is decreased, oral potassium supplementation is preferable to intravenous replacement. Potassium is usually replaced as the chloride salt because coexisting chloride deficiency may limit the ability of the kidney to conserve potassium.

**Table 16-18** Hypokalemia: Treatment

<b>Correct Precipitating Factors</b>
Increased pH
Decreased [Mg <sup>2+</sup> ]
Drugs
<b>Mild Hypokalemia</b> ([K <sup>+</sup> ] > 2 mEq/L)
Intravenous KCl infusion ≤10 mEq/hr
<b>Severe Hypokalemia</b> ([K <sup>+</sup> ] ≤ 2 mEq/L, paralysis or ECG changes)
Intravenous KCl infusion ≤40 mEq/hr
Continuous electrocardiographic monitoring
If life-threatening, 5–6 mEq bolus

Intravenous potassium repletion, when necessary, must be performed cautiously (i.e., usually at a rate of 10 to 20 mEq/hr) of the risk of excessively rapid increases in plasma [K<sup>+</sup>]. The plasma [K<sup>+</sup>] and the ECG must be monitored during rapid repletion (10 to 20 mEq/hr) to avoid hyperkalemic complications. Particular care should be taken in patients who have concurrent acidemia, type IV renal tubular acidosis, or diabetes mellitus, or in those patients receiving nonsteroidal anti-inflammatory agents, ACE inhibitors, or β<sub>2</sub>-blockers, all of which delay movement of extracellular potassium into cells. β<sub>1</sub>-Blockers do not delay movement of extracellular potassium into cells or predispose patients to hyperkalemia.<sup>142</sup>

However, in patients with life-threatening dysrhythmias secondary to hypokalemia, serum [K<sup>+</sup>] must be rapidly increased. Assuming that PV in a 70-kg adult is 3 L, administration of 6 mEq/L of potassium in 1 minute will acutely increase plasma [K<sup>+</sup>] by no more than 2 mEq/L; subsequent redistribution into interstitial fluid and ICV will rapidly decrease plasma [K<sup>+</sup>].

Hypokalemia associated with hyperaldosteronemia (e.g., primary aldosteronism, Cushing syndrome) usually responds favorably to reduced sodium intake and increased potassium intake. Hypomagnesemia, if present, aggravates the effects of hypokalemia, impairs potassium conservation, and should be treated. Potassium supplements or potassium-sparing diuretics should be given cautiously to patients who have diabetes mellitus or renal insufficiency, which limit compensation for acute hyperkalemia. In patients such as those who have diabetic ketoacidosis, who are both hypokalemic and

acidemic, potassium administration should precede correction of acidosis to avoid a precipitous decrease in plasma  $[K^+]$  as pH increases.

In patients with normal serum potassium accompanied by symptoms of potassium depletion (e.g., muscle fatigue) or history of potassium loss or insufficient intake, or in patients in whom potassium depletion may be of special threat (e.g., patients on diuretics, digitalis, or  $\beta_2$ -agonists), muscle biopsy with measurement of muscle potassium concentration may be a useful procedure to detect and quantify potassium depletion.

## Hyperkalemia

 The most lethal manifestations of hyperkalemia ( $[K^+] > 5$  mEq/L) involve the cardiac conducting system and include dysrhythmias, conduction abnormalities, and cardiac arrest. In anesthesia practice, the classic example of hyperkalemic cardiac toxicity is associated with the administration of succinylcholine to paraplegic, quadriplegic, or severely burned patients.<sup>143</sup> If plasma  $[K^+]$  is below 6 mEq/L, cardiac effects are negligible. As the concentration increases further, the ECG shows tall, peaked T waves, especially in the precordial leads. With further increases, the PR interval becomes prolonged, followed by a decrease in the amplitude of the P wave. Finally, the QRS complex widens into a pattern resembling a sine wave, as a prelude to cardiac standstill (Fig. 16-11).<sup>136</sup> Hyperkalemic cardiotoxicity is enhanced by hyponatremia, hypocalcemia, or acidosis. Because progression to fatal cardiotoxicity is unpredictable and often swift,  the presence of hyperkalemic ECG changes mandates immediate therapy.

The life-threatening cardiac effects usually require more urgent treatment than other manifestations of hyperkalemia. However, ascending muscle weakness appears when plasma  $[K^+]$  approaches 7 mEq/L, and may progress to flaccid paralysis, inability to phonate, and respiratory arrest.

The most important diagnostic issues are medical history, emphasizing recent drug therapy, and assessment of renal function. Although the ECG may provide the first suggestion of hyperkalemia in some patients, and despite the well-described effects of hyperkalemia on cardiac conduction and rhythm, the ECG is an insensitive and nonspecific method of detecting hyperkalemia. If hyponatremia is also present, adrenal function should be evaluated.

Hyperkalemia may occur with normal, high, or low total body potassium stores. A deficiency of aldosterone, a major regulator of potassium excretion, leads to hyperkalemia in adrenal insufficiency, renal insufficiency, advanced age, and hyporeninemic hypoaldosteronism, a state associated with diabetes mellitus.<sup>144</sup> Because the kidneys excrete potassium, severe renal insufficiency commonly causes hyperkalemia. Patients with chronic renal insufficiency can maintain normal plasma  $[K^+]$  despite markedly decreased GFR because

urinary potassium excretion depends on tubular secretion rather than glomerular filtration if GFR exceeds 8 mL/min.

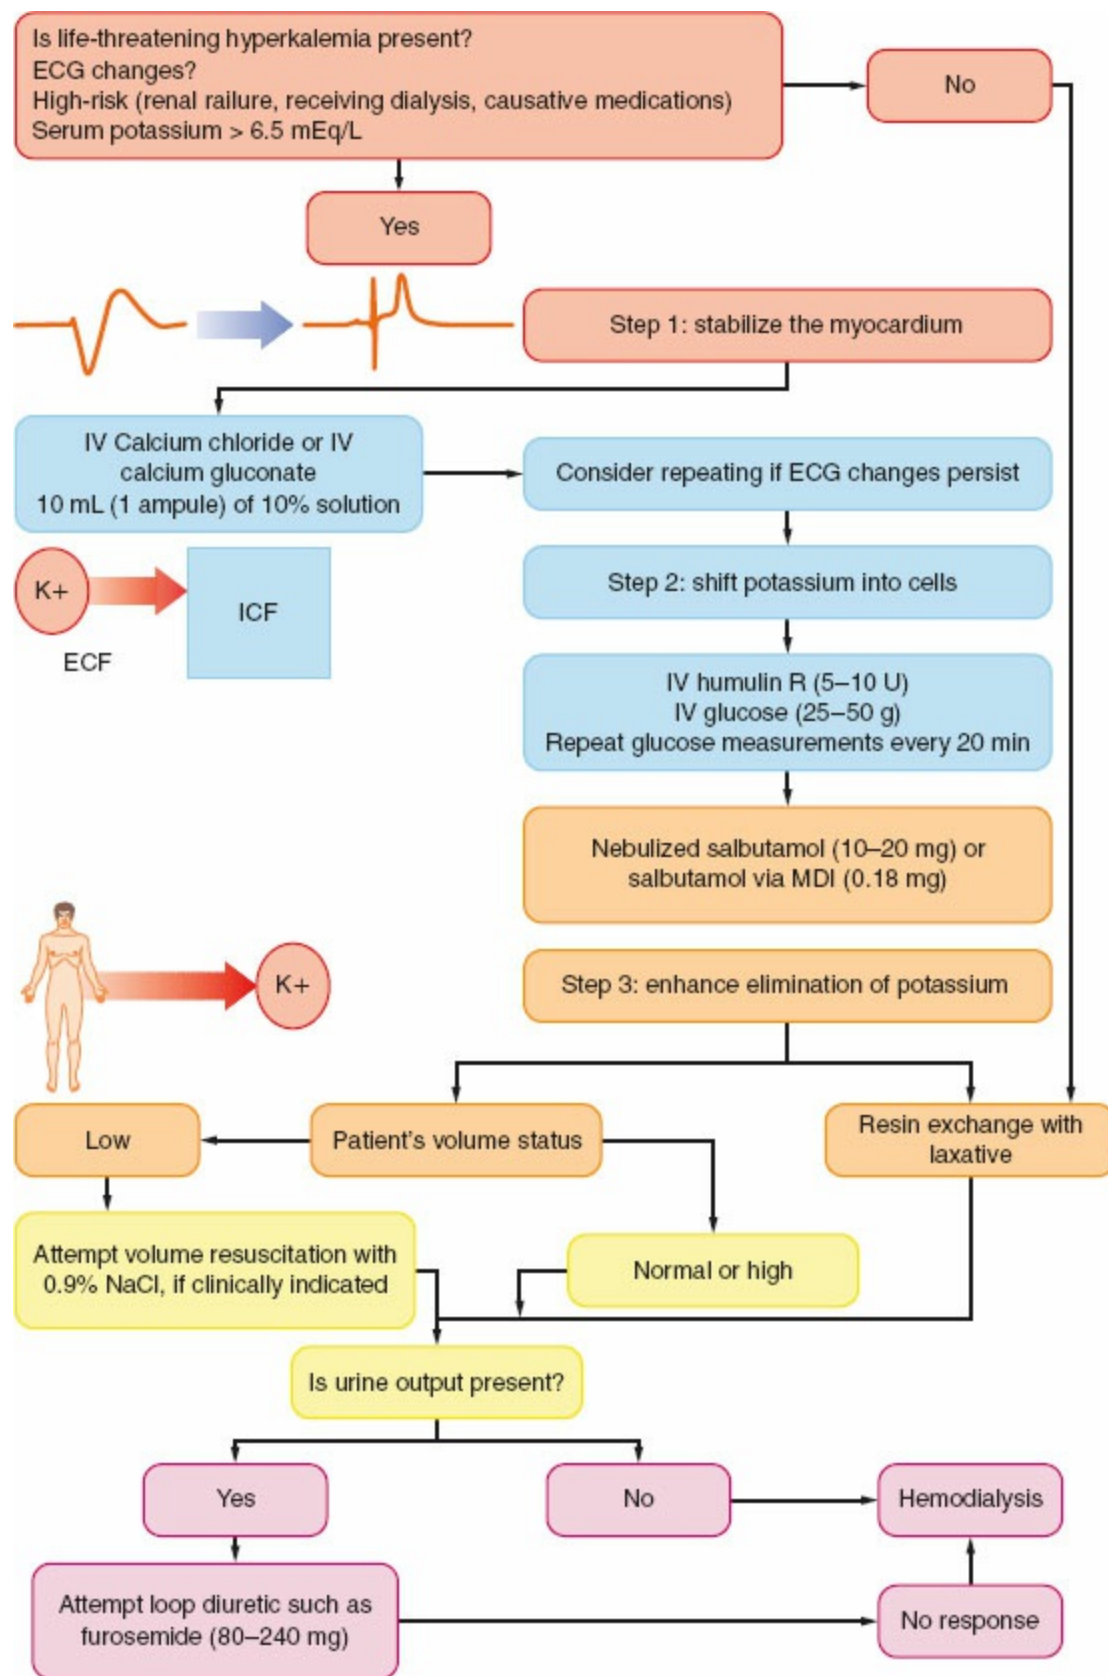

Drugs are now the most common cause of hyperkalemia, especially in elderly patients. Drugs that may limit potassium excretion include nonsteroidal anti-inflammatory drugs, ACE inhibitors, cyclosporine, and potassium-sparing diuretics such as triamterene. Drug-induced hyperkalemia most commonly occurs in patients with other predisposing factors, such as diabetes mellitus, renal insufficiency, advanced age, or hyporeninemic hypoaldosteronism. ACE inhibitors are particularly likely to produce hyperkalemia in patients who have congestive heart failure.<sup>145,146</sup> Up to 38% of patients receiving ACE inhibitors develop hyperkalemia.<sup>147</sup> Two promising newer potassium binders, patiromer and sodium zirconium cyclosilicate, may be useful for chronic prevention of hyperkalemia in patients receiving ACE inhibitors.<sup>148–150</sup>

In patients who have normal total body potassium, hyperkalemia may accompany a sudden shift of potassium from the ICV to the ECV because of acidemia, increased catabolism, or rhabdomyolysis. Metabolic acidosis and respiratory acidosis tend to cause an increase in plasma  $[K^+]$ . However, organic acidoses (i.e., lactic acidosis, ketoacidosis) have little effect on  $[K^+]$ , whereas mineral acids cause significant cellular shifts. In response to increased hydrogen ion activity because of addition of acids, potassium will increase if the anion remains in the ECV. Neither lactate nor ketoacids remain in the extracellular fluid. Therefore, hyperkalemia in these circumstances reflects tissue injury or lack of insulin. Pseudohyperkalemia, which occurs when potassium is released from cells in blood collection tubes, can be diagnosed by comparing serum and plasma  $K^+$  levels from the same blood sample. Hyperkalemia usually accompanies malignant hyperthermia.

Serum potassium	Typical ECG appearance	Possible ECG abnormalities
Mild (5.5–6.5 mEq/L)		Peaked T waves Prolonged PR segment
Moderate (6.5–8.0 mEq/L)		Loss of P wave Prolonged QRS complex ST-segment elevation Ectopic beats and escape rhythms
Severe (>8.0 mEq/L)		Progressive widening of QRS complex Sine wave Ventricular fibrillation Asystole Axis deviations Bundle branch blocks Fascicular blocks

The treatment of hyperkalemia is aimed at eliminating the cause, reversing membrane hyperexcitability, and removing potassium from the body (Fig. 16-12).<sup>136,137,146,151</sup> Mineralocorticoid deficiency can be treated with 9- $\alpha$ -fludrocortisone (0.025 to 0.10 mg/day). Hyperkalemia secondary to digitalis intoxication may be resistant to therapy because attempts to shift potassium from the ECV to the ICV are often ineffective. In this situation, use of digoxin-specific antibodies has been successful.

Hemodialysis
<b>Monitor Electrocardiogram and Serum [K<sup>+</sup>] Level</b>

<sup>a</sup>Potassium concentration ([K<sup>+</sup>]) > 6.5 mEq/L or electrocardiographic changes.  
IV, intravenous; D<sub>10</sub>W, 10% dextrose in water.

Emergent management of severe hyperkalemia is described in detail in [Table 16-19](#). Membrane hyperexcitability can be antagonized by translocating potassium from the ECV to the ICV, removing excess potassium, or (transiently) by infusing calcium chloride to depress the membrane threshold potential.<sup>152</sup> Pending definitive treatment, rapid infusion of calcium chloride (1 g of CaCl<sub>2</sub> over 3 minutes, or two or three ampules of 10% calcium gluconate over 5 minutes) may stabilize cardiac rhythm ([Table 16-19](#)). Calcium should be given cautiously if digitalis intoxication is likely. Insulin, in a dose-dependent fashion, causes cellular uptake of potassium by increasing the activity of the sodium/potassium ATPase pump. Insulin increases cellular uptake of potassium best when high insulin levels are achieved by intravenous injection of 5 to 10 units of regular insulin, accompanied by 50 mL of 50% glucose.<sup>136,145</sup> Larger doses of insulin are no more effective and risk hypoglycemia.<sup>153</sup> β<sub>2</sub>-Adrenergic drugs such as salbutamol and albuterol also increase potassium uptake by skeletal muscle and reduce plasma [K<sup>+</sup>], an action that may explain hypokalemia with severe, acute illness. Salbutamol, a selective β<sub>2</sub>-agonist, decreases serum potassium acutely by 1 mEq/L or more when given by inhalation or intravenously, although cardiac dysrhythmias may occasionally complicate treatment with selective β<sub>2</sub>-agonists.<sup>136</sup> Although administration of sodium bicarbonate has long been considered a part of the treatment of hyperkalemia, bicarbonate, when used alone, is relatively ineffective and is no longer favored, except for patients with metabolic acidosis.<sup>150</sup>

Potassium may be removed from the body by the renal or gastrointestinal routes. Furosemide promotes kaliuresis in a dose-dependent fashion. Sodium polystyrene sulfonate resin (Kayexalate), which exchanges sodium for potassium, can be given orally (30 to 60 g)<sup>154</sup> or as a retention enema (50 g in 200 mL of 20% sorbitol). However, sodium overload and hypervolemia are

potential risks. Hemodialysis and continuous renal replacement therapy may be necessary for patients with acute kidney injury or chronic renal failure.<sup>151</sup>

## Calcium

### Physiologic Role

Calcium is a divalent cation found primarily in the extracellular fluid. The free calcium concentration  $[Ca^{2+}]$  in ECV is approximately 1 mM, whereas the free  $[Ca^{2+}]$  in the ICV approximates 100 nM, an intracellular:extracellular gradient of 10,000 to 1. Circulating calcium consists of a protein-bound fraction (40% to 50%), a fraction bound to inorganic anions (10% to 15%), and an ionized fraction (45% to 50%), which is the physiologically active and homeostatically regulated component. Acute acidemia increases and acute alkalemia decreases ionized calcium.<sup>155</sup> Because mathematical formulae that “correct” total calcium measurements for albumin concentration are inaccurate in critically ill patients,<sup>156</sup> ionized calcium should be directly measured.

In general, calcium is essential for all movement that occurs in mammalian systems. Essential for normal excitation–contraction coupling, calcium is also necessary for proper function of muscle tissue, ciliary movement, mitosis, neurotransmitter release, enzyme secretion, and hormonal secretion. Cyclic adenosine monophosphate (cAMP) and phosphoinositides, which are major second messengers regulating cellular metabolism, function primarily through the regulation of calcium movement. Activation of numerous intracellular enzyme systems requires calcium. Calcium is important both for generation of the cardiac pacemaker activity and for generation of the cardiac action potential and therefore is the primary ion responsible for the plateau phase of the action potential. Calcium also serves vital functions in membrane and bone structure.

Serum  $[Ca^{2+}]$  is regulated by multiple factors (Fig. 16-13),<sup>157</sup> including a calcium receptor<sup>157,158</sup> and several hormones. Parathyroid hormone (PTH) and calcitriol, the most important neurohumoral mediators of serum  $[Ca^{2+}]$ ,<sup>159</sup> mobilize calcium from bone, increase renal tubular reabsorption of calcium, and enhance intestinal absorption of calcium. Vitamin D, after ingestion or cutaneous manufacture under the stimulus of ultraviolet light, is 25-hydroxylated to calcidiol in the liver and then is 1-hydroxylated to calcitriol, the active metabolite, in the kidney. Even in the absence of dietary calcium intake, PTH and vitamin D can maintain a normal circulating  $[Ca^{2+}]$  by mobilizing calcium from bone. In addition to the key roles played by PTH and calcitriol in regulating serum  $[Ca^{2+}]$ , other recently described pathways play key molecular roles in bone resorption. The receptor activator of nuclear

factor  $\kappa$ B (RANK), RANK ligand (RANKL), and osteoprotegerin play key molecular roles; binding of RANKL to RANK stimulates osteoclast activity, whereas binding of RANKL to osteoprotegerin, a soluble decoy receptor, disrupts binding to RANK.<sup>160</sup>

## Hypocalcemia

Hypocalcemia (ionized  $[\text{Ca}^{2+}] < 4 \text{ mg/dL}$  or  $< 1 \text{ mmol/L}$ ) occurs as a result of failure of PTH or calcitriol action or because of calcium chelation or precipitation, not because of calcium deficiency alone. PTH deficiency can result from suppression of the parathyroid glands by severe hypo- or hypermagnesemia or from surgical damage or removal of the parathyroid glands. Permanent hypocalcemia occurs in about 5% of patients who undergo thyroidectomy, with the incidence somewhat higher in patients who undergo central neck dissection.<sup>161</sup> Burns, sepsis, and pancreatitis may suppress parathyroid function and interfere with vitamin D action. Vitamin D deficiency may result from lack of dietary vitamin D or from vitamin D malabsorption in patients who lack sunlight exposure. Hyperphosphatemia-induced hypocalcemia may occur as a consequence of overzealous phosphate therapy, from cell lysis secondary to chemotherapy, or as a result of cellular destruction from rhabdomyolysis. Precipitation of  $\text{CaHPO}_4$  complexes occurs with hyperphosphatemia. However, ionized  $[\text{Ca}^{2+}]$  only decreases approximately 0.019 mM for each 1 mM increase in phosphate concentration. Alkalemia resulting from hyperventilation or sodium bicarbonate injection can acutely decrease  $[\text{Ca}^{2+}]$ . In massive transfusion, citrate may produce hypocalcemia by chelating calcium; however, decreases are usually transient and produce negligible cardiovascular effects, unless citrate clearance is decreased (e.g., by hepatic or renal disease or hypothermia). In massive transfusion, a high proportion of patients develop moderate or severe hypocalcemia.<sup>162</sup>

**Figure 16-13** Schematic representation of the regulatory system maintaining  $\text{Ca}^{2+}$  homeostasis. The *solid arrows and lines* delineate effects of parathyroid hormone (PTH) and  $1,25(\text{OH})_2\text{D}_3$  (dihydroxyvitamin D) on their target tissues; *dashed arrows and lines* show examples of how extracellular  $\text{Ca}^{2+}$  or phosphate ions act directly on tissues regulating mineral ion metabolism. (Adapted with permission from Brown EM, Pollak M, Hebert SC. The extracellular calcium-sensing receptor: Its role in health and disease. *Annu Rev Med.* 1998;49:15–29.)

The hallmark of hypocalcemia is increased neuronal membrane irritability and tetany (Table 16-20). Early symptoms include sensations of numbness and tingling involving fingers, toes, and the circumoral region. In frank tetany, tonic contraction of respiratory muscles may lead to laryngospasm, bronchospasm, or respiratory arrest. Smooth muscle spasm can result in abdominal cramping and urinary frequency. Mental status alterations include irritability, depression, psychosis, and dementia. Hypocalcemia also may cause acute symptomatic seizures.<sup>163</sup> Hypocalcemia may impair cardiovascular function and has been associated with heart failure, hypotension, dysrhythmias, insensitivity to digitalis, and impaired  $\beta$ -adrenergic action.

Reduced *ionized* serum calcium occurs in as many as 88% of critically ill patients, 66% of less severely ill intensive care unit patients, and 26% of

hospitalized non-intensive care unit patients.<sup>164</sup> Patients at particular risk include patients after multiple trauma and cardiopulmonary bypass. In most such patients, ionized hypocalcemia is clinically mild ( $[Ca^{2+}]$  0.8 to 1 mmol/L).

Initial diagnostic evaluation should concentrate on history and physical examination, laboratory evaluation of renal function, and measurement of serum phosphate concentration. Latent hypocalcemia can be diagnosed by tapping on the facial nerve to elicit *Chvostek sign* or by inflating a sphygmomanometer to 20 mmHg above systolic pressure, which produces radial and ulnar nerve ischemia and causes carpal spasm known as *Trousseau sign*. The differential diagnosis of hypocalcemia can be approached by addressing four issues: age of the patient, serum phosphate concentration, general clinical status, and duration of hypocalcemia. Low or normal phosphate concentrations imply vitamin D or magnesium deficiency. An otherwise healthy patient with chronic hypocalcemia probably is hypoparathyroid. High phosphate concentrations suggest renal failure or hypoparathyroidism. In renal insufficiency, reduced phosphorus excretion results in hyperphosphatemia, which downregulates the  $1\alpha$ -hydroxylase responsible for the renal conversion of calcidiol to calcitriol. This, in combination with decreased production of calcitriol secondary to reduced renal mass, causes reduced intestinal absorption of calcium and hypocalcemia.<sup>164</sup> Chronically ill adults with hypocalcemia often have

disorders such as malabsorption, osteomalacia, or osteoblastic metastases.

The definitive treatment of hypocalcemia necessitates identification and treatment of the underlying cause (Table 16-21). Symptomatic hypocalcemia usually occurs when serum ionized  $[Ca^{2+}]$  is less than 0.7 mM.

Unnecessary offending drugs should be discontinued. Hypocalcemia resulting from hypomagnesemia or hyperphosphatemia is treated by repletion of magnesium or removal of phosphate. Treatment of a patient who has tetany and hyperphosphatemia requires coordination of therapy to avoid the consequences of metastatic soft-tissue calcification. Potassium and other electrolytes should be measured and abnormalities should be corrected. Hyperkalemia and hypomagnesemia potentiate hypocalcemia-induced cardiac and neuromuscular irritability. In contrast, hypokalemia protects against hypocalcemic tetany; therefore, correction of hypokalemia without correction of hypocalcemia may provoke tetany.

Mild, ionized hypocalcemia should not be overtreated. For instance, in most patients after cardiac surgery, administration of calcium only increases blood pressure and actually attenuates the  $\beta$ -adrenergic effects of epinephrine. Therefore, calcium infusions should be of limited value in surgical patients unless there is demonstrable evidence of ionized hypocalcemia. Calcium salts appear to confer no benefit to patients already receiving inotropic or vasoactive agents.

The cornerstone of therapy for confirmed, symptomatic, ionized hypocalcemia ( $[Ca^{2+}] < 0.7$  mM) is calcium administration. In patients who have severe hypocalcemia or hypocalcemic symptoms, calcium should be administered intravenously. In emergency situations, in an averaged-sized adult, the “rule of 10s” advises infusion of 10 mL of 10% calcium gluconate (93 mg elemental calcium) over 10 minutes, followed by a continuous infusion of elemental calcium, 0.3 to 2 mg/kg/hr (i.e., 3 to 16 mL/hr of 10% calcium gluconate for a 70-kg adult). Calcium salts should be diluted in 50 to 100 mL D<sub>5</sub>W (to limit venous irritation and thrombosis), should not be mixed with bicarbonate (to prevent precipitation), and must be given cautiously to digitalized patients because calcium increases the toxicity of digoxin. Continuous ECG monitoring during initial therapy will detect cardiotoxicity (e.g., heart block, ventricular fibrillation). During calcium replacement, clinicians should monitor serum calcium, magnesium, phosphate, potassium, and creatinine. Once the ionized  $[Ca^{2+}]$  is stable in the range of 4 to 5 mg/dL (1 to 1.25 mM), oral calcium supplements can substitute for parenteral therapy. Urinary calcium should be monitored in an attempt to avoid hypercalciuria ( $>5$  mg/kg/24 hr) and urinary tract stone formation.

**Table 16-21 Hypocalcemia: Acute Treatment**

<p><b>Administer Calcium</b></p> <p>IV: 10 mL 10% calcium gluconate<sup>a</sup> over 10 min, followed by elemental calcium 0.3–2 mg/kg/hr Oral: 500–1000 mg elemental calcium q6h</p> <p><b>Administer Vitamin D</b></p> <p>Ergocalciferol, 1,200 µg/day (<math>T_{1/2}</math> = 30 days) Dihydroxycholecalciferol, 200–400 µg/day (<math>T_{1/2}</math> = 7 days) 1,25-dihydroxycholecalciferol, 0.25–1 µg/day (<math>T_{1/2}</math> = 1 day)</p> <p><b>Monitor Electrocardiogram</b></p>

<sup>a</sup>Calcium gluconate contains 93 mg elemental calcium per 10-mL vial.  
IV, intravenous;  $T_{1/2}$ , half-life.

When supplementation fails to maintain serum calcium within the normal range, or if hypercalciuria develops, vitamin D or vitamin D analogs may be added. Although the principal effect of vitamin D is to increase enteric calcium absorption, osseous calcium resorption is also enhanced. When rapid changes in dosage are anticipated or an immediate effect is required (e.g., postoperative hypoparathyroidism), shorter-acting calciferols such as dihydroxycholecalciferol may be preferable. Because the effect of vitamin D is not regulated, the dosages of calcium and vitamin D should be adjusted to raise the serum calcium into the low normal range.

Adverse reactions to calcium and vitamin D include hypercalcemia and hypercalciuria. If hypercalcemia develops, calcium and vitamin D should be discontinued and appropriate therapy given. The toxic effects of vitamin D metabolites persist in proportion to their biologic half-lives (ergocalciferol, 20 to 60 days; dihydroxycholecalciferol, 5 to 15 days; calcitriol, 2 to 10 days). Glucocorticoids antagonize the toxic effects of vitamin D metabolites.

Another therapeutic option for patients with persistent hypoparathyroidism is recombinant human PTH, although the expense of the recombinant hormone is a barrier to wider use.<sup>165</sup>

## Hypercalcemia

Although ionized  $[Ca^{2+}]$  most accurately defines hypercalcemia (ionized  $[Ca^{2+}] > 1.5$  mmol/L), hypercalcemia customarily is discussed in terms of total serum calcium (total serum calcium  $> 10.5$  mg/dL). In hypoalbuminemic patients, total serum calcium can be estimated (albeit inaccurately) by assuming an increase of 0.8 mg/dL for every 1 g/dL of albumin concentration below 4 g/dL. Patients in whom total serum calcium is below 11.5 mg/dL are usually asymptomatic. Patients with moderate hypercalcemia (total serum calcium 11.5 to 13 mg/dL) may show symptoms of lethargy, anorexia, nausea, and polyuria. Severe hypercalcemia (total serum calcium  $> 13$  mg/dL) is associated with more severe neuromyopathic

symptoms, including muscle weakness, depression, impaired memory, emotional lability, lethargy, stupor, and coma. The cardiovascular effects of hypercalcemia include hypertension, arrhythmias, heart block, cardiac arrest, and digitalis sensitivity. Skeletal disease may occur secondary to direct osteolysis or humoral bone resorption.

Hypercalcemia impairs urinary concentrating ability and renal excretory capacity for calcium by irreversibly precipitating calcium salts within the renal parenchyma and by reducing renal blood flow and GFR. In response to hypovolemia, renal tubular reabsorption of sodium enhances renal calcium reabsorption. Effective treatment of severe hypercalcemia is necessary to prevent progressive dehydration and renal failure leading to further increases in total serum calcium, because volume depletion exacerbates hypercalcemia.

Hypercalcemia occurs when calcium enters the ECV more rapidly than the kidneys can excrete the excess. Clinically, hypercalcemia most commonly results from an excess of bone resorption over bone formation, usually secondary to malignant disease, hyperparathyroidism, hypocalciuric hypercalcemia, thyrotoxicosis, immobilization, and granulomatous diseases. Granulomatous diseases produce hypercalciuria and hypercalcemia because of conversion by granulomatous tissue of calcidiol to calcitriol.

Malignancy may produce hypercalcemia through either bone destruction or secretion by malignant tissue of hormones that promote hypercalcemia. Examples of malignancy-associated hormonal effects include secretion by solid tumors of parathormone-like peptides and derangement of the RANKL/osteoprotegerin system in multiple myeloma.<sup>166</sup> Primary hyperparathyroidism is associated with weakness, weight loss, and anemia, symptoms that suggest malignancy but may result simply from hyperparathyroidism.<sup>167</sup> To compensate for increased gut absorption or bone resorption of calcium, renal excretion can readily increase from 100 to more than 400 mg/day. Factors that promote hypercalcemia may be offset by coexisting disorders, such as pancreatitis, sepsis, or hyperphosphatemia, that cause hypocalcemia.

Although definitive treatment of hypercalcemia requires correction of underlying causes, temporizing therapy may be necessary to avoid complications and to relieve symptoms. Total serum calcium exceeding 14 mg/dL represents a medical emergency. General supportive treatment includes hydration, correction of associated electrolyte abnormalities, removal of offending drugs, dietary calcium restriction, and increased physical activity. Because anorexia and antagonism by calcium of ADH action result in sodium and water depletion, infusion of 0.9% saline will dilute serum calcium, promote renal excretion, and can reduce total serum calcium by 1.5 to 3 mg/dL. Urinary output should be maintained at 200 to 300 mL/hr. As GFR increases, sodium ions increase calcium excretion by competing with

calcium ions for reabsorption in the proximal renal tubules and the loop of Henle.

Furosemide further enhances calcium excretion by increasing tubular sodium. Patients who have renal impairment may require higher doses of furosemide. During saline infusion and forced diuresis, careful monitoring of cardiopulmonary status and electrolytes, especially magnesium and potassium, is required. Intensive diuresis and saline administration can achieve net calcium excretion rates of 2,000 to 4,000 mg/24 hr, a rate eight times greater than saline alone, but still less than the 6,000 mg every 8 hours that can be removed by hemodialysis.<sup>166</sup> Patients treated with phosphates for hypercalcemia should be well hydrated.

Bone resorption, the primary cause of hypercalcemia, can be minimized by increasing physical activity and initiating drug therapy with bisphosphonates, calcitonin, glucocorticoids, or calcimetrics.<sup>166</sup> Bisphosphonates, currently the first-line therapy for acute hypercalcemia, inhibit osteoclast function and viability. Bisphosphonates are the principal drugs for the management of hypercalcemia mediated by osteoclastic bone resorption.<sup>166</sup> Pamidronate, unlike earlier bisphosphonates, does not appear to worsen renal insufficiency. Risedronate has been associated with less gastrointestinal morbidity than alendronate.<sup>168,169</sup> Zoledronate has the most rapid onset of action among the bisphosphonates and prolongs the duration before relapse of hypercalcemia; however, zoledronate has been associated with compromised renal function.<sup>170</sup> Bisphosphonates also are used to control osteoporosis in both men and women.<sup>171</sup>

Calcitonin, usually reserved as a secondary treatment for life-threatening hypercalcemia, lowers serum calcium within 24 to 48 hours and is more effective when combined with glucocorticoids.<sup>166</sup> Usually calcitonin reduces total serum calcium by only 1 to 2 mg/dL. Although calcitonin is relatively nontoxic, more than 25% of patients may not respond. Thus, calcitonin is unsuitable as a first-line drug during life-threatening hypercalcemia. Hydrocortisone is effective in treating hypercalcemic patients with lymphatic malignancies, vitamin D or A intoxication, and diseases associated with production by tumor or granulomas of 1,25(OH)<sub>2</sub>D or osteoclast-activating factor. Glucocorticoids rarely improve hypercalcemia secondary to malignancy or hyperparathyroidism. Control of hypercalcemia associated with malignancy usually requires control of the underlying cancer.<sup>172</sup>

Primary hyperparathyroidism most commonly occurs secondary to parathyroid adenomas (80% to 85%) with hyperplasia (10% to 15%) and carcinoma (1% to 5%) accounting for the remainder.<sup>167</sup> Although either minimally invasive parathyroidectomy or bilateral neck dissection effectively manages hyperparathyroidism, minimally invasive parathyroidectomy appears to be associated with less frequent postoperative hypocalcemia and

less frequent recurrent laryngeal nerve injury.<sup>173</sup> Calcimimetics have become an attractive treatment option for suppressing primary, secondary, and tertiary hyperparathyroidism, especially in poor surgical candidates. With the first agent, cinacalcet, recently released for clinical use in the United States and others undergoing clinical trials, calcimimetic agents also reduce inorganic phosphate concentration (Pi) and the calcium × phosphate product.<sup>174–176</sup> Although parathyroidectomy remains the treatment of choice for primary hyperparathyroidism, calcimimetics represent an alternative for patients who are not acceptable candidates for surgery.<sup>176</sup> In hyperparathyroidism secondary to chronic renal failure, conventional treatment with calcium supplements, phosphate binders, and vitamin D analogues reduces the associated secondary hyperparathyroidism but also generates undesirable side effects, including hypercalcemia.<sup>176</sup> In effect, such patients develop a variation of the milk–alkali syndrome.<sup>177</sup> In chronic renal failure patients, calcimimetics reduce serum calcium, Pi and the calcium × phosphate product by sensitizing the parathyroid calcium receptor to calcium.<sup>175</sup> In addition, calcimimetics appear to be effective in tertiary hyperparathyroidism, which develops after renal transplantation in 25% to 50% of renal allograft recipients.<sup>175</sup>

Phosphates lower serum calcium by causing deposition of calcium in bone and soft tissue. Because the risk of extraskeletal calcification of organs such as the kidneys and myocardium is less if phosphates are given orally, the intravenous route should be reserved for patients with life-threatening hypercalcemia and those in whom other measures have failed.

## Phosphate

### Physiologic Role

Phosphorus, in the form of inorganic phosphate (Pi), is distributed in similar concentrations throughout the intracellular and the extracellular fluids. Of total body phosphorus, 90% exists in bone, 10% is intracellular, and the remainder, less than 1%, is found in the extracellular fluid. Phosphate circulates as the free ion (55%), complexed ion (33%), and in a protein-bound form (12%). Blood levels vary widely: The normal total Pi ranges from 2.7 to 4.5 mg/dL in adults.

Control of Pi is achieved by altered renal excretion and redistribution within the body compartments.<sup>178</sup> Absorption occurs in the duodenum and jejunum and is largely unregulated. Phosphate reabsorption in the kidney is primarily regulated by PTH, dietary intake, and insulin-like growth factor. Phosphate is freely filtered at the glomerulus, and its concentration in the glomerular ultrafiltrate is similar to that of plasma. The filtered phosphate is

then reabsorbed in the proximal tubule, where it is cotransported with sodium. Cotransport is regulated by phosphorus intake and PTH. Phosphate excretion is increased by volume expansion and decreased by respiratory alkalosis.

Phosphates provide the primary energy bond in ATP and creatine phosphate. Therefore, severe phosphate depletion results in cellular energy depletion. Phosphorus is an essential element of second-messenger systems, including cAMP and phosphoinositides, and is a major component of nucleic acids, phospholipids, and cell membranes. As part of 2,3-diphosphoglycerate, phosphate promotes release of oxygen from the hemoglobin molecule. Phosphorus also functions in protein phosphorylation and acts as a urinary buffer.<sup>178</sup>

## Hypophosphatemia

Hypophosphatemia is characterized by low levels of phosphate-containing cellular components, including ATP, 2,3-diphosphoglycerate, and membrane phospholipids. Serious life-threatening organ dysfunction may occur when the serum Pi falls below 1 mg/dL. Neurologic manifestations of hypophosphatemia include paresthesias, myopathy, encephalopathy, delirium, seizures, and coma.<sup>179</sup> Hematologic abnormalities include dysfunction of erythrocytes, platelets, and leukocytes. Because hypophosphatemia limits the chemotactic, phagocytic, and bactericidal activity of granulocytes, associated immune dysfunction may contribute to the susceptibility of hypophosphatemic patients to sepsis.<sup>180</sup> Muscle weakness and malaise are common. Respiratory muscle failure and myocardial dysfunction are potential problems of particular concern to anesthesiologists. Rhabdomyolysis is a complication of severe hypophosphatemia.

Common in postoperative and traumatized patients, hypophosphatemia (Pi < 2.5 mg/dL) is caused by three primary abnormalities in Pi homeostasis: An intracellular shift of Pi, an increase in renal Pi loss, and a decrease in gastrointestinal Pi absorption. Carbohydrate-induced hypophosphatemia (the “refeeding syndrome”),<sup>181</sup> by insulin-induced cellular Pi uptake, may occur as catabolic patients become anabolic and during medical management of diabetic ketoacidosis.<sup>182</sup> Acute alkalemia, which may reduce serum Pi to 1 to 2 mg/dL, increases intracellular consumption of Pi by increasing the rate of glycolysis. Hyperventilation significantly reduces Pi and, importantly, the effect is progressive after cessation of hyperventilation.<sup>183</sup> Acute correction of respiratory acidemia may also result in severe hypophosphatemia. Respiratory alkalosis probably explains the hypophosphatemia associated with gram-negative bacteremia and salicylate poisoning. Excessive renal loss of Pi explains the hypophosphatemia associated with hyperparathyroidism,

hypomagnesemia, hypothermia, diuretic therapy, and renal tubular defects in Pi absorption. Excess gastrointestinal loss of Pi is most commonly secondary to the use of Pi-binding antacids or to malabsorption syndromes. Hypophosphatemia is associated with anticancer drugs, especially alkylating agents, monoclonal antibodies, and estrogens.<sup>184</sup>

Measurement of urinary Pi aids in differentiation of hypophosphatemia due to renal losses from that due to excessive gastrointestinal losses or redistribution of Pi into cells. Extrarenal causes of hypophosphatemia cause avid renal tubular Pi reabsorption, reducing urinary excretion to below 100 mg/day.

**Table 16-22** Hypophosphatemia: Acute Treatment

Parenteral phosphate, 0.2 mM–0.68 mM/kg (5–16 mg/kg) over 12 hr
Potassium phosphate (93 mg/mL of phosphate)
Sodium phosphate (93 mg/mL of phosphate)

Patients who have severe ( $<1$  mg/dL) or symptomatic hypophosphatemia require intravenous phosphate administration (Table 16-22).<sup>179</sup> In chronically hypophosphatemic patients, 7 to 15 mmol of phosphate can be infused per hour, with the magnitude of the dose proportional to the severity of symptoms.<sup>178</sup> The dosage must be adjusted as indicated by the serum Pi level because the cumulative deficit cannot be predicted accurately. Oral therapy can be substituted for parenteral Pi once the serum Pi level exceeds 2 mg/dL. Continued therapy with Pi supplements is required for 5 to 10 days in order to replenish body stores.

Phosphate should be administered cautiously to hypocalcemic patients because of the risk of precipitating more severe hypocalcemia. In hypercalcemic patients, Pi may cause soft-tissue calcification. Phosphorus must be given cautiously to patients with renal insufficiency because of impaired excretory ability. During treatment, close monitoring of serum Pi, calcium, magnesium, and potassium is essential to avoid complications.

## Hyperphosphatemia

Renal failure is the most common cause of hyperphosphatemia. Renal excretion of Pi remains adequate until the GFR falls below 20 to 25 mL/min. Accumulation of Pi in patients with chronic renal failure merits the inclusion of Pi as a uremic toxin.<sup>185</sup> The clinical features of hyperphosphatemia (Pi  $> 5$  mg/dL) relate primarily to the development of hypocalcemia and ectopic calcification. Hyperphosphatemia is caused by three basic mechanisms: inadequate renal excretion, increased movement of Pi out of cells, and

increased Pi or vitamin D intake. Rapid cell lysis from rhabdomyolysis, sepsis, and the tumor lysis syndrome,<sup>184</sup> can cause hyperphosphatemia, especially when renal function is impaired.

Measurements of BUN, creatinine, GFR, and urinary Pi are helpful in the differential diagnosis of hyperphosphatemia. Normal renal function accompanied by high Pi excretion (>1,500 mg/day) indicates an oversupply of Pi. An elevated BUN, elevated creatinine, and low GFR suggest impaired renal excretion of Pi. Normal renal function and Pi excretion less than 1,500 mg/day suggest increased Pi reabsorption (i.e., hypoparathyroidism).

Hyperphosphatemia is corrected by eliminating the cause of the Pi elevation and correcting the associated hypocalcemia. Calcium supplementation of hyperphosphatemic, hypocalcemic patients should be delayed until serum phosphate has fallen below 2 mmol/L (6 mg/dL).<sup>164</sup> The serum concentration of Pi is reduced by restricting intake, increasing urinary excretion with saline and acetazolamide (500 mg every 6 hours), and increasing gastrointestinal losses by enteric administration of aluminum hydroxide (30 to 45 mL every 6 hours).

Although calcimimetics may replace Pi-binders for managing hyperphosphatemia in patients with chronic renal failure, several Pi-binders remain in common use. Calcium-based binders may contribute to hypercalcemia, sevelamer hydrochloride binds bile acids, and lanthanum carbonate offers the advantage of requiring patients to ingest fewer pills. Hemodialysis and peritoneal dialysis are effective in removing Pi in patients who have renal failure.<sup>179</sup>

## Magnesium

### Physiologic Role

Magnesium is an important, multifunctional, divalent cation located primarily in the intracellular space. Approximately 50% of the typical adult's 24 g of magnesium is located in bone, 12 g is located intracellularly (approximately half in muscle), and less than 1% (<240 mg) of total body magnesium circulates in the serum.<sup>186</sup> Of the normal circulating total magnesium concentration (1.5 to 1.9 mEq/L or 0.75 to 0.95 mmol/L or 1.8 to 2.3 mg/dL), there are three components: protein-bound (30%), anion-bound (15%), and ionized (55%), of which only ionized magnesium is active.

Magnesium is necessary for enzymatic reactions involving DNA and protein synthesis, energy metabolism, glucose utilization, and fatty acid synthesis and breakdown.<sup>187</sup> As a primary regulator or cofactor in many enzyme systems, magnesium is important for the regulation of the sodium-potassium pump, Ca-ATPase enzymes, adenylyl cyclase, proton pumps, and

slow calcium channels. Magnesium has been called an *endogenous calcium antagonist* because regulation of slow calcium channels contributes to maintenance of normal vascular tone, prevention of vasospasm, and perhaps the prevention of calcium overload in many tissues. Because magnesium partially regulates PTH secretion and is important for the maintenance of end-organ sensitivity to both PTH and vitamin D, abnormalities in ionized magnesium concentration ( $[Mg^{2+}]$ ) may result in abnormal calcium metabolism. Magnesium functions in potassium metabolism primarily through regulating sodium–potassium ATPase, an enzyme that controls potassium entry into cells, especially in potassium-depleted states, and controls reabsorption of potassium by the renal tubules. In addition, magnesium functions as a regulator of membrane excitability and serves as a structural component in both cell membranes and the skeleton.

Because magnesium stabilizes axonal membranes, hypomagnesemia decreases the threshold of axonal stimulation and increases nerve conduction velocity. Magnesium also influences the release of neurotransmitters at the neuromuscular junction by competitively inhibiting the entry of calcium into the presynaptic nerve terminals. The concentration of calcium required to trigger calcium release and the rate at which calcium is released from the sarcoplasmic reticulum are inversely related to the ambient magnesium concentration. Thus, the net effect of hypomagnesemia is muscle that contracts more in response to stimuli and is tetany-prone.

Magnesium is widely available in foods and is absorbed through the gastrointestinal tract, although dietary consumption appears to have decreased over several decades.<sup>187</sup> Seventy percent of plasma magnesium is filtered through the glomerular membrane; of the filtered magnesium, 30% is absorbed in the proximal tubule, 60% in the thick ascending loop of Henle, and 10% to 15% in the distal tubule.<sup>186</sup> While both magnesium and Pi are primarily regulated by intrinsic renal mechanisms, PTH exerts a greater effect on renal loss of Pi.

Magnesium has been used to help manage an impressive array of clinical problems in patients who are not hypomagnesemic. Therapeutic hypermagnesemia is used to treat patients with premature labor, preeclampsia, and eclampsia. Because magnesium blocks the release of catecholamines from adrenergic nerve terminals and the adrenal glands, magnesium has been used to reduce the effects of catecholamine excess in patients with tetanus and pheochromocytoma.<sup>187</sup> In patients awaiting liver transplantation, administration of magnesium significantly improved hypocoagulability.<sup>188</sup> Although clinical data are inconsistent, magnesium also may exert an analgesic effect on postoperative pain,<sup>189</sup> perhaps in part due to magnesium's antagonism of the *N*-methyl-D-aspartate glutamate receptor.<sup>189</sup> Magnesium has been proposed as part of an antivasospasm regimen after

subarachnoid hemorrhage, but its efficacy may be limited by induction of hypocalcemia, which in turn could aggravate cerebral vasospasm.<sup>190</sup> Surprisingly, redistribution of magnesium after subarachnoid hemorrhage has been correlated with ECG changes.<sup>191</sup>

Magnesium administration may influence dysrhythmias by direct effects on myocardial membranes, by altering cellular potassium and sodium concentrations, by inhibiting cellular calcium entry, by improving myocardial oxygen supply and demand, by prolonging the effective refractory period, by depressing conduction, by antagonizing catecholamine action on the conducting system, and by preventing vasospasm. Administration of magnesium reduces the incidence of dysrhythmias after myocardial infarction and in patients with congestive heart failure.<sup>192</sup> In addition, magnesium often reverses torsades de pointes, even in normomagnesemic patients.<sup>193</sup> Treatment of hypomagnesemia during cardiopulmonary bypass decreased the incidence of postoperative ventricular tachycardia from 30% to 7% and increased the frequency of continuous sinus rhythm from 5% to 34%.<sup>194</sup>

## Hypomagnesemia

The clinical features of hypomagnesemia ( $[Mg^{2+}] < 1.8$  mg/dL), like those of hypocalcemia, are characterized by increased neuronal irritability and tetany (Table 16-23).<sup>195</sup> Symptoms are rare when the serum  $[Mg^{2+}]$  is 1.5 to 1.7 mg/dL; in most symptomatic patients serum  $[Mg^{2+}]$  is below 1.2 mg/dL. Patients frequently complain of weakness, lethargy, muscle spasms, paresthesias, and depression. When severe, hypomagnesemia may induce seizures, confusion, and coma. Cardiovascular abnormalities include coronary artery spasm, cardiac failure, dysrhythmias, and hypotension. Hypomagnesemia can aggravate digoxin toxicity and congestive heart failure.

Rarely resulting from inadequate dietary intake, hypomagnesemia most commonly is caused by inadequate gastrointestinal absorption, excessive magnesium losses, or failure of renal magnesium conservation. Recent reports demonstrate that hypomagnesemia is associated with administration with proton pump inhibitors, a complication that is resolved if an H<sub>2</sub> antagonist is substituted.<sup>195,196</sup> Hypomagnesemia is particularly frequent in alcoholic patients and in patients in intensive care.<sup>195</sup> Excessive loss of magnesium is associated with prolonged nasogastric suctioning, gastrointestinal or biliary fistulas, and intestinal drains. Inability of the renal tubules to conserve magnesium complicates a variety of systemic and renal diseases, although advanced renal disease with a decreased GFR may lead to magnesium retention. Polyuria, whether secondary to ECV expansion or to pharmacologic or pathologic diuresis, may result in excessive urinary magnesium excretion. Various drugs, including aminoglycosides, cis-platinum,

cardiac glycosides, and diuretics, enhance urinary magnesium excretion. Intracellular shifts of magnesium as a result of thyroid hormone or insulin administration may also decrease serum  $[Mg^{2+}]$ .

Because the sodium–potassium pump is magnesium-dependent, hypomagnesemia increases myocardial sensitivity to digitalis preparations and may cause hypokalemia as a result of renal potassium wasting. Attempts to correct potassium deficits with potassium-replacement therapy alone may not be successful without simultaneous magnesium therapy. Magnesium is important in the regulation of potassium channels. The interrelationships of magnesium and potassium in cardiac tissue have probably the greatest clinical relevance in terms of dysrhythmias, digoxin toxicity, and myocardial infarction. Both severe hypomagnesemia and hypermagnesemia suppress PTH secretion and can cause hypocalcemia. Severe hypomagnesemia may also impair end-organ response to PTH.

**Table 16-23** Manifestations of Altered Serum Magnesium Concentrations

Magnesium Level			Manifestation
mg/dL	mEq/L	mmol/L	
<1.2	<1	<0.5	Tetany Seizures Arrhythmias
1.2–1.8	1–1.5	0.5–0.75	Neuromuscular irritability Hypocalcemia Hypokalemia
1.8–2.5	1.5–2.1	0.75–1.05	Normal magnesium level
2.5–5	2.1–4.2	1.05–2.1	Typically asymptomatic
5–7	4.2–5.8	2.1–2.9	Lethargy Drowsiness Flushing Nausea and vomiting Diminished deep tendon reflex
7–12	5.8–10	2.9–5	Somnolence Loss of deep tendon reflexes Hypotension ECG changes
>12	>10	>5	Complete heart block Cardiac arrest Apnea Paralysis Coma

Hypomagnesemia is associated with hypokalemia, hyponatremia, hypophosphatemia, and hypocalcemia. The reported prevalence of hypomagnesemia in hospitalized and critically ill patients varies from 12 to

65%.<sup>195</sup> Patients who develop hypomagnesemia while in intensive care have an increased mortality.<sup>192</sup> Serum  $[\text{Mg}^{2+}]$  may not reflect intracellular magnesium content. Peripheral lymphocyte magnesium concentration correlates well with skeletal and cardiac magnesium content.

Measurement of 24-hour urinary magnesium excretion is useful in separating renal from nonrenal causes of hypomagnesemia. Normal kidneys can reduce magnesium excretion to below 1 to 2 mEq/day in response to magnesium depletion. Hypomagnesemia accompanied by high urinary excretion of magnesium ( $>3$  to 4 mEq/day) suggests a renal etiology. In the magnesium-loading test, urinary  $[\text{Mg}^{2+}]$  excretion is measured for 24 hours after an intravenous magnesium load.

**Table 16-24** Hypomagnesemia: Acute Treatment

Intravenous  $\text{Mg}^2$ : 8–16 mEq (1–2 g  $\text{MgSO}_4$ ) bolus over 1 hr, followed by 2–4 mEq/hr (250–500 mg/hr  $\text{MgSO}_4$ ) as continuous infusion  
Intramuscular  $\text{Mg}^2$ : 10 mEq q4–6h

<sup>a</sup> $\text{MgSO}_4$ : 1 g = 8 mEq/mg;  $\text{MgCl}_2$ : 1 g = 10 mEq/mg.

Magnesium deficiency is treated by the administration of magnesium supplements (Table 16-24). One gram of magnesium sulfate provides approximately 4 mmol (8 mEq or 98 mg) of elemental magnesium. Mild deficiencies can be treated with diet alone. Replacement must be added to daily magnesium requirements (0.3 to 0.4 mEq/kg/day). Symptomatic or severe hypomagnesemia ( $[\text{Mg}^{2+}] < 1$  mg/dL) should be treated with parenteral magnesium: 1 to 2 g (8 to 16 mEq) of magnesium sulfate as an intravenous bolus over the first hour, followed by a continuous infusion of 2 to 4 mEq/hr. Therapy should be guided subsequently by the serum magnesium level. The rate of infusion should not exceed 1 mEq/min, even in emergency situations, and the patient should receive continuous cardiac monitoring to detect cardiotoxicity. Because magnesium antagonizes calcium, blood pressure and cardiac function should be monitored, although blood pressure and cardiac output usually change little during magnesium infusion.

During repletion, patellar reflexes should be monitored frequently and magnesium withheld if they become suppressed. Patients who have renal insufficiency have a diminished ability to excrete magnesium and require careful monitoring during therapy. Repletion of systemic magnesium stores usually requires 5 to 7 days of therapy, after which daily maintenance doses of magnesium should be provided. Magnesium can be given orally, usually in a dose of 60 to 90 mEq/day of magnesium oxide. Hypocalcemic, hypomagnesemic patients should receive magnesium as the chloride salt because the sulfate ion can chelate calcium and further reduce the serum

[Ca<sup>2+</sup>].

## Hypermagnesemia

Most cases of hypermagnesemia ([Mg<sup>2+</sup>] > 2.5 mg/dL) are iatrogenic, resulting from the administration of magnesium in antacids, enemas, or parenteral nutrition, especially to patients with impaired renal function. Other rarer causes of mild hypermagnesemia are hypothyroidism, Addison disease, lithium intoxication, and familial hypocalciuric hypercalcemia. Hypermagnesemia is rarely detected in routine electrolyte determinations. Hypermagnesemia antagonizes the release and effect of acetylcholine at the neuromuscular junction. The result is depressed skeletal muscle function and neuromuscular blockade. Magnesium potentiates the action of nondepolarizing muscle relaxants and decreases potassium release in response to succinylcholine. The clinical features of progressive hypermagnesemia are listed in [Table 16-23](#).

The neuromuscular and cardiac toxicity of hypermagnesemia can be acutely, but transiently, antagonized by giving intravenous calcium (5 to 10 mEq) to buy time while more definitive therapy is instituted.<sup>179</sup> All magnesium-containing preparations must be stopped. Urinary excretion of magnesium can be increased by expanding ECV and inducing diuresis with a combination of saline and furosemide. In emergency situations and in patients with renal failure, magnesium may be removed by dialysis.

# 17 Hemostasis and Transfusion Medicine

LOUANNE M. CARABINI • GLENN RAMSEY

## Introduction

## Hemostasis and Coagulation

- Primary Hemostasis
- Secondary Hemostasis
- Fibrinolysis

## Laboratory Evaluation of Hemostasis

- Laboratory Evaluation of Primary Hemostasis
- Laboratory Evaluation of Secondary Hemostasis and Coagulation
- Viscoelastic Testing
- Diagnosis of Thromboembolic Disorders
- Monitoring Anticoagulation Therapeutic Agents

## Blood Component Production

- Blood Collection
- Component Processing and Storage
- Plasma Derivatives
- Pathogen Inactivation
- RBC and Platelet Substitutes

## Blood Products and Transfusion Thresholds

- Compatibility Testing
- Red Blood Cells
- Platelets
- Plasma Products
- Cryoprecipitate
- Fibrinogen Concentrate

## The Risks of Blood Product Administration

- Infectious Risks of Blood Product Administration
- Noninfectious Risks of Blood Product Administration

## Blood Conservation Strategies

- Autologous Blood Transfusion

## Disorders of Hemostasis: Diagnosis and Treatment

- Disorders of Primary Hemostasis
- Disorders of Secondary Hemostasis

Hereditary Hypercoagulability  
Acquired Disorders of Hemostasis

## Anticoagulation and Pharmacologic Therapy

Anticoagulation Regimens and Associated Anesthetic Concerns  
Recombinant Activated Factor VII  
Prothrombin Complex Concentrates  
Desmopressin  
Antifibrinolytic Therapy

## Conclusions

## KEY POINTS

- 1 Modern transfusion medicine focuses on patient-centered blood component therapy.
- 2 Blood must not only be maintained as a fluid in normal circulation, but also be capable of forming a solid clot to stanch leaks in the vascular wall, and then dismantling the clot when the need has passed.
- 3 Clotting factors in the plasma are activated at sites of endothelial injury and assemble in enzymatic complexes to activate thrombin.
- 4 Fibrin clots must be broken down after their job is done, and fibrinolysis is a complex process with checks and balances.
- 5 The first screening test for hemostatic problems should always be the patient's medical history.
- 6 Platelet aggregation is the most detailed overall platelet function test (PFT).
- 7 A general oversight of plasma clotting factor activity is obtained by the prothrombin time (PT) for the extrinsic (tissue) pathway and the activated partial thromboplastin time (aPTT) for the intrinsic (contact) pathway.
- 8 Disseminated intravascular coagulopathy (DIC) describes unchecked coagulation initiated by pathologic systemic activation of the intrinsic clotting pathway.
- 9 The risk for venous thromboembolism is increased by intercurrent factors such as physical inactivity or immobilization, malignancy, oral contraceptives, estrogen therapy, and pregnancy.
- 10 Most anticoagulant therapies need ongoing or selective testing for assessment of therapeutic effect.
- 11 Leukoreduction (LR) to remove WBCs from red blood cells (RBCs) and platelets reduces the risk of HLA alloimmunization, febrile nonhemolytic transfusion reactions (FNHTRs), and CMV transmission in patients who require these precautions.

- 12 Plasma derivatives are proteins processed from plasma for therapeutic infusions.
- 13 Techniques have been developed to kill microbial pathogens in blood components.
- 14 Many years of effort have gone into the search for an oxygen-carrying substitute for RBCs.
- 15 Routine RBC compatibility testing includes ABO and RhD typing, an antibody screen for IgG non-ABO RBC antibodies, and an RBC cross-match.
- 16 Over the past decade, transfusion practices for medical and surgical patients shifted from a liberal strategy to more restrictive management with lower thresholds and careful consideration of the balance between transfusion risks and the physiologic consequences of anemia.
- 17 Oxygen delivery to the tissues ( $DO_2$ ) is dependent on cardiac output (CO), regional blood flow, and oxygen-carrying capacity, also known as the oxygen content ( $CaO_2$ ) of blood.
- 18 Numerous recommendations provide guidance for the transfusion management of thrombocytopenia and acquired or inherited platelet disorders.
- 19 Cryoprecipitate is created by a controlled thaw of frozen plasma, which allows for precipitation of large molecules, most notably fibrinogen and vWF.
- 20 Over the past few decades, the risk–benefit ratio of blood product transfusion has been the subject of several studies and review articles.
- 21 Given the extensive use of more sensitive methods for screening and controlling the infectious risks of blood product transfusion, noninfectious complications have emerged as the major source of transfusion-related morbidity and mortality.
- 22 Transfusion-related acute lung injury (TRALI) is a clinical diagnosis that can be clouded by confounding comorbidities or patient acuity; therefore, TRALI tends to be underreported in the literature and is extremely difficult, if not impossible, to study with randomized prospective clinical trials.
- 23 Preoperative autologous donation programs are most effective when double units are donated with ample time for erythropoiesis prior to the date of surgery.
- 24 Over the past decade, RBC salvage techniques have improved drastically and now offer an efficient, cost-effective, and safe method for perioperative blood conservation.
- 25 Disorders of hemostasis can be classified as those that cause a propensity for hemorrhage and those that facilitate inappropriate thrombosis.
- 26 Symptomatically, disorders of primary hemostasis often present with

- superficial signs of bleeding on the skin or mucosa.
- 27 Von Willebrand disease (vWD) is the most common hereditary bleeding disorder, with a prevalence of approximately 1% in the general population.
  - 28 Hemophilia is a genetic disease that results from deficiencies or dysfunction of specific clotting factors.
  - 29 Antiplatelet therapy is indicated for patients at risk for cerebral vascular accident, myocardial infarction, or other vascular thrombosis complications.
  - 30 Heparin-induced thrombocytopenia (HIT) is a clinical disorder that develops after extended use of heparin therapy. It occurs in approximately 1% to 5% of patients receiving heparin and is associated with morbidity from thromboembolic complications.
  - 31 Recombinant activated factor VII (rFVIIa) is only indicated for the treatment of hemophiliacs with inhibitors/antibodies and factor VII deficiency.
  - 32 Prothrombin complex concentrates are now the drug of choice for emergent reversal of warfarin in place of rFVIIa and fresh frozen plasma (FFP).
  - 33 Antifibrinolytic agents have been used to prevent and treat surgical blood loss for several decades.

## Introduction

Recent focus on quality, safety, and cost effectiveness in health care extends **1** into the practice of transfusion medicine. Patient-centered blood management emphasizes the use of evidence-based decisions and blood conservation strategies. There continues to be significant variability in blood product transfusion practices despite consistent guidelines from experts and task forces from the American Society of Anesthesiologists (ASA), the American Association of Blood Banks (AABB), the Society of Cardiac Anesthesiologists (SCA), and the Society of Critical Care Medicine (SCCM).<sup>1,2</sup> Restrictive transfusion practices continue to demonstrate improved outcomes with noninferior or reduced morbidity and mortality; however, it remains unclear which patient characteristics determine the appropriate transfusion goal for a given health-care situation. Therefore, it is imperative for the anesthesia provider to understand the treatment benefits, the rare and common adverse effects, and the specific therapeutic details of blood product preparation, conservation, and delivery in order to best manage their patients.

This chapter begins with a review of primary and secondary hemostasis, fibrinolysis, and regulation of the coagulation pathway. We continue with a

description of the most common coagulation profile tests, followed by the method for blood product collection and storage. The therapeutic indications and risks associated with blood component therapy are discussed at length. The chapter also includes extensive clinical sections discussing congenital and acquired deficiencies in hemostasis and coagulation, as well as an up-to-date presentation of available pharmacologic treatment medications to maintain a balanced hemostatic mechanism.

## Hemostasis and Coagulation

### *Primary Hemostasis*

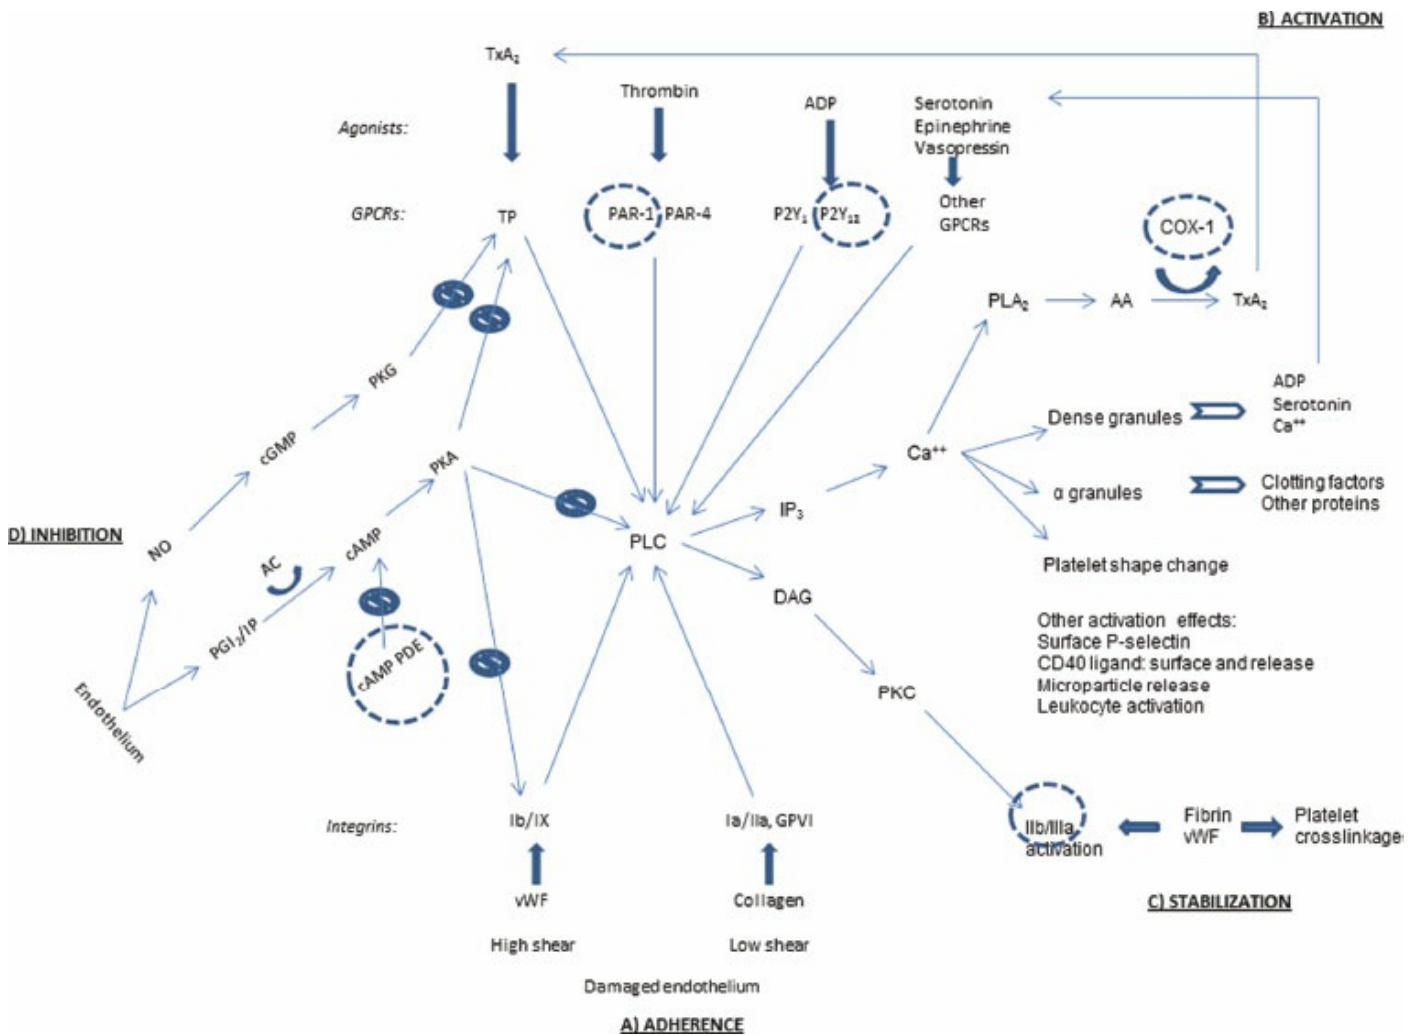

Blood must not only be maintained as a fluid in normal circulation, but also be capable of forming a solid clot to stanch leaks in the vascular wall, and then dismantling the clot when the need has passed. This delicate equilibrium between anticoagulation and coagulation is maintained by a complex system of counterbalanced blood proteins and cells (platelets). Many congenital and acquired disorders can push the system toward either bleeding or thrombosis. The patient care team has a number of tests to evaluate the system, and many therapeutic modalities to correct these imbalances.

*Platelets* adhere to sites of endothelial disruption, undergo activation to recruit more platelets and amplify the platelet response, and then cross-link with fibrin, the end product of the plasma clotting factor cascade, to form a platelet plug. *Primary hemostasis* (Fig. 17-1) describes the initiation of the platelet plug and clotting mechanism.

### **Adherence**

When the endothelial lining is disrupted to expose the underlying matrix, platelets attach to collagen via surface integrin receptors—glycoproteins (GP) Ia/IIa and GP VI (Fig. 17-1A). Collagen adherence is favored in low-shear conditions such as venous circulation.<sup>3</sup> In high-shear arterial blood flow, von Willebrand factor (vWF) from endothelial cells and from pre-existing clot binds to integrin Ib/IX, the other major adherence anchor.<sup>4</sup> In capillary blood flow, platelets are pushed to the periphery by red blood cells (RBCs), so anemia lessens platelet contact and reduces platelet function.<sup>3</sup>

**Figure 17-1** Overview of platelet pathways for adherence, activation, stabilization, and physiologic inhibition. Many pathway intermediaries and other elements are not shown, but are reviewed elsewhere.<sup>3,5</sup> *Thin arrows*: signaling pathways. *Thick arrows*: ligand binding. *Curved arrows*: catalysis. *Clear arrows*: secretion. *Slashed circles*: inhibitory signaling pathways. *Round circles*: antiplatelet drug targets. **(A)** Adherence. vWF, von Willebrand factor. Glycoproteins Ib/IX, Ia/IIa, and VI. **(B)** Activation. Agonists: TxA<sub>2</sub>, thromboxane A<sub>2</sub>; ADP, adenosine diphosphate. Receptors: GPCR, G-protein–coupled receptor; TP, thromboxane prostanoid; PAR, protease-activated receptor. Intermediaries: PLC, phospholipase C; IP<sub>3</sub>, inositol-1,4,5-triphosphate; DAG, diacylglycerol; PKC, protein kinase C; Ca<sup>2+</sup>, calcium; PLA<sub>2</sub>, phospholipase A<sub>2</sub>; AA, arachidonic acid; COX, cyclooxygenase. **(C)** Stabilization. Glycoprotein IIb/IIIa. **(D)** Inhibition. NO, nitric oxide; PGI<sub>2</sub>, prostaglandin I<sub>2</sub> (prostacyclin); IP, PGI<sub>2</sub> receptor; AC, adenylate cyclase; cAMP, cyclic adenosine monophosphate; PDE, phosphodiesterase; cGMP, cyclic guanosine monophosphate; PKA, protein kinase A; PKG, protein kinase G. Targets of antiplatelet drugs. COX-1: aspirin, triflusal. P2Y<sub>12</sub>: clopidogrel, prasugrel, ticlopidine, cangrelor, ticagrelor. cAMP PDE: dipyridamole, cilostazol. IIb/IIIa: abciximab, eptifibatide, tirofiban.

## Activation

Platelet activation can be mediated by numerous signaling pathways from the platelet surface (Fig. 17-1B). In “outside-in” signaling, a central target is

phospholipase C (PLC). The above adherence integrins trigger pathways to activate PLC.<sup>3</sup> Another set of surface receptors, G-protein-coupled receptors (GPCRs), are activated by an array of corresponding agonists, including thrombin from the factor clotting cascade, adenosine diphosphate (ADP), thromboxane A<sub>2</sub> (TxA<sub>2</sub>), serotonin, epinephrine, and vasopressin. Each of these agonist-GPCR pairings set off activation pathways for PLC as well.<sup>5</sup>

Activated PLC leads to several structural changes in the platelets. Via inositol-1,4,5-triphosphate (IP<sub>3</sub>), calcium (Ca<sup>2+</sup>) is released from storage tubules. Calcium ions catalyze release of dense granules and  $\alpha$ -granules at the platelet surface. These granules contain ADP, serotonin, and more Ca<sup>2+</sup>, all of which can activate more platelets.<sup>3</sup> The  $\alpha$ -granules contain numerous proteins, including factor V, fibrinogen, and platelet factor 4 (PF4), which promotes clotting by binding and neutralizing heparin-like compounds and heparin.<sup>3</sup> (This heparin-PF4 complex is the target antigen for the antibodies causing heparin-induced thrombocytopenia [HIT], discussed in depth later in this chapter.) Calcium also facilitates rearrangement of the platelet microskeleton to change the platelet shape from round and discoid to flat and spiky. Furthermore, the Ca<sup>2+</sup> helps activate phospholipase A<sub>2</sub> (PLA<sub>2</sub>), which releases arachidonic acid (AA) from the platelet membrane. AA, as catalyzed by cyclooxygenase-1 (COX-1), is modified to TxA<sub>2</sub>, which can then activate more platelets.<sup>4</sup> Activated platelets also have surface P-selectin and surface-bound and released CD40 ligand. They also release circulating microparticles and attract and activate leukocytes; these features further contribute to hemostasis and also play a role in inflammation.<sup>3</sup>

## Stabilization

The activated PLC initiates “inside-out” signaling of GP IIb/IIIa via diacylglycerol (DAG) and protein kinase C (Fig. 17-1C). This changes the shape of GP IIb/IIIa, which permits it to better bind fibrin and vWF. These proteins can bridge to other activated platelets.<sup>4</sup> The fibrin binding can also enmesh the platelets, contributing to the formation of the platelet plug in the convergence of the platelet and clotting factor systems.

## Inhibition

To maintain hemostatic balance, platelets are naturally inhibited in their endothelial environment. Endothelial cells secrete prostaglandin I<sub>2</sub> (PGI<sub>2</sub>), which binds to a surface receptor to signal increased cyclic adenosine monophosphate (cAMP). Elevated cAMP activates protein kinase A (PKA), a multisite inhibitor of vWF adherence, TxA<sub>2</sub> activation, and PLC internal signaling. However, cAMP is metabolized by cAMP phosphodiesterase (PDE). Endothelial cells also secrete nitric oxide (NO), which at high levels initiates a

signaling pathway leading to inhibition of the TxA<sub>2</sub> receptor.<sup>5</sup>

## Mechanisms of Antiplatelet Medications

Figure 17-1 shows the sites of action for current antiplatelet medications.<sup>6</sup> No drugs are available to counteract the first step, platelet adherence (Fig. 17-1A). Aspirin and triflusal dampen the secretion of TxA<sub>2</sub> by inhibiting COX-1, the enzyme which converts AA into TxA<sub>2</sub> (Fig. 17-1B). Another agonist, ADP, has its P2Y<sub>12</sub> receptor blocked by clopidogrel and several other drugs. The protease-activated receptor-1 (PAR-1) for thrombin activation is blocked by vorapaxar. Formation and stabilization of the platelet plug is blocked by abciximab, eptifibatide, and tirofiban, which act at GP IIb/IIIa (Fig. 17-1C). Finally, the major inhibitory pathway mediated by endothelial PGI<sub>2</sub> is upregulated by dipyridamole and cilostazol (Fig. 17-1D).<sup>6</sup> These medications are discussed later in this chapter.

## Secondary Hemostasis

Clotting factors in the plasma are activated at sites of endothelial injury and assemble in enzymatic complexes to activate thrombin. This *initiates* secondary hemostasis. Thrombin then *amplifies* production of itself by activating other more efficient enzymes, which *propagate* a thrombin burst. Thrombin also converts fibrinogen to fibrin, which cross-links with activated platelets to form the platelet plug. Each of the three enzymatic complexes in the clotting process consists of four parts: an enzyme in the serine protease family, a cofactor, a plasma membrane phospholipid surface such as the platelet, and calcium ion (Ca<sup>2+</sup>). The proteases convert other clotting factors from their inactive circulating configuration to an active form (termed [factor number] a).<sup>7</sup>

*The extrinsic pathway* (Fig. 17-2). The process begins when endothelial disruption exposes tissue factor (TF) on underlying cell membranes extrinsic to the circulation—hence the term “extrinsic pathway.” TF binds both VII and VIIa, which circulate at low levels, and is a cofactor for the activation of factor VII. VIIa enzyme, TF cofactor, cell membrane phospholipid, and Ca<sup>2+</sup> form the first complex, a low-efficiency extrinsic-pathway “tenase” that activates factor X and factor IX. Then Xa enzyme, its cofactor Va (derived in large part from factor V released from activated platelet α-granules), phospholipid, and Ca<sup>2+</sup> assemble to form the second complex, a “prothrombinase,” which converts prothrombin (II) to thrombin (IIa).<sup>7</sup>

*The intrinsic pathway* (Fig. 17-2). Thrombin has several central functions. It activates platelets via surface receptors PAR-1 and PAR-4 (see Primary Hemostasis), cleaves more V to Va, and initiates the “intrinsic” (intravascular)

coagulation pathway by cleaving factor XI to XIa. XIa cleaves more IX to IXa. Thrombin also activates VIII to VIIIa. (VIII is carried and stabilized in the plasma by vWF until needed, so vWF deficiency also results in low plasma VIII levels.) The third complex is then formed: IXa enzyme, VIIIa cofactor, phospholipid, and  $\text{Ca}^{2+}$ . This is a high-efficiency intrinsic-pathway “tenase,” which provides many times more Xa for more prothrombinase complex. Ultimately, thrombin cleaves fibrinogen to fibrin monomers, which then polymerize extensively. Fibrin polymers are cross-linked by factor XIIIa (also activated by thrombin) to form the stable fibrin clot. Fibrin also cross-links activated platelets by their GP IIB/IIIa receptors to enmesh platelets and fibrin in the platelet plug (see Primary Hemostasis).<sup>7</sup>

All of these clotting factors are primarily produced in the liver, except for VIII, which is also released by endothelial cells and is well maintained in liver disease. The plasma half-life of most clotting factors is around 1.5 to 3 days, except for the initiating factor VII (6 hours) and the cofactors V and VIII (8 to 12 hours), which are much shorter. Four critical enzyme factors—VII in the extrinsic tenase, IX in the intrinsic tenase, X in the prothrombinase, and prothrombin (II)—must be carboxylated at multiple glutamic acid residues after translation, in order to interact with phospholipid and  $\text{Ca}^{2+}$ . Vitamin K in its reduced form is the cofactor for the glutamyl-carboxylase enzyme, and thus these four factors (II, VII, IX, X) are vitamin K-dependent.<sup>7</sup>

**Figure 17-2** Schematic diagram of the coagulation cascade of clotting factors, with extrinsic, intrinsic, and common pathways. Von Willebrand factor (vWF) and factor VIII circulate together (><). *Gray arrows:* secretion. *Red:* vitamin K-dependent factors. *Green:* cofactors. *Purple arrows:* thrombin activation. *Black arrow:* uptake. *Dotted lines:* intrinsic-extrinsic crossover. *Solid boxes:* also  $\text{Ca}^{++}$  and platelet phospholipid.

## Inhibition of Clotting Factors

The clotting pathways have three main regulatory inhibitors (Fig. 17-3)<sup>3-5,7,8</sup>:

1. TF pathway inhibitor (TFPI) inhibits the external tenase complex by binding to the VIIa protease and to its Xa product. TFPI is produced in endothelial cells, and its release is stimulated by heparin. Heparin in turn binds to and raises the inhibitory efficiency of TFPI.
2. Antithrombin-III (AT-III) is a serine protease inhibitor or serpin. Serpins disrupt the active sites and increase the clearance of their target proteases. AT-III inhibits proteases in all clotting pathways: VIIa in extrinsic tenase, Xa in prothrombinase, XIa and IXa in the intrinsic tenase pathway, and thrombin. AT-III's inhibitory function is greatly increased when bound to heparin.
3. Protein C-ase is an enzymatic complex with the same four-part structure as the coagulation complexes above: an enzyme, thrombin, its cofactor thrombomodulin, phospholipid, and  $\text{Ca}^{2+}$ . Thrombomodulin is expressed on endothelial cell membranes. In the protein C-ase complex, thrombin cleaves and activates protein C. Activated protein C (APC) brakes clotting by cleaving VIIIa and Va, the cofactors for the external tenase and the prothrombinase complexes. Protein C has a short half-life of 6 hours. Protein S is thought to be a cofactor for protein C; both are vitamin K-dependent.<sup>7</sup>

## Fibrinolysis

Fibrin clots must be broken down after their job is done (fibrinolysis),  and is a complex process with checks and balances. Plasminogen is  activated to plasmin, which breaks down fibrin polymers (Fig. 17-4).<sup>9</sup> The major activator of plasminogen in the blood is tissue plasminogen activator (tPA), which is secreted from endothelial cells and platelets. Both plasminogen and tPA bind to lysine sites on fibrin. When associated with cross-linked fibrin, tPA becomes much more efficient. Once some plasmin is formed, it cleaves tPA to a more active form. tPA also directly cleaves fibrin polymers.

In tissues, urokinase is the main plasminogen activator. Urokinase is secreted from the endothelium, monocytes, macrophages, and urinary epithelium. These cells also bind plasminogen with two receptors, the annexin A2 complex and the urokinase receptor, which facilitate its conversion to plasmin. Plasmin also activates urokinase to a more active form. Urokinase and tPA can be administered as medications to lyse thrombi.

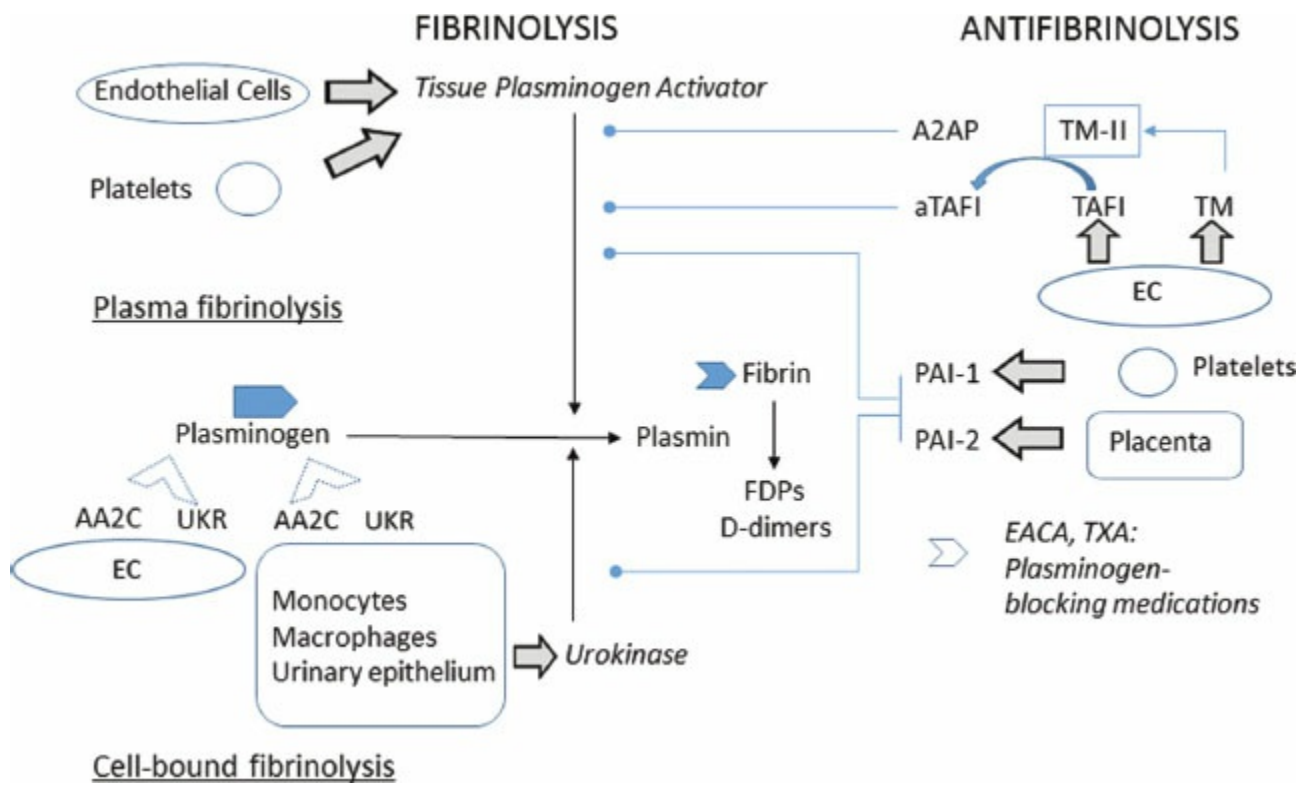

## Inhibition of Fibrinolysis

Plasminogen activation inhibitor-1 (PAI-1) is a serpin which binds to 

tPA and urokinase and accelerates their clearance from plasma (Fig. 17-4). Activated platelets release PAI-1 from  $\alpha$ -granules. PAI-2, which acts similarly to PAI-1, is secreted by the placenta and is prominent in pregnancy. Thrombin-activated fibrinolysis inhibitor (TAFI) is secreted from endothelial cells and is activated by the thrombin–thrombomodulin complex. TAFI cleaves fibrin and fibrin polymers in a fashion that inhibits the action of tPA, and TAFI also inhibits the action of plasmin on fibrin.  $\alpha_2$ -Antiplasmin binds to plasmin and blocks its action, although this also slows the metabolism of plasmin.

**Figure 17-3** Schematic diagram of inhibitory control of the coagulation cascade. *Purple arrows*: thrombin activation. *Blue circle-head arrows*: inhibition. TM, thrombomodulin; TFPI, tissue factor pathway inhibitor. *Red*: vitamin K–dependent factors. *Green*: cofactor.

**Figure 17-4** Fibrinolysis and antifibrinolysis pathways. AA2C, annexin A2 complex; A2AP,  $\alpha$ -2-antiplasmin; EACA, epsilon-aminocaproic acid; EC, endothelial cells; FDPs, fibrin degradation products; PAI, plasminogen activator inhibitor; (a)TAFI, (activated) thrombin-activated fibrinolysis inhibitor; TM, thrombomodulin; II, factor II (thrombin); TXA, tranexamic acid; UKR, urokinase receptor. *Gray arrows*: secretion. *Black arrows*: enzyme activation. *Curved arrow*: thrombin activation. *Round-headed lines*: inhibition. *Dotted angles*: AA2C and UKR cell-membrane receptors binding to plasminogen. *Solid pentagon* on plasminogen: lysine-binding sites attaching to fibrin. *Solid chevron* on fibrin: lysines to which plasminogen binds. *Clear chevron*: antifibrinolytic medications blocking the lysine-binding sites on plasminogen. *Italics*: pharmacologic therapies promoting (tPA, urokinase) or inhibiting (EACA, TXA) fibrinolysis.

Fibrinolysis is inhibited pharmacologically by epsilon-aminocaproic acid (EACA) and tranexamic acid (TXA), which stabilize clots. These drugs are lysine analogues that block the lysine-binding sites of plasminogen, preventing it from acting on fibrin.

## Laboratory Evaluation of Hemostasis

**5** The first screening test for hemostatic problems should always be the patient's medical history.<sup>10</sup> The nature of any abnormal bleeding is helpful; dermal or mucosal bleeding may suggest platelet dysfunction, whereas hemarthroses or soft tissue bleeding suggests factor deficiencies. Besides any direct past history of bleeding, thrombosis, or laboratory abnormalities, the patient's experience with hemostatic challenges such as surgery, dental procedures, and menstruation may help rule-out clinical

problems or suggest a lifelong congenital or more recent acquired disorder. The family history is helpful in diagnosing a congenital problem and the possible pattern of inheritance. Anticoagulants and antiplatelet medications, including over-the-counter drugs, should always be reviewed before ordering laboratory analysis.

### **Laboratory Evaluation of Primary Hemostasis**

The normal automated platelet count in adults is approximately 150,000 to 400,000/ $\mu$ L. The peripheral blood smear should be examined in specimens with abnormal platelet counts. Microscopic review may reveal clotted specimens, artifactual platelet clumping in vitro, or abnormal platelet morphology. Large platelets are seen in some congenital disorders. One of the first platelet function tests (PFTs) was the template bleeding time, in which a standardized small cut is made on the subject's forearm and the bleeding duration timed. However, this test is invasive, labor-intensive, impractical to repeat frequently, poorly reproducible, and only modestly predictive for bleeding problems.

In vitro PFTs use various platelet agonists to activate and aggregate the patient's platelets.<sup>11</sup> For example, the PFA-100 device (Siemens, Munich, Germany) simulates capillary blood flow through a chamber after activation by collagen and either epinephrine or ADP. Prolonged "closure time" with collagen/epinephrine, but not collagen/ADP, suggests aspirin or other antiplatelet medications. In contrast, when both pairs are abnormal, other congenital or acquired platelet dysfunctions may be present. This type of testing is sometimes used as a screen in patients with a history suggesting platelet problems or von Willebrand disease (vWD). However, the sensitivity and specificity are low. False negatives are common and abnormal results can also be caused by thrombocytopenia, uremia, or anemia. Several other devices test for specific antiplatelet medication effects from aspirin or P2Y<sub>12</sub> inhibitors.<sup>11</sup>

**6** Platelet aggregation is the most detailed overall PFT. Platelets are tested with multiple isolated agonists to assess their patterns of physical aggregation and, in turn, the platelets' own agonist release. Some uncommon congenital disorders lack responses to specific agonists in a characteristic fashion. More detailed testing may be needed for a specific diagnosis, such as electron microscopy for granule defects, flow cytometry for surface receptors and granule markers, or genetic testing.<sup>12</sup>

vWD is a factor deficiency with clinical features of platelet dysfunction, due to the central role of vWF in cross-linking activated platelets to form the platelet plug.<sup>13</sup> Up to 1% of all patients have vWD, with a wide range of severity due to either quantitative or functional defects of vWF. Diagnostic

testing is integral to deciphering the specific defect and type of vWD to ensure the appropriate treatment. Since vWF is the carrier for factor VIII (FVIII) in plasma, vWF protein levels usually correlate with FVIII levels. Initial testing for vWD should include the vWF antigen level, vWF activity level, and FVIII activity level for comparison with vWF. Blood group O persons have shorter plasma half-life and lower normal levels of vWF, so ABO blood typing is needed to interpret a borderline vWF level. Type 1 vWD is a quantitative deficiency, with decreased antigen and activity. Type 2 vWD may have normal antigen levels, but decreased activity from a defective protein. Within type 2, there are several subtypes with different molecular defects, and specialized identification is needed in order to determine the best therapy. Type 3 vWD is a rare, very severe autosomal recessive deficiency.<sup>13</sup> Acquired vWD occurs through removal of vWF from the plasma by adsorption to paraproteins or high number of platelets (hematologic disorders), autoantibodies to vWF, or depletion by turbulent blood flow in congenital heart disease, dysfunctional heart valves, and left ventricular assist devices.<sup>14</sup> The clinical features and management of vWD are discussed later in this chapter.

### **Laboratory Evaluation of Secondary Hemostasis and Coagulation**

**7** A general oversight of plasma clotting factor activity is obtained by the *prothrombin time (PT)* for the extrinsic (tissue) pathway and the *aPTT* for the intrinsic (contact) pathway (Fig. 17-2), with both tests relevant to the common pathway.<sup>10</sup> These clotting tests are performed in blood specimens collected in a chelator (3.2% citrate), which binds  $\text{Ca}^{2+}$  to prevent clotting in the tube. The *in vitro* clotting test is activated by TF in the PT, or by negatively charged surfaces in the aPTT, using phospholipid as a platform (substituting for platelets).  $\text{Ca}^{2+}$  is then added to overcome the specimen chelation, and the time until complete fibrin clotting is measured. Representative normal ranges are around 12 to 15 seconds for the PT and 25 to 35 seconds for the aPTT, but are defined by each laboratory using its own equipment, reagents, and normal specimens. Testing is routinely performed at 37°C, but hypothermia in the patient impairs the enzymatic reactions of clot formation.

Clotting physiology is more complicated than the traditional diagrams of separate cascade pathways for these two tests. For example, thrombin from the extrinsic pathway can activate the intrinsic pathway. *In vitro*, the aPTT clotting test is activated by synthetic contact materials that initiate via factor XII, so deficiencies of XII and other related contact factors cause a prolonged aPTT. However, deficiencies of these contact factors do not cause bleeding and may be associated with impaired fibrinolysis and thrombosis. Fibrinogen

activity is also a critical parameter. Most assays measure the functional conversion of fibrinogen to fibrin, although the fibrinogen protein level can also be measured for comparison to assess fibrinogen dysfunction. Normal fibrinogen levels are around 150 to 400 mg/dL.

## Mixing Studies

To investigate elevated PT or aPTT values, the test should be repeated after mixing the patient's plasma with equal volumes of normal plasma. Even in severe factor deficiencies, the PT or aPTT shows substantial correction toward normal in a mixing study. However, if the patient's plasma contains an inhibitor or an anticoagulant, the normal plasma will also be affected and the PT or aPTT will not be corrected.

Individual factor level activities are determined by the degree of correction observed when patient plasma is mixed with factor-deficient plasma. The classic congenital factor deficiencies are FVIII deficiency (hemophilia A) and factor IX deficiency (hemophilia B). Both are X-linked and thus nearly always in males. Factor XI deficiency is most often seen in persons of Ashkenazi Jewish descent. Acquired factor deficiencies usually involve multiple factors.<sup>15</sup> The vitamin K–dependent factors are II (thrombin), VII, IX, and X. In liver disease, all-factor synthesis is deficient except FVIII, which also comes from endothelium. However, FVIII and other factors can be low in disseminated intravascular coagulation (DIC). As noted, FVIII may be low as part of vWD. Isolated factor X deficiency occurs in some patients with amyloidosis because the abnormal protein absorbs this factor. Assessing factors V (liver disease), VII (liver disease or vitamin K deficiency), and VIII (consumption) may suggest a pattern to aid in the diagnosis of specific clinical syndromes.

*Coagulation inhibitors* are substances, usually antibodies, that block one or more clotting factors. Most do not cause bleeding; the most common examples are lupus anticoagulants (LAs), a type of antiphospholipid antibodies (APLA). However, factor-specific inhibitor antibodies can block clotting in vivo and cause bleeding.<sup>15</sup> They are identified by their effect on the plasma factor's activity and semiquantified by assessing how much interference the patient's plasma gives to factor level measurements in normal plasma. Some severe hemophiliacs and other factor-deficient patients develop alloantibodies to therapeutic clotting factors, interfering with treatment and necessitating alternative factor therapies or immunosuppression. Bovine thrombin used for topical hemostasis can induce cross-reacting antibodies to the patient's own factor V. Autoantibodies to specific clotting factors, most commonly FVIII, can cause serious coagulopathy.

DIC describes unchecked coagulation initiated by pathologic systemic

activation of the intrinsic clotting pathway. The specific pathophysiology of DIC is discussed later in this chapter, but diagnostic criteria require an inciting condition such as extensive tissue injury or a systemic inflammatory response secondary to infection, obstetrical complication, or malignancy. Intravascular platelet activation and fibrin formation lead to thrombocytopenia, hypofibrinogenemia, and RBCs sheared by fibrin strands (schistocytes). The results of coagulation testing vary, but often show prolonged PT and aPTT. In some patients, thrombosis is the most prominent clinical finding, but in most patients, the depletion of platelets and clotting factors with accompanying activation of fibrinolysis leads to diffuse consumptive coagulopathy. Fibrin formation followed by fibrinolysis generates the fibrin fragments called D-dimers, which when quantified in immunologic testing are a useful indicator of DIC.

Three other tests are commonly performed during surgery with whole-blood specimens: the *activated clotting time (ACT)*, *ecarin clotting time (ECT)*, and viscoelastic whole-blood clotting. The ACT, a point of care test, assesses the intrinsic clotting pathway and is used mainly to monitor heparin anticoagulation and its protamine reversal during cardiopulmonary bypass or vascular surgery. The ECT also describes the intrinsic clotting function, but it is primarily used for measuring the clinical effects of direct thrombin inhibitors (DTIs) such as bivalirudin and dabigatran. The ACT and aPTT also reflect the clinical efficacy of DTIs, but at high doses required for cardiopulmonary bypass, ECT is more accurate.<sup>16</sup> However, the ECT is not widely available.

### **Viscoelastic Testing**

Whole-blood clotting and fibrinolysis can be assessed by viscoelastic testing in thromboelastography (TEG, Haemoscope Corp., Niles, IL, USA) or rotation thromboelastometry (ROTEM, Pentapharm GmbH, Munich, Germany).<sup>17</sup> These tests measure the rate, strength, and lysis, if any, of clot formation. Numerous parameters can be measured with these tests; accordingly, the TEG–ROTEM working group attempted to standardize the parameters obtained from both testing modalities in order to make them more clinically relevant. There are minor differences in the mechanisms for TEG versus ROTEM; however, both involve the use of whole blood in a heated cup with the addition of a sensor pin. The cup or the pin oscillates while the blood clots. The increasing resistance to oscillation is transmitted through the sensor pin, resulting in a graphic depiction of clot formation. The patterns obtained can implicate defects in factor levels, platelet function, fibrinogen concentration, and/or the presence of abnormal fibrinolysis, the last of which is difficult to measure rapidly otherwise. Testing can be performed in the

presence of inhibitors of heparin or fibrinolysis to help judge whether these drugs would be effective therapies. This test format has also been adapted to assess antiplatelet therapy in patients with ventricular assist devices.<sup>18</sup> Viscoelastic testing is helpful in determining the appropriate therapy, including platelets, plasma, fibrinogen replacement, or antifibrinolytics, particularly complex bleeding syndromes such as massive hemorrhage with consumptive or dilutional coagulopathy progress.

## **Diagnosis of Thromboembolic Disorders**

**9** The risk for deep venous thrombosis (DVT), pulmonary embolism (PE), venous thromboembolism (VTE), and other thromboses is increased by intercurrent factors such as physical inactivity or immobilization, malignancy, oral contraceptives, estrogen therapy, and pregnancy. However, in addition to or especially in the absence of such factors, laboratory testing often identifies an underlying congenital or acquired predisposing abnormality that tips the hemostatic systems toward thrombosis. Discovery of one or more risk factors may influence the course of therapy and suggest benefit from family studies.

### **Congenital Risk Factors for Thrombosis**

The most commonly tested congenital problems discussed below increase the risk of VTE.<sup>19</sup> Although arterial thrombosis may involve a few of these factors, platelets are more directly involved on the arterial side, and congenital contributions are less well defined. Some investigators have described a “sticky platelet syndrome,” with hyperactive platelet aggregometry. Although severe congenital problems may present in childhood, they are rare; most thrombotic presentations are in adulthood over a lifetime of potential risk. Congenital problems are mostly categorized as deficiencies in antithrombotic pathways or hypercoagulable clotting factors.

Several congenital factors involve the protein C-ase complex and its function. The most common hypercoagulable mutation is factor V Leiden (FVL), in about 5% of Caucasians.<sup>20</sup> FV is the cofactor for FX when the latter activates prothrombin to thrombin. APC is the natural brake on FV, by cleaving it at Arg506. FVL carries the autosomal dominant mutation Arg506Gln, rendering FV fairly resistant to APC. Thus, FV is overactive and thrombin formation is favored. The FVL polymorphism is readily identified genetically. However, a small percentage of persons with resistance to APC have other mutations in FV or other conditions. Therefore, slightly more inclusive is the functional clotting test for APC resistance, which assesses plasma clotting time with and without reagent APC.

Protein C itself is functionally deficient in up to 0.5% of the population,

with autosomal dominant inheritance. This leads to overactive FVIII and FV cofactors in their respective intrinsic tenase and prothrombinase complexes. Most have low activity and antigen (type I), but some have low activity with normal antigen levels (type II). Homozygous protein C deficiency is a very severe thrombotic disorder beginning in infancy. Protein S deficiency can lead to thrombosis because of its cofactor role to protein C. Around 1 in 700 persons has autosomal dominant deficiency. Protein S circulates partly bound to the complement C4 binding protein and partly as the unbound (free) active form. Nearly all cases of protein S deficiency can be identified by assaying the free antigen and then categorized as to whether the total antigen is low (type I) or normal (type II). Type II is rare, and has low function but normal antigen levels. Both protein C and protein S are vitamin K–dependent, and therefore vitamin K deficiency or warfarin interferes with laboratory assessment of their activities. Warfarin-induced skin necrosis in protein C or S deficiencies is discussed in antithrombotic therapy testing below. In AT-III deficiency, the relative lack of its normal blocking function on the key enzymes VIIa, IXa, Xa, and XIa leads to thrombosis risk. Testing for AT-III activity will detect both quantitative and qualitative defects.

The best characterized congenital gain in thrombotic function is the prothrombin mutation G20210A (guanine to adenine). This autosomal dominant condition is found in about 1 in 50 Caucasians, but is much less prevalent in African and Asian backgrounds. Persons with this variant have high circulating prothrombin levels as the reason for thrombosis risk. Genetic testing for the mutation is more definitive than prothrombin levels. Elevated FVIII levels may be a modest risk factor for thrombosis, but FVIII is an acute-phase reactant and rises in many intercurrent conditions. Whether there is an inherited element to persistently elevated FVIII levels is unclear.

## Acquired Risk Factors for Thrombosis

Several factors increase the risk of thrombosis.<sup>21</sup> APLA are associated with both arterial and venous thrombosis risk. These antibodies bind to phospholipid–protein complexes. Several possible mechanisms for their in vivo effects have been proposed. They may bind to and activate endothelial cells, which in turn could directly initiate coagulation and/or cause vascular injury. They may interfere with phospholipids in the protein C-ase enzyme complex, leading to diminution of protein C's regulatory function. The various antigenic targets and mechanisms of APLA require multiple tests for their detection. Studies should include tests of clotting function, most notably LA tests, and tests of solid-phase binding to antigen targets, such as anticardiolipin antibodies (ACLA) and anti- $\beta_2$ -glycoprotein-1 (A $\beta$ GP). A $\beta$ GP is a protein often present in the phospholipid–protein complex targeted by these

antibodies.

LA antibodies are a common cause of prolonged aPTT that does not correct by mixing with normal plasma. It should be emphasized that the prolonged aPTT is a phenomenon of the in vitro test and is NOT associated with bleeding. However, not all LAs prolong the aPTT. Laboratories testing for LA should use at least two different tests to improve detection. One is usually a test based on the aPTT, but modified with phospholipid reagent selected to be sensitive to LA interference. A second clotting-based test is also recommended, such as the dilute Russell viper venom time (DRVVT), in which the snake venom activates FX in the common pathway, leading to thrombin formation. This test's reagent phospholipid is adjusted by dilution to be LA sensitive, but because the venom bypasses the usual initiating factors, the DRVVT is not affected by autoantibody inhibitors of FVIII or other upstream factors, a potential cause of confusion in the PTT-based assays.

ACLA and A $\beta$ GP antibody tests usually employ enzyme immunoassays (EIAs). A $\beta$ GP may be more specific for physiologic thrombotic effect, by presenting an actual target of in vivo antibodies, whereas ACLA may develop in other conditions such as infections. For example, false-positive nontreponemal syphilis serology is sometimes seen with ACLA.

Hyperhomocysteinemia is a risk factor for venous and possibly arterial thrombosis. This amino acid is made from methionine and is then either converted back or processed to cysteine. The mechanism for thrombosis risk is unclear, but endothelial cell injury has been proposed. Fasting total homocysteine is the initial screening test. Hyperhomocysteinemia can be due to various congenital mutations in homocysteine's metabolic pathways, or can be acquired via vitamin deficiencies affecting its metabolism (folate, B<sub>12</sub>, B<sub>6</sub>) or in many other medical conditions.

## *Monitoring Anticoagulation Therapeutic Agents*

**10** Most anticoagulant therapies need ongoing or selective testing for assessment of therapeutic effect. Appropriate monitoring ensures that these agents are maintained within the therapeutic range; otherwise patients are at risk for thromboembolism and bleeding complications, which can have devastating consequences.

### **Warfarin Anticoagulation**

Warfarin therapy must be monitored by the PT and its analogue for this purpose, the international normalized ratio (INR), in order to avoid under- or overcoagulation. PT methods and reagents can widely differ between laboratories, yielding varying PT values for the same degree of factor

deficiency. However, each PT test vendor supplies a conversion parameter to express the PT as the INR for patients on warfarin. The INR is a normalized value which is intended to compare results across laboratories for evaluating combined deficiencies of factors II, VII, IX, and X, the warfarin-dependent factors. The INR's therapeutic range for warfarin anticoagulation is generally 2.0 to 3.0, except for mechanical heart valves and prevention of myocardial infarction (INR 2.5 to 3.5).<sup>22</sup>

When warfarin is started or stopped, the factors with the fastest plasma turnover (i.e., the shortest half-lives) decline or rise the fastest, respectively. Thus, the inhibitor protein C, with a 6-hour half-life, declines faster than most clotting factors as warfarin takes effect. This can cause an imbalance toward clotting during the initiation of warfarin therapy. Warfarin-induced skin necrosis is a thrombotic complication often occurring when previously unrecognized congenital protein C deficiency accentuates this imbalance.

Warfarin's pharmacology is affected by genetic variations in the metabolism of the drug (cytochrome P450, CYP2C9) or its counterbalancing vitamin K (vitamin K epoxide reductase complex subunit 1, VKORC1). Genetic polymorphism testing has been advocated for achieving more rapid therapeutic effect when initiating therapy or in assessing difficulty achieving the target INR, but clinical trials are divided on its benefit.<sup>23</sup> The INR is not calibrated to evaluate nonwarfarin deficiencies such as liver disease, which affects most other clotting factors. Thus, the INR is not intended to be used in other conditions, including liver disease.

## **Heparin Anticoagulation Testing**

The aPTT is used to assess heparin anticoagulation. Each laboratory determines its own therapeutic target range for heparin anticoagulation, typically of the order of 1.5 to 2.5 times the normal mean. The laboratory determines the exact range for their test system based on a functional enzymatic test for heparin action, the antifactor Xa activity (aFXa). (This is a different test than the clotting factor X activity level). Using the aFXa assay, therapeutic target heparin levels of 0.3 to 0.7 aFXa units/mL are correlated with aPTT results for that range. aFXa testing can be helpful in assessing heparin resistance.

Low-molecular-weight heparin (LMWH) drugs and their analogue, synthetic pentasaccharide (e.g., fondaparinux), do not affect the aPTT assay, and coagulation testing is usually not needed. However, if necessary, the drugs' plasma activity levels can be assessed by aFXa assays calibrated for each drug.<sup>24</sup> This may be helpful in renal failure affecting drug excretion, or in pregnant women, obese patients, and neonates for whom drug levels are less certain after subcutaneous injection. Like heparin, these agents inhibit

factor Xa indirectly via their enhancing effect on AT.

Heparin (and to a lesser degree LMWH) can stimulate the production of antibodies against the heparin–PF4 complex. These antibodies can in turn cause HIT and/or activation of platelets to induce thrombosis.<sup>25</sup> If thrombocytopenia or thrombosis develops in a patient on these drugs, tests for HIT antibodies are available by EIA or by functional measures such as serotonin release. Patients with HIT must avoid heparin and LMWH.

Several newer anticoagulants have become widely used alternatives to warfarin for some indications. These are direct anticoagulants that are not mediated by AT. The oral “xaban” class of drugs, including rivaroxaban and apixaban, directly inhibit factor Xa.<sup>26</sup> Monitoring is not routinely needed. If drug activity must be assessed, the PTT is prolonged but is unreliable; aFXa assays calibrated for each specific drug are used.<sup>27</sup>

DTIs also pose challenges for coagulation testing. These include hirudin from leeches, its recombinant “-rudin” mimicking molecules (intravenous bivalirudin, desirudin), and small synthetic molecules acting at the same site as hirudin on thrombin (intravenous argatroban, oral dabigatran). They all prolong the PT and aPTT and interfere with clot-based fibrinogen assays. There is no consensus on how to quantify the effect of these drugs. The ECT has been promulgated.<sup>27</sup> In the ECT, ecarin, an enzyme in snake venom, cleaves prothrombin to a metabolic intermediate, which is inhibited by hirudin and its analogues. The dilute thrombin time has also been used. However, neither of these tests are widely available.

Emergency reversal of these anticoagulants is becoming available.<sup>28</sup> Idarucizumab, a monoclonal antibody fragment that functionally neutralizes dabigatran, was recently approved by the FDA. Clotting tests are usually corrected by the drug, but additional drug can be given if clotting tests become reelevated and bleeding recurs. Two drugs that block the action of anti-Xa inhibitors are in clinical trials.

## Blood Component Production

### *Blood Collection*

The production of blood components is highly controlled by regulations and accreditation requirements in the interests of donor and recipient safety, as well as therapeutic efficacy. Blood donors are carefully screened and tested, and blood products are made in specialized laboratories and other facilities. Regional blood centers collect and provide most blood components for transfusion, although some hospitals collect blood or platelets to augment their supply. Virtually all blood components come from volunteer unpaid donors. Pharmaceutical companies process plasma into various derivatives or

synthesize some desired proteins for infusion.

Blood donors undergo a confidential interview to screen for medical problems for their own donation safety, as well as for risks of disease transmission to their recipients.<sup>29</sup> They are questioned about risk factors, exposure, or signs of human immunodeficiency virus (HIV), hepatitis, and other infections. There are geographically based deferral criteria for tropical exposure to malaria and (in US donors) European exposure to variant Creutzfeldt–Jakob disease (vCJD). The donor's pulse, blood pressure, and hemoglobin/hematocrit level (US minimum 12.5 g/dL or 38%) are checked. Phlebotomy is performed with validated antiseptic measures to reduce the risk of bacterial contamination in the blood bags. In the United States, donors are deferred for 8 weeks after a whole-blood donation to avoid iron deficiency.

Table 17-1 shows the contents and storage parameters for blood components. In whole-blood donations, 450 to 500 mL of blood is collected into citrate anticoagulant and then separated by centrifugation into RBCs, platelets, and/or plasma. The RBC units usually have most plasma removed and replaced with preservative. In the United States, the plasma must be frozen within 6 hours of collection to be labeled fresh frozen plasma (FFP). A large proportion of plasma is now made as plasma frozen within 24 hours, with minimal effect on clotting factor content compared to FFP. Cryoprecipitate is made from barely thawed FFP, which yields a precipitate rich in fibrinogen; the precipitate is isolated by centrifugation and refrozen.<sup>30</sup> Five bags of “cryo” comprise a typical adult dose. Whole-blood–derived platelets (sometimes called “random-donor platelets”) are derived from platelet-rich plasma in the United States and from the buffy-coat centrifugation layer in other countries.<sup>31</sup> Four to six units are pooled to yield one adult-sized dose of platelets. Traditionally, pooling was done at the hospital just before transfusion, but blood centers can now provide prepooled platelets to hospitals.

Blood components are also collected by apheresis, in which the donor's blood is processed by *ex vivo* centrifugation, the desired component(s) are siphoned off into citrate anticoagulant, and the remainder returned to the donor. Most platelets are produced by apheresis (sometimes called single-donor platelets). Plasma and RBCs can also be collected by apheresis, and if the donor's blood volume and cell counts permit, two doses of the desired component can be obtained in one collection session.

All donors are checked against files of deferred donors, and all donations are tested for blood-borne infectious agents. Tests for HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) are universally required.<sup>32</sup> The addition of sensitive nucleic acid testing (NAT; e.g., polymerase chain reaction) to routine serology shortens the window period in a recently infected donor down to 7

to 10 days for HIV and HCV and 1 month for HBV. The US FDA also requires testing for syphilis, human T-cell lymphotropic virus (HTLV), and West Nile virus (WNV). Also available for donors at risk is a test for *Trypanosoma cruzi* (Chagas disease). Cytomegalovirus (CMV) is found mainly in leukocytes (WBCs). Selected patients at risk for complications of infection from cellular components can receive either CMV-negative units or leukoreduced units.

At some centers, directed donations can be made by family or friends for a specific patient. These donations augment the overall supply of blood and donors, and potentially reduce the number of donor exposures by using the same donor(s) more than once. However, the infectious risk from these units is not considered any less than from community volunteer donors. Cellular components from blood relatives must be irradiated to prevent the risk of transfusion graft-versus-host disease (GVHD) from closely matched donor lymphocytes that are not rejected by the recipient.

Autologous donations by the patient can be made in advance of scheduled surgery, with physician approval. The usual minimum hemoglobin or hematocrit is 11 g/dL or 33%, respectively, which is lower than the minimum allowed for regular donors. Patients should be on erythropoietin or iron supplementation to support RBC replenishment. In order to achieve a net gain in RBC mass, donations should be scheduled with some lead time within the 6-week storage period to permit erythropoiesis before surgery. Erythropoietin assists with multiple donations. Autologous units are only used for the patient and cannot be given to anyone else, since they often have a lower RBC content than normal requirements, and surgical patients frequently have conditions disqualifying them for regular donation. Autologous donations often create iatrogenic anemia with limited efficacy; they are best reserved for patients with difficult cross-match problems.

### **Component Processing and Storage**

*Leukoreduction* (LR) to remove WBCs from RBCs and platelets reduces the risk of human leukocyte antigen (HLA) alloimmunization, febrile nonhemolytic transfusion reactions (FNHTRs), and CMV transmission in patients who require these precautions. LR is usually performed by filtration, although some apheresis collections have sufficiently precise cell separation to minimize WBC content. The WBC content is typically reduced from around  $10^9$  WBCs/unit to less than  $10^6$  WBCs/unit. 11

**Table 17-1** Blood Components

Component	Average Volume	Storage Parameters
Packed red blood cells	300 mL	1°–6°C for 21–35 d or 42 d with additive solution
Red blood cells, frozen	300 mL	<–65°C for 10 yr
Platelets, whole-blood derived	50 mL per bag, usual dose 4–6 bags	20°–24°C for 5 d
Platelets, apheresis	300 mL	20°–24°C for 5 d
Plasma, fresh frozen	250 mL	<–18°C for 1 yr or <–65°C for 7 yr
Plasma, frozen within 24 h	250 mL	<–18°C for 1 yr
Cryoprecipitate	15 mL per bag, usual dose 4–6 bags	<–18°C for 1 yr

In addition to the routine indications above, LR has been studied for the prevention of transfusion-related acute lung injury (TRALI) and so-called transfusion-related immunomodulation (TRIM)—possible immunosuppressive and proinflammatory effects mediated by donor WBCs. “Universal” LR of all cellular components is done in many countries; however, randomized controlled trials have been mostly inconclusive for benefit. Meta-analysis of available data has highlighted cardiac surgery as a setting in which there may be postoperative survival benefit associated with leukoreduced blood components.<sup>33</sup>

*Washing* cellular components with saline is mostly done to remove plasma in patients with allergic transfusion reactions such as those who are IgA deficient. It does not affect the antigens on the cells and does not remove enough WBCs to prevent GVHD or HLA alloimmunization.

*Irradiation* of cellular components is performed to prevent transfusion GVHD from directed-donor units from blood relatives, or in highly immunosuppressed patients at risk for this complication because of leukemia, lymphoma, hematopoietic stem cell transplants, congenital cellular immunodeficiencies, and purine analogues such as fludarabine.<sup>34</sup> The units are exposed to gamma irradiation (2,500 cGy) to damage donor WBC DNA and prevent a cellular immune proliferative response to the recipient’s tissues. Irradiation is often performed in cesium-137 blood irradiators. The blood units do not come in contact with the radioisotope and are not radioactive, but laboratory personnel must comply with radiation safety regulations. In recent years, x-ray generators that do not contain radioisotopes have been approved for blood components.

*Platelets* are stored at room temperature to preserve clotting function, but this increases the risk of bacterial growth in contaminated units, compared to other blood components. Accordingly, bacterial detection has become routine in many countries. Platelet testing must be done after a short period of storage in order to detect growing bacteria. Blood centers can take culture samples from platelet pheresis units and prepoled whole-blood–derived platelets before product release. However, culturing is not feasible from the small volumes of individual whole-blood–derived platelets when the

transfusion service is pooling the units just before use. In this situation, bacterial antigen testing is available to transfusion services and is required by accrediting agencies in the United States.

*RBC preservation* solutions use CPDA—Citrate for anticoagulation, Phosphate as a buffer, 1 to 2 g of Dextrose (D-glucose), and Adenine—to maintain adenosine triphosphate (ATP) levels and RBC membrane integrity. However, despite preservatives, several metabolic changes occur during RBC storage. 2,3-Diphosphoglycerate (2,3-DPG) is depleted in the first 2 weeks, and shifts the oxygen dissociation curve to the left, increasing hemoglobin binding of oxygen (although this reverses after transfusion). Furthermore, by the end of the 42-day shelf life of additive-solution RBCs, the pH is 6.5, the plasma  $K^+$  is 50 mmol/L from RBC leakage and hemolysis, and 15% to 20% of the RBCs are nonviable.<sup>35</sup> RBC storage lesions may be related to observations linking older units to adverse outcomes such as short-term mortality and multiple organ failure.<sup>36</sup> However, randomized trials comparing outcomes with fresher RBCs versus routinely stored RBCs have thus far not shown overall benefit for fresher units.<sup>37</sup>

## Plasma Derivatives

Plasma derivatives are proteins processed from plasma for therapeutic infusions. They include albumin, immunoglobulins (IGs), clotting factors, and other proteins. Derivatives are purified from plasma using physicochemical fractionation methods initially developed by Edwin J. Cohn in the 1930s. Donors for plasma derivatives are screened and tested similarly to blood component donors, and the separation techniques provide a degree of purification from microbial pathogens. However, the large number of donor units that must be pooled together for production of plasma derivatives introduces the possibility of contamination of an entire lot by a small number of infected donors. Such was the case in the early years of HIV when factor concentrates infected a large proportion of hemophiliacs before the risk was known. Because intact cells are not required, many derivatives can undergo purification and pathogen inactivation methods which are impractical for blood components. 12

*Albumin* is produced in large quantities for intravascular volume support and is pasteurized at 60°C for sterility. IGs are given for immune support or for immunomodulation to suppress native antibody production. IGs can also withstand robust pathogen inactivation processes, and in some cases are nanofiltered to remove viruses. To be given intravenously, IGs need extra processing to avoid reaction-provoking protein aggregates. Hyperimmune globulins are fractionated from the plasma of donors with high levels of antibody to specific antigens of interest, such as viruses (HBV, CMV, varicella

zoster) or the Rh blood group D antigen (RhIG to prevent anti-D formation in RhD-negative women).

Factor concentrates for patients with congenital deficiencies are made with special techniques to ultrapurify factors VIII, IX, X, XIII, vWF, fibrinogen, and in some countries, factor XI, while also applying pathogen inactivation methods and viral filtration to remove microbes. However, recombinant factors VIII, IX, and vWF are also available to further allay concern about disease transmission, and recombinant activated factor VII (rFVIIa) is approved for rare VII-deficient patients. Some hemophiliacs develop inhibitory antibodies to the FVIII or factor IX they are missing. These inhibitor patients often need products that “bypass” their missing clotting step. The therapeutic potential of prothrombin complex concentrates (PCCs) containing multiple factors or rFVIIa to bypass secondary hemostasis and generate a thrombin burst is discussed later in this chapter. On the antithrombotic side of hemostasis, AT concentrate is available.

Other plasma proteins that are purified for selected deficiencies include complement C1 esterase inhibitor (for hereditary angioedema) and  $\alpha_1$ -antitrypsin.

### *Pathogen Inactivation*

Techniques have been developed to inactivate microbial pathogens in **13** blood components.<sup>38</sup> The major advantage of this approach is protection against unrecognized infectious agents. The methods vary by blood component. Solvent–detergent treatment is approved for plasma, and psoralen treatment for plasma and platelets, although these products are not yet widely available in the United States. In Europe and other countries, these types of products are broadly used, along with methylene blue treatment for plasma and riboflavin treatment for plasma and platelets.

Cell-free plasma, either in pools or as individual units, can be treated with membrane-disrupting solvent–detergent treatments for enveloped viruses. Nonenveloped viruses, most prominently hepatitis A and parvovirus, are less susceptible to this process, but NAT can be added to detect these agents.

More robust methods involve agents that damage nucleic acids. When methylene blue, psoralen, or riboflavin is added to the blood bag, they bind to nucleic acids. Then photoinactivation is performed with agent-specific wavelengths of light, cross-linking DNA, and RNA to prevent microbial function. Not yet approved (but under investigation) is ultraviolet light treatment of platelets alone, without a photosensitizer chemical. RBC units are less amenable to photoinactivation because of the hemoglobin, but nucleic acid alkylation technology is under development.

The nucleic acid damage agents also inactivate donor WBCs and thus

prevent transfusion GVHD. Adverse effects of these techniques include somewhat reduced platelet counts and plasma clotting factor levels, and potential toxicity from some of the added agents if they are not sufficiently removed after treatment.<sup>39</sup>

## **RBC and Platelet Substitutes**

**14** Many years of effort have gone into the search for an oxygen-carrying substitute for RBCs. Oxygen-avid perfluorocarbon chemicals underwent international trials, but 100% O<sub>2</sub> administration was needed and clinical trials were unsuccessful.<sup>40</sup> Several hemoglobin solutions have been made from pools of human or bovine hemoglobin, or from recombinant hemoglobin, all of which were chemically modified to facilitate extracellular O<sub>2</sub> offloading.<sup>41</sup> However, the potentially toxic effects of free hemoglobin, including intravascular binding of the vasodilator nitrous oxide (NO), are not sufficiently understood for regulatory approval. US clinical trials were unsuccessful in demonstrating clinical advantage in prehospital trauma management. None of these agents appear to hold much promise for clinical application in the near future. A more recent avenue of exploration is the possibility of “growing” RBCs in cell culture systems. They would be biocompatible and low in pathogen risk, and their RBC antigens could be engineered to some extent to maximize compatibility. The biology of cultivating mature normal RBCs in large scale is under investigation.

Platelets are so complex that it would be difficult to replace their functions fully. However, some early work has emerged on preserved platelets (e.g., freeze dried or fixed) and on biocompatible platforms bearing hemostatic proteins, such as fibrinogen-coated albumin beads, which could supply some degree of platelet-like clotting function. Culturing platelets in vitro for therapeutic uses is also being pursued.<sup>42</sup>

## **Blood Products and Transfusion Thresholds**

### **Compatibility Testing**

**15** Routine RBC compatibility testing includes ABO and RhD typing, an antibody screen for IgG non-ABO RBC antibodies, and an RBC cross-match.<sup>43</sup> RBCs must be ABO compatible to avoid intravascular hemolysis, and RhD-negative patients should receive D-negative RBCs to avoid anti-D alloimmunization. Rh, Kell, Kidd, Duffy, and some other non-ABO antibodies can also hemolyze transfused RBCs; 1% of all patients and 5% to 20% of heavily transfused patients have such antibodies. If no antibodies are present, the cross-match can be electronic; that is, RBC units

are selected by the laboratory computer to be ABO and RhD compatible. But if hemolytic antibodies are detected or are on record, RBC units negative for the incompatible antigen(s) must be found, and a serologic cross-match of patient plasma versus donor RBCs is performed to confirm compatibility. Most hospitals have blood order schedules for their most common surgical procedures, which set forth a recommended number of RBC units to cover 80% to 90% of patients undergoing each procedure.

RBC compatibility testing takes 45 to 60 minutes, and much longer if antibodies are found. Hence, testing in advance of scheduled surgery is desirable. In emergencies, uncross-matched group O RBCs can be given, albeit with the risk of non-ABO antibody incompatibility. Group AB is the universal donor plasma and avoids transfusing anti-A or anti-B versus the patient's RBCs.

## Red Blood Cells

Over the past decade, transfusion practices for medical and surgical patients shifted from a liberal to a more restrictive strategy, with lower thresholds for transfusion and careful consideration of the balance between transfusion risks and the physiologic consequences of anemia. The ASA's most recent update to the *Practice Guidelines for Perioperative Blood Management* defines restrictive practices as "hemoglobin criteria for transfusion less than 8 g/dL and hematocrit values less than 25%." The ASA recommendations for RBC transfusion thresholds are consistent with the guidelines published by other international societies in perioperative management and critical care medicine, whose goals for hemoglobin range between 7 and 10 g/dL (Table 17-2).<sup>44</sup>

There are countless studies comparing liberal versus restrictive transfusion practices for acute anemia, but the most critical large randomized controlled trials include the Transfusion Requirements in Critical Care (TRICC), the Transfusion Requirements After Cardiac Surgery (TRACS) trial, the Functional Outcomes in Cardiovascular Patients Undergoing Surgical hip fracture repair (FOCUS) study, and a recent randomized controlled trial with patients suffering from acute upper gastrointestinal bleeding.<sup>45-48</sup> Unfortunately, there is still little evidence to support a clear recommendation for hemoglobin thresholds in patients at high risk of tissue hypoxia and end-organ dysfunction in the setting of acute coronary syndrome, sepsis, and acute neurologic injury as often these patients are excluded from studies with restrictive transfusion practices.

The TRICC trial included critically ill, but euvolemic patients in a large multicenter randomized controlled trial. The investigators compared the survival of patients transfused to hemoglobin levels greater than 10 g/dL in

the liberal group, with patients treated under a restrictive strategy with a goal hemoglobin greater than 7 g/dL. Overall survival for more than 800 patients did not differ between the groups.<sup>47</sup> Subsequent subgroup analysis and several meta-analyses and systematic reviews confirmed these results, and also established the risks associated with liberal transfusion management for various patient populations, including those less than 55 years old, trauma patients, and those with stable cardiovascular disease.<sup>46,49</sup>

Traditionally, patients with cardiovascular disease and anemia were considered to be at significant risk of tissue ischemia and thought to benefit from higher hemoglobin goals in the perioperative and critical care settings. These recommendations were based on two studies that showed an association between anemia and mortality that improved with transfusion.<sup>50</sup> Several retrospective studies and systematic reviews have since contradicted these findings by documenting the safety of hematocrits less than 24% during cardiac surgery with cardiopulmonary bypass.<sup>46</sup> The TRACS trial randomized postcardiac surgery patients to restrictive (hematocrit >24%) versus liberal (hematocrit >30%) transfusion strategies and found no difference in 30-day mortality or severe morbidity. Furthermore, transfusion was found to be an independent risk factor for morbidity and mortality.<sup>46</sup> Accordingly, the most recent Society of Thoracic Surgeons (STS) and the SCA's *Blood Conservation Clinical Practice Guidelines* recognizes that all cardiac surgery patients are at risk for tissue hypoxia and transfusion. These guidelines report that tissue oxygenation does not improve with transfusion for hemoglobin levels greater than 10 g/dL, stating that "Transfusion is reasonable in most postoperative patients whose hemoglobin is less than 7 g/dL." For patients with hemoglobin levels between 7 and 10 g/dL the two societies recommend transfusion in patients with "critical noncardiac end-organ ischemia," active blood loss, or clinical indication of tissue hypoxia (low mixed venous oxygen saturation or electrocardiographic or echocardiographic evidence of myocardial ischemia).<sup>51</sup>

**Table 17-2** International Society Transfusion Guidelines

Guideline Sponsoring Society	Asymptomatic ICU Patients	ACS	Neurologic Injury	Other
American Society of Anesthesiologists (ASA), <i>Anesthesiology</i> 2015				Restrictive goal: 6–10 g/dL
British Committee for Standards in Haematology (BCSH), <i>BJH</i> 2013	>7 g/dL	8–9 g/dL	TBI: 7–9 g/dL Ischemia: >9 g/dL	Early sepsis: >9 g/dL Late sepsis: 7–9 g/dL
European Society of Anaesthesiology (ESA), <i>Eur J Anaesthesia</i> 2013			TBI: 7–9 g/dL	7–9 g/dL for active bleeding
AABB (Former American Association of Blood Banks), <i>JAMA</i> 2016	>7 g/dL	>8 g/dL	No supportive evidence	Postoperative: >8 g/dL
Society of Cardiovascular Anesthesiologists and Society of Thoracic Surgeons (SCA/STS), <i>Ann Thor Surg</i> 2011	>6–7 g/dL			Higher goal >7 g/dL for at-risk patients
Society of Critical Care Medicine (SCCM), <i>CCM</i> 2009	>7 g/dL	>8 g/dL	No supportive evidence	

ICU, intensive care unit; ACS, acute coronary syndrome; TBI, traumatic brain injury.

The noninferiority of restrictive transfusion practice for at-risk patients was again confirmed with the FOCUS trial, which enrolled 2016 patients over 50 years old undergoing hip fracture repair with a history of cardiovascular disease, diabetes, peripheral vascular disease, or smoking. This trial is most influential for reporting functional outcomes in the form of a walking test, in addition to 30- and 60-day mortality and morbidity. The investigators found no difference in outcomes, despite the restrictive group receiving a third of the transfusions, compared to the liberal group, with 59% of patients receiving no RBCs compared to only 3% in the liberal group.<sup>45</sup> Villanueva et al. demonstrated improved mortality and morbidity in the restrictive arm of a study involving patients with active upper gastrointestinal hemorrhage. These authors also showed an association in the liberal group between receiving more RBC transfusions and demonstrating progressive bleeding and poor hemostasis.<sup>48</sup> These large trials in acute care or perioperative patients confirm the recommendations of the ASA and SCA/STS as well as the AABB, the European Society of Anaesthesiology (ESA), and the British Committee for Standards in Haematology (BCSH) guidelines for patient blood management outlined in [Table 17-2](#).<sup>44,51–54</sup>

Patients with acute neurologic illness such as ischemic stroke, subarachnoid hemorrhage, and traumatic brain injury are at significant risk for secondary injury from tissue hypoxia. Acute and chronic anemia both initiate physiologic compensatory mechanisms discussed below, as well as neuroprotective strategies for tolerating decreases in cerebral oxygen delivery at critically low hemoglobin levels between 4 and 5 g/dL, as demonstrated by studies in Jehovah’s Witness patients. However, the hemoglobin level at which anemia induces detrimental patient outcomes for those with acute neurologic injury remains unclear.<sup>55</sup> Evidence indicates that a hemoglobin level less than 9 g/dL is independently predictive of poor outcome, especially

in patients with cerebrovascular injury. However, transfused RBCs do not function as well as endogenous erythrocytes. Therefore, it remains controversial whether RBC transfusion significantly improves tissue oxygenation and overall patient outcomes.<sup>56</sup> This leaves the clinician with little guidance to decide when and who should be transfused.

## Physiologic Compensation for Anemia

There is ample evidence for the human tolerance of both acute and chronic anemia. Oxygen delivery to the tissues ( $DO_2$ ) is dependent on cardiac output (CO), regional blood flow, and the blood's oxygen-carrying capacity (i.e., oxygen content [ $CaO_2$ ]). The relationship between these variables and oxygen consumption ( $VO_2$ ) is shown in [Table 17-3](#).<sup>57,58</sup> Hemoglobin plays an integral role in oxygen transport and delivery to the tissues. The clinical justification for RBC transfusion assumes that increasing the hemoglobin will improve oxygen-carrying capacity and therefore avoid tissue hypoxia. However, given the ability of the body to compensate for anemia, it is unclear whether increasing hemoglobin in a stable anemic patient actually improves tissue oxygenation. There are several compensatory mechanisms for anemia, most notably increased CO, altered microcirculatory blood flow, and improved tissue oxygen extraction from hemoglobin. These physiologic changes, together with the detrimental impact of RBC storage limit the therapeutic effects of transfusion.<sup>59</sup>

1. *Increased CO.* There are several mechanisms that increase CO as compensation for isovolemic hemodilution. First, the heart rate increases secondary to a sympathetic surge initiated by anemia and hypoxia.<sup>57,58,60</sup> Second, higher stroke volume results from increased preload secondary to decreases in both systemic vascular resistance and afterload. Isovolemic hemodilution occurs when acute blood loss is resuscitated with crystalloid or colloid fluids, thereby maintaining blood volume with a lower hemoglobin. The resultant decrease in blood viscosity reduces shear stress in the microvasculature, which significantly increases flow and venous return. Furthermore, tissue acidosis induces arteriolar vasodilation, thereby decreasing overall afterload.<sup>57,58,60</sup>
2. *Altered microcirculatory blood flow.* The decrease in blood viscosity associated with isovolemic hemodilution and chronic anemia improves blood flow through the microcirculation secondary to lower shear force in capillary beds.<sup>57,60</sup> Furthermore, microcirculatory blood flow increases with dilation of arterioles secondary to the release of NO from endothelial cells in response to tissue hypoxia. NO also induces arteriovenous shunting and recruitment of new circulatory beds,

thereby increasing blood flow to ischemic tissue. Patients with chronic anemia also increase angiogenesis and overall microcirculatory blood volume to compensate for the decreased oxygen-carrying capacity.<sup>60</sup> These mechanisms are extremely efficient. In fact, studies in anemic critically ill patients fail to show additional improvements in tissue oxygenation measures after transfusion.<sup>59</sup>

3. *Increased tissue oxygen extraction.* Anemia causes the oxyhemoglobin disassociation curve to shift to the right secondary to increased levels of 2,3-DPG in RBCs. This adaptive process is particularly influential for the physiologic compensation of chronic anemia, and often is the only mechanism necessary to maintain oxygen delivery. Isovolemic hemodilution to hematocrit levels less than 25% generates an increase in 2,3-DPG levels. Furthermore, acidemia associated with acute hemorrhage also shifts the oxygen dissociation curve to the right, thereby decreasing the affinity of oxygen for hemoglobin and improving the tissue oxygen extraction ratio.<sup>57,60</sup>

**Table 17-3** Equations for Tissue Oxygenation

Parameter	Unit	Equation
Oxygen delivery (DO <sub>2</sub> )	mL O <sub>2</sub> /min	DO <sub>2</sub> = CO (L/min) × C <sub>a</sub> O <sub>2</sub> (mL/dL)
Arterial oxygen content (C <sub>a</sub> O <sub>2</sub> )	mL O <sub>2</sub> /dL	C <sub>a</sub> O <sub>2</sub> = 1.36 × Hgb (g/dL) × S <sub>a</sub> O <sub>2</sub> (%) + [P <sub>a</sub> O <sub>2</sub> × 0.003]
Venous oxygen content (C <sub>v</sub> O <sub>2</sub> )	mL O <sub>2</sub> /dL	C <sub>v</sub> O <sub>2</sub> = 1.36 × Hgb (g/dL) × S <sub>v</sub> O <sub>2</sub> (%) + [P <sub>v</sub> O <sub>2</sub> × 0.003]
Blood flow, cardiac output (CO)	L/min	Flow = $\pi r^4 \Delta P / 8 \eta L$ ( $r$ = radius, $\Delta P$ = change in pressure, $\eta$ = viscosity, and $L$ = length of the vessel)
Oxygen consumption (VO <sub>2</sub> )	mL O <sub>2</sub> /min	VO <sub>2</sub> = CO (L/min) × [C <sub>a</sub> O <sub>2</sub> - C <sub>v</sub> O <sub>2</sub> ]
Oxygen extraction ratio (O <sub>2</sub> EF)	%	O <sub>2</sub> EF = [C <sub>a</sub> O <sub>2</sub> - C <sub>v</sub> O <sub>2</sub> ] / C <sub>a</sub> O <sub>2</sub> × 100% or = VO <sub>2</sub> / DO <sub>2</sub> × 100%

Hgb, hemoglobin; P<sub>a</sub>O<sub>2</sub>, partial pressure of oxygen in arterial blood; P<sub>v</sub>O<sub>2</sub>, partial pressure of oxygen in venous blood.

There continues to be controversy about RBC transfusion given the lack of evidence to support a universal transfusion threshold. Despite the wealth of literature documenting its potential harm, transfusion continues to be the mainstay of treatment for acute and chronic anemia. Healthy patients are most often able to compensate for anemia and tolerate critically low hemoglobin levels; however, the risk of tissue hypoxia in acute situations or in patients who are unable to compensate remains unclear. As CO increases to compensate for anemia with increased heart rates and a disproportionate increase in coronary blood flow, the critical hemoglobin level for each patient varies with their amount of cardiovascular reserve.<sup>57</sup>

Further studies of restrictive versus liberal transfusion strategies for patients with acute coronary syndrome, including ST-elevation and non-ST-elevation myocardial infarction or unstable angina, are needed to answer the question of transfusion thresholds for these patients. Pilot studies are inconclusive—the CRIT Randomized Pilot Study by Cooper et al. reported

noninferiority of restrictive transfusion, but Carson et al. demonstrated that liberal management improved mortality in nonbleeding patients with acute coronary syndrome.<sup>61,62</sup>

Overall, each clinician must take into account the patient's comorbidities, the acuity of anemia, and their ability to compensate adequately without signs or symptoms of tissue hypoxia (Table 17-4). Furthermore, it is important to measure the response to transfusion with follow-up hemoglobin levels in order to identify consumptive anemia, hemolysis, or ongoing bleeding as well as to guide further transfusions. In stable patients without ongoing bleeding, the hemoglobin should rise 1 g/dL (approximately 3% rise in hematocrit) for each unit of packed RBCs given.<sup>49,52,54</sup>

The above discussion focuses on isovolemic hemodilution secondary to chronic anemia or acute hemorrhage and fluid resuscitation, when compensatory mechanisms allow adaptation to the detrimental effects of decreased hemoglobin levels. It is important to recognize that further transfusion may be necessary prior to the availability of measured hemoglobin and hematocrit levels during acute hemorrhage, intraoperative bleeding, or trauma resuscitation. In the case of uncompensated blood loss, hemoglobin levels may be normal or misleadingly high. In these situations, the clinician must estimate blood loss from the patient's hemodynamic picture and assessment of the operative field, in order to guide transfusion management. The BCSH and AABB guidelines recommend a goal of hemoglobin over 8 g/dL, and the ESA recommends a target hemoglobin between 7 and 9 g/dL for the patients with acute hemorrhage.<sup>52,54</sup>

**Table 17-4** Clinical Indications of Tissue Hypoxia

- Unstable vital signs
  - Tachycardia
  - Hypotension
  - Tachypnea or dyspnea
- Laboratory and invasive monitor indices
  - Mixed venous O<sub>2</sub> saturation (SV<sub>m</sub>O<sub>2</sub>) <50%
  - Central venous O<sub>2</sub> saturation (SV<sub>c</sub>O<sub>2</sub>) <60%
  - Increased O<sub>2</sub> extraction ratio (O<sub>2</sub>ER) >50%
  - Lactic acidosis (metabolic acidemia with lactate >2 mmol/L)
- Signs of end-organ dysfunction
  - Electrocardiographic (ST changes, onset of arrhythmias) or echocardiographic indications of myocardial ischemia
  - Electroencephalographic indications of cerebral hypoperfusion
  - New onset oliguria (less than 0.5 mL/kg/h for >6 h)

## Platelets

**18** Numerous recommendations provide guidance for the transfusion

management of thrombocytopenia and acquired or inherited platelet disorders.<sup>51,63–65</sup> The indications for platelet transfusion depend on both quantitative and qualitative measures of platelet activity and the clinical setting. [Table 17-5](#) outlines typical platelet thresholds for transfusion based on the clinical situation and patient history. For stable patients with severe thrombocytopenia, transfusion can be held until counts fall below 10,000  $\mu\text{L}$ , in the absence of signs or symptoms of bleeding.<sup>66</sup> Prophylactic platelet transfusion is necessary for patients with severe thrombocytopenia (below 50,000/ $\mu\text{L}$ ) who are about to undergo major surgery or invasive procedures such as lumbar puncture, liver biopsy, neuraxial anesthesia, or endoscopy with biopsy.<sup>44,63</sup> The most recent guidelines from the AABB recommend a threshold of less than 20,000/ $\mu\text{L}$  for prophylaxis prior to placement of a central venous catheter.<sup>67</sup> In preparation for surgery on the eye or the central nervous system, the platelet count should be raised to above 100,000/ $\mu\text{L}$ . Any patient with critical blood loss or hemorrhagic shock should be transfused to a platelet target of 75,000 to 100,000/ $\mu\text{L}$ .<sup>65</sup>

Transfusion is not necessary for platelet counts over 100,000/ $\mu\text{L}$  in clinically stable patients without suspicion of platelet dysfunction, whereas most patients with counts below 50,000/ $\mu\text{L}$  and clinical bleeding require therapeutic transfusion.<sup>44,63,67</sup> There are several relative indications for transfusion of platelet counts between 50,000 and 100,000/ $\mu\text{L}$ . In particular, patients having surgery on the eye or central nervous system, or patients with multiple traumatic injuries benefit from higher transfusion goals.<sup>63,65,67</sup> Furthermore, patients undergoing massive transfusion or hemorrhage with estimated blood loss of more than two blood volumes and ongoing bleeding should have a transfusion threshold of at least 75,000/ $\mu\text{L}$  to ensure the level does not fall below 50,000/ $\mu\text{L}$ .<sup>65</sup>

**Table 17-5** Indications for Platelet Transfusion

Stable patients without evidence of bleeding or coagulopathy	<10,000/ $\mu$ L
Prophylaxis for central venous catheterization	<20,000/ $\mu$ L
Prophylaxis for invasive procedures such as lumbar puncture, neuraxial anesthesia, endoscopy with biopsy, liver biopsy, or major nonneuraxial surgery	<50,000/ $\mu$ L
Stable patients with clinical evidence of bleeding or coagulopathy including DIC	<50,000/ $\mu$ L
Patients undergoing massive transfusion	<75,000–100,000/ $\mu$ L
Patients having surgery at critical sites such as the eye or central nervous system	<80,000–100,000/ $\mu$ L
Microvascular bleeding attributed to platelet dysfunction such as uremia, liver disease, postcardiopulmonary bypass	Clinician judgment

DIC, disseminated intravascular coagulation.

**Table 17-6** Causes of Acquired Platelet Dysfunction

Uremia
Liver disease
Paraproteinemia (multiple myeloma, Waldenström macroglobulinemia, monoclonal gammopathy, or polyclonal hypergammaglobulinemia)
Myeloproliferative disease
Myelodysplastic syndrome
Disseminated intravascular coagulopathy
Extracorporeal circulation (dialysis, cardiopulmonary bypass, plasmapheresis)
Medications (aspirin, NSAIDs, thienopyridines, GPIIb/IIIa antagonists, $\beta$ -lactam antibiotics, antidepressants, phenothiazines)
Herbal remedies (fish oil, flaxseed oil, ginger, <i>Ginkgo biloba</i> , garlic, grape seed extract, saw palmetto, feverfew, bilberry, bromelain)

NSAIDs, nonsteroidal anti-inflammatory drugs; GP, glycoprotein.

Platelet transfusion should not be guided by platelet counts alone, but also by the clinical suspicion of platelet dysfunction that can be inherited or acquired. Qualitative dysfunction is often associated with systemic diseases such as uremia, liver failure, and disseminated intravascular coagulopathy (DIC). It also occurs after cardiopulmonary bypass, extracorporeal circulation such as dialysis or plasmapheresis, and as a result of medication side effects (Table 17-6).<sup>44,67</sup> Regardless of the platelet count, if bleeding is out of proportion to the level of thrombocytopenia, qualitative deficiency should be suspected and treated.

The average dose of platelets is one concentrate from apheresis donation, or pools of five to eight concentrates from whole-blood or buffy-coat collections. These “units” generally contain about  $3 \times 10^{11}$  to  $4 \times 10^{11}$  platelets each.<sup>63</sup> Once platelets are given, a posttransfusion response should be followed to guide further therapy and to rule-out ongoing consumptive pathophysiology. Refractoriness at 20 to 24 hours is generally associated with older platelets or increased consumption secondary to fever, infection, bleeding, or medications. Adjunctive therapy for platelet dysfunction can be established with antifibrinolytics, DDAVP (1-deamino-8-D-arginine vasopressin, desmopressin), or PCCs as discussed later in this chapter.<sup>44,51,63</sup>

## **Plasma Products**

Plasma contains all the factors involved in hemostasis. Modern preparations of plasma now include fresh frozen within 8 hours of phlebotomy (FFP), plasma frozen within 24 hours of collection (PF24), or “thawed plasma,” which includes units of frozen plasma that have been thawed for more than 24 hours yet remain usable for up to 4 additional days. The preparation and storage method for each formulation involves either separation from whole blood or apheresis; both maintain normal levels of stable factors and at least 70% normal levels of labile factors such as FVIII and FV. Prior to use, each unit must be thawed at 30° to 37°C, but can be stored at  $4^\circ \pm 2^\circ\text{C}$  for up to 24 hours as thawed FFP or 5 days as thawed plasma.<sup>68–70</sup> Throughout this chapter, the inclusive term, “plasma” will be used for FFP, PF24, and thawed plasma unless otherwise specified. During preparation and distribution, care must be taken to ensure ABO compatibility for plasma transfusion to avoid transfusion of donor anti-A and anti-B antibodies that may lead to hemolysis.<sup>71</sup>

**Table 17-7** Indications for the Use of Plasma Products

- Correction of inherited factor deficiencies when there is no specific factor concentrate (e.g., factor V) and when the PT or aPTT is >1.5 times the mean control or INR >2.0.
- Replacement of multifactor deficiencies with clinical bleeding after transfusion of more than one blood volume (>70 mL/kg) when PT, INR, or aPTT cannot be obtained immediately.
- Correction of acquired multifactor deficiencies with clinical evidence of bleeding or in anticipation of major surgery or an invasive procedure with PT or aPTT >1.5 times the control, or INR >2.0.
  - Liver dysfunction with clinical signs of bleeding.
  - DIC with clinical signs of bleeding.
  - Reversal of vitamin K antagonists (warfarin) *when PCCs are not available*.
  - Heparin resistance secondary to AT deficiency when AT concentrate is not available.
  - Treatment of thrombotic microangiopathies (thrombotic thrombocytopenic purpura, HELLP syndrome, or hemolytic uremic syndrome).
- Treatment of hereditary angioedema when C1-esterase inhibitor is not available.

DIC, disseminated intravascular coagulation; PT, prothrombin time; aPTT, activated partial thromboplastin time; PCCs, prothrombin complex concentrates; AT, antithrombin; HELLP, hemolytic anemia elevated liver enzymes and low platelet count.

Plasma is indicated for the treatment of coagulopathy secondary to congenital or acquired factor deficiencies. The specific indications for plasma products outlined in [Table 17-7](#) are based on one of the most recent guidelines from the ASA, BCSH, SCA/STS, and AABB.<sup>44,51,69,71</sup> The initial therapeutic dose of plasma averages 10 to 15 mL/kg in an attempt to obtain at least 30% factor activity. Repeat dosing is guided by serial diagnostic coagulation tests such as the PT, INR, and aPTT.<sup>44,51,71</sup> Recent updates to these guidelines are guarded in their recommendations for prophylactic use of plasma for patients at risk for hemorrhage but without clinical evidence of bleeding. Systematic reviews fail to demonstrate the efficacy of prophylactic plasma to reduce RBC transfusion, morbidity, or mortality, especially when given to patients with mild derangements in PT, INR, or aPTT and no clinical signs of bleeding.<sup>69,72,73</sup> The administration of plasma carries risks of several transfusion reactions, most notably TRALI, allergic reactions, and transfusion-associated circulatory overload (TACO). Together with limited prophylactic benefits and high frequency of inappropriate use, these risks arguably make plasma the riskiest blood component currently in use.<sup>69,72,73</sup>

Over the past decade there has been growing debate over “damage control” resuscitation protocols for trauma patients with major bleeding. Traditionally, trauma patients were resuscitated first with fluid and RBCs, and only received plasma based on the results of coagulation tests.<sup>65</sup> However, it has been argued that this method perpetuates dilutional coagulopathy and prolonged microvascular bleeding, especially when long turn-around-time

coagulation assays are used to assess hemostasis.<sup>74,75</sup> Numerous observational studies originally showed improved outcomes with higher ratios of plasma to RBC units (more than 2:3) and with transfusion protocols that provide a balanced ratio of platelets, plasma coagulation factors, and RBCs.<sup>76</sup> However, these retrospective findings are likely confounded by injury severity and potential “survivor bias” that occurs when patients die of massive hemorrhage before plasma can be thawed and transfused.<sup>76,77</sup>

Two large prospective multicenter trials—the Prospective, Observational, Multicenter Major Trauma Transfusion (PROMMTT) trial and the Pragmatic, Randomized Optimal Platelets, and Plasma Ratios (PROPPR) trial—were both designed to definitively answer the question of whether fixed ratio transfusion protocols for trauma resuscitation can improve patient outcomes. Both trials demonstrated the feasibility of providing patients with thawed plasma in a timely manner, although this practice significantly increases the wastage rate.<sup>74,78,79</sup> When plasma resuscitation is delayed, patients are at increased risk of hemorrhagic shock and death, supporting one trauma society’s recommendations that Level I trauma centers have thawed universal donor plasma available. However, neither trial demonstrated a survival benefit at either 24 hours or 30 days for patients receiving a higher ratio of platelets to plasma to RBCs (1:1:1 vs. 1:1:2).<sup>74,78</sup> Those with the higher ratio of plasma were less likely to expire secondary to exsanguination at 6 hours; however, overall mortality at 24 hours and 30 days did not differ between groups and most commonly resulted from traumatic brain injury, sepsis, and multiorgan system failure.<sup>78</sup> The influence of plasma use in traumatic brain injury raises additional questions, as many studies demonstrate increased mortality with the use of plasma products over normal saline.<sup>73</sup> Accordingly, guidelines from the AABB, ASA, and SCA/STS continue to recommend using fixed ratios of plasma only for resuscitation of massive hemorrhage, until coagulation profile assay results become available to further guide blood product transfusion.<sup>44,51,69</sup>

## Cryoprecipitate

Cryoprecipitate is created by a controlled thaw of FFP, which allows for precipitation of large molecules. It is then centrifuged, the supernatant removed, and the final product resuspended in 10 to 15 mL of plasma, containing fibrinogen (about 15 g/L), fibronectin, vWF, FVIII, and FXIII.<sup>30,68</sup> These small concentrates are typically combined for a single adult dose from five pools and frozen at  $-18^{\circ}\text{C}$  for up to 12 months. This dose should increase fibrinogen levels by approximately 50 g/dL.<sup>30,68</sup> Current use of cryoprecipitate is limited to a few countries (United States and Canada) and generally only indicated for hypofibrinogenemia (Table 17-8). Compared to

plasma, cryoprecipitate contains more fibrinogen per volume (15 vs. 2.5 g/L in plasma)<sup>71</sup> and therefore functions as a low-volume alternative for fibrinogen replacement, especially during acquired hypofibrinogenemia states such as DIC and massive hemorrhage. It carries similar transfusion risks as plasma, and consequently has been replaced in several countries, including in Europe, with fibrinogen concentrates that can be virally inactivated.<sup>30,68</sup>

**Table 17-8** Indications for Fibrinogen Replacement

- Microvascular bleeding with hypofibrinogenemia
  - DIC with fibrinogen <150 mg/dL
  - Hemorrhage or massive transfusion with fibrinogen <180–200 mg/dL
- Prophylaxis in patients with hemophilia A and vWD (if specific factor concentrates are unavailable or ineffective due to inhibitors)
- Prophylaxis for patients with congenital dysfibrinogenemias

DIC, disseminated intravascular coagulation; vWD, von Willebrand disease.

## Fibrinogen Concentrate

Fibrinogen concentrates are derived from plasma after several steps of viral inactivation that also minimize antibodies and antigens to produce a lyophilized powder formulation that can be stored at room temperature and reconstituted for administration in less than 10 minutes. They are used frequently around the world as a safe, low-volume alternative to cryoprecipitate, but are only available in the United States for treatment of congenital hypofibrinogenemias. Several studies demonstrate the efficacy of fibrinogen concentrates in settings of acute hemorrhage, cardiac surgery, and obstetrical hemorrhage; however large randomized controlled trials have not been reported.<sup>30,68</sup>

Fibrinogen is primarily responsible for clot stabilization, but it also assists with platelet activation and aggregation and, at adequate concentrations, may compensate for low thrombin states.<sup>80,81</sup> Traditionally, the threshold for fibrinogen replacement has been at levels less than 80 to 100 mg/dL. This continues to be included in many blood management guidelines, despite little evidence to support its validity.<sup>30,44,68,82</sup> Several studies and subspecialty societies have suggested more conservative goals (fibrinogen concentrations of 180 to 200 g/dL) to optimize clot stability.<sup>30,68,82,83</sup>

## The Risks of Blood Product Administration

**20** According to the 2011 update from the National Blood Collection and Utilization Survey, over 20 million blood products are transfused annually

throughout the United States. The Center for Disease Control and Prevention (CDC)-supported Hemovigilance Module of the National Healthcare Safety Network (NHSN) has small, but growing participation from transfusion centers and hospitals (4.5%). Data from this module suggest that the overall risk of a transfusion reaction is approximately 239.5 per 100,000 components with 8% of reactions, infectious and noninfectious, being severe or life-threatening.<sup>8,84,85</sup>

National hemovigilance networks worldwide suspect both underreporting of transfusion reactions and avoidable morbidity and mortality secondary to clerical errors or inadequate clinical evaluation of patients undergoing blood product transfusion. Patients receiving blood component therapy should be continuously monitored for fever, hypotension, and cardiopulmonary complications. Mild fever with or without pruritus or rash is still the most common reaction, and can be treated symptomatically with antihistamines or antipyretics. In the event of a more severe fever ( $\geq 39^{\circ}\text{C}$ , or  $\geq 2^{\circ}\text{C}$  rise in temperature) with constitutional symptoms (e.g., rigors, myalgia, nausea, vomiting, or diaphoresis), transfusion should be halted and the product returned to the blood bank for retesting of compatibility and antibodies. Sepsis should be ruled out if fever is persistent. Pulmonary symptoms should be investigated for TRALI, TACO, or anaphylaxis. Typically, acute hemolytic reactions will involve hypotension, shock, and cardiopulmonary collapse. Transfusion should not be discontinued if shock symptoms are likely secondary to hemorrhage.<sup>86</sup>

### *Infectious Risks of Blood Product Administration*

In the mid-1980s, the realization of transfusion-transmissible infections such as HIV and hepatitis raised concerns about the infectious risks of blood product administration. Since the introduction of Nucleic Acid Amplification Testing (NAT) for major transfusion-transmittable viral infections (HCV in 2000, HIV in 2003, and HBV in 2006), the risk of infection from blood product transfusion has decreased substantially.<sup>87,88</sup> Prior to the institution of NAT, the blood supply was simply tested for the presence of viral antibodies. This left a long window period when the blood was potentially infectious, but with insufficient time for the donor to mount an antibody response detectable by conventional testing. NAT increased the sensitivity of donor screening by testing for the presence of specific viral DNA or RNA. This significantly shortened the window period between when a donor gets infected and when the viral load is detectable. The residual risk of transfusion-transmitted infections now depends mostly on the length of this window period, relative to the reproductive rate of each virus and the prevalence of the disease. There are additional risks of false negatives NATs or the mistaken release of

quarantined blood products; however, these events account for less than 0.5% of the residual risk of transfusion-transmitted viral infection.<sup>89,90</sup>

The true risk of transfusion-transmittable infections is difficult to accurately quantify given the variability of donor response to inoculation and the immune state of the recipient. However, the residual risk can be mathematically modeled from the prevalence of infection in donors and the known window period of each viral illness. The estimated residual risk of major viral infection and the viral-specific window periods are shown in [Table 17-9](#), based on the reported incidence of infection in donors for the American Red Cross Blood Services.<sup>89,90</sup> These residual risks are likely overestimates, since not all transfusions of known infected blood products result in recipient infection.<sup>91,92</sup> The mathematical modeling of residual risk assumes 100% infectivity with even one infectious unit of viral particles per blood bag. It also presumes that the collection and storage process is harmless to viral reproduction. Furthermore, viral infectivity will vary depending on the acute phase of infection when an immunocompetent recipient could resist transmission or the chronic phase of infection when antibodies are present and reduce infectivity.<sup>92</sup>

Transfusion-transmitted viral infections traditionally receive the most attention from patients due to their associated morbidity and mortality. Despite increased awareness and public health initiatives, the prevalence of HIV and HCV in the donor population continues to increase secondary to prolonged survival of patients, making the prevalence of HIV and HCV in the general population higher. Contrary to HIV and HCV, the prevalence of HBV has decreased since 1999 presumably due to high vaccination rates. Overall, the prevalence of disease in the general population is now the largest determinant of transfusion-transmittable infection risk.<sup>90</sup> Many patients inquire about directed donations from family and friends. They should be made aware of the stringent processes for random donor screening for infectious risk factors, as well as the significantly increased prevalence of viral infections—especially HCV and HBV—in directed donations.<sup>93</sup>

**Table 17-9** Residual Risk of Transfusion-transmitted Infections

Infection	Residual Risk	Window Period and Comments
Viral infections		
Human immunodeficiency virus (HIV)	1/2,300,000	7–10-d window
Hepatitis C (HCV)	1/1,800,000	7–10-d window
Hepatitis B (HBV)	1/280,000–1/352,000	38-d window
Human T-cell lymphotropic virus (HTLV)	1/2,993,000	51-d window, cell associated
West Nile virus (WNV)	Rare	11 cases reported from 2003–2010
Cytomegalovirus (CMV)—all donors	1–3%	
Leukoreduced products	0.023%	
Emerging infections		
Chagas and malaria	Rare	Incidence is too small to estimate
Creutzfeldt–Jakob (vCJD)		Donor screening limits risk in the United States
Dengue virus and <i>Babesia</i> species		Incubation for years
Parvovirus (B19v)		Transient epidemics increase risks
Bacterial contamination—all types	1/3,000	May cause aplastic anemia in immunosuppressed patients
Packed red blood cells	1/35,000	
Platelets, apheresis	1/15,000	Lower risk than platelet concentrates
		Apheresis decreases risk

## Human Immunodeficiency Virus

As a retrovirus, HIV is transmitted as RNA and requires translation into DNA prior to replication. This virus was highly transmittable in the US blood supply until sensitive NAT and donor screening became available. The incidence of transfusion transmission of HIV was as high as 1 in every 100 donations in the early 1980s, but only 1 in every 400,000 donations in 1997.<sup>94</sup> The residual risk of HIV has fallen to lower than 1 per 2.3 million blood product transfusions.<sup>89</sup> However, despite a short window period of 7 to 10 days, the residual risk of HIV transmission via blood supply is expected to increase slightly or remain stagnant secondary to increased prevalence of HIV in the general population due to improved treatments and prolonged survival.<sup>90</sup>

## Hepatitis C Virus

Although HCV is rarer than the other types of transmittable hepatitis and has a relatively benign acute phase, it progresses to chronic carrier state in up to 80% to 85% of infections and is associated with significant risk of fulminant hepatic failure, cirrhosis, hepatocellular carcinoma, and death.<sup>89,91</sup> Similar to HIV, the transfusion risk of HCV decreased drastically with the increased sensitivity of NAT testing and donor screening. However, the prevalence of donor HCV increased over the past 5 to 7 years due to increases in both incidence and prevalence in the general population. Recent reports have

implicated higher infectivity rates in non-hospital-based health-care facilities and endoscopic procedures.<sup>90,91</sup> Furthermore, HCV infections become more aggressive and transmittable in patients coinfecting with HIV due to the increased viral load that results from immunosuppression.<sup>87</sup>

## **Hepatitis B Virus**

HBV is a common blood-borne pathogen with fairly high incidence of infection in the general population and over 300 million carriers worldwide.<sup>91</sup> The United States has a low prevalence rate of 2%, compared with 8% to 15% in the Middle East, Africa, and parts of South America and Asia.<sup>87,91</sup> The acute infection associated with HBV is asymptomatic in most patients, or limited to mild constitutional signs and jaundice. Rarely, however, it can progress to fulminant hepatic failure. The residual risk of transfusion-transmitted HBV remains high, given the common prevalence of the disease and a long window period. This risk is now decreasing with substantial prevalence reductions in the general population that are likely secondary due to the increased availability of and compliance with HBV vaccine.<sup>89-91</sup>

## **Human T-Cell Lymphotropic Virus-1 and Virus-2**

HTLV-1 causes T-cell leukemia and lymphoma, or HTLV-associated myelopathy in a small percentage of infected persons. HTLV-2 does not have any significant consequences for immunocompetent or even HIV coinfecting patients.<sup>89</sup> Regardless of the relatively infrequent disease association with HTLV, the US blood supply is routinely tested for anti-HTLV antibodies indicative of previous infection.<sup>89,90</sup> Given that HTLV is cell associated, the transmission via transfusion may be eradicated with LR.

## **Cytomegalovirus**

CMV is ubiquitous in the general population with a prevalence of about 40% to 80%.<sup>89</sup> Consequently, it is the most common transfusion-transmitted infection with an incidence of 1% to 3%.<sup>90</sup> In immunocompetent recipients the infection is often asymptomatic or mild and self-limited. However, in immunocompromised patients—in particular, neonates, patients with HIV, and transplant recipients—the disease can be associated with severe multiorgan system failure involving the liver, lungs, kidneys, hematologic system, gastrointestinal tract, and the central nervous system.<sup>90,95</sup> The CMV virus is carried by white blood cells and transmitted via CMV-seropositive cellular components. LR decreases the infectivity of CMV-positive donor products, but has not completely eradicated the transfusion transmission of CMV.<sup>89,95</sup> Therefore, it is recommended that patients at highest risk for CMV

infection, such as neonates and pregnant women, receive LR blood products from CMV-seronegative-only donors.<sup>89,90,96</sup>

## Emerging Infections

HIV remains the most noteworthy microbe to recently infect the blood. Several pathogens have also emerged through changes in ecologic and geographic factors such as travel, climate change, or new insect and animal vectors. The most recent example of a significant new transfusion-transmissible infection is the West Nile Virus (WNV), a mosquito-borne flavivirus that emerged in 1999. WNV causes only a mild febrile illness in healthy patients, but may progress to encephalitis or meningitis in up to 40% of immunosuppressed patients.<sup>89</sup> The peak of the WNV epidemic occurred in 2002 to 2003, with 23 transfusion-transmitted illnesses that year. However, since the institution of donor screening with NAT testing in 2003, the incidence of transfusion-transmitted WNV has dropped to only 11 reported cases from 2003 to 2010.<sup>89,90</sup> Surveillance studies continue to investigate the virulence of various strains of WNV worldwide and the ability of the current NAT test to recognize seroconversion in donors.<sup>97</sup>

A few other pathogens have been red flagged by the AABB Transfusion-Transmitted Disease Committee as potential threats to the safety of the US blood supply. Most concerning are human vCJD, *Babesia* species, Chagas, dengue virus, and the *Plasmodium* species, which causes malaria.<sup>89</sup> vCJD is the human form of bovine spongiform encephalitis. It results in fatal degenerative neurologic disease secondary to prion proteins that precipitate an abnormal formation and structure of other proteins. It gained attention after an epidemic of cases in the 1980s to 1990s throughout the United Kingdom. Thus far, there have been three cases of confirmed transfusion-transmitted vCJD.<sup>89</sup> There are no known effective treatments, and the incubation period is reported in years. Currently no testing regimens exist for diagnosis of prion disease in donors or collected blood, but donor deferral for those who resided in the United Kingdom during the epidemic has avoided any known transfusion transmissions within the United States.<sup>89</sup> The incidence and infectivity of other viral and parasitic pathogens is so rare that they do not warrant a careful discussion here. However, it is important to remember that there may be emerging infections that are yet unrecognized, leaving the blood supply at constant risk. Western countries continue to evaluate the risk-benefit ratios and ethical cost considerations for screening tests and donor deferrals, with the knowledge that testing to ensure 100% sensitivity is highly unlikely and adds significant costs.<sup>88</sup>

## Bacterial Contamination

Despite significant public concern for transfusion-transmitted viral disease, bacterial contamination of blood components poses the largest risk of transfusion-related infection by two or three orders of magnitude. Bacteremia may progress to sepsis and continues to be one of the major causes of transfusion-associated fatality, according to the FDA.<sup>98</sup> Frequent pathogens implicated in bacterial contamination of blood products stem from skin flora, including *Staphylococcus* and *Bacillus* species, but gram-negative species such as *Escherichia coli* and *Enterobacter cloacae* more frequently lead to sepsis.<sup>89</sup> Platelet concentrates carry the highest risk of bacterial contamination, since they are stored at 20° to 24°C, which provides a more suitable environment for bacterial replication, as opposed to RBCs, which are stored at 4°C, or plasma, which is frozen.<sup>89</sup>

Several methods aimed at reducing the risk of transfusion-transmitted bacterial infections have proven beneficial. Single-donor collections are associated with less contamination than platelet concentrates from pooled units, likely due to fewer venipunctures and exposures to skin flora, and to collection processes. It is now standard practice to divert the first 20 to 40 mL of collected blood into a separate collection chamber to avoid contaminating the whole donation with blood and epidermal tissue from the initial venipuncture. Standards for skin preparation prior to blood donation and sterile techniques for collection and processing procedures have also decreased contaminants. Furthermore, all apheresis platelets are culture tested prior to storage.<sup>89,99</sup> Bacterial sepsis continues to be a significant cause of transfusion morbidity and mortality, with increasing interest in development of efficient product testing to minimize the risks.<sup>100</sup> Traditional testing of platelet products in the United States relied on indirect testing of pH, glucose, and platelet morphology. As new methodologies such as automated cultures and rapid immunoassays become available, sensitivity for detecting infection increases; however, a residual risk of bacterial transmission remains. New techniques for pathogen reduction (e.g., photoactivity) are currently in use in Europe, but not approved for use in the United States at this time.<sup>31</sup>

### **Noninfectious Risks of Blood Product Administration**

Given the extensive use of more sensitive methods for screening and controlling the infectious risks of blood product transfusion, noninfectious complications have emerged as the major source of transfusion-related morbidity and mortality.<sup>98</sup> **Table 17-10** summarizes the relative incidences and main features of the most common noninfectious risks of blood product administration.

## Immune-Mediated Transfusion Reactions

### Febrile Nonhemolytic Transfusion Reactions

Allergic and febrile reactions are the most common complications of transfused blood products, although the incidence of both has decreased with increased use of LR and single-donor apheresis platelet units.<sup>85</sup> FNHTRs classically present within 4 hours of transfusion with an increase in temperature of 1° to 2°C, and may be associated with chills, rigors, anxiety, and headache.<sup>86</sup> They are typically self-limited, but can be prevented or treated with anti-inflammatory or antipyretic medications. The pathophysiology of FNHTRs involves recipient alloimmunization to HLAs from donor WBCs and the release of leukocyte-derived cytokines during product storage.<sup>101</sup> As a result, the risk of febrile reactions increases with repetitive transfusions. Prior to the widespread institution of LR, the incidence of FNHTR was as high as 30%, but currently it is between 0.03% and 2.18%.<sup>101</sup> Although these reactions are common, more serious adverse effects of transfusion, such as sepsis, anaphylaxis, and hemolysis may also present with fever, and should be ruled out prior to diagnosing an FNHTR.

**Table 17-10** Noninfectious Transfusion Reactions

Adverse Reaction	Incidence	Notes
<b>Immune-mediated Reactions</b>		
Febrile nonhemolytic transfusion reaction	0.03–2%	
Minor allergic reactions (urticaria, flushing)	1–3%	
Anaphylactic/toid reactions		IgA deficiency increases risk
Packed red blood cells	0.5/100,000	Washing may avoid reaction
Fresh frozen plasma and platelets	2–3/100,000	More prevalent with plasma-containing products
Acute hemolytic transfusion reaction (AHTR)	1/80,000	
Delayed hemolytic transfusion reaction (DHTR)	1/1,500	Associated with alloantibodies to minor RBC antigens, Kidd, or Rh; One-third have clinical reaction
Transfusion-related immunomodulation (TRIM)	100%	
Alloimmunization	2%	For all patients, risk increases with number of units transfused
Transfusion-related acute lung injury (TRALI)	1/1,300–5,000	Varies with blood product component and patient population
Graft-versus-host disease (TA-GVHD)	1/5,000	Related to immunosuppression; reduced risk with irradiation
Posttransfusion purpura (PTP)	Rare	Attributed to antihuman platelet antigen-1a
<b>Reactions Related to Patient Comorbidities or Transfusion Practice</b>		
Transfusion-associated cardiovascular overload (TACO)	1–8%	Higher in patients with CHF and CRI
Metabolic derangements		
Hyperkalemia		
Citrate toxicity		
Iron overload		
Hypothermia		

Frequencies are presented as percentages when >0.1% and otherwise as ratios.  
IgA, immunoglobulin A; CHF, congestive heart failure; CRI, chronic renal insufficiency.

### Allergic Reactions

Minor allergic reactions, a relatively common type of transfusion reaction, occur in about 1% to 3% of transfusions. Symptoms are most commonly described as urticaria, hives with or without pruritus, and angioedema.<sup>86,102</sup> The specific cause of allergic reactions is unclear, but likely involves an immune response to recipient WBC antigens or transfused plasma proteins.<sup>86,102</sup> Prophylaxis with antihistamines is common practice for patients with a history of allergic reactions to blood products, but several studies have demonstrated no symptom reduction with pretreatment. Best practice should be to reduce the rate of transfusion and treat supportively when symptoms arise.<sup>86</sup> If symptoms become severe with recurrent or frequent transfusion needs, cellular products can be washed.

Major allergic reactions present as anaphylactoid or anaphylactic reactions with hemodynamic instability, bronchospasm, rash, flushing, and/or angioedema.<sup>86,103</sup> These reactions are rare—only 1 in 50,000 transfusions for absolute IgA-deficient individuals when premedication and product preparation are ensured (Table 17-10)—but the reaction can be fatal if unrecognized.<sup>103</sup> Pathophysiologically, the recipient—typically patients who are IgA deficient with anti-IgA antibodies—mounts an immediate immune response to transfused plasma proteins or cellular antigens. Classically, anaphylaxis requires an immediate type I hypersensitivity IgE-mediated reaction; however, most major allergic responses to blood transfusions do not show laboratory evidence of IgE antibodies, and are therefore anaphylactoid reactions.<sup>102</sup> These transfusion complications can be prevented in patients with known IgA deficiency by washing blood products prior to transfusion or by using products obtained from IgA-deficient donors.<sup>103</sup>

*Acute hemolytic transfusion reactions* (AHTRs) remain one of the leading causes of transfusion-related fatalities. They occur with the transfusion of incompatible blood products when pre-existing IgM or IgG antibodies in recipients form complexes with donor RBC antigens, causing complement activation and immediate intravascular hemolysis. Classically, AHTRs result from ABO incompatibility secondary to native anti-A or anti-B IgM. Careful adherence to protocols for specimen phlebotomy and blood component administration is vital for prevention. However, growing evidence exists for the implication of other RBC antigens such as Kidd, Kell, and Duffy, causing acute hemolytic reactions in patients with a history of transfusion exposure and alloimmunization.<sup>104</sup> Rarely, the transfusion of incompatible plasma (type O plasma or whole blood to a patient with type A, B, or AB blood) has resulted in AHTRs as well.<sup>104,105</sup> These reactions are rare and have become less frequent with the institution of safety measures to reduce clerical error and improve the availability of cross-matched blood products. Data from national surveillance databases in the United States and the United Kingdom report AHTR as the third leading cause of transfusion-related mortalities.

Fortunately, less than half of patients transfused with incompatible blood products become symptomatic. The overall fatality rate from incompatible transfusion is 10%, but is significantly dependent on the volume transfused with fatality risk more than 20% with the infusion of more than 50 mL.<sup>85,98,104</sup>

AHTRs occur secondary to IgM-mediated antibody–antigen complexes that activate complement and result in intravascular and extravascular hemolysis in the spleen and liver. The release of bradykinin causes fever, hypotension, and hemodynamic instability, while histamine release from mast cells leads to bronchospasm and urticaria, as well as symptoms of dyspnea, flushing, and severe anxiety. Hemolysis results in the release of free hemoglobin that is bound by haptoglobin and plasma proteins, but will also be eliminated by the kidney when these proteins are unavailable.<sup>104</sup> Severe hemolysis may lead to renal failure, DIC, and death. General anesthesia can mask several of the presenting symptoms of AHTRs; therefore, vigilance during transfusion of an anesthetized patient must remain high, as survival depends on discontinuing the transfusion.

The diagnosis of hemolytic reactions is confirmed with laboratory findings of free hemoglobin, low haptoglobin, bilirubin increases, a positive direct antiglobulin (Coombs) test, and hematuria. Suspicion of a transfusion reaction should prompt immediate discontinuation of the transfusion, and investigation into the donor and recipient blood types and antigen–antibody components. Treatment of AHTR involves supportive care for hemodynamic instability and microvascular bleeding, as well as maintenance of adequate urine output to avoid renal failure associated with hemaglobinuria. Anemia can be profound, as the immediate hemolysis can destroy over 200 mL of blood per hour.<sup>104</sup>

*Delayed hemolytic transfusion reactions* (DHTRs) result from passive transfusion of RBC antibodies to native antigens in the recipient, or more commonly, alloantibodies in the recipient to minor RBC antigens in the Rh, Kell, Kidd, Duffy, MNSs, and other blood groups. There are at least 35 recognized blood groups at this time.<sup>104,105</sup> DHTRs generally present 3 to 10 days after transfusion of an apparently “compatible” blood component. Typically, the recipient has IgG alloantibodies to a particular RBC antigen, and will mount an anamnestic immune response; however, the pretransfusion antibody levels are too low for serologic detection. Symptoms of DHTRs are much milder than AHTRs and rarely result in major morbidity or mortality because the hemolysis occurs extravascularly in the reticuloendothelial system, liver, and spleen. Patients experience mild fever and possible rash, with laboratory and clinical signs of hemolysis such as jaundice, hemaglobinuria, low haptoglobin, positive direct Coombs test, and decreasing hemoglobin levels. The incidence of DHTRs is likely underreported as symptoms are subtle and may be attributed to the patient’s underlying

systemic illness. Studies estimate the risk of alloimmunization is up to 30% of transfusions. Symptoms are generally self-limited and treated supportively with hydration to protect the renal tubules during hemolysis, with further compatible transfusions to support anemia as indicated. Anemia is typically not severe, with less than 400 mL of RBCs destroyed over a 24-hour period.<sup>104</sup>

## **Transfusion-related Immunomodulation**

In the 1970s, transfusion-related immunomodulation (TRIM) was discovered from improved survival of renal allografts in patients who had received a transfusion pretransplant. This highlighted the potential immunosuppressant effects of stored allogeneic blood products. However, these beneficial effects are patient-specific. Immunosuppression also proved to increase the recurrence of malignancies and the incidence of serious health-care-associated infections, as well as long-term mortality after cardiac surgery.<sup>106–108</sup> Given multiple studies demonstrating the detrimental effects of just one transfused unit (including TRALI, multiorgan system failure, and increased rates of infection), efforts to define its immunomodulation mechanisms are in progress.<sup>106,109,110</sup>

Results point to a multifactorial pathophysiology that implicates transfused WBCs, donor plasma HLA class 1 peptides, cytokines, and immune mediators released during blood product storage, as well as the immune function of transfused RBCs within the microvasculature of the recipient.<sup>109,110</sup> Several experts propose a “two-insult” model for TRIM similar to the pathophysiologic mechanism for TRALI and acute respiratory distress syndrome.<sup>109</sup> Presumably, most patients requiring blood products are suffering from a precondition that “primes” both the immune system and vascular endothelium (e.g., trauma, surgery, or acute illness). This constitutes the first insult and causes active neutrophils to adhere to vascular endothelial cells and become hypersensitive to blood-borne immune mediators. The second insult occurs with the infusion of transfused blood products that contain WBCs with HLA class I antigens, as well as soluble immune response modifiers in the form of cytokines, complement factors, and the breakdown products of lipid membranes.<sup>106,109,110</sup> Several studies demonstrate a decrease in T-cell responsiveness and the inhibition of monocyte function after transfusion of RBCs.

The degree of TRIM-induced injury has been attributed to progressive storage lesions thought to be related to the age of RBC products at the time of transfusion. However, several recent trials, including the ARIPI trial in premature infants, the ABLE trial in critically ill patients, the RECESS trial in cardiac surgery, and the TOTAL trial in children with hemorrhagic shock,

consistently report no significant association between RBC storage duration and mortality or other adverse transfusion outcomes.<sup>37,111–113</sup> Also, prestorage LR and poststorage WBC filtration have been investigated as a means of limiting the deleterious effects of TRIM; however, results thus far are variable and inconclusive.<sup>100,106</sup> Nevertheless, evidence collected over the past 30 years from clinical trials and animal studies supports the hypothesis that TRIM involves both proinflammatory mechanisms and systemic immunosuppression.

### *Alloimmunization*

Alloimmunization refers to the induction of an immune response to allogenic antigen exposure. This process occurs occasionally through pregnancy, but the majority of alloimmunization results from transfusion of blood products containing immunogenic antigens on the surface of RBCs. Unlike classic ABO antigens, which consist of carbohydrate chains, most of the non-ABO alloantigens (Kell, Kidd, Duffy, etc.) result from single amino acid polymorphisms between the recipient and donor.<sup>114</sup> Healthy donor populations are expected to have an incidence of approximately 1% for blood group antibodies other than ABO.<sup>104</sup> AHTRs result in an immediate IgM-mediated immune response to ABO incompatibility with naturally occurring anti-A or anti-B antibodies. In contrast, alloimmunization prompts an anamnestic IgG-mediated humoral immunity to foreign proteins and does not result in RBC destruction until the second antigen exposure, which may cause complement activation and delayed extravascular hemolysis.<sup>104,114</sup> Thus, the clinical consequences of alloimmunization are rarely immediate or fatal, but the generation of antibodies may cause DHTRs and adds difficulty to subsequent cross-matching.

The incidence of alloimmunization is estimated between 4.4% and 10.5% from multiple longitudinal studies, but up to 40% to 58% in chronically transfused patients such as those with sickle cell disease, hematologic malignancy, or thalassemia.<sup>115,116</sup> This is especially evident for patients who require frequent platelet transfusions. Platelets carry significant levels of multiple human platelet antigens (HPA 1 to 15) and other polymorphisms that can result in the destruction of transfused platelets and refractory thrombocytopenia.<sup>114</sup> The use of single-donor apheresis units may limit the exposure to HPA and HLA. Furthermore, early studies demonstrate that preemptive matching of RBC units beyond just ABO blood groups reduces the risk of alloimmunization by up to 64%.<sup>116</sup> This practice could significantly alter the long-term prognosis for chronic transfusion patients.

### *Transfusion-Related Acute Lung Injury*

For at least the past decade, TRALI has been internationally recognized as the leading cause of transfusion-associated mortality, according to the United Kingdom's SHOT database. In recent data from the FDA, TRALI accounts for over 40% of US transfusion-related fatalities.<sup>85,98,117</sup> The incidence of TRALI is estimated to range from 0.04% to 8.0%, depending on patient risk factors and blood products used. A recent study of noncardiac surgery patients reported an incidence of 1.3% for all blood components.<sup>118</sup> Other estimates predict an incidence of 1 in 5,000 products (highest with plasma-containing products), and mortality rates of 5% to 25%.<sup>119</sup> Over the past decade, more consistent criteria have been used to diagnose TRALI—acute onset hypoxemia occurring within 6 hours of transfusion ( $\text{PaO}_2/\text{FiO}_2 \leq 300$  mmHg or oxygen saturation  $\leq 90\%$  on room air) and no evidence of left atrial hypertension. Possible TRALI can be diagnosed when alternative risk factors for acute lung injury are present, such as trauma or sepsis.<sup>118,120,121</sup> TRALI remains a clinical diagnosis that can be confounded by comorbidities or patient acuity. Consequently, TRALI tends to be underreported in the literature and difficult to study with randomized prospective clinical trials.

The pathophysiology of TRALI is complex and not yet fully understood. The clinical picture involves low-pressure pulmonary edema secondary to neutrophil activation and sequestration in the lungs. This results in endothelial injury and capillary leakage of proteinaceous fluid into the interstitium and intra-alveolar spaces. There are two leading theories on the mechanism of lung injury, both with sound experimental and clinical evidence. The antibody-mediated model stems from evidence of antibody-antigen complexes in the plasma of transfusion recipients who suffered from TRALI.<sup>119,120</sup> These antibodies are mostly against HLAs (class I and II) and human neutrophil antigens (HNAs).<sup>119,120</sup> Antibodies form in the donor plasma after alloimmunization from pregnancy, prior transfusion, or prior transplantation. Accordingly, plasma donation from multiparous women has been implicated as one of the highest risks associated with TRALI.<sup>119</sup> Once the antibodies are transfused into the recipient, they complex with native WBC antigens on the surface of monocytes (HLA class II), endothelial cells (HLA class I), and neutrophils (HNAs and HLA class I), thereby activating the neutrophils to facilitate aggregation and release of cytotoxic mediators. Subsequently, the endothelial lining of capillaries in the lung is damaged, resulting in extravasation of WBCs and leakage of edema fluid.<sup>119</sup>

The second proposed mechanism of TRALI was termed the “Two-Hit Model” in the late 1990s by Silliman et al., when they discovered the role of biologic response modifiers in its pathophysiology. Stored blood components accumulate lipid degradation products (mostly phosphatidylcholine derivatives) that function to activate neutrophils primed and sequestered on the endothelial vascular lining of lung tissue.<sup>122</sup> Patients with the highest

incidence of TRALI often suffer from a pre-existing proinflammatory state such as active infection, trauma, surgery, or multiple transfusions.<sup>118,120</sup> Acute illness causes the immune system to be hyperreactive, with neutrophils poised on the microvasculature endothelium and “primed” to be activated by various biologic response modifiers, including cytokines, complement, and leukotrienes.<sup>122</sup> The transfusion of stored blood products and associated reactive lipid particles marks the second “hit,” which activates primed neutrophils and results in the destruction of the capillary lining of lung microvasculature.<sup>120,122</sup> The overall pathophysiology of TRALI likely involves both of these mechanisms.

The management of TRALI focuses on supportive measures to limit lung injury and optimize oxygenation. This includes maximizing positive end-expiratory pressures, avoiding volume overload, and using low tidal volume strategies. Several studies have demonstrated decreased incidence of TRALI with deferral of high risk alloimmunization donors such as those with history of pregnancy, transfusion, or high antibody titers. Laboratory testing for antibody titers is time-consuming and inefficient; however, forcing many blood management services to use male-only donors for platelet and plasma products.<sup>120</sup> LR is also used to minimize the incidence and severity of TRALI, and likely has a significant clinical benefit for patients at high risk with critical illness or immunosuppression.<sup>96</sup> However, a recent systematic review demonstrated no definitive evidence to support universal leukoreduction for all patients.<sup>96</sup> Overall, prevention is the best treatment for TRALI, and is currently a major focus of clinical and experimental study, with emphasis on blood conservation strategies and restrictive transfusion practices.

### *Transfusion-Associated Graft-versus-Host Disease*

Transfusion-associated GVHD (TA-GVHD) is a rare but fulminant and fatal complication of blood products containing cellular components (platelets and RBCs). Although its incidence is decreasing secondary to preventative  $\gamma$  irradiation and LR, mortality is more than 90%. It occurs when donor lymphocytes engraft in the recipient and attack host cells they recognize as foreign. Patients at risk for TA-GVHD include those immunocompromised from stem cell transplants, B-cell malignancies (e.g., multiple myeloma, non-Hodgkin lymphoma) or acute lymphocytic leukemia, or with Hodgkin’s disease or congenital immunodeficiency syndromes.<sup>123</sup> Immunocompetent patients may also be at risk when transfused with directed donations from blood relations with similar HLA types because transfused donor lymphocytes are not recognized as foreign, yet still reject the recipient’s tissue.<sup>119</sup> TA-GVHD classically presents 4 to 21 days after transfusion, but clinical suspicion should exist for up to 6 weeks. Symptoms progress rapidly and generally affect the skin, hepatic, digestive, and hematopoietic organ systems causing

fever, rash, liver dysfunction, diarrhea, and pancytopenia.<sup>119,123</sup>

### *Posttransfusion Purpura*

Defined as severe thrombocytopenia with purpura occurring 5 to 10 days posttransfusion, posttransfusion purpura (PTP) is a very rare complication of transfusion, but associated with high morbidity and mortality. Most patients are female and have platelet-specific alloantibodies such as anti-HPA-1a.<sup>124</sup> These antibodies are almost exclusively found in previously pregnant women and cause platelet destruction of both transfused and autologous platelets. Intravenous IG is the first line of treatment, but plasmapheresis may be necessary to remove antibody and avoid bleeding complications.<sup>124</sup>

## **Nonimmune-Mediated Transfusion Reactions**

### *Transfusion-Associated Cardiovascular Overload*

Transfusion-associated cardiovascular overload (TACO) describes the occurrence of hydrostatic pulmonary edema after transfusion of blood component therapy. It differs from TRALI in that it is not immune mediated or associated with increased capillary permeability, and it responds rapidly to diuretic therapy and afterload reduction. The recent CDC definition requires evidence of acute respiratory distress within 6 hours of transfusion with features of left heart failure including increased central venous pressure or increased brain natriuretic peptide.<sup>125</sup> Similar to TRALI, TACO can be difficult to diagnose and is likely underreported in the literature. The overall incidence of TACO ranges from 1% to 8% of transfused patients, and is more prevalent in critically ill and postoperative patients with a history of congestive heart failure, chronic diuretic dependence, and underlying renal insufficiency.<sup>126,127</sup> Other risk factors for TACO include the volume and rate of transfusion, plasma products, and positive fluid balance.<sup>125,127</sup>

Recent reports from the FDA and the United Kingdom's SHOT database describe significant morbidity and mortality risks associated with TACO, the second leading cause of transfusion-related fatality over the past 5 years.<sup>98,117</sup> Furthermore, TACO increases the length of both ICU and hospital stay.<sup>127</sup> Preventative measures include slowing the rate of transfusion when appropriate, administering one blood product at a time, frequent assessment of vital signs, symptoms, and pulmonary status, and rapid treatment of volume overload with diuretics.

### *Metabolic Derangements*

The metabolic derangements from transfusion are usually not evident unless patients received a large volume transfusion or rapid infusion rates, but often

include hyperkalemia, citrate toxicity, and hypothermia.<sup>128</sup> As storage time for blood products increases, the cellular components leak potassium and metabolize glucose into lactate, resulting in hyperkalemia and/or acidemia in the transfused product. The acidosis is quickly cleared by physiologic buffers, as citrate preservative in blood products is metabolized to bicarbonate; therefore, ongoing acidosis in patients undergoing massive transfusion is likely secondary to tissue hypoxia and not to transfusion of acidic blood products. However, hyperkalemia results from high-volume transfusion, especially when infusion rates exceed 100 to 150 mL/hr. Packed RBCs can contain over 7 mEq/dL of potassium depending on the storage age and can produce consequences of hyperkalemia, such as ventricular arrhythmia or sudden cardiac arrest, particularly in neonates and patients with renal insufficiency.<sup>128</sup>

Citrate is a common anticoagulant used in stored blood products and is readily metabolized by the liver and quickly eliminated. However, with rapid infusion rates, massive transfusion, or in patients with liver dysfunction, citrate accumulates in the plasma and chelates calcium, resulting in hypocalcemia. Severe hypocalcemia leads to muscle weakness, tetany, arrhythmias, myocardial dysfunction, and acquired coagulopathy.<sup>128</sup>

Blood product transfusion can also lead to hypothermia, especially during rapid infusion of previously cold or recently thawed blood products. Coagulation factor activity decreases by 10% for every 1°C decrease in core body temperature. Fluid warmers are standard of care for rapid transfusion; nevertheless, hypothermia is commonly associated with massive transfusion and can result in platelet and coagulation factor dysfunction, arrhythmias, hepatic dysfunction, decreased citrate and drug metabolism, and myocardial depression. Additional preventative measures include warming the surrounding environment, surface warming, heated and humidified inspired gases, and fluid warmers for all infusion lines.<sup>128</sup>

### *Iron Overload*

Packed RBCs carry increasing concentrations of iron as a result of hemolysis during storage and transfusion. Iron stores accumulate in patients who require frequent transfusions for chronic anemia or hemoglobinopathies, with increased mortality demonstrated for patients who receive more than 20 units of PRBCs. Iron overload occurs when deposits in the liver, heart, and endocrine systems result in organ dysfunction. Stored iron is not directly detrimental to organ systems; however, iron metabolism produces harmful intracellular free radicals, which in turn cause cellular dysfunction and organ failure. Patients often suffer from cardiomyopathy and cirrhosis.<sup>129</sup> Furthermore, iron availability for microorganisms increases the risk of recurrent infections to patients with chronic transfusion requirements.

Chelation therapy is the first line of treatment, but difficult to administer secondary to the bioavailability and side effect profile of chelating agents. Exchange transfusion therapy decreases the iron load better than traditional transfusion, but it is expensive and associated with complications from central venous access and a larger amount of blood products.<sup>129</sup>

## **Blood Conservation Strategies**

Most healthy patients undergoing routine surgery will not require allogenic blood transfusion. However, there are some elective procedures such as liver resection, orthopedic surgery, cardiac surgery, and scoliosis correction where the risk of blood transfusion exceeds 30%.<sup>130</sup> As discussed in detail earlier, blood component therapy is associated with significant morbidity and mortality for all patient populations. It is also scarce and costly. Several methodologies have been suggested to conserve perioperative transfusion (Table 17-11), with the most recent guidelines from the ASA emphasizing many of these adjunctive techniques.<sup>44</sup>

### ***Autologous Blood Transfusion***

Autologous blood conservation (ABC) first gained popularity because of the rising risk of transfusion-transmitted viral infections. All forms of ABC reduce the need for allogenic blood components; however, now that the incidence of infectious risks with allogenic blood has declined substantially, the utility and cost-effectiveness of ABC is not as certain, especially when the process involves blood storage. ABC encompasses three separate processes: (1) preoperative autologous blood donation (PAD); (2) acute normovolemic hemodilution (ANH); and (3) perioperative blood cell salvage.

**Table 17-11** Perioperative Blood Conservation Strategies

Technique	Comments
Preoperative autologous donation (PAD)	Increased overall transfusion requirement; lower preoperative hemoglobin
Acute normovolemic hemodilution (ANH)	Limited benefit; contains clotting factors and platelets
Intraoperative blood salvage (IOBS)	Cost-effective, low risk, and highly efficacious
Postoperative blood salvage (POBS)	Efficacious for high-risk orthopedic surgery
Pharmacologic agents	
Stimulants of erythropoiesis	Erythropoietin, vitamin B <sub>12</sub> , folate
Prohemostatic agents	Vitamin K, DDAVP, antifibrinolytics, factor concentrates

DDAVP, 1-deamino-8-D-arginine vasopressin.

*PAD* summarizes the process of patients donating their own whole blood in the weeks preceding a planned surgical procedure to ensure that they receive autologous blood, should red cell replacement be necessary. *PAD* was initially popular in the 1980s, when concern for transfusion-transmitted HIV was high; however, it has since become less frequently used given the reduced risk of viral infections and new concerns about the risks and adverse effects of stored blood. *PAD* eliminates the risk of transfusion-transmitted infection and alloimmunization, and it may also decrease the risk of TRALI. However, recipients of stored autologous blood remain at risk for clerical error, TACO, bacterial infection, metabolic derangements, and TRIM. *PAD* reduces the need for allogenic blood transfusion when performed with appropriate protocols that include early donation and erythrocyte-stimulating agents (ESA) to allow for sufficient erythropoiesis. However, intraoperative blood salvage (IOBS) techniques have improved their efficiency. Given the increased tolerance for lower perioperative hemoglobin levels, the increased wastage of *PAD* units (up to 45%), diminishes the efficacy and cost effectiveness of its routine use.<sup>130,131</sup>

*PAD* is currently indicated for use in patients in whom it would be difficult to find compatible blood products due to multiple antibodies or rare blood types, those who refuse to receive allogenic transfusion, and those undergoing elective surgery where more than 4 units of RBC transfusion is anticipated.<sup>130,131</sup> Typically, each donation session collects a single or double unit of whole blood and can technically be repeated weekly until 72 hours prior to the scheduled procedure.<sup>131</sup> Patients are rarely able to donate more than 4 units because of the limited storage time, and hemoglobin must remain above 11 g/dL before donation.<sup>130</sup> However, the earlier the donation, the more time a patient has to recover from iatrogenic anemia. Despite the ability

to donate up until 72 hours before surgery, it is not recommended to undergo donation within 28 days of planned surgery as PAD rapidly loses its effectiveness when donation occurs in proximity to surgery and patients **23** present with preoperative anemia.<sup>130,131</sup> PAD is most effective when used in conjunction with erythropoietin, which increases the tolerance for repeat donations. Iron supplementation is not indicated and generally not helpful in patients who are already iron replete; however, oral iron should be administered to patients known to be iron deficient prior to autologous donation and surgery.<sup>130,131</sup>

PAD should be avoided if the scheduled procedure is at risk of postponement because autologous donated units may become outdated if surgery does not proceed on time. Furthermore, directed donations are not subjected to the same testing or deferral procedures as allogenic blood collection, and therefore cannot be used by the general population if they are not transfused into the patient. Transfusion of autologous blood should still be guided by the same indications for transfusion of allogenic RBCs—avoiding wastage is not an appropriate reason to transfuse autologous units. In other words, patients should not be overtransfused simply because they have stored autologous blood. In large retrospective studies comparing PAD to IOBS techniques, PAD is less effective at reducing allogenic transfusion rates and presents several risks such as symptomatic donation, preoperative anemia (average preoperative hemoglobin level 1.1g/dL below controls), increased rates of overall transfusion, and higher costs.<sup>130,131</sup> As with any perioperative management plan, the advantages and disadvantages should be individually considered in the context of the patient's history, planned procedure, and physical state before implementing a PAD program.

*ANH* is the process of extracting multiple units of blood immediately before surgical incision while maintaining euvolemia with crystalloid or colloid supplementation. The withdrawn blood is high in hematocrit and contains clotting factors and functional platelets. After ANH, the patient loses blood with lower hemoglobin and fewer red cells. This process reduces the oxygen-carrying capacity of blood, but healthy patients maintain oxygen delivery with intact compensatory mechanisms such as increased CO and oxygen extraction. At the end of surgery, the autologous units are reinfused, thereby replacing RBCs, platelets, and plasma proteins active in hemostasis. This process eliminates the infectious and alloimmunization risks of allogenic transfusion, as well as the immunomodulatory risks of blood storage. ANH was first introduced in the 1970s and gained popularity in the 1990s, when transfusion-transmitted infectious risks were high. In the last 20 years, however, three large meta-analyses documented only modest decreases in the risk of allogenic transfusion rates, and highlighted limitations and controversy associated with publication bias for ANH trials.<sup>132,133</sup> Furthermore, a recent

mathematical modeling study demonstrated ANH to be inferior to high-efficiency IOBS and protocolized PAD.<sup>131</sup>

Procedurally, ANH involves the removal of a predetermined volume of blood after the induction of anesthesia, but prior to surgical incision. Target hematocrit nadirs will vary based on individual patient history and baseline physiologic state; however, these usually range from 25% to 30%.<sup>133</sup> The simple formula for allowable blood loss is used to calculate the volume to be removed.  $\text{Volume to be removed} = \text{EBV} \times [(\text{Hct}_i - \text{Hct}_t) / \text{Hct}_{\text{ave}}]$  where EBV is the estimated blood volume;  $\text{Hct}_i$ , the starting hematocrit;  $\text{Hct}_t$ , the target low hematocrit;  $\text{Hct}_{\text{ave}}$ , the average of Hct. Euvolemia should be maintained with either crystalloids at a ratio of 3:1 with colloids at a ratio of 1:1 relative to the volume of blood removed.<sup>131</sup>

Given the limited evidence of benefit, ANH is not recommended for routine use. However, it may be considered for patients with multiple antibodies or a rare blood type that creates difficulty with finding compatible products, or for patients who refuse allogenic transfusion or stored blood component therapy such as Jehovah's Witnesses. ANH is most effective in patients with high preoperative hemoglobin levels, minimal cardiovascular comorbidities that allow intraoperative anemia, and a surgical risk for large volume blood loss. This technique of autologous transfusion is favorable compared to PAD in selected patient populations.<sup>132</sup>

## Perioperative Erythropoietin

Erythropoietin is the primary regulator of erythropoiesis. Its endogenous release is stimulated by anemia or physiologic hypoxia. It is currently FDA-approved for treatment of anemia in oncology patients with chemotherapy-induced anemia and patients with chronic renal failure. It has also been used to optimize patients with preoperative anemia undergoing surgery with significant risk of transfusion and patients undergoing PAD<sup>134</sup> (because conventional PAD programs maintain hematocrit levels well above the threshold for endogenous erythropoietin release, causing insufficient native stimulation of erythropoiesis). Several studies have shown a clear decrease in the requirements for allogenic blood transfusion, when erythropoietin is used in conjunction with a PAD program for adolescent spine, orthopedic, or cardiac surgery that maintains preoperative hemoglobin concentrations between 10 and 13 g/dL.<sup>134,135</sup> However, there is ongoing concern for increased risk of thromboembolic events and overall safety issues when erythropoietin is used routinely. For these reasons, its generalized use is not recommended at this time.

## Perioperative Blood Salvage

RBC salvage was first attempted in the early nineteenth century for patients with postpartum hemorrhage. Not surprisingly, it was fraught with complications throughout its early development. It was not until the 1970s that commercial cell salvage devices became available for clinical use, yet there were still frequent complications such as hemolysis, air embolism, and **24** coagulopathy.<sup>136</sup> Over the past decade RBC salvage techniques have improved significantly and now offer an efficient, cost-effective, and safe method for perioperative blood conservation. In general, cell salvage involves the collection of shed surgical blood, which is filtered and/or washed prior to reinfusion. This process can be carried out intraoperatively with direct suction of the surgical field, or postoperatively in the case of orthopedic, cardiac, and thoracic surgery with the use of blood from wound drainage.

IOBS requires the use of a double-lumen suction catheter with one port for aspiration from the surgical field and the other for the addition of an anticoagulant solution, usually heparin or citrate. Suctioned blood is then collected in a reservoir, filtered to remove large debris, and centrifuged to produce RBC concentrates. The final step of washing clears the product of residual contaminants such as plasma, platelets, free hemoglobin, cellular fragments, WBCs, and the remaining heparin or citrate. The resultant red cells are resuspended in saline and ready for reinfusion. This is usually reinfused to the patient immediately through standard blood filters, but may be stored at 4°C for up to 6 hours with careful patient and product identification. On average, IOBS yields a hematocrit ranging from 50% to 80%.<sup>131,136</sup> The efficiency depends on several factors including the volume of blood processed at a time, the length of time that blood remains in the wound, and the rate and precision of suctioning, since increased turbulence from the surgical field adds shear stress, which damages RBCs. Most modern-day cell savers, when used appropriately, provide RBC concentrates with a hematocrit of 60% to 70%.<sup>131,136</sup>

IOBS has proven benefits for reducing allogenic blood transfusion in major surgery, particularly multilevel spine fusions and cardiac surgery.<sup>136-139</sup> However, recent studies and a meta-analysis on the use of cell salvage in routine knee and hip arthroplasty demonstrate reduced efficacy and cost effectiveness for IOBS. This is likely secondary to more restrictive transfusion practices, better preoperative optimization of hemoglobin levels, and the use of antifibrinolytics.<sup>135,140,141</sup> However, IOBS continues to be indicated for patients with low preoperative hemoglobin who cannot tolerate PAD or ANH, those unwilling to consent to allogenic transfusion, and patients with pre-existing bleeding risks or multiple alloantibodies.<sup>131,142,143</sup> Evidence shows that salvaged blood has better oxygen-carrying capacity and tissue oxygenation than stored blood, secondary to retention of red cell's biconcave disc shape and increased levels of 2,3-DPG and ATP.<sup>136,144</sup> There are very few

studies directly comparing IOBS to ANH and PAD. One mathematical modeling study demonstrated the superiority of IOBS to PAD and ANH when high-efficiency systems are able to recover more than 70% of blood loss.<sup>131</sup> Overall, IOBS is cost-effective, convenient, and advantageous for emergency procedures and surgeries with high risk of significant perioperative blood loss.

The complications of IOBS are rare and are mostly associated with either the method of suctioning or contamination from the surgical field. Risks include nonimmunogenic hemolysis, fever, and contamination with various substances such as topical anticoagulants, urine, amniotic fluid, or bacteria. Washing the salvaged blood clears most contaminants, and variable suction devices limit the sheer stress that causes hemolysis. Reinfusion of salvaged blood in volumes greater than 50% of the estimated blood volume can result in dilutional coagulopathy similar to massive transfusion of allogenic RBCs, since neither contains clotting factors or platelets. Lastly, IOBS can cause gas embolism if the reinfusion bag is connected in a continuous circuit with the patient.<sup>136,145</sup> Careful adherence to the recommended application of modern cell-saver devices effectively eliminates many of these concerns.

Traditionally, cell salvage was contraindicated in cancer surgery and operations where blood loss is contaminated by urine, anticoagulants, or amniotic fluid. However, several studies now demonstrate the safety of cell salvage when blood is processed, washed, and administered through a leukodepletion filter.<sup>136,145</sup> Use in surgery for prostate cancer and gynecologic oncology, which often involves urine and malignant cells contaminating the field, has not shown significant increases in morbidity, mortality, or cancer recurrence. However, it is recommended that IOBS be filtered and irradiated when there is concern for malignancy, and avoided completely when the tumor is ruptured causing an overwhelming concentration of cancer cells in shed blood.<sup>136</sup> The use of IOBS for obstetric cases raises concerns about inducing alloimmunization or amniotic fluid embolism, recently termed “anaphylactoid syndrome of pregnancy.” Because this syndrome is very rare, it is difficult to establish the safety of a new technique. However, Goucher et al.<sup>145</sup> reviewed the results of seven IOBS trials for almost 300 obstetric patients and found no increased incidence of amniotic fluid emboli. Leukodepletion filters remove most of the amniotic fluid, immune mediators, and debris. Although fetal RBCs cannot be differentiated from maternal red cells and may potentiate alloimmunization, this risk is already present during delivery and not exacerbated by the use of IOBS. Cell salvage should be considered for high-risk obstetric patients such as those undergoing planned cesarean hysterectomy or those with placenta accreta.<sup>145</sup> The only absolute contraindications to IOBS are microbial contamination of the surgical field, and cancer surgery where tumor rupture or direct

manipulation is likely.<sup>136</sup>

Postoperative blood salvage (POBS) involves the collection and reinfusion of blood shed into surgical wound drains in the immediate postoperative period. The recovered blood product can be processed in one of the two ways: “washed” POBS is centrifuged, washed, and resuspended as RBC concentrates, whereas “unwashed” POBS is simply filtered before reinfusion. The resultant hematocrit of unwashed POBS ranges from 20% to 30% and should not be expected to increase the patient’s hemoglobin level. Rather, it will aid in avoidance of dilutional anemia associated with the fluid resuscitation for postoperative bleeding. There are advantages and disadvantages to both techniques, resulting in continued controversies over the safety and efficacy of POBS.

POBS studies are limited, but meta-analyses demonstrate efficacy in orthopedic procedures such as knee and hip arthroplasty. Unwashed POBS is most commonly used in orthopedics, as it is highly efficacious, cost-effective, and requires little additional training in comparison to use of washed POBS.<sup>146,147</sup> POBS has also been studied in postcardiac surgery patients and shown to be efficacious at reducing the need for allogenic blood transfusion.<sup>146</sup> However, shed blood from surgical wounds, involving the thorax and mediastinum, contains inflammatory mediators, activated clotting factors, fibrin and fibrin split products, and the products of hemolysis such as free hemoglobin. These substances can precipitate renal damage, lung injury, or coagulopathy. POBS for cardiac surgery should be washed prior to reinfusion in accordance with the most recent guidelines from the SCA.<sup>51,148</sup>

POBS continues to be part of the multimodal approach to perioperative patient blood management. Complications include concern for hemolysis and immunomodulation, and its overall efficacy and cost effectiveness remain unclear. However, POBS continues to be used in routine orthopedic and cardiac surgery.<sup>146–148</sup> It is contraindicated for patients with pre-existing hemoglobinopathies such as sickle cell disease and thalassemia.<sup>146</sup> Furthermore, similar to IOBS, blood should not be reinfused if it has been contaminated with microbials or drugs used topically in the surgical field that are not indicated for systemic use (e.g., betadine, chlorhexidine, and topical antibiotics).<sup>146</sup>

*Jehovah’s Witnesses* belong to an international and well-established religious society with over 7.8 million followers who believe in a literal translation of the Bible. Passages such as Genesis 9, verse 4 (“But you shall not eat flesh with its life, that is, its blood”) and Leviticus 17, verse 10 (“If any one of the house of Israel...eats any blood, I will ... cut him off from among his people”) lead to a proscription against receiving blood product transfusions. Followers believe that once blood has left the body it should not be consumed in any way. Receipt of a blood transfusion is believed

to cause irreversible death to a member's soul without hope of eternal life.<sup>142,143</sup> Most Jehovah's Witnesses understand and accept the threat of death as a possible result of refusing therapeutic transfusion. Clearly this is challenging for treating physicians, especially in the case of emergent hemorrhage. The best management for Jehovah's Witnesses is to have a well-prescribed perioperative management plan to maximize blood conservation strategies and a clear conversation about the patient's individual concerns and beliefs. Some patients consent to blood component therapy, factor concentrates derived from blood (e.g., albumin or PCCs), or extracorporeal circulation, which may include cardiopulmonary bypass, ANH, and IOBS if left in continuous circulation with the body. These decisions can be made based on a patient's review of their conscience and their own interpretation of religious scripture.<sup>143</sup>

Jehovah's Witnesses are fully aware of how their belief system affects medical management with routine life-sustaining treatments. Accordingly, there are over 1,700 Hospital Liaison Committees worldwide designed to assist with personal health-care management plans that provide both patient autonomy and the best medical care available.<sup>143</sup> Some of the most challenging questions arise with minors, emergencies, and unconscious patients, when the physician is unable to have a clear conversation about the patient's specific beliefs. There is a great deal of individual variability within the religion that can lead to drastically different management plans for bleeding and acute anemia. Often adult Jehovah's Witnesses will carry cards with an advance directive; however, if questions arise, physicians should seek the guidance of their hospital ethics committees and legal advisors. An urgent application to the court system is appropriate in the case of minors or unconscious patients without decision-making capacity.<sup>142,143</sup>

In preparation for elective surgery for a Jehovah's Witness patient, the use of prohemostatic medications such as ESAs, antifibrinolytics, vitamin K, factor concentrates, and desmopressin should be considered, and should be available. In addition, the patient's preoperative hemoglobin should be optimized by stimulating erythropoiesis with recombinant erythropoietin, iron, and supplemental vitamin B<sub>12</sub> and folate.<sup>142,143</sup> There is ongoing research into the clinical use of hemoglobin-based oxygen carriers that could revolutionize the treatment not only of Jehovah's Witnesses, but have yet to be approved in the United States.<sup>142</sup>

## **Disorders of Hemostasis: Diagnosis and Treatment**

As discussed previously, hemostasis is a complex mechanism of checks and balances that aims to control bleeding from sites of vascular injury while maintaining blood flow throughout the rest of the body. It involves countless

proteins, enzymes, ligands, and molecules to serve as activators, cofactors, regulators, and inhibitors in hemostasis. When the equilibrium of this process is disrupted, it results in abnormal bleeding or clotting, depending on the specific dysfunction or deficiency. Accordingly, disorders of hemostasis 25 can be classified as those that facilitate hemorrhage and those that facilitate inappropriate thrombosis. The disorders are further separated by the involvement in primary hemostasis (the initial platelet plug) or secondary hemostasis (the clotting cascade and fibrin cross-linkage). Finally, hemostatic disorders are caused by either inherited genetic disease or acquired deficiencies.

Symptomatic disorders of primary hemostasis often present with superficial signs of bleeding on the skin or mucosa. Patients complain of petechiae, mucosal bleeding, and easy bruising. They often suffer from 26 prolonged bleeding from minor injury, frequent epistaxis, and menorrhagia secondary to deficient or dysfunctional platelet activity. In contrast, disorders of secondary hemostasis involve qualitative or quantitative dysfunction of clotting factors and cause more severe and deep tissue bleeding. These patients present with spontaneous hemarthroses, hematomas, and excessive hemorrhage after traumatic injuries. Treatments depend on the specific cause of the disorder and often involve blood component therapy or pharmacologic agents that enhance, inhibit, or bypass specific sites in the hemostatic process.

### **Disorders of Primary Hemostasis**

Primary hemostasis involves the initial recruitment of platelets at the site of vascular injury to form a fragile platelet plug. Once platelets bind to the injured subendothelium, they become activated, thereby exposing additional receptor sites and releasing factors involved in further platelet recruitment, activation, aggregation, and the initiation of secondary hemostasis.

*Hereditary disorders of platelets* are rare and usually associated with defective receptor binding. Bernard–Soulier syndrome is an autosomal recessive disorder that results from an abnormality of the GP Ib receptor. This qualitative and quantitative dysfunction impairs platelet adhesion to exposed vWF at the site of vascular injury.<sup>149</sup> Glanzmann thrombasthenia is an autosomal recessive genetic disorder that results from a defect in the platelet integrin  $\alpha\text{IIb}\beta\text{3}$  receptor which, under normal circumstances, allows fibrinogen and other ligands to bind and facilitate platelet aggregation. Other inherited disorders of platelets generally involve ligand receptors or defects in the signaling cascade for molecules involved in platelet activation (e.g., thromboxane and adenine diphosphate).<sup>149</sup>

27 *vWD* is the most common hereditary bleeding disorder, with a

prevalence of approximately 1% in the general population, although it is only reportedly symptomatic in 0.01%.<sup>150</sup> The clinical features and severity of vWD vary immensely, since it has several different types and classifications depending on the nature of the genetic mutation and its effect on the functionality of vWF (Table 17-12). Different genetic mutations affect various domains of vWF, causing different quantitative and functional deficiencies. Each type of vWD presents differently, and in fact there are several complex laboratory evaluations necessary to classify the exact type of disease for each patient. It is important to reach the correct diagnosis, since appropriate treatment and prophylaxis differs for each class of the disorder.<sup>150</sup>

vWF is produced in endothelial cells and megakaryocytes, and functions in primary platelet adhesion and aggregation at the site of vascular injury through interaction with the GP Ib receptor on the platelet surface. Once exposed, vWF facilitates the interaction of platelets with collagen within the subendothelium as well as platelet–platelet interactions. Both of these result in the initial platelet plug and subsequent platelet activation.<sup>150</sup> Furthermore, vWF circulates as a complex with FVIII, providing stability to the otherwise labile clotting factor until vWF binds to activated platelets via the GP IIb/IIIa receptor. This localizes FVIII to the site of injury.<sup>150,151</sup> The clinical features of vWD vary with differing levels of functionality that result from inherited disorders in protein synthesis, structure, function, and clearance. However, most types of vWD result from decreased levels or deficient function of vWF in primary hemostasis. Patients typically present with mucocutaneous bleeding (e.g., epistaxis), menorrhagia, and prolonged bleeding from minor wounds and dental extractions. Frequently, patients are not aware of the disorder until they undergo a bleeding questionnaire in anticipation of major surgery.

There are three types of vWD. Types 1 and 3 result from quantitative deficiencies of vWF, whereas type 2 occurs with various mutations causing qualitative dysfunction. Type 2 is further classified (A, B, M, and N) depending on the domain of the protein that is affected and the functional defect (Table 17-12).<sup>150,152</sup> Type 1 has an autosomal dominant inheritance pattern and results from a partial quantitative deficiency in vWF levels either from decreased synthesis and secretion or from accelerated proteolysis and clearance. It is the most common and mildest type of vWD.<sup>150</sup> Type 3 is the most severe, but also the rarest; it has a recessive pattern of inheritance and results in significantly depressed levels of vWF. This is the only type likely to cause spontaneous hemorrhage in joints and soft tissues.<sup>150</sup> Types 2A and 2M result in deficiencies in platelet adhesion and decreased activity of vWF relative to the factor levels within the plasma. Type 2B involves increased affinity of vWF for the GP Ib receptor on the platelet surface. This causes spontaneous binding of vWF to circulating platelets, thereby increasing the

cleavage and clearance of vWF. This type of vWD can be associated with thrombocytopenia. DDAVP treatment is commonly used to increase cleavage from FVIII and overall availability.<sup>150</sup> Lastly, type 2N is characterized by decreased affinity for FVIII and deficiencies in secondary hemostasis. This type is often confused with hemophilia A, given the depressed levels of FVIII associated with significantly decreased factor half-life.<sup>150,152</sup>

The three primary criteria for diagnosis of vWD are (1) a history of mucosal bleeding or prolonged bleeding after dental extractions, surgical procedures, or postpartum hemorrhage; (2) a family history of bleeding disorders (understanding this can be unreliable or unavailable); and (3) reduced activity of vWF demonstrated by various assays designed to test platelet adhesion, aggregation, and levels of vWF or FVIII complexes (e.g., vWF:factor antigen, vWF:ristocetin cofactor activity, vWF:collagen-binding activity, and vWF:GP 1b binding activity).<sup>152</sup> The laboratory diagnosis and classification of vWD is complex and often requires a hematologist to correctly specify the type of disorder, and to prescribe the appropriate prophylaxis and treatment options. Overall, it is important to recognize that traditional coagulation profile tests such as PT and aPTT are often normal in patients with vWD.

There are two primary treatment options for patients with vWD—DDAVP and factor concentrates. DDAVP promotes the cleavage of vWF from FVIII and increases the availability of both. This is beneficial for most patients with type I partial deficiency and some type 2 subclassifications of vWD (with the exception of type 2B as discussed above). DDAVP may not be therapeutic by itself for patients with type 3 and severely depressed levels of vWF. Often these patients require treatment with additional hemostatic medications such as antifibrinolytics and/or factor replacement with plasma-derived vWF/FVIII concentrates (Heamate P/Humate P). These concentrates are only needed in approximately 20% of patients with vWD who do not respond to DDAVP, and may vary in efficacy. Accordingly, it is important to obtain the correct diagnosis in order to best manage each patient prophylactically before surgery and therapeutically in the event of uncontrolled bleeding.<sup>153</sup>

On rare occasions, vWD may be acquired in association with various disease processes such as lymphoproliferative or myeloproliferative disorders; autoimmune disease; cardiac dysfunction (e.g., aortic stenosis, ventricular assist devices), or medication-induced from quinolones, valproic acid, and hydroxyl ethyl starches. The pathophysiology of acquired vWD is multifactorial and may involve various mechanisms including immune-mediated clearance by ADAMTS-13-mediated cleavage of high-molecular-weight vWF, binding or absorption with large molecules such as the starches, or enhanced proteolysis secondary to shear stress.<sup>151</sup> Treatment starts with discontinuation of the offending agent or management of the underlying

condition; however, adjunctive treatment with DDAVP and/or antifibrinolytics are helpful.

**Table 17-12** Classification of Inherited von Willebrand Disease

Type	Pathophysiology	Comments
1	Partial quantitative deficiency of vWF	Mildest; most common; responds to DDAVP
2A	Dysfunction in platelet adhesion	May respond to DDAVP
2M	Dysfunction in platelet adhesion	May respond to DDAVP
2B	Increased platelet-binding affinity	Thrombocytopenia with DDAVP
2N	Decreased FVIII-binding affinity	Often confused with hemophilia A
3	Severe quantitative deficiency of vWF	Rarest; most severe; usually requires factor concentrates

vWF, von Willebrand factor; DDAVP, desmopressin; FVIII, factor VIII.

## Disorders of Secondary Hemostasis

### The Hemophilias

**28** Hemophilia is a genetic disease that results from deficiencies or dysfunction of specific clotting factors. The most common form is hemophilia A, which accounts for about 85% of the disease and stems from deficiencies of FVIII. Hemophilia B (Christmas disease) involves a defect in the production of factor IX, and is the second most common type of hemophilia. Both hemophilia A and B are X-linked recessive disorders and are found almost exclusively in male patients, although new mutations are common and account for about a third of hemophilias in male and female patients without family history.<sup>154</sup> Hemophilia was originally called the “royal disease,” since Queen Victoria of England was a carrier of hemophilia B and passed the disorder to the royal families of Spain, Germany, and Russia. Lastly, hemophilia C is very rare (1% of all hemophiliacs), and results from genetic mutations in FXI, and is the only form that has an autosomal recessive inheritance pattern.

*Hemophilia A* affects approximately 1 in 5,000 males worldwide. Clinically, these patients suffer from spontaneous bleeding into their joints, muscles, and internal organs, often requiring orthopedic surgery for long-term complications of hemarthroses. Central nervous system bleeding is rare, but can lead to severe disability and death.<sup>154</sup> Normal plasma concentrations of FVIII range between 100 and 200 ng/mL, and the severity of disease varies depending on the residual factor activity. Patients with mild disease maintain factor levels between 5% and 40% of normal, and account for about 50% of patients with hemophilia A. Approximately 10% of patients have moderate disease, with only 1% to 5% of residual FVIII activity. The most severely affected patients account for about 40% of the disease prevalence and have less than 1% of normal factor activity.<sup>154,155</sup> Carrier females generally

maintain about 50% of FVIII activity with no clinical signs of bleeding. Homozygous females may present with hemophilia, but this is rare and often associated with Turner syndrome or X-chromosomal mosaicism. Diagnosis starts with patients reporting a personal and/or family history of bleeding disorders among male relations. Confirmatory laboratory evidence includes prolonged aPTT and low factor activity levels. Typically, the PT and bleeding times will be normal.<sup>156</sup>

Treatment for all hemophilia patients involves replacement of coagulation factor deficiencies, which can be accomplished with plasma transfusion or factor concentrates. Historically, hemophiliacs were exposed to several transfusion-related infectious risks prior to the availability of recombinant and virally inactivated factor concentrates. In the 1980s, a significant percentage of patients with hemophilia contracted AIDS from transfusion-transmitted HIV. Frequent transfusions for these patients are clearly associated with numerous infectious and noninfectious transfusion risks, including the development of factor inhibitors and alloantibodies. Up to 30% of patients with severe hemophilia develop inhibitor antibodies to FVIII by the time they reach adulthood, making them less responsive to factor concentrates. Patients with severe hemophilia are at highest risk for developing inhibitors, since they require frequent high-dose treatment and primary prophylaxis starting at younger ages.<sup>157</sup>

The goals of managing hemophilia continue to focus on prophylaxis against spontaneous bleeding, as well as aggressive blood conservation strategies for anticipated invasive procedures. Patients with mild hemophilia A and hemophilia C often benefit from treatment with DDAVP, to raise the circulating availability of FVIII by increasing dissociation from vWF.<sup>154,158</sup> However, those with more severe disease require treatment of spontaneous and traumatic bleeding episodes, as well as prophylaxis to avoid the long-term complications of hemarthroses. This is accomplished with transfusion of specific factor concentrates derived from virally inactivated plasma-derived or recombinant products.<sup>155</sup> Patients with inhibitors to FVIII or FIX often respond to bypass agents such as rFVIIa or PCCs.<sup>158,159</sup> Factor concentrates are given in anticipation of surgery or invasive procedures, and are dosed individually depending on severity of illness and risk of bleeding. The appropriate dosing regimen for prophylaxis is highly variable among patients, due to differing levels of disease severity and the impact of factor inhibitors. Titration of the dose of factor concentrates to trough levels of no less than 1 IU/dL (1% of normal) is recommended during long-term prophylaxis.<sup>154,155</sup>

*Hemophilia B* is clinically and pathophysiologically similar to hemophilia A, except it involves FIX and is much less common worldwide, affecting roughly 1 in 25,000 males. This form of hemophilia is treated with recombinant FIX concentrates, but requires less frequent dosing regimens than FVIII

concentrates due to a longer half-life (18 hours as opposed to 12 hours). Fortunately, the development of factor inhibitors is much less prevalent in patients with hemophilia B than in patients with hemophilia A, and occurs in only 1% to 6% of severe patients. These patients are also generally responsive to bypass treatment with PCCs or rFVIIa in the case of urgent bleeding.<sup>160</sup>

*Acquired hemophilia* is a rare disease that usually develops in association with connective tissue disorders, pregnancy, or malignancy. It rarely occurs in young patients and stems from the development of antibodies to FVIII. The clinical symptoms of acquired hemophilia typically include subcutaneous bleeding episodes and soft tissue hematomas, as opposed to the hemarthroses common to congenital hemophilia.<sup>156</sup> Diagnostically, the aPTT is prolonged in conjunction and low FVIII levels do not correct in a mixing study due to the presence of inhibitors. The treatment for acquired hemophilia with acute bleeding depends on bypass agents such as rFVIIa or PCCs, although some patients with mild disease will respond to adjunctive therapies such as DDAVP and antifibrinolytics. Once hemostasis is achieved, long-term management involves immunosuppression with steroids or cytotoxic agents.<sup>156</sup>

### **Hereditary Hypercoagulability**

The *FVL* genetic mutation causes resistance to the anticoagulant effects of APC on clotting factor V. It is the most common hereditary risk factor for hypercoagulability. Heterozygous patients have a fivefold increase in the risk of venous thromboembolism. This rises to 20- to 80-fold increased risk in homozygotes. Treatment involves lifelong therapeutic anticoagulation. The prevalence amongst Caucasians is approximately 5% throughout North America and Europe. Some investigators propose that the high prevalence in Caucasians stems from a protective genetic interplay against bleeding and mortality risk associated with hemophilia.<sup>20</sup>

*Protein C and S deficiencies* are autosomal dominant genetic diseases that result in increased risk of venous thromboembolism. Protein C inactivates factor V to curb the clotting cascade, and depends on protein S as a cofactor for appropriate function. Accordingly, deficiencies or dysfunction in either protein C or S result in a prothrombotic state. Clinically, patients present with venous thromboembolism in early adulthood, but arterial thrombosis is rare. Treatment of acute thrombosis requires therapeutic anticoagulation. Warfarin is indicated for long-term management, but should be started slowly once the patient is therapeutic on heparin, to avoid the risk of warfarin limb necrosis.<sup>161</sup>

### **Acquired Disorders of Hemostasis**

## Vitamin K Deficiency

Vitamin K is one of the essential fat-soluble vitamins required for the synthesis and final processing of several hemostatic factors, including factors II, VII, IX, X, and proteins C and S. Without vitamin K, these proteins do not undergo carboxylation and therefore cannot actively bind to the phospholipid membrane of platelets during secondary hemostasis. There are two sources of vitamin K—phyloquinone (K<sub>1</sub>) is available in a number of foods such as leafy greens, whereas menaquinone (K<sub>2</sub>) is synthesized in the GI tract by intestinal bacteria and accounts for the bulk of vitamin K stored in the liver. The absorption of both types occurs in the small intestine and depends on the availability of bile salts. Accordingly, liver insufficiency, the sterile gut in newborns, and oral antibiotic treatments are some of the leading causes of vitamin K deficiency.<sup>162</sup> Other causes include chronic kidney disease, total parenteral nutrition, intestinal obstruction, or hyperperistalsis.<sup>162</sup>

Vitamin K deficiency presents with prolonged PT and aPTT, but can also be diagnosed by low vitamin K levels or measures of noncarboxylated prothrombin. It is treated with vitamin K replacement, which can be administered parenterally, orally, or subcutaneously. Oral administration has the best bioavailability, but can take 24 hours for full effect. When rapid correction for a bleeding patient is needed, improvements in PT can be seen within 6 to 8 hours of intravenous administration, especially with high doses of 5 to 10 mg.<sup>163</sup>

## Liver Disease

Patients with severe liver disease often present with bleeding complications, including central nervous system hemorrhage or gastrointestinal bleeding. They were traditionally managed with prophylactic transfusions and adjunctive hemostatic medications prior to surgical procedures or in response to a prolonged PT. However, new guidelines recommend against prophylaxis without clinical symptoms of bleeding. There are several etiologies of bleeding diathesis associated with liver disease, including endothelial dysfunction, portal hypertension, thrombocytopenia, and the procoagulant imbalance discussed in the following section. However, the hemostatic system in chronic liver disease often remains in balance, although fragile. Conventional laboratory tests such as the PT and aPTT overestimate the bleeding tendency of patients with liver disease and should not be used as the sole method for titrating plasma transfusion or treatment with hemostatic agents.<sup>164,165</sup>

Primary hemostasis was typically thought to be inefficient in chronic liver disease because of thrombocytopenia secondary to decreased production of thrombopoietin in the liver. However, the low platelet count is often balanced

with increased circulating levels of vWF that result from a reduced presence of ADAMTS-13, the protease that regulates plasma concentrations of vWF.<sup>164,165</sup> This balance remains fragile, given that patients with severe liver disease and acute illness are also prone to endothelial and platelet dysfunction.

Secondary hemostasis is also affected because liver disease results in deficiencies of factors II, V, VII, IX, X, and XI that will prolong the PT and aPTT in vitro. However, the liver is also responsible for the synthesis of protein C, protein S, and AT, which are integral anticoagulant factors.<sup>164</sup> Furthermore, these patients have increased circulating levels of FVIII in association with the increases in vWF mentioned above. Thus, the decreased levels of procoagulant factors are offset by deficient amounts of anticoagulant factors and increased FVIII activity,<sup>164,165</sup> maintaining secondary hemostasis.

Although hemostatic equilibrium is generally maintained with chronic liver disease, the balance is not stable and can be tipped toward either hemorrhage or thrombosis by acute illness, malnutrition, renal injury, infection, or medications. Laboratory testing difficult because conventional PT and aPTT conducted in vitro do not mimic the in vivo compensation mechanisms associated with chronic liver disease. Thrombin generation by procoagulant factors is regulated in vivo by the anticoagulant activity of protein C and its main activator, thrombomodulin.<sup>164,165</sup> In contrast, in vitro thrombin generation only assesses activation by procoagulant factors and will misrepresent the actual bleeding tendency of the patient.

Lastly, fibrinolysis is also maintained in chronic liver disease. Although these patients are plasminogen deficient, they have higher than normal levels of tPA secondary to lower levels of TAFI. This maintains the normal ratio of plasminogen to plasmin.<sup>164,165</sup> However, the balance of fibrinolysis and antifibrinolysis can be disrupted by infection, trauma, surgery, and medications common to chronic liver patients.

As mentioned above, conventional hemostatic tests such as PT and aPTT assays do not reflect the bleeding or thrombotic tendencies of chronic liver disease. Patients with normal coagulation profiles can present with catastrophic gastrointestinal bleeding or prolonged PTs, yet develop venous, arterial, and portal thrombosis. The overall hemostatic state can be evaluated with viscoelastography, or by measuring thrombin generation in the presence and absence of thrombomodulin. The circumstances of these tests are more akin to the in vivo state of patients with liver disease than conventional PT and aPTT tests. Accordingly, it is no longer recommended to prophylactically transfuse plasma in response to PT times, elevated INR, or prior to minor procedures in such patients without clinical signs of bleeding. Furthermore, despite prolonged coagulation tests, patients with liver disease are still at significant risk for venous and arterial thrombosis and should be treated with

appropriate prophylactic anticoagulation.<sup>165</sup>

## **Disseminated Intravascular Coagulopathy (DIC)**

DIC is a disorder characterized by systemic activation of coagulation. It is always associated with a comorbid condition such as infection, inflammation, or malignancy, which causes widespread activation of the coagulation cascade.<sup>166–168</sup> Table 17-13 lists the medical diseases and syndromes known to cause DIC. Supportive care and treatment of the underlying disorder are the mainstays of DIC management. In severe cases of major hemorrhage or ischemic organ failure, DIC is treated with factor and fibrinogen replacement, anticoagulation, or pharmacologic therapies.<sup>166,168</sup>

The exact pathophysiology of DIC depends on the causative condition, but primarily involves uncontrolled activation of hemostatic mechanisms for thrombin generation with simultaneous inhibition of fibrinolysis. Thrombin generation in DIC is initiated by TF and activated factor VII in the extrinsic pathway for coagulation. The exposure of TF is facilitated by extensive vascular injury, expression on neoplastic cells, or the release of proinflammatory cytokines such as interleukin-6. DIC progresses as the regulation of thrombin generation is impaired secondary to decreased levels of naturally occurring anticoagulants including AT-III, protein C, and TFPI. Finally, impaired fibrinolysis from an inappropriate increase in circulating levels of PAI-1 facilitates the progression of vascular microthrombi.<sup>167,168</sup>

DIC is a catastrophic complication for many hospitalized patients with both chronic and acute illness. The clinical presentation of DIC ranges from thromboembolism and organ dysfunction to consumptive coagulopathy and major bleeding. The kidneys and lungs are particularly vulnerable to ischemia from microthrombi and may progress to acute renal failure and acute respiratory distress syndrome, especially in patients with DIC secondary to obstetric complications or sepsis.<sup>168</sup> The bleeding type of DIC results from widespread activation of hemostasis with consumption of coagulation factors and platelets. The primary diagnosis for these patients is often trauma or hematopoietic malignancy, who present with bleeding from sites of vascular injury, or spontaneous intracranial or intraperitoneal hemorrhage.<sup>167,168</sup> DIC with features of microthrombi, organ dysfunction, and consumption results in severe thrombocytopenia and often leads to massive hemorrhage with a poor overall prognosis.<sup>167</sup> However, major bleeding is rather infrequent with DIC and usually occurs only with platelets less than 50,000/ $\mu\text{L}$  or patients undergoing procedures. In fact, in a study of DIC with sepsis, transfusion for major bleeding was only required in 5% to 12% of patients.<sup>167,168</sup>

The diagnosis of DIC must consider the underlying disorder in conjunction with an abnormal hemostasis profile. Unfortunately, there is not a single

laboratory finding indicative of DIC. High levels of fibrin split products are a sensitive marker, but carry very low specificity.<sup>166-168</sup> Rather, the compilation of prolonged PT and aPTT, thrombocytopenia, hypofibrinogenemia, and increasing fibrin degradation products in a patient with an associated condition leads to the clinical diagnosis of DIC. The International Society of Thrombosis and Hemostasis developed a scoring algorithm for the diagnosis of overt DIC that depends on these four laboratory findings (Table 17-14).<sup>166-168</sup> This algorithm is only one of several clinically used scoring systems worldwide, but was prospectively validated and found to have a sensitivity of 91% and a specificity of 97%.<sup>167</sup> Overall, DIC is a dynamic condition and most accurately diagnosed with repeated measures of coagulation tests showing progression of thrombocytopenia and hypofibrinogenemia, with increasing prolongation of PT and levels of fibrin degradation products.

The management for DIC primarily involves treatment of the causative condition and supportive measures to control progressive thrombosis and hemorrhage. Consumptive coagulopathy and thrombocytopenia with clinical signs of bleeding are treated with transfusion of plasma and platelets, respectively. There is no evidence for improved outcomes with transfusion of plasma or platelets unless thrombocytopenia is severe (platelet counts <10,000 to 20,000/ $\mu$ L) or moderate (<50,000/ $\mu$ L), with clinical signs of bleeding, or in preparation for invasive procedures.<sup>166-168</sup>

Plasma is the mainstay of replacement therapy for consumption of clotting factors in DIC; however, it often requires large volumes (10 to 15 mL/kg) to correct the coagulopathy.<sup>166-168</sup> In the past, rFVIIa and PCCs have been used for patients with active bleeding and consumptive coagulopathy; however, the administration of active factor concentrates in the preparations of rFVIIa and PCCs can lead to progressive thrombosis in patients with overt DIC and is not recommended. Rather, the use of specific factor concentrate is preferred for measured factor deficiencies in patients with active bleeding.<sup>166-168</sup> Cryoprecipitate is the product of choice for treatment of overt DIC with consumptive coagulopathy and major bleeding, because it contains FVIII and fibrinogen with a low overall volume of transfusion.<sup>167,168</sup>

Arterial and venous thromboembolisms are more concerning than hemorrhage in patients with DIC and evidence of acute organ dysfunction. Anticoagulation is indicated to inhibit further activation of hemostasis in patients with signs of microthrombi such as organ failure or diagnosed thromboembolism.<sup>167,168</sup> Studies of patients with DIC in sepsis proved the efficacy of heparin to halt thrombin generation, improve the coagulation profile, and reduce the risk of thrombosis. It is understandably difficult to initiate therapeutic anticoagulation on a patient with signs or risks of bleeding; however, maintaining chemoprophylaxis against venous

thromboembolism is of utmost importance, especially early in the course of DIC in the absence of major bleeding. Literature support is limited, but LMWH alternatives to unfractionated heparin (UFH) may provide better efficacy with lower bleeding risks.<sup>167,168</sup>

AT-III levels decrease in DIC, and several animal studies have shown improved survival in DIC models after AT-III replacement. However, multiple studies failed to demonstrate survival benefit with AT-III treatment for patients with DIC secondary to sepsis, obstetric complications, liver disease, and burn injury.<sup>166</sup> Treatment with APC for septic patients with severe DIC was reported beneficial for morbidity and mortality, especially in patients with multiorgan dysfunction. In 2009, the BCSH recommended its use as standard treatment for patients with DIC in severe sepsis without pre-existing risks of bleeding or thrombocytopenia. However, subsequent reviews of treatment with APC failed to show consistent survival benefits, yet documented increased risks of bleeding complications. Consequently, in 2012, the BCSH changed its recommendation and APC concentrates were removed from the market.<sup>169</sup> Overall, the best therapy for overt DIC of any cause is to treat the underlying condition, continue to support organ function, and maintain control of hemostasis.

**Table 17-13** Common Disorders Associated with Disseminated Intravascular Coagulation

Disorder	Average Incidence of DIC	Comments
Sepsis	30–50%	Highest with gram-negative bacilli
Trauma and burns	Rare	Associated with the degree of tissue injury
Malignancy	Up to 20%	Highest with adenocarcinoma or leukemia and lymphoma
Vascular disease	Rare	Higher with giant hemangiomas
Obstetric complication	Up to 50%	Including preeclampsia, placental abruption, or amniotic fluid embolism
Hemolysis	Rare	Higher with intravascular hemolysis
Severe organ dysfunction	Rare	Including pancreatitis, hepatitis, and end-stage renal failure

**Table 17-14** Scoring Algorithm for the Diagnosis of Disseminated Intravascular Coagulation

Diagnostic Test	Score
Platelet count	>100,000/mm <sup>3</sup> = 0
	<100,000/mm <sup>3</sup> = 1
	<50,000/mm <sup>3</sup> = 2
Prothrombin time prolongation	<3 s = 0
	>3 s but <6 s = 1
	>6 s = 2
Fibrin degradation products	No increase = 0
	Moderate increase = 2
	Strong increase = 3
Fibrinogen level	>1 g/L = 0
	<1 g/L = 1
Score calculation:	
If ≥5, consistent with overt DIC.	
If <5, not likely overt DIC; repeat tests in 1–2 days.	

Algorithm developed by the International Society of Thrombosis and Hemostasis.

## Anticoagulation and Pharmacologic Therapy

### Anticoagulation Regimens and Associated Anesthetic Concerns

**29** *Antiplatelet therapy* is indicated for patients at risk for cerebral vascular accident, myocardial infarction, or other vascular thrombosis complications. There are several mechanisms for platelet dysfunction including COX inhibition, PDE inhibition, ADP receptor antagonism, and GP IIb/IIIa receptor antagonism.

### Cyclooxygenase Inhibitors

Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most notable members of this class. There are two forms of the COX enzyme with variable distribution throughout the body. COX-1 plays an integral part in maintaining the integrity of the gastric lining, renal blood flow, and initiating the formation of TxA<sub>2</sub>, an important molecule for platelet aggregation. Inhibition of COX-1 puts the patient at risk for bleeding, as well as for gastrointestinal and renal morbidity. COX-2 is primarily responsible for synthesizing the prostaglandin mediators of pain and inflammation. Aspirin is a noncompetitive and irreversible inhibitor of both COX enzymes.<sup>170</sup> Consequently, the effects of aspirin therapy last the lifetime of the affected platelets and can only be fully reversed with platelet transfusion, although DDAVP is frequently used to improve platelet function in the presence of aspirin.<sup>163</sup>

NSAIDs are competitive antagonists whose effects last only as long as the drug's time to elimination. Most NSAIDs (naprosyn and ibuprofen) are

nonselective COX inhibitors. However, the development of selective COX-2 antagonists such as celecoxib aimed to provide pain relief without the gastrointestinal bleeding complications. Unfortunately, the initial benefits of COX-2 inhibitors were not sustained in long-term outcome studies, and the decreased incidence of gastrotoxicity is clinically insignificant when patients are simultaneously taking aspirin.<sup>170</sup> Postmarket clinical trials with selective COX-2 antagonists reported increased risks for cardiovascular complications likely secondary to impaired vascular endothelial function. The mechanism for cardiovascular risk is thought to be unchecked inhibition of PGI<sub>2</sub> without antagonizing the synthesis of TxA<sub>2</sub> from COX-1 within platelets. This tips the balance in favor of a prothrombotic state.<sup>170,171</sup> In 2007, the American Heart Association (AHA) recommended a stepwise approach to prescribing NSAIDs in patients with cardiovascular disease, emphasizing the use of nonselective or partially selective COX inhibitors first. If selective COX-2 inhibitors, namely celecoxib, are needed they recommend the lowest effective dose in conjunction with a proton pump inhibitor and low-dose aspirin.<sup>171</sup>

### **Phosphodiesterase Inhibitors**

*PDE inhibitors* are primarily used for stroke prophylaxis, since they increase the production of cAMP, an active inhibitor of platelet aggregation. These medications are rarely the drug of choice for patients with cerebrovascular disease, but rather used in conjunction with aspirin therapy. Dipyridamole is a reversible ADP reuptake inhibitor and the prime therapeutic agent in this class, but caffeine, aminophylline, and theophylline also result in reversible platelet dysfunction.<sup>163</sup>

### **ADP Receptor Antagonists**

*P2Y<sub>12</sub> ADP receptor antagonists*, such as clopidogrel, prasugrel, and ticagrelor, prevent the expression of GP IIb/IIIa on the surface of activated platelets, thereby inhibiting platelet adhesion and aggregation. These drugs are indicated for patients with coronary artery disease to prevent myocardial infarction and in-stent thrombosis, or for patients with cerebrovascular or peripheral artery disease to inhibit thromboembolism. Clopidogrel is the most commonly prescribed agent in this class and is a noncompetitive and irreversible antagonist. It is an inactive prodrug that requires oxidation to its active metabolite.<sup>73,172</sup> Recently, a genetic polymorphism was discovered that results in the inability to metabolize clopidogrel, making it ineffective and putting patients at risk for cardiovascular morbidity and mortality. The FDA put a black box warning on the medication to remind clinicians to monitor the activity. Platelet function studies are insensitive and unreliable for clopidogrel, but tests are now available to measure the inhibition of the P2Y<sub>12</sub>

ADP receptor.<sup>73,172,173</sup> Patients who are resistant to clopidogrel may be converted to prasugrel or ticagrelor for increased antiplatelet effects.<sup>173</sup> Prasugrel is also an irreversible P2Y<sub>12</sub> ADP inhibitor indicated for primary prevention of acute coronary syndrome, but not recommended by the AHA for immediate use in patients presenting with acute myocardial ischemia. Ticagrelor is a reversible inhibitor with similar mechanism of action, with AHA endorsement for use in acute coronary syndrome. Both ticagrelor and prasugrel are associated with higher bleeding risk than clopidogrel and should not be used with aspirin doses over 100 mg/day.<sup>73</sup>

## GP IIb/IIIa Receptor Antagonists

*GP IIb/IIIa receptor blockers* inhibit the cross-linkage of fibrinogen, the final step in the common hemostatic pathway for platelet aggregation. They include the monoclonal antibody abciximab, and two other molecules which simulate the binding site of fibrinogen, tirofiban, and eptifibatid. These agents are administered intravenously and primarily used for management of acute coronary syndrome. Their effects are monitored with ACTs and reversed by clearance of the drug. Most of these agents are renally excreted, with half-lives around 20 to 40 minutes, except for abciximab which has a significantly longer context-sensitive half-time secondary to protein binding (24 to 48 hours).<sup>163</sup> All of these drugs cause thrombocytopenia, but the effect is strongest with abciximab with an incidence of about 2.5%, as opposed to 0.5% with the other receptor antagonists.<sup>174</sup> Vorapaxar, a *PAR-1 antagonist*, is a reversible agent with a very long half-life (3 to 4 days) that clinically inhibits thrombin activity for significantly longer than its partner agents in this class of anticoagulants. Vorapaxar's clinical usefulness is limited, but it is available for patients with significant renal insufficiency.<sup>163,174</sup>

## Vitamin K Antagonists

*Warfarin* is an oral anticoagulant therapy frequently used for management of hypercoagulable disorders, venous thromboembolism, and stroke prophylaxis in patients with atrial fibrillation, artificial heart valves, or mechanical assist devices. Mechanistically, it competes with vitamin K for carboxylation-binding sites and inhibits the synthesis of vitamin K-dependent clotting factors II, VII, IX, and X. Proteins C and S are also dependent on vitamin K, and thus are inhibited with warfarin therapy. In fact, patients may be hypercoagulable during the initial phase of treatment, since proteins C and S have shorter half-lives than most clotting factors and will be inhibited first, thereby leaving thrombin generation unregulated. Accordingly, patients at high risk for thromboembolism must be bridged with another anticoagulation regimen until the target INR is achieved.<sup>175</sup> Warfarin therapy is monitored

with the INR (see section on laboratory interpretation). Therapeutic targets generally range between 2.0 and 3.0, and will vary depending on the disease and the patient's bleeding risk.<sup>175</sup>

There is a significant risk of bleeding with any anticoagulation regimen, which demands appropriate protocols for reversal of the specific drug effects. The management protocol for warfarin reversal depends on the patient's symptoms and the urgency. Because warfarin inhibits the synthesis of vitamin K–dependent clotting factors II, VII, IX, and X, the most logical and appropriate reversal agent is replacement of vitamin K. Guidelines for the administration and reversal of warfarin were written and updated by the BCSH in 2011.<sup>175</sup> For patients with INR higher than 5.0 and no signs or symptoms of bleeding, warfarin administration should be held for one to two doses. Oral vitamin K should be administered if the INR is over 8.0. Patients who present with high INR and nonmajor bleeding should be reversed with 1 to 3 mg of intravenous vitamin K; this usually corrects the INR within 6 to 8 hours. Emergency reversal for patients with major bleeding or those who require immediate surgery can be achieved with PCCs. Four-factor PCCs (II, VII, IX, X) are generally preferred to three-factor PCCs because the three-factor formulations lack sufficient amounts of factor VII to reliably reverse the effects of warfarin. Furthermore, patient-centered protocols that include weight-based dosing and consideration for the INR and clinical bleeding risks are preferred.<sup>163,175</sup> The half-life of most PCCs is short, and vitamin K should be given simultaneously for sustained results. Historically, emergency reversal of warfarin was achieved with plasma; however, this requires large volumes of transfusion (10 to 30 mL/kg) and provides unreliable results with inherent delay in treatment secondary to the time needed to type and screen the patient, thaw, prepare, and administer multiple units of plasma.<sup>163</sup> rFVIIa has also been used to reverse warfarin, but the supporting literature is retrospective. Although it reliably corrects the INR, it does not consistently correct clinical bleeding likely secondary to the ongoing inhibition of other vitamin K–dependent clotting factors, and is no longer an appropriate reversal agent for warfarin toxicity.<sup>175</sup> Consequently, the BCSH, SCCM, and Neurocritical Care Society recommend the use of plasma only when PCCs are not available, especially for patients with warfarin-related intracranial hemorrhage.<sup>163,175</sup>

Anticoagulation regimens using oral vitamin K antagonists can be difficult to regulate within the target range. Warfarin has a long onset and offset of action that puts patients at risk for thrombosis and bleeding, especially in the perioperative period. It also has many food and drug interactions, and its metabolism is subject to pharmacogenomics that make dosing highly variable. Warfarin is hepatically metabolized by the P450 CYP2 enzymes and will interact with other commonly used medications such as antibiotics,

barbiturates, phenytoin, and proton pump inhibitors. Alterations in dietary intake of vitamin K will also vary the clinical effect of maintenance dosages. Furthermore, there are genetic polymorphisms for the CYP2 enzymes that decrease the metabolism of warfarin and increase bleeding risk.<sup>176</sup> For these reasons, alternative oral anticoagulant agents have been pursued for many years, with a new focus on oral DTIs and FXa inhibitors.

## **New Oral Anticoagulants**

Dabigatran (a DTI), and the FXa inhibitors, rivaroxaban, apixaban, and edoxaban have completed phase III trials and passed FDA approval for stroke prophylaxis and therapeutic anticoagulation for patients with history of venous thromboembolism.<sup>177</sup> Thrombin and factor X are at the end of the common pathway for clot formation and stabilization, and play an integral part in secondary hemostasis. Consequently, they are highly desirable targets for antagonism of anticoagulation. These agents are significantly easier to manage than warfarin. They have short half-lives and rapid onsets of action that negate the need for bridging therapy. They are also reliably bioavailable and have little interindividual variability. Thus, coagulation monitoring is unnecessary, although efficacy can be measured with diluted thrombin times or anti-Xa assays.<sup>177</sup> Lastly, new oral anticoagulants (NOACs) have few drug or dietary interactions. All of these agents have a wide therapeutic window, making dosing simple and universal with the exception of patients on dialysis. Dabigatran and rivaroxaban in particular rely on renal excretion for clearance. Dabigatran may be cleared with dialysis; however, both carry FDA warnings against use in patients with end-stage renal disease (Table 17-15).<sup>177,178</sup>

The Re-Ly investigators, the ARISTOTLE group, and the EINSTEIN, ENGAGE-AF, and ROCKET-AF trials, all compared dabigatran, apixaban, rivaroxaban, and edoxaban to warfarin, in large, multicenter, randomized controlled trials.<sup>179-182</sup> These trials were mostly noninferiority studies documenting the efficacy of NOACs compared to warfarin for treatment of venous thromboembolism, and stroke prevention in valvular and nonvalvular atrial fibrillation. Recent trials demonstrate their usefulness for prevention of venous thromboembolism in perioperative orthopedic patients undergoing knee and hip arthroplasty.<sup>177,183</sup> Their full clinical potential has yet to be determined, especially in the perioperative setting. Unfortunately, there is currently no reliable coagulation test to monitor the clinical effects of these agents. They may prolong the aPTT, thrombin time, or the ECT, but these are not sensitive monitors for increased risk of bleeding. This is an active area for research at this time.<sup>177</sup>

In an emergency, there is limited evidence to guide therapeutic reversal of the NOACs. Various societies drafted recommendations for the use of

activated PCCs, and a monoclonal antibody (idarucizumab) was recently FDA approved for reversal of dabigatran after favorable results were published in the interim analysis of the RE-VERSE AD study.<sup>184</sup> Furthermore, dabigatran can be cleared with dialysis.<sup>178</sup> However, no reliable regimen for drug reversal exists for the direct FXa inhibitors at this time. Because NOACs are competitive inhibitors of thrombin and FXa, PCCs containing factors II, VII, IX, and X can reverse the antagonistic effects. Current guidelines from the SCCM and the Neurocritical Care Society recommend activated PCCs, PCCs, or rFVIIa to reverse the clinical bleeding risks associated with direct FXa inhibitors, and idarucizumab for reversal of dabigatran.<sup>163</sup> Perioperatively, these agents should be discontinued 24 hours before minor surgery or diagnostic procedures, and 48 hours before major surgery or procedures involving the eye, spine, or brain. The half-lives of these agents are approximately 12 hours; thus, assuming normal hepatic and renal function, more than four half-lives ensure significant drug clearance. However, further research is needed to document the best method for reversing the clinical effects of NOACs.

**Table 17-15** Oral Anticoagulation Medications

	Warfarin	Dabigatran	Apixaban	Rivaroxaban	Edoxaban
Target	Vitamin K	Thrombin	Factor Xa	Factor Xa	Factor Xa
Time to peak (h)	72–96	0.5–2	3–4	2–4	1.5
Half-life (h)	36–42	14–17	12	5–13	6–11
Protein binding (%)		35	87	95	55
Monitoring test	INR	Thrombin time	Anti-Xa	Anti-Xa	Anti-Xa
Renal excretion (%)	None	85	54	73	56
Metabolism	CYP2C9	minimal	CYP3A4	CYP3A4	CYP3A4

## Heparin Therapy

*Heparin therapy* is one of the oldest and most common anticoagulation regimens. There are two main forms of heparin, UFH and LMWH. UFH indirectly inhibits thrombin and FXa by binding to AT-III, causing a conformational shape change which significantly increases its activity. Although the use of UFH for prophylaxis against venous thromboembolism has decreased in favor of LMWH and indirect FXa inhibitors, it is still used for immediate anticoagulation with acute coronary syndrome, pulmonary embolism, and during cardiopulmonary bypass or vascular surgery. The clinical effects of heparin therapy are monitored with the aPTT or ACT. Patients may be resistant to UFH if they have a hereditary insufficiency of AT-III or an acquired deficiency from prolonged heparin administration. AT-III is replenished with plasma transfusion. UFH is given parenterally and its clinical effects are fully reversible with protamine.<sup>163</sup> The main complication is HIT,

discussed later.

*LMWH* is a fractionated form of heparin with similar mechanism of action, but with more specific inhibition of FXa. Several agents are currently available, including enoxaparin, dalteparin, and reviparin. LMWH is preferred over UFH for both DVT prophylaxis and treatment because laboratory monitoring is unnecessary, and its longer half-life allows for once- or twice-daily dosing. Treatment can be monitored with FXa levels, but this is only necessary for obese patients and those with renal insufficiency, which prolongs elimination. Reversal with protamine is unpredictable and not likely to completely resolve bleeding tendencies.<sup>163</sup>

## Indirect Factor Xa Antagonists

Fondaparinux is the principal agent used in this class. It is a highly specific antagonist for free FXa that also acts via binding with AT-III. Like LMWH, it is popular for DVT treatment and prophylaxis because it has a long half-life and requires only once-daily dosing, and highly reliable absorption that negates the need for coagulation monitoring. However, fondaparinux undergoes renal elimination, necessitating a lower dose or coagulation monitoring with FXa levels in patients with renal insufficiency. There is no available antidote in the event of bleeding or the need for emergency procedures. Fortunately, the incidence of HIT is relatively low for this class of agents, although they are not approved for use in patients with a history of HIT.<sup>185</sup>

## Heparin-Induced Thrombocytopenia

HIT is a clinical disorder that develops after extended heparin therapy. It occurs in approximately 1 in 5,000 hospitalized patients, with the highest incidence of 1% to 3% in patients recovering from cardiac surgery. It is associated with significant organ failure, vascular compromise, and mortality from thromboembolic complications.<sup>25,186,187</sup> There are two types: HIT1 describes mild thrombocytopenia, is benign and does not involve immune complexes. HIT2 is an immune-mediated response and carries a significant risk of hypercoagulability. IgG antibodies bind to heparin–PF4 complexes on the surface of platelets, thereby initiating primary hemostasis and thrombin generation.<sup>25,187</sup> HIT2 can occur in any patient receiving heparin therapy. Typically, 5 to 10 days are required to mount a significant immune response, but patients who have recent exposure to heparin or a history of HIT can present with clinical symptoms immediately. Any form of heparin therapy can initiate HIT; however, UFH is more likely than LMWH to lead to immune complexes because the fractionated form is less antigenic with a weaker bond to heparin–PF4.<sup>25,187</sup>

30

6

There are no specific laboratory tests for the clear diagnosis of HIT, and clinical signs can be clouded by alternative causes of thrombocytopenia and thrombosis. Guidelines from the American College of Chest Physicians and the national European guidelines recommend a diagnostic scoring algorithm to determine the pretest probability of clinical HIT. Variables to consider include the degree of thrombocytopenia (defined as a fall in platelet count of 30% to 50%), the timing of platelet decrease (typically day 5 to 10 of heparin therapy), any thromboembolic complications, and the likelihood of alternative diagnoses. Intermediate to high clinical suspicion of HIT is then confirmed with laboratory tests. The enzyme-linked immunosorbent assay (ELISA) for heparin–PF4 IgG antibodies is sensitive, but not as specific as the serotonin release functional assay, which is currently the gold standard test.<sup>25,187</sup> Patients suspected of having HIT should be managed with therapeutic anticoagulation and immediate discontinuation of all heparin therapy including heparin-coated indwelling catheters. The most commonly used agents are the parenteral DTIs such as bivalirudin and argatroban. Oral vitamin K antagonists are contraindicated for HIT treatment because the decreased synthesis of proteins C and S enhances the patient's prothrombotic state. Furthermore, warfarin has been shown to cause gangrenous thrombosis of the limbs in patients with HIT.<sup>25,186</sup> Platelet transfusion should also be held unless the patient is severely thrombocytopenic ( $<20,000/\mu\text{L}$ ) with signs of bleeding.

### **Parenteral Direct Thrombin Inhibitors**

Argatroban and bivalirudin are synthetic agents that directly inhibit thrombin in its free and fibrin-bound states. They are not immunogenic and there is no risk of HIT.<sup>185</sup> The half-lives of these agents vary. Furthermore, there are currently no known antidotes to the DTIs; therefore, reversal depends upon clearance. Clinical effects can be monitored with ACT or aPTT measurements. They are both approved for use in the United States for treatment of HIT. Argatroban is metabolized by the liver, with variable clearance in patients with hepatic dysfunction. It is commonly used for patients with HIT, who suffer from concurrent renal failure. Argatroban will prolong the INR as well as the aPTT, which can complicate clinical titration of warfarin therapy for long-term anticoagulation. Bivalirudin is a short-acting DTI with rapid onset of action and renal excretion. It is the drug of choice for patients with both renal and hepatic dysfunction, and its clinical versatility makes it a good agent for use during cardiopulmonary bypass in patients with HIT.<sup>25</sup>

### **Recombinant Activated Factor VII**

Recombinant activated factor VII (rFVIIa) was originally FDA approved for prophylaxis and treatment of patients with hemophilia A or B complicated by inhibitors to FVIII and factor IX concentrates. It is now also indicated for the treatment of acquired hemophilia and factor VII deficiency.<sup>188</sup> However, most of its use is off-label for the prevention and treatment of coagulopathy and major blood loss in patients with postpartum hemorrhage, trauma, reversal of various anticoagulants, and high-risk cardiac surgery. The supporting data for these uses stem from retrospective reports, observational studies, and case series. There are few randomized controlled trials showing improved clinical outcomes and no trials that report definitive mortality benefits.<sup>134</sup> In fact, a recent meta-analysis demonstrated an increased risk of arterial thromboembolism, especially in elderly patients with use of high doses of rFVIIa ( $>120 \mu\text{g}/\text{kg}$ ).<sup>188</sup> The current guidelines for the reversal of NOACs recommend PCCs as the drugs of choice; however, if activated PCCs are not available, low dose rFVIIa (15 to 20  $\mu\text{g}/\text{kg}$ ) should be considered for life-threatening hemorrhage. Overall, the lack of consistent dosing protocols and definitive evidence leaves one without clear indications for the use of rFVIIa for critical bleeding.<sup>134</sup>

The mechanism for rFVIIa remains unclear, but likely involves more than the physiologic role of factor VII in secondary hemostasis. Theoretically, rFVIIa will only act with TF exposed from the vascular endothelial lining at a site of injury. However, certain hemorrhagic disorders such as DIC or polytrauma can initiate systemic release of TF. Furthermore, rFVIIa can directly activate factor X and platelets, generating a thrombin burst for procoagulant activity.<sup>134</sup> These mechanisms explain why arterial and venous thromboembolism are the major adverse effects of rFVIIa, and why DIC and high thromboembolism risk are the main contraindications.<sup>134,188</sup>

### *Prothrombin Complex Concentrates*

PCCs have been available for treatment of patients with hemophilia B for several decades. They were first used as a source of factor IX in the 1970s prior to the advent of specific factor concentrates. Subsequently they provided bypass treatment for hemophiliacs with factor inhibitors. Over the years, the safety and efficacy of PCCs have improved dramatically, and they are now FDA approved for use in hemophilia and reversal of vitamin K antagonists. PCCs are also the first-line agents for reversal of NOACs, although evidence is limited and their use for this indication remains off label.<sup>134</sup>

There are several commercially available formulations of PCCs, containing varying amounts of three to four coagulation factors, as well as one or more type of anticoagulant. The compositions include the vitamin K-dependent factors (II, VII, IX, and X), although not all products contain significant

concentrations of factor VII. Some PCCs are “three-factor” concentrates lacking factor VII, but most formulations contain all four factors, with the addition of a natural anticoagulant such as heparin or AT to decrease the thrombogenic risks. Activated PCCs such as the Factor Eight Inhibitor Bypass Agent (FEIBA) are frequently used for bypass therapy in hemophilia patients with inhibitors, or for reversal of direct antifactor Xa antagonists.<sup>134</sup>

PCCs are now the drug of choice for immediate reversal of oral anticoagulants in place of rFVIIa and FFP, although in phase III trials, rFVIIa failed to show significant outcome improvements for warfarin-related intracerebral hemorrhage.<sup>134</sup> This is likely because it only replaces one of the vitamin K–dependent factors and, although the INR and PT decrease, this did not translate to meaningful survival benefits. PCCs are now preferred over plasma for several reasons. First, they provide faster correction of coagulopathy. The factors in plasma are relatively dilute, and a large volume (10 to 15 mL/kg) is required for clinical reversal of oral anticoagulants. It takes additional time to match the patient’s blood type and thaw the plasma, putting the patient at risk for volume overload. Furthermore, PCCs stem from human plasma, but they are treated with at least one viral reduction process, whereas transfusion of several units of plasma carries a significant risk of infectious and noninfectious transfusion reactions. It is important to remember that although PCCs provide factor replacement for thrombin generation, their action still depends on adequate concentrations of platelets and fibrinogen.

The potential for PCCs to generate a significant thrombin burst puts patients at risk for thrombotic complications. The exact pathogenesis for thrombosis remains unclear, but animal models indicate that the accumulation of prothrombin, inactive factor II, and/or factor X after PCC administration correlates with thrombogenesis. Furthermore, this risk is associated with patients having thrombotic tendencies, such as those on anticoagulation and elderly patients who have a history of stroke. There are very few outcome studies evaluating their safety, but thus far no significant thrombotic complications have been reported with PCCs for critical bleeding.<sup>189</sup>

The thromboembolic risk can be minimized by avoiding repeat dosing. The factors within PCCs have varied half-lives, with prothrombin remaining active in plasma for up to 60 hours and factor X present for 30 hours. This is in contrast to labile factor VII, whose half-life is only approximately 6 hours. Consequently, factors II and X, which are thought to be primarily responsible for thrombotic complications, have the potential to accumulate with repeat doses of PCCs. The need for repeat dosing can be avoided by the coadministration of vitamin K in patients treated for oral anticoagulant toxicity. This allows for increased synthesis of coagulation factors. Furthermore, PCC dosing should be guided by the appropriate coagulation

profile test. PT and INR only measure the procoagulant half of the hemostatic mechanism, and ignore the presence of anticoagulant activity such as AT or proteins C and S. In patients with severe liver disease or dilutional coagulopathy, the PT and INR times may be prolonged, but the concentrations of anticoagulants are also decreased, leaving hemostasis balanced. Thrombin generation times or thromboelastography are more appropriate measures of the patient's risk of bleeding and better indicators of the efficacy of PCC. These tests should be considered before redosing, since these patients may require simultaneous treatment with AT, platelets, or fibrinogen. The only absolute contraindications to PCC administration are in patients at high risk for thrombosis, such as those in DIC or with active HIT.<sup>134,189</sup>

### *Desmopressin*

Desmopressin (DDAVP) is a synthetic analogue for the endogenous antidiuretic hormone, vasopressin. It acts at the V2 receptor found in the nephron and within endothelial cells. DDAVP was originally introduced for treatment of diabetes insipidus, but it was also found to improve hemostasis and platelet function. Consequently, it is one of the drugs of choice for treatment of mild bleeding in patients with vWD and mild hemophilia A, as discussed earlier.<sup>134</sup> Mechanistically, it causes the release of FVIII and vWF from within vascular endothelial cells, thereby improving platelet function. The appropriate dose for hemostasis is 0.3 µg/kg intravenously over 20 to 30 minutes, with therapeutic effects lasting for approximately 6 to 8 hours. Clinical benefits have been demonstrated for high-risk surgery, especially in patients with aspirin-induced platelet dysfunction.<sup>134,190</sup> Hypotension is the most commonly reported side effect, presumably secondary to arterial vasodilation from the release of NO; it is best avoided with slower infusion rates. Hyponatremia and water retention are rare complications, but have been reported in pediatric patients. As with all prothrombotic agents, DDAVP should be avoided in patients at high risk for thromboembolism, although the most recent meta-analysis did not report a significant incidence of thromboembolic complications.<sup>134,190</sup>

The hemostatic potential for DDAVP has been carefully studied for patients with critical bleeding from cardiac or spine surgery, uremia, antiplatelet agents, and liver disease. Several meta-analyses of randomized controlled trials report mild decreases in blood loss (80 mL per patient), but fail to translate into significant outcome improvements. There is no apparent effect on the number of patients transfused or the incidence of postoperative complications (including reoperation). The only consistent clinical benefit of DDAVP is improved bleeding times for patients with congenital or acquired platelet dysfunction from cardiopulmonary bypass, chronic renal failure, or

aspirin therapy.<sup>134,190</sup>

## Antifibrinolytic Therapy

Antifibrinolytic agents have been used to prevent and treat surgical blood loss for several decades. There are two types—the lysine analogues EACA and TXA, and a serine protease inhibitor, aprotinin. Aprotinin was reported to have superior efficacy for reducing blood loss, minimizing transfusions, and preventing reoperations in cardiac surgery. However, it was removed from the market after observational studies raised concern for relative risk of renal failure, myocardial infarction, and death. These findings were confirmed by the Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART), which was stopped early due to significantly higher mortality associated with aprotinin when compared to EACA and TXA.<sup>191–193</sup> However, the risks may have been exaggerated with mechanistic concerns in the BART trial. Aprotinin is currently available in Canada and worldwide. Both the lysine derivatives are widely used throughout the United States. Today, they are commonly administered as part of a multimodal approach to perioperative blood conservation strategies.

*Aprotinin* is a nonspecific serine protease inhibitor. It prevents the action of several proteins involved in coagulation and fibrinolysis, including trypsin, plasmin, and kallikrein. It may also have an indirect effect on platelets to preserve their function, especially during extracorporeal circulation. The clinical efficacy of aprotinin to reduce perioperative blood loss, transfusions, and reoperations is clear; however, there is also much evidence reporting the negative association with renal failure and mortality.<sup>134,192,193</sup> Overall, aprotinin remains an option for perioperative blood conservation, but it is perhaps not worth the increased risks of adverse reactions.

### Lysine Analogues

EACA and TXA are synthetic derivatives of the amino acid, lysine. They competitively inhibit the binding site on plasminogen, thereby preventing cleavage to plasmin and the resultant fibrinolysis. Both agents are excreted by the kidney and may be administered intravenously or topically. Although there is more evidence to support the use of TXA, these agents appear to have equivalent efficacy and have been shown to moderately decrease perioperative blood loss in cardiac surgery, as well as liver transplantation, orthopedic operations, and spine fusions.<sup>134,192,193</sup> Active research continues to focus on clarifying the appropriate dosing regimens and patient population to determine effects on rates of transfusion, reoperation, length of stay, morbidity, and mortality. The lysine analogues

33

7

are inexpensive compared to aprotinin, and there have been no reports of increased risk of thrombotic complications or renal failure. The only documented adverse effects are possible seizure risk with TXA at high doses.<sup>134,192,193</sup> Besides perioperative indications, antifibrinolytics were recently studied for their potential to minimize critical bleeding in trauma patients. The CRASH II multinational randomized controlled trial compared TXA with placebo in trauma patients with major hemorrhage and documented a reduced all-cause mortality and risk of death due to bleeding.<sup>190</sup> Overall, the lysine analogues are inexpensive and low-risk adjunctive agents that should be considered for use in major surgery or critical bleeding as part of a multimodal approach to blood conservation.

## Conclusions

Clinical anesthesiology is a perioperative specialty that aims to maintain the patient's health and wellness throughout the course of surgery. This requires a clear understanding of how a person's pre-existing comorbid status and anticipated surgical procedure can best be managed to gain the most therapeutic benefits from interventions with the least incurred risk. The anesthesiologist must remain vigilant in order to anticipate the possibility of derangements to coagulation and hemostasis that may occur with surgery, trauma, or critical illness. They must also know the best methods for avoiding and treating hemorrhagic or thrombotic complications of surgery while limiting the risks of transfusion therapy and hemostatic pharmacologic agents.

Overall, understanding the hemostatic mechanisms and the specifics of transfusion therapy is integral to the practice of anesthesia.

## **Clinical Utility of Volatile Anesthetics**

For Induction of Anesthesia  
For Maintenance of Anesthesia

## **KEY POINTS**

- 1 At equilibrium, the CNS partial pressure of inhaled anesthetics equals their arterial partial pressure, which in turn equals their alveolar partial pressure if cardiopulmonary function is normal.
- 2 The inspired concentration and the blood:gas solubility of an inhaled anesthetic are the major determinants of the speed of induction. Solubility alone determines the rate of elimination, provided there is normal cardiopulmonary function.
- 3 Isoflurane is the most potent of the volatile anesthetics in clinical use, desflurane is the least soluble, and sevoflurane is the least irritating to the airways.
- 4 Nitrous oxide (N<sub>2</sub>O) can expand a pneumothorax to double or triple its size in 10 to 30 minutes, and washout of N<sub>2</sub>O can lower alveolar concentrations of oxygen and carbon dioxide, a phenomenon called *diffusion hypoxia*.
- 5 Minimum alveolar concentration (MAC) is the alveolar concentration of an inhaled anesthetic at one atmosphere that prevents movement in

response to a surgical stimulus in 50% of patients. Concentrations of inhaled anesthetics that provide loss of awareness and recall are about 0.4 to 0.5 MAC.

- 6 MAC decreases approximately 6% per decade.
- 7 Volatile anesthetics depress cerebral metabolic rate and increase cerebral blood flow (CBF) in a dose-dependent manner. The latter effect may increase intracranial pressure in patients with a mass-occupying lesion of the brain.
- 8 Hypocapnia may blunt or abolish volatile anesthetic-induced increases in coronary blood flow depending on when the hypocapnia is produced and the nature of the cerebral disease process.
- 9 Volatile anesthetics produce dose-dependent depression of the electroencephalogram, sensory-evoked potentials, and motor-evoked potentials.
- 10 Volatile anesthetics in current use decrease arterial blood pressure, systemic vascular resistance, and myocardial function comparably and in a dose-dependent fashion.
- 11 Volatile anesthetics decrease tidal volume, decrease ventilatory response to hypercarbia and hypoxia, increase respiratory rate, and relax airway smooth muscle in a dose-dependent fashion.
- 12 Unlike halothane, volatile anesthetics in current use have minimal adverse effects on the liver and might afford some protection for hepatocytes from ischemic and/or hypoxic injury.
- 13 Volatile anesthetics are potent triggers for malignant hyperthermia in genetically susceptible patients.
- 14 CO<sub>2</sub> absorbents degrade sevoflurane, desflurane, and isoflurane to carbon monoxide when the normal water content of the absorbent (13% to 15%) is markedly decreased (<5%).

## Introduction and Overview

Inhalation anesthetics are the most common drugs used for the provision of general anesthesia. Adding only a fraction of a volatile anesthetic to the inspired oxygen results in a state of unconsciousness and amnesia. When combined with intravenous adjuvants, such as opioids and benzodiazepines, a balanced technique is achieved that results in analgesia, further sedation/hypnosis, and amnesia. Inhaled anesthetics for surgical procedures are popular because of their ease of administration and the clinician's ability to reliably monitor their effects with both clinical signs and end-tidal concentrations. In addition, the volatile anesthetic gases are relatively inexpensive in terms of overall cost.

Sevoflurane, desflurane, and isoflurane are the most popular potent

inhaled anesthetics used in adult surgical procedures (Fig. 18-1). Although there are many similarities in terms of the overall effects of the volatile anesthetics (e.g., they all have a dose-dependent effect to decrease blood pressure [BP]), there are some unique differences that might influence the clinician's selection process depending on the patient's age, health, and the surgical procedure. For example, sevoflurane is the most commonly used anesthetic in the pediatric population based on its relative lack of pungency when inhaled and its relative speed of emergence. These beneficial attributes outweigh the emergence agitation associated with the use of sevoflurane in pediatric patients. Discussion of the attributes of the three most popular inhaled anesthetics provides the major emphasis of this chapter. For the sake of completeness and for historical perspective related to metabolism and toxicity, comments on halothane and enflurane are also included.

**Figure 18-1** Chemical structure of inhaled anesthetics. Halothane is an alkane, a halogen-substituted ethane derivative. It is no longer available commercially. Isoflurane and enflurane are isomers that are methyl ethyl ethers. Desflurane differs from isoflurane in the substitution of a fluorine for a chlorine atom and sevoflurane is a methyl isopropyl ether.

## Pharmacokinetic Principles

Kety<sup>1</sup> in 1950 was the first to examine the pharmacokinetics of inhaled agents in a systematic fashion. Eger<sup>2</sup> accomplished much of the early research in the field, leading to his landmark text on the subject in 1974. The inhaled anesthetics differ substantially from nearly all other therapeutic drugs because they are gases given via inhalation. Drug pharmacology is classically divided

into two disciplines, pharmacodynamics and pharmacokinetics. *Pharmacodynamics* can be defined as what drugs do to the body. It describes the desired and undesired effects of drugs, as well as the cellular and molecular changes leading to these effects. *Pharmacokinetics* can be defined as how the body handles drugs. It describes where drugs are distributed, how they are transformed, and the cellular and molecular mechanisms underlying these processes.

Tissues are often grouped into hypothetical *compartments* based on perfusion. An important implication of different compartments and perfusion rates is the concept of redistribution. After a given amount of drug is administered, it reaches highly perfused tissue compartments first, where it can equilibrate rapidly and exert its effects. With time, however, compartments with lower perfusion rates receive sufficient drug to reach equilibrium between blood and tissue. As the tissues with lower perfusion rates absorb the drug, maintenance of equilibria throughout the body requires drug transfer from highly perfused compartments back into the bloodstream. This lowering of drug concentration in one compartment by delivery into another compartment is called *redistribution*.

In discussions of the inhaled anesthetics, the absorption phase is usually called *uptake*, the metabolic phase is usually called *biotransformation*, and the excretion phase is usually called *elimination*.

## **Unique Features of Inhaled Anesthetics**

### **Speed, Gas State, and Route of Administration**

The inhaled anesthetics are among the most rapidly acting drugs in existence, and when used for general anesthesia, this speed provides a margin of safety. The ability to quickly increase or decrease anesthetic levels as necessary can mean the difference between an anesthetic state and an anesthetic misadventure. Speed also means efficiency. Rapid induction and recovery may lead to faster operating room turnover times, shorter recovery room stays, and earlier discharge times to home.

Only N<sub>2</sub>O and xenon are true gases, while the so-called *potent anesthetics* are the vapors of volatile liquids. But for simplicity, all of them are referred to as gases because they are all in the gas phase when administered via the lungs. As gases, none deviate significantly from ideal gas behavior. These anesthetics are all nonionized and have low molecular weights. This allows them to diffuse rapidly without the need for facilitated diffusion or active transport from bloodstream to tissues. The other advantage of gases is that they can be delivered to the bloodstream via a unique route available in all patients: the lungs.

 Speed, gaseous state, and route of administration combine to form the major beneficial feature of the inhaled anesthetics: the ability to decrease plasma concentrations as easily and as rapidly as they are increased.

## Physical Characteristics of Inhaled Anesthetics

The physical characteristics of inhaled anesthetics are shown in [Table 18-1](#). The goal of delivering inhaled anesthetics is to produce the anesthetic state by establishing a specific concentration of anesthetic molecules in the central nervous system (CNS), which is done by establishing the specific partial pressure of the agent in the lungs that ultimately equilibrates with the brain and spinal cord.<sup>1</sup> At equilibrium, CNS partial pressure equals blood partial pressure, which in turn equals alveolar partial pressure:

$$P_{\text{CNS}} = P_{\text{blood}} = P_{\text{alveoli}} \quad (18-1)$$

where  $P$  is partial pressure. Equilibration is a result of three factors:

1. Inhaled anesthetics are gases rapidly transferred bidirectionally via the lungs to and from the bloodstream and subsequently to and from CNS tissues as partial pressures equilibrate.
2. Plasma and tissues have a low capacity to absorb the inhaled anesthetics relative to the amount we can deliver to the lungs, allowing us to quickly establish or abolish anesthetizing concentrations of anesthetic in the bloodstream and ultimately the CNS.
3. Metabolism, excretion, and redistribution of the inhaled anesthetics are minimal relative to the rate at which they are delivered or removed from the lungs. This permits easy maintenance of blood and CNS concentrations.

The so-called permanent gases, such as oxygen and nitrogen, exist only as gases at ambient temperatures. Gases such as  $\text{N}_2\text{O}$  can be compressed into liquids under high pressure at ambient temperature. *Potent volatile anesthetics* with the exception of desflurane are liquids at ambient temperature and pressure. If volatile liquids reside in a closed container, molecules of the substance will equilibrate between the liquid and gas phases. At equilibrium, the pressure exerted by molecular collisions of the gas against the container walls is the *vapor pressure*. One important property of vapor pressure is that as long as *any* liquid remains in the container, the vapor pressure is independent of the volume of that liquid. As with any gas, however, vapor pressure is proportional to temperature.

At room temperature, most of the potent agents have a vapor pressure that is below atmospheric pressure. If the temperature is raised, the vapor pressure increases. The *boiling point* of a liquid is the temperature at which its

vapor pressure exceeds atmospheric pressure in an open container. Desflurane is bottled in a special container because its boiling point of 23.5°C makes it boil at typical room temperatures. Boiling does not occur within the bottle because it is countered by buildup of vapor pressure within the bottle, but once opened to air, the desflurane would quickly boil away.

**Table 18-1** Physiochemical Properties of Volatile Anesthetics

Property	Sevoflurane	Desflurane	Isoflurane	Enflurane	Halothane	N <sub>2</sub> O
Boiling point (°C)	59	24	49	57	50	-88
Vapor pressure at 20°C (mmHg)	157	669	238	172	243	38,770

MAC, minimum alveolar concentration; N<sub>2</sub>O, nitrous oxide.

## Gases in Mixtures

For any mixture of gases in a closed container, each gas exerts a pressure proportional to its *fractional mass*. This is its *partial pressure*. The sum of the partial pressures of each gas in a mixture of gases equals the total pressure of the entire mixture (Dalton’s law):

$$P_{\text{total}} = P_{\text{gas1}} + P_{\text{gas2}} + \dots + P_{\text{gasN}} \quad (18-2)$$

Another way to state this is that each gas in a mixture of gases at a given volume and temperature has a partial pressure, that is, the pressure it would have *if it alone* occupied the volume. The entire mixture behaves just as if it were a single gas according to the ideal gas law.

## Gases in Solution

Partial pressure of a gas in solution is a bit complex because pressure can only be measured in the gas phase, while in solution the amount of gas is measured as a concentration. Partial pressure of a gas in solution refers to the pressure of the gas in the gas phase (if it were present) in equilibrium with the liquid.

However, it is important to talk of partial pressures, because gases equilibrate based on partial pressures, not concentrations.

Gas molecules within a liquid interact with solvent molecules to a much larger extent than do molecules in the gas phase. *Solubility* is the term used to describe the tendency of a gas to equilibrate with a solution, hence determining its concentration in solution. Henry's law expresses the relationship of concentration of a gas in solution to the partial pressure of the gas with which the solution is in equilibrium:

$$C_g = kP_g \quad (18-3)$$

where  $C_g$  is concentration of gas in solution,  $k$  is a solubility constant, and  $P_g$  is the partial pressure of the gas. From Eq. 18-3 one can see that doubling the pressure of a gas doubles its concentration in solution. A more clinically useful expression of solubility is the solubility coefficient,  $\lambda$ :

$$\lambda = V_{\text{dissolved gas}}/V_{\text{liquid at } 37^\circ\text{C}} \quad (18-4)$$

where  $V$  = volume. This equation states that for any gas in equilibrium with a liquid, a certain volume of that gas dissolves in a given volume of liquid.

The principles of partial pressures and solubility apply in mixtures of gases in solution. That is, the concentration of any one gas in a mixture of gases in solution depends on two factors: (1) its partial pressure in the gas phase in equilibrium with the solution, and (2) its solubility within that solution.

The implications of these properties are that anesthetic gases administered via the lungs diffuse into blood until the partial pressures in alveoli and blood are equal. The concentration of anesthetic in the blood depends on the partial pressure at equilibrium and the blood solubility. Likewise, transfer of anesthetic from blood to target tissues also proceeds toward equalizing partial pressures, but at this interface there is no gas phase. A partial pressure still exists to force anesthetic molecules out of solution and into a gas phase but there is no gas phase because blood (outside the lungs) and tissues are like closed, liquid-filled containers. Remember the principle: The partial pressure of a gas in solution represents the pressure that the gas in equilibrium with the liquid *would have* if a gas phase existed in contact with the liquid phase.

The concentration of anesthetic in target tissue depends on the partial pressure at equilibrium and the target tissue solubility. Because inhaled anesthetics are gases, and because partial pressures of gases equilibrate throughout a system, *monitoring the alveolar concentration of inhaled anesthetics provides an index of their effects in the brain.*

In summary:

1. Inhaled anesthetics equilibrate based on their partial pressures in each tissue (or tissue compartment), *not* based on their concentrations.

2. The partial pressure of a gas in solution is defined by the partial pressure in the gas phase with which it is in equilibrium. Where there is no gas phase the partial pressure reflects a force to move out of solution.
3. The concentration of anesthetic in a tissue depends on its partial pressure and the tissue solubility of the anesthetic.

Finally, the particular terminology used when referring to gases in the gas phase or absorbed in plasma or tissues is important. Inspired concentrations or fractional volumes of inhaled anesthetic are typically used rather than partial pressure. Partial pressure is expressed in millimeters of mercury (mmHg) or Torr (1 Torr = 1 mmHg) or kilopascals (kPa). For most drugs, concentration is expressed as mass (milligram [mg]) per volume (milliliter [mL]), but it can also be expressed in percent by weight or volume. Since volume of a gas in the gas phase is directly proportional to mass according to the ideal gas law, it is easier to express this fractional concentration as a percent by volume. In the gas phase, fractional concentration is equal to the partial pressure divided by ambient pressure, usually atmospheric, or:

$$\text{Fractional volume} = P_{\text{anesthetic}}/P_{\text{barometric}} \quad (18-5)$$

### **Anesthetic Transfer: Machine to Central Nervous System**

When the fresh gas flow (FGF) and the vaporizer are turned on, fresh gas with a fixed fractional concentration of anesthetic leaves the fresh gas outlet and mixes with the gas in the circuit—the bag, tubing, absorbent canister, and piping. It is immediately diluted to a lower fractional concentration, then slowly rises as this compartment equilibrates with the delivered flow. With spontaneous patient ventilation by mask, the anesthetic gas passes from circuit to airways. The fractional concentration of anesthetic leaving the circuit is designated as  $F_I$  (fraction inspired). In the lungs the gas comprising the dead space in the airways (trachea, bronchi) and the alveoli further dilutes the circuit gas. The fractional concentration of anesthetic present in the alveoli is  $F_A$  (fraction alveolar). The anesthetic then passes across the alveolar–capillary membrane and dissolves in pulmonary blood according to the partial pressure of the gas and its blood solubility. It is further diluted and travels via bulk blood flow throughout the vascular tree. The anesthetic then passes via simple diffusion from blood to tissues as well as between tissues.

The vascular system delivers blood to three physiologic tissue groups: the vessel-rich group (VRG), the muscle group, and the fat group. The VRG includes the brain, heart, kidney, liver, digestive tract, and glandular tissues. The percent of body mass and perfusion of each group are shown in [Table 18-2](#). The CNS tissues of the VRG are referred to as *tissues of desired effect*. The

other tissues of the VRG that comprise the compartment are referred to as *tissues of undesired effects*. The tissues of the muscle and fat groups comprise the *tissues of accumulation*.

**Table 18-2** Distribution of Cardiac Output by Tissue Group

Group	% Body Mass	% Cardiac Output	Perfusion (mL/min/100 g)
Vessel-rich	10	75	55–500
Muscle	50	19	3
Fat	20	6	1

Anesthetic is delivered most rapidly to the VRG because of high blood flow. Here it diffuses according to partial pressure gradients. CNS tissue takes in the anesthetic according to the tissue solubility, and at a high enough tissue concentration, unconsciousness and anesthesia are achieved. Increasing CNS tissue concentrations cause progressively deeper stages of anesthesia. As this is occurring, anesthetic is also distributing to other VRG tissues. Also coincident with delivery to the CNS, anesthetic is being delivered—albeit more slowly because of lower perfusion—to muscle and fat, where it accumulates and may affect the speed of emergence from the anesthetic. In reality, the fat solubilities provide little influence on emergence in cases lasting more than 4 hours since the delivery of anesthetic to fat tissue is extremely slow as a result of low blood flow. The concentration of inhaled anesthetic in a given tissue at a particular time during the administration depends not only on tissue blood flow, but also on tissue solubility, which governs how the inhaled anesthetics partition themselves between blood and tissue. Partitioning depends on the relative solubilities of the anesthetic for each compartment. These relative solubilities are expressed by a partition coefficient,  $\delta$ , which is the ratio of dissolved gas (by volume) in two-tissue compartments at equilibrium. Some of the partition coefficients for the inhaled anesthetics are shown in [Table 18-1](#).

## Uptake and Distribution

### $F_A/F_I$

A simple, common way to assess anesthetic uptake is to follow the ratio of fractional concentration of alveolar anesthetic to inspired anesthetic ( $F_A/F_I$ ) over time. Experimentally derived data for  $F_A/F_I$  versus time during induction are shown in [Figure 18-2](#). The faster  $F_A$  rises relative to  $F_I$ , the faster the speed of induction since  $F_A$  is proportional to  $P_A$  ( $F_A = P_A/P_{\text{barometric}}$ ) and  $P_A = P_{\text{blood}} = P_{\text{CNS}}$ ; that is, the alveolar fraction is directly

proportional to the partial pressure of anesthetic in the CNS.

**2** As fresh gas carrying anesthetic begins to flow into the air-filled circuit (assuming complete mixing), the concentration in the circuit ( $F_I$ ) will rise according to first-order kinetics:

$$F_I = F_{FGO}(1 - e^{-T/\tau}) \quad (18-6)$$

$F_{FGO}$  is the fraction of inspired anesthetic in the gas leaving the fresh gas outlet (i.e., the vaporizer setting),  $T$  is time, and  $\tau$  is a time constant. The time constant is simply the volume or “capacity” of the circuit ( $V_C$ ) divided by the FGF or  $\tau = V_C/\text{FGF}$ . For example, if the bag, tubing, absorbent canister, and piping comprise 8 L, and the FGF is 2 L, the time constant  $\tau = 8/2 = 4$ . One of the characteristics of first-order kinetics is that 95% of maximum is reached after three time constants—in this case,  $3 \times 4 = 12$  minutes.

**Figure 18-2** The rise in alveolar ( $F_A$ ) anesthetic concentration toward the inspired ( $F_I$ ) concentration is most rapid with the least soluble anesthetics,  $N_2O$  (nitrous oxide), desflurane, and sevoflurane. It rises most slowly with the more soluble anesthetics, such as halothane. All data are from human studies.<sup>181,182</sup>

Since 12 minutes is relatively long, starting with a higher  $F_{FGO}$  can increase the rate of rise of  $F_I$ . Using the earlier example with  $\tau = 4$ , by first-order kinetics 63% of maximum is reached after one time constant, or 4 minutes. To attain an  $F_I$  of 2% at 4 instead of 12 minutes, the  $F_{FGO}$  can be set to 3.2% (2% divided by 0.63) and then lowered to 2% at the 4-minute mark.

Other ways to speed the increase in  $F_I$  include increasing the FGF, thus decreasing  $\tau$ . Furthermore, the rebreathing bag can be collapsed prior to

starting the FGF, such that the capacity in the circuit ( $V_C$ ) is less, which also decreases  $\tau$ . Finally, at high flows ( $>4$  L/min) there is far less mixing because fresh gas pushes “old” gas out of the circuit via the pop-off valve before complete mixing occurs, causing  $F_I$  to increase at a greater rate; this is the most important factor in rapidly increasing  $F_I$  to the desired concentration.

One factor that delays the rate of rise of  $F_I$  is that  $\text{CO}_2$  absorbent can adsorb and decompose the inhaled anesthetics. From a practical standpoint, this does not affect the rate of rise in  $F_I$  to a significant extent compared with other factors. Another factor that delays the rate of rise of  $F_I$  is solubility of the inhaled anesthetics in some of the plastic and rubber parts of the anesthesia circuit. This absorption has been quantified, but plays only a small role in decreasing the rate of rise of  $F_I$ .

### Rise in $F_A$ in the Absence of Uptake

The rate of rise in  $F_I$  discussed earlier assumes that no anesthetic is mixing with gas in the patient’s lungs. In reality, circuit gas mixes with exhaled gases from the lung with each breath, thus lowering  $F_I$  within the circuit. If high FGFs ( $>4$  L/min), which produce a high volume of gas at the desired concentration, are used, little mixing with exhaled air occurs and  $F_I$  is relatively fixed. In this situation, circuit gas enters the lungs where it mixes with alveolar gas. If there were no blood flow to the lungs,  $F_A$  would rise in a fashion analogous to  $F_I$ ; that is:

$$F_A = F_I(1 - e^{-t/\tau}) \quad (18-7)$$

In this equation,  $\tau$  is the time constant for alveolar rise in anesthetic concentration and equals the functional residual capacity (FRC) of the patient’s lungs divided by minute ventilation ( $V_A$ ). There are two ways to speed the equilibration of  $F_A$  with  $F_I$ , that is, to decrease  $\tau$ . One way is to increase minute ventilation, and the other is to decrease FRC. Both of these methods can be used to speed induction by mask; the patient can exhale deeply before applying the mask (to decrease the initial FRC), and the patient can breathe deeply and rapidly (to increase) after the mask is applied. Importantly, high alveolar ventilation relative to uptake from the lungs to the bloodstream generates the initial high slope to the curves shown in [Figure 18-2](#).

One of the reasons that pediatric inductions by spontaneous breathing of inhaled anesthetics are so much quicker than adult inductions is that the low FRC relative to  $V_A$  of children makes for a low time constant, and hence a more rapid increase in  $F_A/F_I$ . One important caveat about the relationship of  $F_A$  to FRC is that FRC includes airway dead space; thus, in reality,  $F_A$  by Eq. 18-7 is not just the concentration of inhaled anesthetic in the alveoli but also

the concentration in the entire lung. However, it is simply called the alveolar concentration because the dead space in the airways is relatively insignificant and only the alveolar gas is exchanging anesthetic with the blood.

### Rise in $F_A$ in the Presence of Uptake

Anesthetics *are* soluble in tissues, thus uptake of anesthetic from alveoli to blood is again characterized by first-order kinetics:

$$P_{bl} \text{ (blood)} = P_A \text{ (alveoli)} \times (1 - e^{-t/\tau}),$$

where

$$P_A = F_A \times P_B \text{ (barometric)} \quad (18-8)$$

Here,  $P_B$  is the barometric pressure and the time constant,  $\tau$ , equals “capacity” (volume of anesthetic dissolved in blood at the desired alveolar partial pressure) divided by flow (volume of anesthetic delivered per unit time). For any given flow of anesthetic into the system, this capacity for the more soluble halothane is greater than the capacity for the less soluble desflurane; thus,  $\tau$  for halothane is greater than that for desflurane. The more soluble the inhaled anesthetic, the larger the capacity of the blood and tissues for that anesthetic, and the longer it takes to saturate at any given delivery rate.

The most important factor in the rate of rise of  $F_A/F_I$  is uptake of anesthetic from the alveoli into the bloodstream. The rate of rise of  $F_A/F_I$  (especially the position of the “knees” in the curves of [Fig. 18-2](#)) reflects the speed at which alveolar anesthetic ( $F_A$ ) equilibrates with that being delivered to the lungs ( $F_I$ ). Since there is uptake from alveoli to blood,  $F_A$  is not solely a function of  $F_I$  and time. The greater the uptake, the slower the rate of rise of  $F_A/F_I$ , and vice versa. Since uptake is proportional to tissue solubility, the less soluble the anesthetic (such as desflurane), the lesser its uptake and the faster it reaches equilibrium,  $P_A = P_{\text{blood}} = P_{\text{CNS}}$ .

Consider a hypothetical example. Suppose that halothane and desflurane are soluble in blood, but insoluble in all other tissues. Suppose further that total lung capacity and blood volume were both 5 L. If a fixed volume of anesthetic is delivered to the lungs (by asking the patient to take one deep breath and hold it), according to the blood:gas partition coefficients for halothane (2.5) and desflurane (0.42), 71.4% of the delivered halothane will be transferred to the blood while 28.6% remains in the alveoli (71.4/28.6 = 2.5). In contrast, 29.6% of the desflurane will be transferred to the blood while 70.4% remains in the alveoli (29.6/70.4 = 0.42). Therefore, 2.4 times (71.4/29.6) more halothane than desflurane (by volume or number of molecules) will be transferred from alveoli to bloodstream before partial

pressures equilibrate. At equilibrium, the alveolar partial pressures of halothane and desflurane are 28.6% and 70.4% of their inhaled values, respectively. This means that  $F_A$  rises faster with desflurane than halothane, as does  $F_A/F_I$ .

Blood uptake of anesthetic is expressed by the equation:

$$\dot{V}_B = \delta_{b/g} * Q \times ((P_A - P_V)) / P_B \quad (18-9)$$

where  $V_B$  is blood uptake,  $\delta_{b/g}$  is the blood:gas partition coefficient,  $Q$  is cardiac output,  $P_A$  is alveolar partial pressure of anesthetic,  $P_V$  is mixed venous partial pressure of anesthetic, and  $P_B$  is barometric pressure. This is the Fick equation applied to blood uptake of inhaled anesthetics. *The greater the value of  $V_B$ , the greater the uptake from alveoli to blood, and the slower the rise in  $F_A/F_I$ .*

From the preceding paragraphs, the parameters that increase or decrease the rate of rise in  $F_A/F_I$  during induction can now be clearly delineated and these important factors have been substantiated in experimental models.

### **Distribution (Tissue Uptake)**

The maximum  $F_A/F_I$  at a given inspired concentration of anesthetic, cardiac output, and minute ventilation depends entirely on the solubility of that drug in the blood as characterized by the blood:gas partition coefficient  $\delta_{b/g}$ . This can be seen in the time curves for the rise in  $F_A/F_I$  during induction for the various inhalation anesthetics shown in [Figure 18-2](#). The first “knee” in each curve in [Figure 18-2](#) represents the point at which the rapid rise in  $P_V$  begins to taper off; that is, when significant inhaled anesthetic concentrations begin to build up in the bloodstream because of distribution to and equilibration with the various tissue compartments.

As blood is equilibrating with alveolar gas, it also begins to equilibrate with the VRG, muscle, and, more gradually, the fat compartments based on perfusion. Muscle is not that different from the VRG, having partition coefficients that range from 1.2 ( $N_2O$ ) to 3.4 (halothane), just under a threefold difference; and for each anesthetic except  $N_2O$ , the muscle partition coefficient is approximately double that for the VRG. Although both VRG and muscle are lean tissues, the muscle compartment equilibrates far more slowly than the VRG. The explanation comes in part due to the mass of the compartments relative to perfusion. The perfusion of the VRG is about 75 mL/min/100 g of tissue, whereas it is only 3 mL/min/100 g of tissue in the muscle ([Table 18-2](#)). This 25-fold difference in perfusion between VRG (especially brain) and muscle means that even if the partition coefficients were equal, the muscle would still take 25 times longer to equilibrate with

blood.

Fat is perfused to a lesser extent than muscle and its time for equilibration with blood is considerably slower because the partition coefficients are so much greater. All of the potent agents are highly lipid-soluble. Partition coefficients range from 27 (desflurane) to 51 (halothane). On average, the solubility for these agents is about 25 times greater in fat than in the VRG group. Thus, fat equilibrates far more slowly with the blood and does not play a significant role in determining speed of induction. After long anesthetic exposures (>4 hours), the high saturation of fat tissue may play a role in delaying emergence.

Nitrous oxide represents an exception. Its partition coefficients are fairly similar in each tissue: It does not accumulate to any great extent and is not a very potent anesthetic. Its utility lies as an adjunct to the potent agents, and as a vehicle to speed induction.

## Metabolism

Data suggest that enzymes responsible for biotransformation of inhaled anesthetics become saturated at less than anesthetizing doses of these drugs, such that metabolism plays little role in opposing induction. It may, however, have some significance to recovery from anesthesia, as discussed later.

## Overpressurization and the Concentration Effect

There are several ways to speed uptake and induction of anesthesia with the inhaled anesthetics. The first is *overpressurization*, which is analogous to an intravenous bolus. This is the administration of a higher partial pressure of anesthetic than the alveolar concentration ( $F_A$ ) actually desired for the patient. Inspired anesthetic concentration ( $F_I$ ) can influence both  $F_A$  and the *rate of rise* of  $F_A/F_I$ . The greater the inspired concentration of an inhaled anesthetic, the greater the rate of rise. This concentration effect has two components: the concentrating effect and an augmented gas inflow effect.

For example, consider the administration of 10% anesthetic (10 parts anesthetic and 90 parts other gas) to a patient in whom 50% of the anesthetic in the alveoli is absorbed by the blood. In this case, five parts ( $0.5 \times 10$ ) anesthetic remain in the alveoli, five parts enter the blood, and 90 parts remain as other alveolar gas. The alveolar concentration is now  $5/(90 + 5) = 5.3\%$ . Consider next administering 50% anesthetic with the same 50% uptake. Now 25 parts anesthetic remain in alveoli, 25 parts pass into blood, and 50 parts remain as other alveolar gas. The alveolar concentration becomes  $25/(50 + 25) = 33\%$ . Giving five times as much anesthetic will lead to a  $33\%/5.3\% = 6.2$  times greater alveolar concentration. The higher the  $F_I$ ,

the greater the effect. Thus N<sub>2</sub>O, typically given in concentrations of 50% to 70%, has the greatest concentrating effect. This is why the  $F_A/F_I$  versus time curve in Figure 18-2 rises the most quickly with N<sub>2</sub>O, even though desflurane has a slightly lower blood:gas solubility.

This is not the complete picture; there is yet another factor to consider. As gas is leaving the alveoli for the blood, new gas at the original  $F_I$  is entering the lungs to replace that which is taken up by the blood. This other aspect of the concentration effect has been called *augmented gas inflow*. Again, take the example of 10% anesthetic delivered with 50% uptake into the bloodstream. The five parts anesthetic absorbed by the bloodstream are replaced by gas in the circuit that is still 10% anesthetic. The five parts anesthetic and 90 parts other gas left in the lungs mix with five parts replacement gas, or  $5 \times 0.10 = 0.5$  parts anesthetic. Now the alveolar concentration is  $(5 + 0.5)/(100) = 5.5\%$  (as compared to 5.3% without augmented inflow). For 50% anesthetic and 50% uptake, 25 parts of anesthetic removed from the alveoli are replaced with 25 parts of 50% anesthetic, giving a new alveolar concentration of  $(25 + 12.5)/(100) = 37.5\%$  (as compared to 33% without augmented inflow). Thus, 5 times the  $F_I$  leads to  $37.5/5.5 = 6.8$  times greater  $F_A$  (compared to 6.2 times without augmented gas inflow). Of course, this cycle of absorbed gas being replaced by fresh gas inflow is continuous and has a finite rate, so our example is a simplification.

**Figure 18-3** The second gas effect is demonstrated in the graphs. The  $F_A/F_I$  ratio for a more soluble gas such as halothane rises more rapidly when given with 70% N<sub>2</sub>O than when given with 10% N<sub>2</sub>O. This effect is less with less soluble gases. (Adapted from Epstein RM, Rackow H, Salanitro E, et al. Influence of the concentration effect on the uptake of anesthetic mixtures: the second gas effect. *Anesthesiology*. 1964;25:364.)

## Second Gas Effect

A special case of concentration effect applies to administration of a potent anesthetic with N<sub>2</sub>O, that is, two gases simultaneously. Along with the concentration of potent agent in the alveoli via its uptake, there is further concentration via the uptake of N<sub>2</sub>O, a process called the *second gas effect*. The principle is simple (Figs. 18-3 and 18-4). Consider, for example, administering 2% of a potent anesthetic in 70% N<sub>2</sub>O and 28% oxygen. In this case, N<sub>2</sub>O, with its extremely high partial pressure (despite low solubility), partitions into the blood more rapidly than the potent anesthetic, decreasing the alveolar N<sub>2</sub>O concentration by some amount (e.g., by 50%). Ignoring uptake of the potent anesthetic, the uptake of N<sub>2</sub>O is 35 parts, leaving 35 parts N<sub>2</sub>O, 28 parts O<sub>2</sub>, and two parts potent agent in the alveoli. The anesthetic gas is now present in the alveoli at a concentration of  $2/(2 + 35 + 28) = 3.1\%$ . The potent agent has been concentrated and  $F_A$  is increased.

### Ventilation Effects

As indicated by Figure 18-2, inhaled anesthetics with very low tissue solubility have an extremely rapid rise in  $F_A/F_I$  with induction. This suggests that there is very little room to improve this rate by increasing or decreasing ventilation, which is demonstrated in Figure 18-5. The greater the solubility of an inhaled anesthetic, the more rapidly it is absorbed by the bloodstream, such that anesthetic delivery to the lungs may be rate limiting to the rise in  $F_A/F_I$ . Therefore, for more soluble anesthetics, augmentation of anesthetic delivery by increasing minute ventilation also increases the rate of rise in  $F_A/F_I$ .

However, spontaneous minute ventilation is not static, and to the extent that the inhaled anesthetics depress spontaneous ventilation with increasing inspired concentration,  $V_A$  will decrease and so will the rate of rise of  $F_A/F_I$ . This is demonstrated in Figure 18-5. This negative feedback should not be considered a drawback of the inhaled anesthetics because the respiratory depression produced at high anesthetic concentrations essentially slows the rise in  $F_A/F_I$ . This might arguably add a margin of safety in preventing an overdose. Controlled ventilation does not offer this margin of safety.

**Figure 18-4** A graphic and relative equation to demonstrate the second gas effect. In this hypothetical example, the second gas is set at 2% of a potent anesthetic and the model is set for 50% uptake of the first gas (N<sub>2</sub>O [nitrous oxide]) in the first inspired breath. The second gas is concentrated because of the uptake of N<sub>2</sub>O (**middle panel**). On replenishing the inspired second gas (F<sub>1</sub> = 2%) in the next breath, the second gas has been concentrated to be 2.7% because of the uptake of N<sub>2</sub>O in the previous breath.

### Perfusion Effects

As with ventilation, cardiac output is not static during the course of induction. For the less soluble agents, changes in cardiac output do not affect the rate of rise of F<sub>A</sub>/F<sub>I</sub> to a great extent, but for the more soluble agents the effect is noticeable ([Figure 18-5](#)). However, as inspired concentration increases, greater cardiovascular depression reduces anesthetic uptake and actually increases the rate of rise of F<sub>A</sub>/F<sub>I</sub>. This positive feedback can rapidly lead to profound cardiovascular depression.

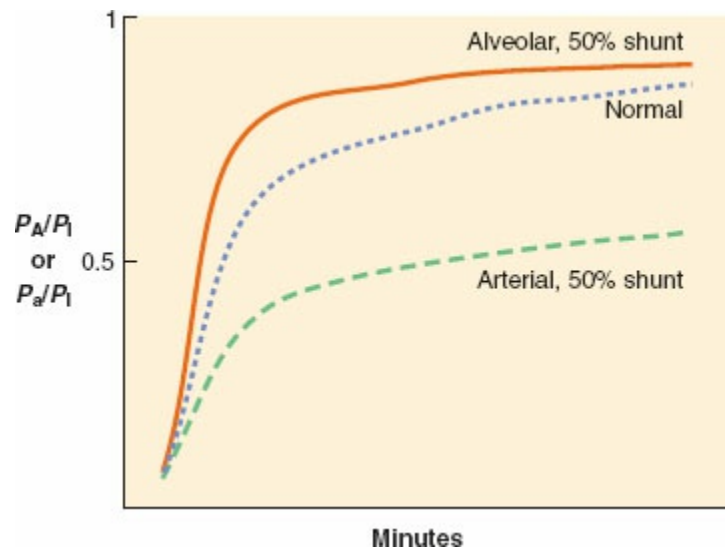

**Figure 18-5** The  $F_A/F_I$  ratio rises more rapidly if ventilation and the anesthetic concentration are increased. A decreasing  $P_A-P_V$  gradient that occurs shortly after anesthetic induction, slows anesthetic uptake and increases the rate of rise of  $F_A/F_I$ . A low CO and low blood:gas solubility slow anesthetic uptake (Equation 18-9) and increases the rate of rise of  $F_A/F_I$ . The influence of CO and ventilation on  $F_A/F_I$  are magnified for the more soluble anesthetics.

### Ventilation–Perfusion Mismatching

Ventilation and perfusion are normally fairly well matched in healthy patients, such that  $P_A$  (alveolar partial pressure)/ $P_I$  and  $P_a$  (arterial partial pressure)/ $P_I$  are the same curve. However, if significant intrapulmonary shunt occurs, as in the case of inadvertent bronchial intubation, the rate of rise of alveolar and arterial anesthetic partial pressures can be affected (Fig. 18-6). Ventilation of the intubated lung is dramatically increased while perfusion increases slightly. The nonintubated lung receives no ventilation, while perfusion decreases slightly. For the less-soluble anesthetics, increased ventilation of the intubated lung cannot appreciably increase alveolar partial pressure relative to inspired concentration on that side, but alveolar partial pressure on the nonintubated side is essentially zero. Pulmonary mixed venous blood, therefore, comprises nearly equal parts of blood containing normal amounts of anesthetic and blood containing no anesthetic; that is, diluted relative to normal. Thus the rate of rise in  $P_a$  (arterial) relative to  $P_I$  is significantly reduced. There is less total anesthetic uptake, so the rate of rise of  $P_A$  (alveolar) relative to  $P_I$  increases even though induction of anesthesia is slowed because CNS partial pressure equilibrates with  $P_a$ . For the more soluble anesthetics, increased ventilation of the intubated lung *does* increase the alveolar partial pressure relative to inspired concentration on that side. Pulmonary venous blood from the intubated side contains a higher concentration of anesthetic that lessens the dilution by blood from the

nonintubated side. Thus, the rate of rise of  $P_a/P_I$  is not as reduced and induction of anesthesia is less delayed relative to normal.

**Figure 18-6** When no ventilation/perfusion abnormalities exist, the alveolar ( $P_A$ ) and arterial ( $P_a$ ) anesthetic partial pressures rise together (*dotted blue lines*) toward the inspired partial pressure ( $P_I$ ). When 50% of the cardiac output is shunted through the lungs, such as with a mainstem intubation, the rate of rise of the alveolar partial pressure,  $P_A$  (*orange lines*) is accelerated while the rate of rise of the arterial partial pressure,  $P_a$  (*dotted green lines*) is slowed, resulting in a slower induction of anesthesia. The greatest effect of shunting is found with the least soluble anesthetics, e.g., sevoflurane and desflurane.

## Elimination

### Percutaneous and Visceral Loss

Although the loss of inhaled anesthetics via the skin is very small, it does occur and the loss is the greatest for  $N_2O$ . These anesthetics also pass across gastrointestinal viscera and the pleura. During open abdominal or thoracic surgery there is some anesthetic loss via these routes. Relative to losses by all other routes, losses via percutaneous and visceral routes are insignificant.

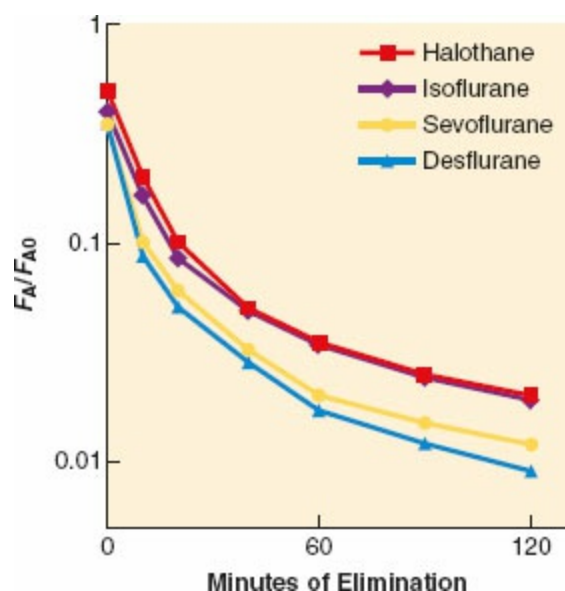

### Diffusion Between Tissues

Using more elaborate mathematical modeling of inhaled anesthetic pharmacokinetics than presented here, several laboratories have derived a five-compartment model that best describes tissue compartments. These compartments are the alveoli, the VRG, the muscle, the fat, and one additional compartment. Current opinion is that this fifth compartment represents adipose tissue adjacent to lean tissue that receives anesthetic via intertissue diffusion. This transfer of anesthetic is not insignificant, and may

account for up to one-third of uptake during long administration.

## Exhalation and Recovery

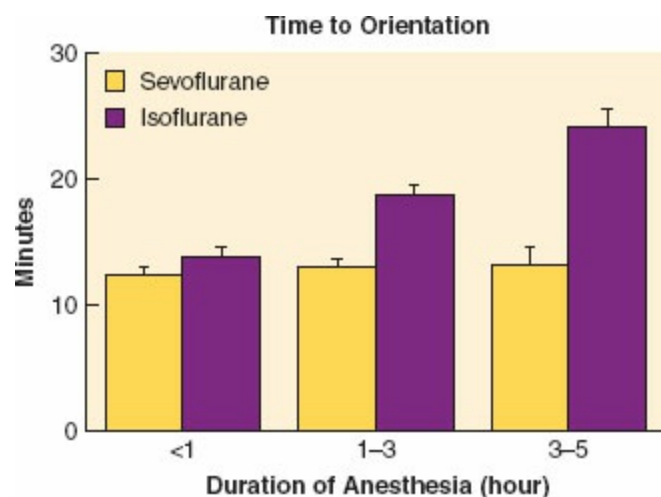

Recovery from anesthesia, like induction, depends on anesthetic solubility, cardiac output, and minute ventilation. Solubility is the primary determinant of the rate of fall of  $F_A$  (Fig. 18-7). The greater the solubility of inhaled anesthetic, the larger the capacity for absorption in the bloodstream and tissues. The “reservoir” of anesthetic in the body at the end of administration depends on tissue solubility (which determines the capacity) and the dose and duration of anesthetic (which determine how much of that capacity is filled). Recovery from anesthesia, or “washout,” is usually expressed as the ratio of expired fractional concentration of anesthetic ( $F_A$ ) to the expired concentration at time zero ( $F_{A0}$ ) when the anesthetic was discontinued (or  $F_A/F_{A0}$ ). One of the arguments for using sevoflurane and desflurane has been their relative speed in terms of emergence from anesthesia. This argument has been tempered somewhat by the basic knowledge that downward titration of volatile anesthetics can speed emergence times. Even the more soluble drug, isoflurane, can be titrated downward guided by clinical experience and/or a processed EEG monitor, permitting fast wake-ups. However, in general the use of the less-soluble drugs in the longest surgical cases makes awakening a simpler and expedient process (Fig. 18-8).<sup>3</sup>

**Figure 18-7** Elimination of anesthetic gases is defined as the ratio of end-tidal anesthetic concentration ( $F_A$ ) to the last  $F_A$  during administration and immediately before the beginning of elimination ( $F_{A0}$ ). During the 120-minute period after ending the anesthetic delivery, the elimination of sevoflurane and desflurane is 2 to 2.5 times faster than isoflurane or halothane (note logarithmic scale for the ordinate).<sup>181,182</sup>

There are two major pharmacokinetic differences between recovery and

induction. First, whereas overpressurization can increase the speed of induction, there is no “underpressurization.” Both induction and recovery rates depend on the  $P_A$  to  $P_v$  gradient, and  $P_A$  can never fall below zero. Second, whereas all tissues begin induction with zero anesthetic, each begins recovery with quite different anesthetic concentrations. The VRG tissues begin recovery with the same anesthetic partial pressure as that in alveoli, since  $P_{CNS} = P_{blood} = P_{alveoli}$ . The partial pressures in muscle and fat depend on the inspired concentration during anesthesia, the duration of administration, and the anesthetic tissue solubilities. As long as an arterial-to-tissue partial pressure gradient exists, these tissues will absorb anesthetic—especially fat, since it is a huge potential reservoir whose anesthetic partial pressures are typically minimal after hours of anesthesia. After discontinuation of anesthesia, muscle and fat may continue to absorb anesthetic, even hours later. The redistribution continues until blood/alveolar anesthetic partial pressure falls below tissue partial pressure. This redistribution causes the early rate of decline in alveolar anesthetic concentration during recovery to exceed its early rate of increase during induction.

**Figure 18-8** The recovery times to orientation after anesthesia of varying durations. With the less soluble anesthetic sevoflurane, the time to orientation was independent of the anesthetic duration. In contrast, long anesthetic durations with isoflurane were associated with delayed times to orientation. (Adapted from Ebert TJ, Robinson BJ, Uhrich TD, et al. Recovery from sevoflurane anesthesia: a comparison to isoflurane and propofol anesthesia. *Anesthesiology*. 1998;89:1524.)

Because VRG tissues are highly perfused and washout of anesthetic is mostly via elimination from these tissues early in recovery, all anesthetics, regardless of duration of administration, have approximately the same rate of elimination to 50% of  $F_{A0}$ . Unfortunately, halving the CNS concentration of anesthetic is rarely sufficient for waking the patient. More commonly, 80% to 90% of inhaled anesthetic must be eliminated before emergence. At these

amounts of washout, the more soluble anesthetics are eliminated more slowly than less soluble agents.

## Diffusion Hypoxia

During recovery from anesthesia, washout of high concentrations of N<sub>2</sub>O can lower alveolar concentrations of oxygen and carbon dioxide, a phenomenon called *diffusion hypoxia*. The resulting alveolar hypoxia can cause hypoxemia, and alveolar hypocarbia can depress respiratory drive, which may exacerbate hypoxemia. It is therefore appropriate to initiate recovery from N<sub>2</sub>O anesthesia with 100% oxygen rather than less concentrated O<sub>2</sub>/air mixtures.

## Clinical Overview of Current Inhaled Anesthetics

### Isoflurane

Isoflurane is a halogenated methyl ethyl ether that is a clear, nonflammable liquid at room temperature and has a high degree of pungency. It is the most potent of the volatile anesthetics in clinical use, has great physical stability, and undergoes essentially no deterioration during storage for up to 5 years or on exposure to sunlight. It has become the “gold standard” anesthetic since its introduction in the 1970s. There was a brief period of controversy concerning the use of isoflurane in patients with coronary disease because of the possibility for coronary “steal” arising from the potent effects of isoflurane on coronary vasodilation. In clinical use, however, this has been, at most, a rare

**3** occurrence.

### Desflurane

Desflurane is a fluorinated methyl ethyl ether that differs from isoflurane by just one atom: A fluorine atom is substituted for a chlorine atom on the  $\alpha$ -ethyl component of isoflurane (Fig. 18-1). Fluorination of the ether molecule has several effects. It decreases blood and tissue solubility (the blood:gas solubility of desflurane equals that of N<sub>2</sub>O), which results in a loss of potency (the minimum alveolar concentration [MAC] of desflurane is five times higher than isoflurane). It also results in a high vapor pressure owing to decreased intermolecular attraction, requiring an electrically driven, heated, pressurized vaporizer to deliver a regulated concentration of desflurane as a gas. One of the advantages of desflurane is the near-absent metabolism to serum trifluoroacetate. This makes immune-mediated hepatitis a rare occurrence. Desflurane is the most pungent of MAC-equivalent volatile anesthetics and, if administered via the facemask, results in coughing, salivation, breath holding,

and laryngospasm. In extremely dry CO<sub>2</sub> absorbers, desflurane (and to a lesser extent isoflurane, enflurane, and sevoflurane) degrades to form carbon monoxide. Desflurane has the lowest blood:gas solubility of the potent volatile anesthetics; moreover, its fat solubility is roughly half that of the other volatile anesthetics. Thus, desflurane requires less downward titration in long surgical procedures to achieve a rapid emergence by virtue of decreased tissue saturation. This may be particularly advantageous in the morbidly obese patient.<sup>4</sup> Desflurane has been associated with tachycardia and hypertension when used with minimal opioids and, in select cases, myocardial ischemia when used in high concentrations or when rapidly increasing the inspired concentration.

## Sevoflurane

Sevoflurane is a sweet smelling, completely fluorinated methyl isopropyl ether (Fig. 18-1). Its vapor pressure is roughly one-fourth that of desflurane and it can be used in a conventional vaporizer. The blood:gas solubility of sevoflurane is second only to desflurane in terms of potent volatile anesthetics. Sevoflurane is approximately half as potent as isoflurane, and some of the preservation of potency, despite fluorination, is because of the bulky propyl side chain on the ether molecule. Its pleasant odor, lack of pungency, and potent bronchodilating characteristics make sevoflurane administration via the facemask for induction of anesthesia in both children and adults a reasonable alternative to IV anesthetics. Sevoflurane is half as potent a coronary vasodilator as isoflurane, but is 10 to 20 times more vulnerable to metabolism than isoflurane. The metabolism of sevoflurane results in inorganic fluoride but has not been associated with renal-concentrating defects. Unlike other potent volatile anesthetics, sevoflurane is not metabolized to trifluoroacetate; rather, it is metabolized to an acyl halide (hexafluoroisopropanol). This does not stimulate formation of antibodies associated with hepatitis.

Sevoflurane exposed to purposely dried absorbent can form carbon monoxide and can cause high heat and fire via an exothermic reaction. New generic versions of sevoflurane have the potential to break down to hydrogen fluoride when exposed to metal compounds because of their lack of adequate water in the formulation. Sevoflurane also breaks down in the presence of the carbon dioxide absorber to form a vinyl halide called *compound A*. Compound A has been shown to be a dose-dependent nephrotoxin in rats, but has not been associated with renal injury in human volunteers or patients, with or without renal impairment, even when FGFs are 1 L/min or less.

## Xenon

Xenon is an inert gas occurring naturally in air at 0.05 parts per million (ppm). Xenon has received considerable interest in the last few years because it has many characteristics approaching those of an “ideal” inhaled anesthetic.<sup>5</sup> It has a quick onset and offset, minimal effects on the cardiovascular and neural systems, and it is not a trigger for malignant hyperthermia (MH). It is not a pollutant or an occupational hazard, and does not add to global warming or the greenhouse gas effect. Its blood:gas partition coefficient is 0.115, and unlike the other potent volatile anesthetics (except methoxyflurane), xenon provides some degree of analgesia. This action is likely due to N-Methyl-d-aspartate (NMDA) receptor inhibition. The MAC of xenon in humans is 71%, which might prove to be a limitation. It is nonexplosive, nonpungent, and odorless, and thus can be inhaled with ease. In addition, it does not produce significant myocardial depression or alter coronary blood flow.<sup>6</sup> Because of its scarcity and high cost related to extraction by fractional distillation of the atmosphere, its role as a replacement for current lower cost anesthetics remains uncertain. It may have potential for neuroprotection in select settings via its inhibitory action of the NMDA receptor glycine site.

## Nitrous Oxide

Nitrous oxide is a sweet-smelling, nonflammable gas of low potency (MAC = 104%), and is relatively insoluble in blood. It is most commonly administered as an anesthetic adjuvant in combination with opioids or volatile anesthetics during the conduct of general anesthesia. At room temperature it is a gas; its boiling point is  $-88.48^{\circ}\text{C}$  (Table 18-1). It is stored in cylinders and condensed to 50 atmospheres, leading to a pressure of 745 psi. Only cylinder weight is a reliable indicator of the volume of  $\text{N}_2\text{O}$  in storage tanks since psi is maintained until no liquid remains. Although not flammable,  $\text{N}_2\text{O}$  will support combustion. Unlike the potent volatile anesthetics in clinical use,  $\text{N}_2\text{O}$  does not produce significant skeletal muscle relaxation, but it does have modest analgesic effects. Despite a long track record of use, controversy has surrounded  $\text{N}_2\text{O}$  in four areas:<sup>7</sup> its role in postoperative nausea and vomiting; its potential toxic effects on cell function via inactivation of vitamin  $\text{B}_{12}$ ; its adverse effects related to absorption and expansion into air-filled structures and bubbles; and lastly, its effect on embryonic development. The most valid and most clinically relevant concern is the ability of  $\text{N}_2\text{O}$  to expand air-filled spaces because of its greater solubility in blood compared to nitrogen. This might explain the increased postoperative nausea and vomiting (PONV) associated with  $\text{N}_2\text{O}$  use since closed gas spaces reside in the middle ear and

bowel. Other closed spaces may occur as a result of disease or surgery, such as a pneumothorax. Since nitrogen in air-filled spaces cannot be removed readily via the bloodstream, N<sub>2</sub>O delivered to a patient diffuses from the blood into these closed gas spaces quite easily until the partial pressure equals that of the blood and alveoli. Compliant spaces will continue to expand until sufficient pressure is generated to oppose further N<sub>2</sub>O flow into the space. The higher the inspired concentration of N<sub>2</sub>O, the higher the partial pressure required for equilibration.

Seventy-five percent N<sub>2</sub>O can expand a pneumothorax to double or triple its size in 10 and 30 minutes, respectively. Air-filled cuffs of pulmonary artery catheters and endotracheal tubes also expand with the use of N<sub>2</sub>O, possibly causing tissue damage via increased pressure in the pulmonary artery or trachea, respectively. Accumulation of N<sub>2</sub>O in the middle ear can diminish hearing postoperatively<sup>8</sup> and is contraindicated for tympanoplasty because the increased pressure can dislodge a tympanic graft.

## Neuropharmacology of Inhaled Anesthetics

### Minimum Alveolar Concentration

Pharmacodynamic effects of anesthetics are based on their dosing. In the case of inhaled agents, we describe dose as the *minimum alveolar concentration* or MAC. MAC is the alveolar concentration of an anesthetic at one atmosphere (in volume%) that prevents movement in response to a surgical stimulus in 50% of patients. It is analogous to the ED<sub>50</sub> expressed for intravenous drugs and can be used to compare anesthetic potency, that is, the lower the MAC the more potent the agent. Movement to a surgical stimulus, commonly abdominal incision, has been used to establish the MAC for each inhaled anesthetic. MAC values for humans for the inhaled anesthetics are shown in [Table 18-1](#).

The 95% confidence ranges for MAC are approximately  $\pm 25\%$  of the listed MAC values. Manufacturer's recommendations and clinical experience establish 1.2 to 1.3 times MAC as a dose that will often prevent patient movement during a surgical stimulus. Loss of consciousness typically precedes the absence of stimulus-induced movement by a wide margin.

Concentrations of inhaled anesthetics that provide loss of self-awareness and recall are about 0.4 to 0.5 MAC barring other conditions that increase MAC in a given patient ([Table 18-3](#)). Several lines of reasoning support the assertion. First, most patients receiving only 50% N<sub>2</sub>O (approximately 0.4 to 0.5 MAC), as in a typical dentist's office, will have no recall of their procedure during N<sub>2</sub>O administration. Second, various studies have shown that a shift in electroencephalogram (EEG) dominance to the anterior leads,

that is, the shift from self-aware to non-self-aware, accompanies loss of consciousness, and in primates, the EEG shift and loss of consciousness occur at 0.5 MAC.<sup>9</sup> Third, in dogs, loss of consciousness accompanies a sudden nonlinear fall in cerebral metabolic rate (CMRO<sub>2</sub>) at approximately 0.5 MAC (Fig. 18-9).

MAC values can be established for any measurable response. For example, MAC-awake and MAC-BAR. MAC-awake is the alveolar concentration of anesthetic at which a patient opens his or her eyes to command, and it varies from 0.15 to 0.5 MAC. Interestingly, transition from awake to unconscious and back typically shows some hysteresis in that it quite consistently takes 0.4 to 0.5 MAC to lose consciousness, but less than that (as low as 0.15 MAC) to regain it. This may be because of the speed of alveolar wash-in versus wash-out.<sup>10</sup> MAC-BAR is the alveolar concentration of anesthetic that blunts adrenergic responses to noxious stimuli. It has been approximated at 50% higher than standard MAC.<sup>11</sup> MAC values also have been established for discreet levels of EEG activity, such as onset of burst suppression or isoelectricity.

Standard MAC values are roughly additive. Administering 0.5 MAC of a potent agent and 0.5 MAC of N<sub>2</sub>O is equivalent to 1 MAC of potent agent in terms of preventing *patient movement*, although this does not hold over the entire range of N<sub>2</sub>O doses. MAC effects for other response parameters such as cardiovascular or respiratory measures, are not necessarily additive. For example, combining 0.6 MAC of N<sub>2</sub>O with 0.6 MAC of isoflurane produces less hypotension than 1.2 MAC of isoflurane alone because isoflurane is a more potent vasodilator and myocardial depressant at equivalent MAC than N<sub>2</sub>O.

**Table 18-3** Factors that Increase Minimum Alveolar Concentration

Increased central neurotransmitter levels (monoamine oxidase inhibitors, acute dextroamphetamine administration, cocaine, ephedrine, levodopa)
Hyperthermia
Chronic ethanol abuse (determined in humans)
Hypernatremia

**Figure 18-9** The effects of isoflurane on cerebral metabolic rate of oxygen consumption ( $CMRO_2$ ) as a percentage of control (“awake”).  $CMRO_2$  is plotted versus end-tidal isoflurane concentration. Regression lines for changes in  $CMRO_2$  are drawn for each electroencephalogram-determined area. The pattern depicted here is characteristic of all of the anesthetics examined (enflurane, halothane, and isoflurane). MAC, minimum alveolar concentration. (Adapted from Stullken EH Jr, Milde JH, Michenfelder JD, et al. The nonlinear responses of cerebral metabolism to low concentrations of halothane, enflurane, isoflurane and thiopental. *Anesthesiology*. 1977;46:28.)

Various factors increase (Table 18-3) or decrease (Table 18-4) MAC. Unfortunately, no single mechanism explains these alterations, supporting the view that anesthesia is the net result of numerous and widely varying physiologic alterations. In general, those factors that increase CNS metabolic activity, neurotransmission, and CNS neurotransmitter levels increase MAC; upregulated CNS responses to chronically depressed neurotransmitter levels (as in chronic alcoholism) also seem to increase MAC. Conversely, those factors that decrease CNS metabolic activity, neurotransmission, and CNS neurotransmitter levels, as well as downregulated CNS responses to chronically elevated neurotransmitter levels all seem to decrease MAC. Many notable factors do not alter MAC, including duration of administration, gender, type of surgical stimulation, thyroid function, hypo- or hypercarbia, metabolic alkalosis, hyperkalemia, and magnesium levels. However, there may be a genetic component influencing MAC. Red-haired females may have altered pain thresholds, perhaps explaining the 19% increase in MAC compared with dark-haired females.<sup>12</sup> Studies suggest involvement of mutations of the melanocyte stimulating hormone receptor (*MC1R*) allele. MAC also can vary in relationship to genotype and chromosomal substitutions as shown in rats.<sup>13</sup>

### The Effect of Age on MAC

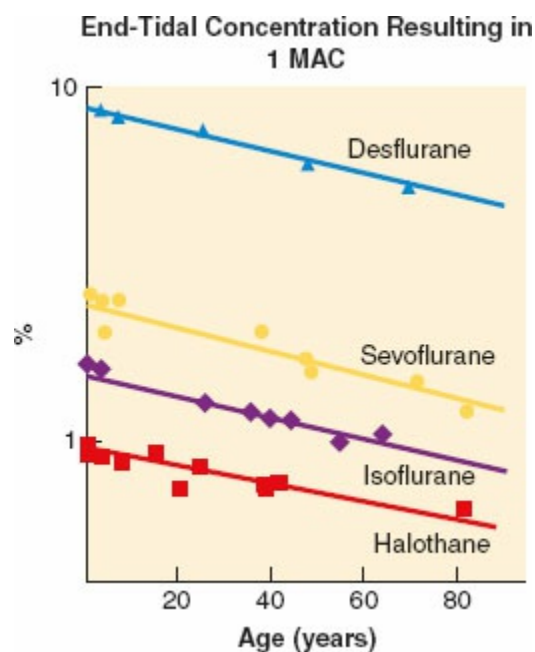

The MAC for each of the potent anesthetic gases shows a clear, age-related

change (Fig. 18-10). MAC decreases with age and there are similarities between agents in the decline in MAC and age. There is a linear model that describes a change in MAC of approximately 6% per decade, a 22% decrease in MAC from age 40 to 80 years, and a 27% decrease in MAC from age 1 to 40 years.<sup>14</sup>

**Table 18-4** Factors that Decrease Minimum Alveolar Concentration

Increasing age
Metabolic acidosis
Hypoxia (PaO <sub>2</sub> , 38 mmHg)
Induced hypotension (mean arterial pressure <50 mmHg)
Decreased central neurotransmitter levels (α-methyl dopa, reserpine, chronic dextroamphetamine administration, levodopa)
α <sub>2</sub> -agonists
Hypothermia
Hyponatremia
Lithium
Hypo-osmolality
Pregnancy
Acute ethanol administration <sup>a</sup>
Ketamine
Pancuronium <sup>a</sup>
Physostigmine (10 times clinical doses)
Neostigmine (10 times clinical doses)
Lidocaine
Opioids
Opioid agonist-antagonist analgesics
Barbiturates <sup>a</sup>
Chlorpromazine <sup>a</sup>
Diazepam <sup>a</sup>
Hydroxyzine <sup>a</sup>
Δ-9-Tetrahydrocannabinol
Verapamil
Anemia (<4.3 mL O <sub>2</sub> /dL blood)

<sup>a</sup>Determined in humans.

**Figure 18-10** Effect of age on minimum alveolar concentration (MAC) is plotted. Regression lines are fitted to published values from separate studies. Data are from patients' ages 1 to 80 years. (Adapted from Mapleson WW. Effect of age on MAC in humans: a meta-analysis. *Br J Anaesth*. 1996;76:179.)

### Other Alterations in Neurophysiology

The modern potent anesthetics, isoflurane, desflurane, and sevoflurane, all have reasonably similar effects on a wide range of parameters including  $CMRO_2$ , the EEG, cerebral blood flow (CBF), and flow–metabolism coupling. There are notable differences in effects on intracerebral pressure (ICP),  $CO_2$  vasoreactivity, CBF autoregulation, and cerebral protection. Nitrous oxide departs from the potent agents in several important respects, and is therefore discussed separately.

Although neuroprotection from volatile anesthetics is a well-defined concept, the volatile anesthetics can cause injury in certain conditions via cerebral vasodilation and increases in intracranial pressure. A full understanding of the anesthetic effects on cerebral physiology helps prevent adverse cerebral events in clinical practice.

### Cerebral Metabolic Rate and Electroencephalogram

For most of the potent agents,  $CMRO_2$  is decreased only to the extent that spontaneous cortical neuronal activity (as reflected on the EEG) is decreased. Once this activity is absent (an isoelectric EEG), no further decreases in  $CMRO_2$  are generated. (Historically, halothane was the exception.) Isoflurane causes a larger MAC-dependent depression of  $CMRO_2$  than halothane, and because of this, can abolish EEG activity at clinical doses that are usually well tolerated from a hemodynamic standpoint.<sup>15</sup> Desflurane and sevoflurane both cause decreases in  $CMRO_2$  similar to isoflurane.<sup>16,17</sup> Interestingly, while both desflurane and sevoflurane depress the EEG and abolish activity at clinically tolerated doses of approximately 2 MAC<sup>16,17</sup> in dogs, desflurane-induced isoelectric EEG reverts to continuous activity with time despite an unchanging MAC, a property unique to desflurane.<sup>16</sup>

Sevoflurane has no noteworthy adverse effects on cerebral physiology at normal  $CO_2$  and BP.<sup>18</sup> During sevoflurane use combined with extreme hyperventilation to decrease CBF by half, brain lactate levels can increase. High, long-lasting concentrations of sevoflurane (1.5 to 2.0 MAC), a sudden increase in cerebral sevoflurane concentrations, especially in females, and/or hypocapnia can trigger EEG abnormalities that have resulted in increases in heart rate (HR) in both adults and children.<sup>19,20</sup> These data question the appropriateness of sevoflurane in patients with epilepsy,<sup>21</sup> but it remains

uncertain if sevoflurane truly has a proconvulsant effect.

## Cerebral Blood Flow, Flow–Metabolism Coupling, and Autoregulation

All of the potent agents increase CBF in a dose-related manner. Isoflurane, sevoflurane, and desflurane cause far less cerebral vasodilation per MAC-multiple than halothane (Fig. 18-11). Desflurane and sevoflurane both influence CBF in a manner similar to isoflurane, with minimal changes in CBF at concentrations less than 1.5 MAC.<sup>16,17,22</sup> An initial dose-dependent increase in CBF with halothane and isoflurane administration to animals subsequently recovers to preinduction levels in approximately 2 to 5 hours. The mechanism of this recovery is unclear.

7 The increase in CBF with increasing anesthetic dose occurs despite decreases in CMRO<sub>2</sub>. This phenomenon has been called *uncoupling*, but from a mechanistic standpoint, true uncoupling of flow from metabolism may not occur. That is, as CMRO<sub>2</sub> is depressed by the volatile anesthetics, there still is a coupled decline in CBF opposed by a coincident direct vasodilatory effect on the cerebral blood vessels. The net effect on the cerebral vessels depends on the sum of indirect vasoconstricting and direct vasodilating influences.

**Figure 18-11** Cerebral blood flow (and velocity) measured in the presence of normocapnia and in the absence of surgical stimulation in volunteers receiving halothane or isoflurane.<sup>188,189</sup> At light levels of anesthesia, halothane (but not isoflurane) increased cerebral blood flow. At 1.6 minimum alveolar concentration (MAC), isoflurane also increased cerebral blood flow. Cerebral blood flow velocity measured before and during sevoflurane and desflurane anesthesia up to 1.5 MAC showed no change in cerebral blood flow and velocity.

Autoregulation is the intrinsic myogenic regulation of vascular tone. In normal brain, the mechanisms of autoregulation of CBF over a range of mean arterial pressures from 50 to 150 mmHg are incompletely understood. Because the volatile anesthetics are direct vasodilators, all are considered to

diminish autoregulation in a dose-dependent fashion such that at high anesthetic doses CBF is essentially pressure-passive. Sevoflurane preserves autoregulation up to approximately 1 MAC.<sup>17</sup> At 1.5 MAC, the dynamic rate of autoregulation (change in middle cerebral artery blood flow after a rapid transient decrease in BP) is better preserved with sevoflurane than isoflurane.<sup>23</sup> This may be result in a lesser direct vasodilator effect of sevoflurane, preserving the ability of the vessel to respond to changes in BP at 1.5 MAC. Based on a similar model but a separate study of dynamic autoregulation of CBF, both desflurane and isoflurane reduced autoregulation in a dose-dependent manner.<sup>24</sup>

## **Intracerebral Pressure**

For most anesthesiologists, the area of greatest clinical interest is the effect of volatile anesthetics on ICP. In general, ICP will increase or decrease in proportion to changes in CBF. Isoflurane increases ICP minimally in animals both with and without brain pathology, including those with an already elevated ICP.<sup>25</sup> In human studies there usually are mild increases in ICP with isoflurane administration that are blocked or blunted by hyperventilation or barbiturate coadministration.<sup>26</sup> However, there are some contradictory data. In one human study, hypocapnia did not prevent elevations in ICP with isoflurane administration in patients with space-occupying brain lesions.<sup>27</sup>

Like isoflurane, both sevoflurane and desflurane greater than 1 MAC produce mild increases in ICP, paralleling their mild increases in CBF.<sup>16,17,28,29</sup> One potential advantage of sevoflurane is that its lower pungency and airway irritation may lessen the risk of coughing and bucking and the associated rise in ICP as compared with desflurane or isoflurane. In fact, introduction of desflurane after propofol induction of anesthesia has led to significant increases in HR, mean arterial pressure, and middle cerebral artery blood flow velocity.<sup>30</sup> This may relate to the airway irritant effects of desflurane rather than a specific alteration in neurophysiology. However, several studies in both children and adults suggest that increases in ICP from desflurane are slightly greater than from either isoflurane or sevoflurane.<sup>30,31</sup> CSF production and resorption are modestly and variably affected by volatile anesthetics and are clinically far less important than anesthetic effects on CBF. The bottom line is that all three potent agents may be used at appropriate doses, especially with adjunctive and compensatory therapies, in nearly any neurosurgical procedure.

## **Cerebral Blood Flow Response to Hypercapnia and Hypocapnia**

Significant hypercapnia is associated with dramatic increases in CBF whether or not volatile anesthetics are administered. As discussed earlier, hypocapnia

can blunt or abolish volatile anesthetic-induced increases in CBF depending on when the hypocapnia is produced. This vasoreactivity to CO<sub>2</sub> may be somewhat altered by the volatile anesthetics as compared with normal. Isoflurane does not abolish hypocapnic vasoconstriction.<sup>32</sup> Similarly, CO<sub>2</sub> vasoreactivity under desflurane anesthesia is normal up to 1.5 MAC,<sup>25</sup> and CO<sub>2</sub> vasoreactivity for sevoflurane is preserved at 1 MAC.<sup>33</sup>

## Cerebral Protection

When isoflurane is used to lower BP and cerebral perfusion, tissue oxygen content is improved as compared to a similar BP effect created by other pharmacologic means. The improvement is most likely due to the beneficial effect of isoflurane to decrease CMRO<sub>2</sub>.<sup>34</sup> Both sevoflurane and desflurane have been shown to improve neurologic outcome after incomplete cerebral ischemia in a rat model.<sup>35,36</sup> In piglets undergoing low-flow cardiopulmonary bypass, desflurane improved neurologic outcome compared with a fentanyl/droperidol-based anesthetic.<sup>37</sup>

In humans, desflurane has been shown to increase brain tissue PO<sub>2</sub> during administration, and to maintain PO<sub>2</sub> to a greater extent than thiopental during temporary cerebral artery occlusion during cerebrovascular surgery.<sup>38</sup> Neuroprotection and clinical outcome studies for sevoflurane and desflurane have not been published.

## Postoperative Cognitive Dysfunction

 Postoperative cognitive dysfunction (POCD) is defined as impairment to the mental processes of perception, memory, and information processing. These alterations are associated with increased morbidity and mortality in the first year after surgery from causes such as decubiti, pneumonia, and deep vein thrombosis.<sup>39</sup> In the elderly in particular, subtle cognitive dysfunction can persist long after expected drug clearance.

The effect of isoflurane on POCD has been more widely investigated than that of the other potent agents. As early as 1992, Tsai et al.<sup>40</sup> reported that desflurane was superior to isoflurane in both emergence characteristics and the recovery of cognitive function. Chen et al.<sup>41</sup> have demonstrated that sevoflurane and desflurane have similar profiles when it comes to cognitive recovery, and multiple other studies have further confirmed this. These results seem to be in conflict with those produced by Kanbak et al.<sup>42</sup> who demonstrated in cardiopulmonary bypass patients that isoflurane promoted better neurocognitive function than either sevoflurane or desflurane. It is clear from the wide variations in the results available in the literature that more research is required into this important topic. Further, while the mechanisms involved in the development of POCD are not well delineated, it

seems clear that all modern anesthetics are associated with its development to one degree or another.

As with the potent inhalational anesthetics, use of N<sub>2</sub>O is also associated with POCD and delirium, and high doses of N<sub>2</sub>O seem to be associated with interference with many cognitive functions.<sup>43</sup> Interestingly, the development of postoperative delirium after exposure to N<sub>2</sub>O in a mixed anesthetic has a similar incidence to that when not exposed, suggesting that the mechanisms, while possibly different, are not additive.<sup>44</sup>

## Processed Electroencephalograms and Neuromonitoring

All of the volatile anesthetics produce dose-dependent effects on the EEG, sensory-evoked potentials (SEPs), and motor-evoked potentials (MEPs). 9 EEGs recorded on the scalp can be processed to quantify the amount of activity in each of four frequency bands:  $\delta$  (0 to 3 Hz),  $\theta$  (4 to 7 Hz),  $\alpha$  (8 to 13 Hz), and  $\beta$  (>13 Hz). All three currently used agents at greater than 1 MAC and N<sub>2</sub>O at 30% to 70% can produce shifts to increasing frequencies. Between 1 and 2 MAC the potent agents produce shifts to decreasing frequencies and increases in amplitude. At greater than 2 MAC, all of the potent agents can produce burst suppression or electrical silence. These are important factors to remember because EEG changes during administration of general anesthesia can also be caused by hypoxia, hypercarbia, and hypothermia. The EEG must always be interpreted within the appropriate clinical context.

All of the volatile agents cause a dose-dependent increase in latency and decrease in amplitude in all cortical SEP modalities. In subcortical modalities, such as brainstem auditory evoked potentials, these agents are associated with negligible effects. In general, visual evoked potentials are somewhat more sensitive to the effects of the volatile anesthetics than somatosensory evoked potentials. Like EEGs, these effects from anesthetics must be kept in mind when changes during SEPs occur, and appropriate doses of the volatile agents must be used. Sudden changes in the anesthetic regimen (>0.5 MAC) also seem to have greater effects on SEPs than more gradual changes.

MEPs evaluate the functional integrity of descending motor pathways. The evoked response is most commonly recorded as a muscle potential or a peripheral nerve signal. The trigger is typically transosseous activation via electrical or magnetic stimulation. MEPs are exquisitely sensitive to depression by volatile anesthetics, which are usually avoided in these cases.

## Nitrous Oxide

The effects of N<sub>2</sub>O on cerebral physiology are not clear. Both the MAC for N<sub>2</sub>O and its effects on CMRO<sub>2</sub> vary widely depending on species. The

difference in CMRO<sub>2</sub> effects may in part be accounted for by differences in MAC, but MAC-equivalent effects on CMRO<sub>2</sub> also differ. Several studies in dogs, goats, and swine found that N<sub>2</sub>O increases CMRO<sub>2</sub> and CBF, while in rodents no such increases or only slight increases occur. In human studies, N<sub>2</sub>O administration preserved CBF but decreased CMRO<sub>2</sub>.<sup>15</sup>

Another problem is that N<sub>2</sub>O is a co-anesthetic used to supplement potent agents, not a complete anesthetic in itself, and CMRO<sub>2</sub> effects may differ depending on the presence or absence of potent agent as well as the particular agent and dose. Addition of N<sub>2</sub>O to 1 MAC isoflurane does not alter CMRO<sub>2</sub>, but it does increase CBF.

Barbiturates, narcotics, or a combination of the two appear to decrease or eliminate the increases in CMRO<sub>2</sub> and CBF produced by N<sub>2</sub>O. N<sub>2</sub>O administration increases ICP, but as is the case for CMRO<sub>2</sub> and CBF, changes in ICP are decreased or eliminated by a variety of co-anesthetics and, more importantly, by hypocapnia.

Nitrous oxide may be neuroprotective in rat models of cerebral ischemia, but other work suggests it is neurotoxic.<sup>45</sup> Given the conflicting data on the effects of N<sub>2</sub>O on CMRO<sub>2</sub>, CBF, ICP, and neuroprotection during ischemia, avoidance or discontinuation of its use should be considered in surgical cases with a high likelihood of elevated ICP or significant cerebral ischemia.

## The Circulatory System

### *Hemodynamics*

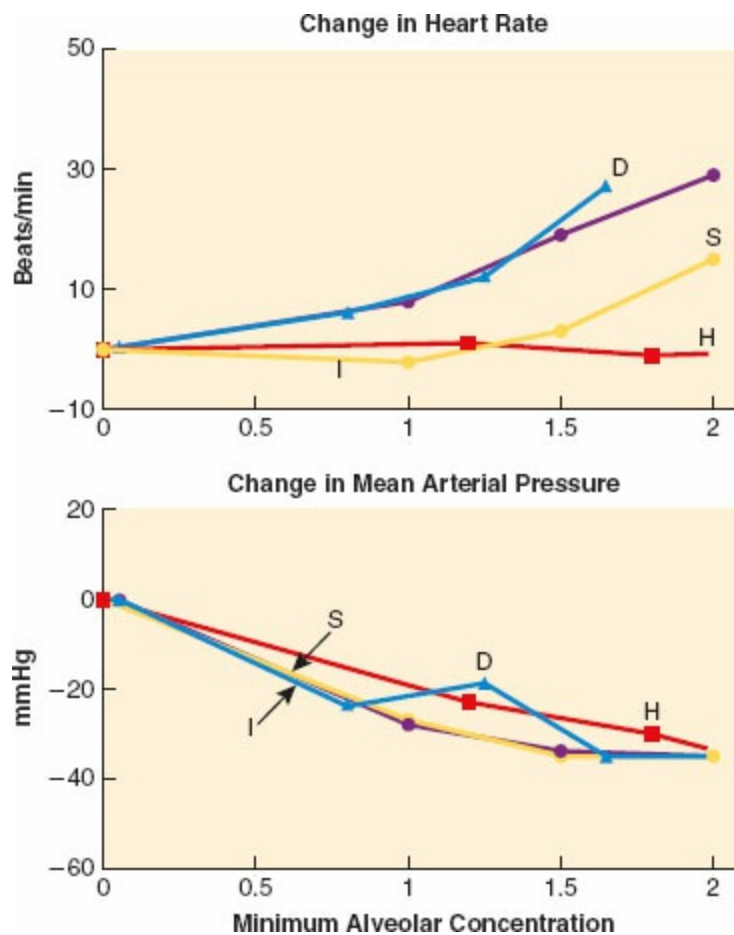

The cardiac, vascular, and autonomic effects of the volatile anesthetics have been defined through a number of studies carried out in human volunteers not undergoing surgery.<sup>46–50</sup> In general, the information from these volunteer studies has translated well to the patient population commonly exposed to these anesthetics during elective and emergent surgeries.

A common effect of the potent volatile anesthetics has been to decrease BP in a dose-related fashion with essentially no differences noted between the volatile anesthetics at equianesthetic concentrations (Fig. 18-12). Their primary mechanism to decrease BP is via a potent effect to relax vascular smooth muscle leading to decreases in regional and systemic vascular resistance (Fig. 18-13). They have only minimal effects on cardiac **10** output.

In volunteers, sevoflurane up to about 1 MAC does not change HR while isoflurane and desflurane result in 5% to 10% increases in HR from baseline (Fig. 18-12). Both desflurane and, to a lesser extent, isoflurane have been associated with transient and significant increases in HR during rapid increases in the inspired concentration of either anesthetic.<sup>51,52</sup> The

mechanism(s) underlying these transient HR surges is likely due to the relative pungency of these anesthetics, which stimulates airway receptors to elicit a reflex tachycardia.<sup>53</sup> The tachycardia can be lessened with opioid or  $\alpha_2$ -agonist pretreatment.<sup>54-56</sup>

**Figure 18-12** Heart rate and blood pressure changes (from awake baseline) in volunteers receiving general anesthesia with isoflurane (I), desflurane (D), or sevoflurane (S). Sevoflurane produced little or no change in heart rate below 1.5 minimum alveolar concentration.<sup>47,60</sup> All anesthetics caused similar decreases in blood pressure. Halothane (H) is presented for historical perspective.

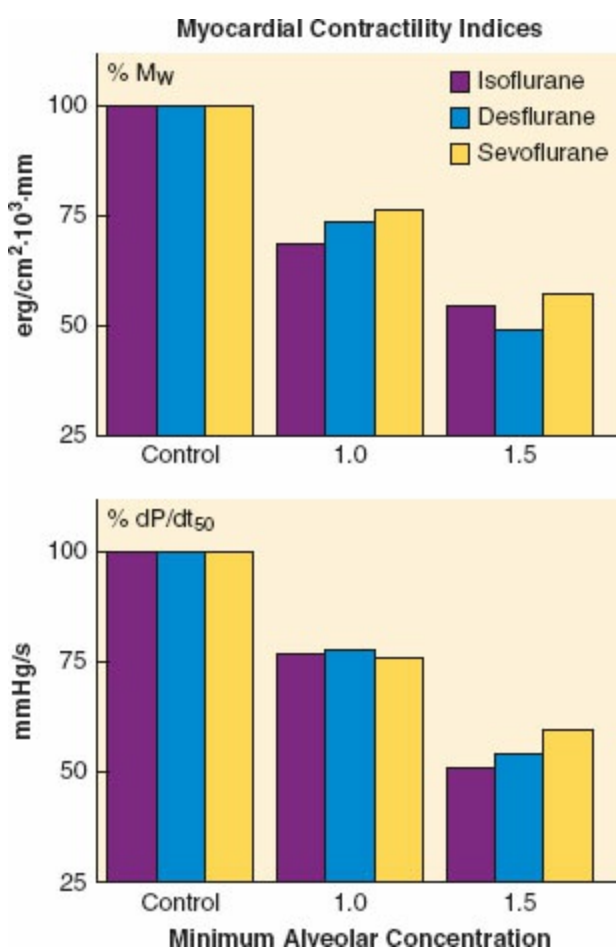

**Figure 18-13** Cardiac index, central venous pressure (or right atrial pressure), and systemic vascular resistance changes (from awake baseline) in volunteers receiving general anesthesia with isoflurane (I), desflurane (D), or sevoflurane (S).<sup>47,60</sup> Increases in central venous pressure from desflurane might be due to venoconstriction. Halothane (H) is presented for historical perspective.

### Myocardial Contractility

Myocardial contractility indices have been directly evaluated in animals and indirectly evaluated in human volunteers during the administration of each of the volatile anesthetics. Isoflurane, desflurane, and sevoflurane produced similar dose-dependent reductions in indices of myocardial function in an autonomically denervated dog model (Fig. 18-14). Echocardiographic-determined indices of myocardial function in healthy humans, including the more noteworthy measurement of the velocity of circumferential fiber shortening have not been diminished by isoflurane, desflurane, or sevoflurane.<sup>47-49</sup> However, in cardiac patients with ejection fractions above

40%, 1 MAC sevoflurane and desflurane reduced contractility, assessed as  $dp/dt_{max}$ . Despite the small reduction in baseline contractility, the anesthetics did not affect the ability of the myocardium to respond to an acute increase in cardiac preload. Thus, functional reserve of the heart was not impaired by the volatile anesthetics.<sup>57</sup> In addition, when comparing sevoflurane and desflurane to propofol in cardiac patients with impaired ventricular function after CABG surgery, the volatile anesthetics preserved and propofol worsened ventricular responses to acute increases in preload.<sup>58</sup> In patients without pre-existing diastolic dysfunction, volatile anesthetics do not have any clinically relevant negative effect on early diastolic relaxation, although resultant decrease in global atrial function may impact late diastolic left ventricular filling.<sup>59</sup>

**Figure 18-14** Myocardial contractility indices from chronically instrumented dogs.<sup>183,184</sup> For these measurements, pharmacologic blockade of the autonomic nervous system was established to eliminate neural or circulating humoral influences on the inotropic state of the heart. The conscious control data were assigned 100%, and subsequent reductions in the inotropic state are depicted for both 1 and 1.5 minimum alveolar anesthetic concentrations of sevoflurane, desflurane, and isoflurane. There were no differences between these three volatile anesthetics.  $M_w$ , slope of the regional preload recruitable stroke work relationship;  $dP/dt_{50}$ , change in pressure per unit of time.

## Other Circulatory Effects

Most of the volatile anesthetics have been studied during both controlled and spontaneous ventilation.<sup>47,49,60</sup> The process of spontaneous ventilation reduces the high intrathoracic pressures from positive pressure ventilation. The negative intrathoracic pressure during the inspiratory phase of spontaneous ventilation augments venous return and cardiac filling and improves cardiac output and BP. Spontaneous ventilation is associated with higher PaCO<sub>2</sub>, causing cerebral and systemic vascular relaxation. This contributes to an improved cardiac output via afterload reduction. Spontaneous ventilation in theory would improve the safety of volatile anesthetic administration because the anesthetic concentration that produces cardiovascular collapse exceeds the concentration that results in apnea.

Nitrous oxide is commonly combined with potent volatile anesthetics to maintain general anesthesia. Nitrous oxide has unique cardiovascular actions. It increases sympathetic nervous system activity and vascular resistance when given in a 40% concentration.<sup>50</sup> When N<sub>2</sub>O is combined with volatile anesthetics, systemic vascular resistance and BP are greater than when equipotent concentrations of the volatile anesthetics are evaluated without N<sub>2</sub>O.<sup>47,61</sup> These effects might not be due solely to sympathetic activation from N<sub>2</sub>O per se, but may be partially attributed to a decrease in the concentration of the coadministered potent volatile anesthetic required to achieve a MAC equivalent when using N<sub>2</sub>O.

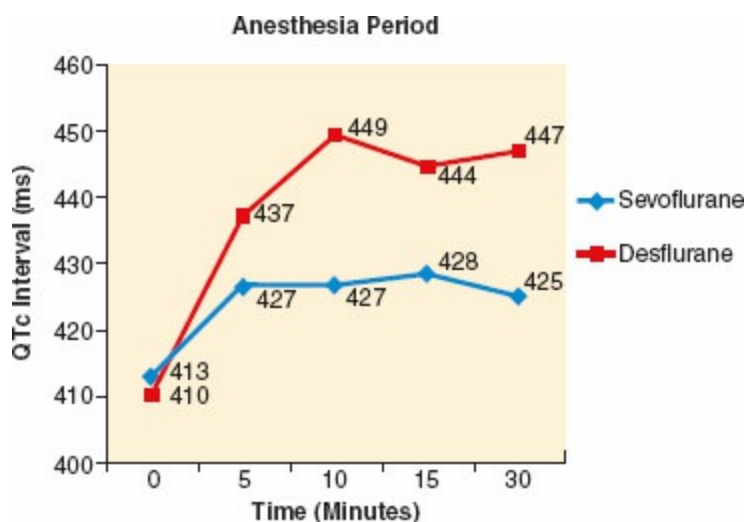

Oxygen consumption is decreased approximately 10% to 15% during general anesthesia.<sup>62</sup> The distribution of cardiac output also is altered by anesthesia. Blood flow to liver, kidneys, and gut is decreased, particularly at deep levels of anesthesia. In contrast, blood flow to the brain, muscle, and skin is increased or not changed during general anesthesia.<sup>63</sup> In humans, increases in muscle blood flow are noted with isoflurane, desflurane, and sevoflurane with minimal differences between anesthetics at equipotent concentrations.<sup>64</sup>

Isoflurane, sevoflurane, and desflurane do not sensitize the heart to the arrhythmogenic effects of epinephrine (Fig. 18-15). Volatile anesthetics have direct effects on cardiac pacemaker cells and conduction pathways.<sup>65</sup> Sinoatrial node discharge rate is slowed by the volatile anesthetics, and conduction in the His–Purkinje system and conduction pathways in the ventricle also is prolonged by the volatile anesthetics. The volatile anesthetics prolong QT<sub>c</sub> interval and in theory, especially with a baseline prolongation in myocardial repolarization, may predispose to ventricular tachyarrhythmias including *torsade de pointes*. Such an effect has been noted in a child with congenital prolonged QT syndrome.<sup>66</sup> In children studied at steady state 1 MAC, QT<sub>c</sub> was more prolonged with desflurane than sevoflurane (Fig. 18-

16).<sup>67</sup> When the effects of sevoflurane, propofol, and desflurane on QT interval dispersion and p dispersion were evaluated in adults, only desflurane prolonged intervals, although no increase in cardiac dysrhythmias was noted.<sup>68</sup>

**Figure 18-15** The dose of epinephrine associated with cardiac arrhythmias in animal and human models was least with halothane. The ether-based anesthetics—isoﬂurane, desﬂurane, and sevoflurane—required three- to sixfold greater doses of epinephrine to cause arrhythmias.

**Figure 18-16** Mean QTc intervals in children, age 1 to 14 years, after inhalation of 2% sevoflurane or 6% desflurane, both in 66% N<sub>2</sub>O/O<sub>2</sub>. (Adapted from Aypar E, Karagoz AH, Ozer S, et al. The effects of sevoflurane and desflurane anesthesia on QTc interval and cardiac rhythm in children. *Pediatr Anaesth.* 2007;17:563–567.)

### Coronary Steal, Myocardial Ischemia, and Cardiac Outcome

Isoflurane (and most other potent volatile anesthetics) increases coronary blood flow beyond that of the myocardial oxygen demand, thereby creating potential for “steal.” Steal is the diversion of blood from a myocardial bed with limited or inadequate perfusion to a bed with more adequate perfusion; especially one that has a remaining element of autoregulation.

Despite early worries that the potent vasodilation from isoflurane might cause coronary steal, clinical outcome studies have been unable to find an association between the use of isoflurane in patients undergoing coronary artery bypass graft (CABG) operations with an increased incidence of myocardial infarction or perioperative death.<sup>69,70</sup> This is in agreement with findings in a chronically instrumented dog model of multivessel coronary artery obstruction where neither isoflurane, sevoflurane, or desflurane at concentrations up to 1.5 MAC resulted in abnormal collateral coronary blood flow redistribution (steal), whereas adenosine, a potent coronary vasodilator, clearly resulted in abnormal flow distribution.<sup>71-73</sup>

Several studies in patients with coronary artery disease undergoing either noncardiac or CABG surgery have demonstrated that myocardial ischemia and outcome from sevoflurane was no different from isoflurane.<sup>74,75</sup> Desflurane also appears to result in similar outcome effects as isoflurane in cardiac patients having CABG<sup>76</sup> with one exception. In a study in which desflurane was given without opioids to patients with coronary artery disease requiring CABG surgery, significant ischemia mandating the use of  $\beta$ -blockers was noted.<sup>77</sup> Desflurane has not been evaluated in terms of ischemia and outcome in a patient population with coronary disease undergoing noncardiac surgery. Most studies would suggest that determinants of myocardial oxygen supply and demand, rather than the anesthetic, are of far greater importance to patient outcomes.

### *Cardioprotection from Volatile Anesthetics*

A preconditioning stimulus such as brief coronary occlusion and ischemia initiates a signaling cascade of intracellular events that helps protect the cardiac myocyte and reduce reperfusion myocardial injury following subsequent ischemic episodes. Ischemic preconditioning consists of early and late phase protection. The early phase, lasting approximately 2 hours, is mediated by the release of adenosine, inducing a protective signal through the activation of mitochondrial potassium channels ( $K_{ATP}$ ) and opioid and bradykinin receptors.<sup>78,79</sup> The late phase, while not as strong as the early phase, provides additional myocardial protection for 24 to 72 hours. This delayed effect relates to induction of nitric oxide synthase, superoxide dismutase, and heat-shock proteins. The volatile anesthetics given before (preconditioning) or immediately after (postconditioning) mimic ischemic preconditioning and trigger a similar cascade of intracellular events resulting in reduced myocardial injury and myocardial protection that lasts beyond the elimination of the anesthetic.<sup>79,80</sup> Numerous factors may be involved in the protection, including the sodium:hydrogen exchanger, activation of opioid, bradykinin or adenosine receptors (particularly  $\alpha_1$  and  $\alpha_2$  subtypes),

inhibitory G proteins, protein kinase C, tyrosine kinase, and potassium (K<sub>ATP</sub>) channel opening. Pharmacologic blockade of these factors reduces or eliminates the cardioprotective effect of ischemic or volatile anesthetic preconditioning.<sup>80,81</sup> Alternatively, administration of certain drugs can mimic ischemic or volatile anesthetic preconditioning. These include adenosine, opioid agonists, and K<sub>ATP</sub> channel openers.

Lipophilic volatile anesthetics diffuse through myocardial cell membranes and alter mitochondrial electron transport, leading to reactive oxygen species formation.<sup>81</sup> This may be the trigger for preconditioning via protein kinase C activation of K<sub>ATP</sub> channel opening.<sup>82,83</sup> Approximately 30% to 40% of the cardioprotection from the volatile anesthetics appears to be related to a reduced loading of calcium into the myocardial cells during ischemia. This reduction in calcium accumulation improves the recovery of contractile function following reperfusion and makes the mitochondrial membrane more permeable to ATP precursors.<sup>78</sup> Preconditioned hearts may tolerate ischemia for 10 minutes longer than nonconditioned hearts.<sup>84</sup>

While these findings generally derive from animal models, there now is increasing evidence in cardiac patient populations that anesthetic cardioprotection lessens myocardial damage and improves cardiac outcomes during “on and off pump” cardiac surgery.<sup>85,86</sup> One meta-analysis of 22 trials including nearly 2,000 patients undergoing CABG surgery found that sevoflurane and desflurane compared to a TIVA technique were associated with a 50% reduction in MI, reductions in cardiac troponin I peak levels, inotropic support, and all cause mortality, and shorter periods of mechanical ventilation and ICU stay.<sup>87</sup> Preconditioning effects of sevoflurane are noted at a minimum of 1 MAC with a dose of 1.5 MAC needed for full efficacy.<sup>78</sup> Sulfonylurea oral hyperglycemic drugs close K<sub>ATP</sub> channels, abolishing anesthetic preconditioning. They should be discontinued 24 to 48 hours prior to elective surgery in high-risk patients.<sup>80</sup> But hyperglycemia also prevents preconditioning, so insulin therapy should be started when holding oral agents.<sup>88</sup> Recent evidence suggests that volatile anesthetics as well as xenon may protect other organs from ischemic injury, including kidney, liver, and brain.<sup>89–92</sup>

**Figure 18-17** Consecutive measurements of sympathetic nerve activity (SNA; mean  $\pm$  SE) from human volunteers during induction of anesthesia with propofol and the subsequent mask administration of sevoflurane or desflurane for a 10-minute period. The inspired concentration of these anesthetics was increased at 1-minute intervals beginning after propofol administration (0.41 MAC of sevoflurane and desflurane). In both groups, propofol reduced SNA and mean arterial pressure. Desflurane resulted in significant increases in SNA that persisted throughout the 10-minute mask administration period. (Adapted from Ebert TJ, Muzi M, Lopatka CW. Neurocirculatory responses to sevoflurane in humans: a comparison to desflurane. *Anesthesiology*. 1995;83:88.)

## Autonomic Nervous System

The autonomic nervous system is modulated by baroreceptor reflex mechanisms. Studies have examined the behavior of the arterial baroreflex system during a hypotensive or hypertensive stimulus by evaluating changes in HR and sympathetic nerve activity in humans. Anesthetic mediated, dose-dependent decreases in reflex control of sympathetic output are most prominent at the 1 MAC or greater of the volatile anesthetics.<sup>93–96</sup> At these concentrations, there is a greater reduction in the reflex response to hypovolemia than at normovolemia. This may lead to earlier recognition of blood loss intraoperatively, as there is less masking of hypovolemia by sympathetic regulation of vasoconstriction and tachycardia.

Desflurane has a unique and prominent effect on sympathetic outflow in humans, which is not apparent in animal models. With increasing steady state concentrations of desflurane, there is a progressive increase in resting sympathetic nervous system activity and plasma norepinephrine levels.<sup>97</sup> Despite this increase in tonic sympathetic outflow, BP decreases similarly to sevoflurane and isoflurane (Fig. 18-12). This raises the question as to whether desflurane has the ability to uncouple neuroeffector responses. In addition, when the inspired concentration of desflurane is increased, especially to concentrations above 5% to 6%, it can cause substantial activation of the

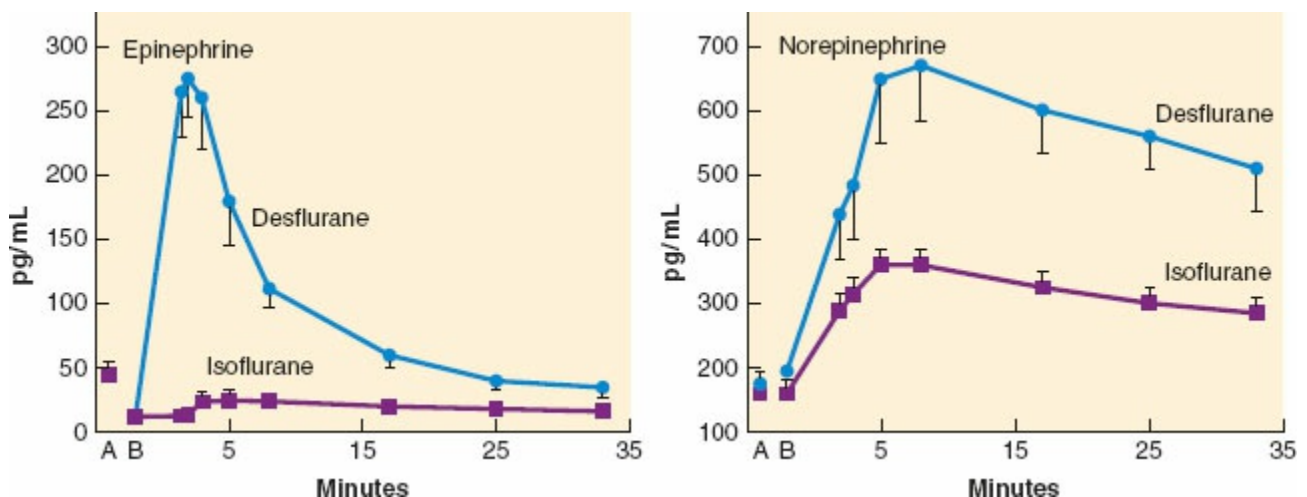

sympathetic nervous system leading to hypertension and tachycardia (Fig. 18-17).<sup>97</sup> Furthermore, the endocrine axis is activated as evidenced by 15- to 20-fold increases in plasma antidiuretic hormone, epinephrine, and norepinephrine (Fig. 18-18). The hemodynamic response persists for 4 to 5 minutes and the endocrine response persists for up to 30 minutes.<sup>46,51,52</sup> Adequate concentrations of opioids or clonidine given prior to increasing the concentration of desflurane have been shown to attenuate these responses.<sup>54-56</sup> The source of the neuroendocrine activation is likely from receptors in both the upper and lower airways that initiate the sympathetic activation.<sup>53</sup>

## The Pulmonary System

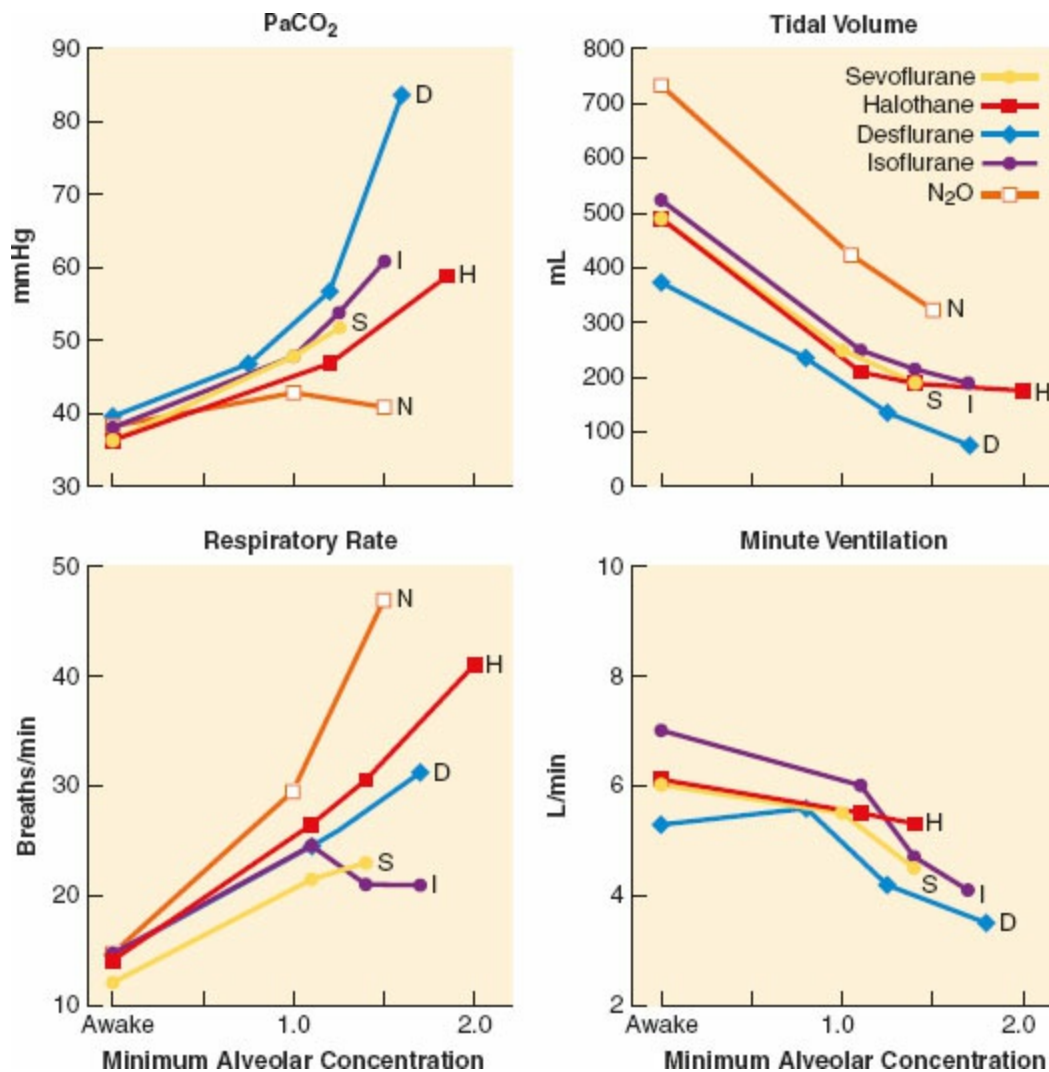

### General Ventilatory Effects

All volatile anesthetics decrease tidal volume and increase respiratory rate such that there are only minor effects on decreasing minute ventilation (Fig. 18-19). The ventilatory effects are dose-dependent, with higher concentrations of volatile anesthetics resulting in greater decreases in tidal volume and greater increases in respiratory rate, with the exception of **11** isoflurane, which does not increase respiratory rate above 1 MAC. Their net effect of a gradual decrease in minute ventilation has been associated with increasing resting PaCO<sub>2</sub>. The respiratory depression can be partially antagonized during surgical stimulation where respiratory rate and tidal volume have been shown to increase, resulting in a decrease in the PaCO<sub>2</sub>. Nitrous oxide increases respiratory rate as much or more than the inhaled anesthetics. When N<sub>2</sub>O is added to sevoflurane or desflurane, resting PaCO<sub>2</sub> decreases relative to equ-MAC concentrations of sevoflurane or desflurane in O<sub>2</sub>.

**Figure 18-18** Stress hormone responses to a rapid increase in anesthetic concentration, from 4% to 12% inspired. Volunteers given desflurane showed a larger

increase in plasma epinephrine and norepinephrine concentrations than when given isoflurane. Data are mean  $\pm$  SE. A = awake value; B = value after 32 minutes of 0.55 minimum alveolar concentration; time represents minutes after the first breath of increased anesthetic concentration. (Adapted from Weiskopf RB, Moore MA, Eger EI II, et al. Rapid increase in desflurane concentration is associated with greater transient cardiovascular stimulation than with rapid increase in isoflurane concentration in humans. *Anesthesiology*. 1994;80:1035.)

**Figure 18-19** Comparison of mean changes in resting PaCO<sub>2</sub>, tidal volume, respiratory rate, and minute ventilation in patients anesthetized with isoflurane, sevoflurane, desflurane, or N<sub>2</sub>O(N).<sup>185–187</sup> Anesthetic-induced tachypnea compensates in part for the ventilatory depression caused by all volatile anesthetics (decrease in minute ventilation and tidal volume, and concomitant increase in PaCO<sub>2</sub>). Desflurane results in the greatest increase in PaCO<sub>2</sub> with corresponding reductions in tidal volume and minute ventilation. Isoflurane, like all other inhaled agents, increases respiratory rate, but does not result in dose-dependent tachypnea.

### Ventilatory Mechanics

FRC is decreased during general anesthesia; this has been explained by a

number of mechanisms including a decrease in the intercostal muscle tone, alteration in diaphragm position, changes in thoracic blood volume, and the onset of phasic expiratory activity of respiratory muscles. About 40% of the muscular work of breathing is via intercostal muscles and about 60% is from the diaphragm. During anesthesia, the diaphragmatic muscle function is relatively spared when contrasted to the parasternal intercostal muscles. However, inspiratory rib cage expansion is reasonably well maintained during anesthesia because of preserved activity of the scalene muscles. Expiration is generally considered a passive function mediated by the elastic recoil of the lung. The process of applying a resistance or load to expiration typically results in a slowing of respiration, but under anesthesia, further responses include a substantial asynchrony of the thoracic movements with respiration. This suggests that in patients with pulmonary disease associated with increased expiratory resistance, the act of spontaneous ventilation during general anesthesia might be poorly tolerated.

### *Response to Carbon Dioxide and Hypoxemia*

In conscious humans, the central chemoreceptors respond vigorously to changes in arterial carbon dioxide tension such that minute ventilation increases 3 L/min per a 1 mmHg increase in PaCO<sub>2</sub>. All of the inhaled anesthetics produce a dose-dependent depression of the ventilatory response to hypercarbia (Fig. 18-20). The addition of N<sub>2</sub>O to a volatile anesthetic has been thought to diminish PaCO<sub>2</sub> responses less than an equi-MAC dose of the anesthetic alone. The threshold where respiratory drive ceases is called the apneic threshold. It is generally 4 to 5 mmHg below the prevailing resting PaCO<sub>2</sub> in a spontaneously breathing patient. It is unrelated to the slope of the CO<sub>2</sub> response curves or to the level of the resting PaCO<sub>2</sub>. The clinical relevance of this threshold may be realized when assisting ventilation in an anesthetized patient who is breathing spontaneously. This only serves to lower the PaCO<sub>2</sub> to approach that of the apneic threshold, therefore mandating more control of ventilation.

**Figure 18-20** All inhaled anesthetics produce similar dose-dependent decreases in the ventilatory response to carbon dioxide (CO<sub>2</sub>). N<sub>2</sub>O, nitrous oxide. (Adapted from Eger EI II. Desflurane. *Anesth Rev.* 1993; 20:87.)

Inhaled anesthetics, including N<sub>2</sub>O, also produce a dose-dependent attenuation of the ventilatory response to hypoxia. This action appears to depend on the peripheral chemoreceptors. In fact, even subanesthetic concentrations of volatile anesthetics (0.1 MAC) elicit anywhere from a 25% to 75% depression of the ventilatory drive to hypoxia (Fig. 18-21). The extreme sensitivity of the volatile anesthetics to inhibit ventilatory responses to hypoxia has important clinical implications, especially in patients who depend on hypoxic drive to set their level of ventilation, such as those with chronic respiratory failure or patients with obstructive sleep apnea. Residual effects of volatile anesthetics would be unwanted in the recovery room. In this regard, the short-acting anesthetics (sevoflurane and desflurane) may prove advantageous because of their more rapid washout and their minimal effect on hypoxic sensitivity at subanesthetic concentrations.

**Figure 18-21** Influence of 0.1 minimum alveolar concentration (MAC) of four volatile anesthetic agents on the ventilatory response to a step decrease in end-tidal oxygen concentration. Values are mean  $\pm$  SD. Subanesthetic concentrations of the volatile anesthetics, except desflurane and sevoflurane, profoundly depress the response to hypoxia. (Adapted from Sarton E, Dahan A, Teppema L, et al. Acute pain and central nervous system arousal do not restore impaired hypoxic ventilatory responses during sevoflurane sedation. *Anesthesiology*. 1996;85:295.)

### **Bronchiolar Smooth Muscle Tone**

Bronchoconstriction under anesthesia can result: (1) from direct stimulation of the laryngeal and tracheal areas, (2) from the administration of adjuvant drugs that cause histamine release, and (3) from noxious stimuli activating vagal afferent nerves. The reflex response to these stimuli may be greater in lightly versus deeply anesthetized patients.<sup>98</sup> The response also is enhanced in patients with known reactive airway disease, including those requiring bronchodilator therapy or those with chronic smoking histories.

Airway smooth muscle extends as far distally as the terminal bronchioles and is under the influence of both parasympathetic and sympathetic nerves. The volatile anesthetics relax airway smooth muscle primarily by directly reducing smooth muscle tone and indirectly by inhibiting the reflex neural pathways.<sup>99</sup> Direct effects of the volatile anesthetics partially depend on an intact bronchial epithelium, suggesting that epithelial damage or inflammation secondary to asthma or a respiratory virus may lessen their bronchodilating effect.<sup>100</sup> In animal models studying fourth order bronchi, desflurane and sevoflurane were better bronchodilators than isoflurane.<sup>100</sup> The dilation was epithelium-dependent and mediated in part by a cyclooxygenase product and nitric oxide. In humans, early administration of desflurane after tracheal intubation and high concentrations (1.5 MAC) at steady state lessen the decrease in respiratory system resistance seen with sevoflurane (Fig. 18-22).<sup>101,102</sup> This may be attributed to a direct effect on bronchial smooth muscle from the pungency of desflurane. Volatile anesthetics have been used effectively to treat status asthmaticus when other conventional treatments have failed, and appear to bronchodilate in patients with COPD.<sup>103,104</sup>

### **Mucociliary Function**

Ciliated respiratory epithelium extends from the trachea to the terminal bronchioles. Cells and glands in the tracheobronchial tree secrete mucus that captures surface particles for transport via ciliary action. There are a number of factors involved in diminished mucociliary function, particularly in the

mechanically ventilated patient where dried, inspired gases impair ciliary movement, thicken the protective mucus, and reduce the ability of mucociliary function to transport surface particles out of the airway. Volatile anesthetics and N<sub>2</sub>O reduce ciliary movement and alter the characteristics of mucus.<sup>105</sup> Smokers have impaired mucociliary function, and the combination of a volatile anesthetic in a smoker who is mechanically ventilated sets up a scenario for inadequate clearing of secretions, mucus plugging, atelectasis, and hypoxemia.

### ***Pulmonary Vascular Resistance***

Although systemic vascular smooth muscle is notably affected by the volatile anesthetics, the pulmonary vascular relaxation from clinically relevant concentrations of inhaled anesthetics is minimal. The small amount of pulmonary vasodilation from volatile anesthetics is offset by anesthetic-related decreases in cardiac output, resulting in little or no change in pulmonary artery pressures and pulmonary blood flow. Even N<sub>2</sub>O, which has little effect on cardiac output and pulmonary blood flow, has at most a small effect to increase pulmonary vascular resistance. However, pulmonary vascular constriction from N<sub>2</sub>O may be magnified in patients with resting pulmonary hypertension.<sup>106</sup>

Perhaps more important in terms of volatile anesthetics and pulmonary blood flow is their potential to attenuate hypoxic pulmonary vasoconstriction (HPV). During periods of hypoxemia, HPV reduces blood flow to underventilated areas of the lung, thereby diverting blood flow to areas of the lung with greater ventilation. The net effect is to improve the V/Q matching, resulting in a reduced amount of venous admixture and improved arterial oxygenation. Although all of the modern inhaled anesthetics in high concentrations have been shown to attenuate HPV in animal models, the situation is less clear in patient studies. This may reflect the multifactorial effects of the volatile anesthetics on factors involved in pulmonary blood flow, including their cardiovascular, autonomic, and humoral actions. Furthermore, nonpharmacologic variables impair HPV, including surgical trauma, temperature, pH, PaCO<sub>2</sub>, size of the hypoxic segment, and intensity of the hypoxic stimulus. One-lung ventilation (OLV) serves as a model where HPV should lessen the expected decrease in PaO<sub>2</sub> and intrapulmonary shunt fraction (Q<sub>s</sub>/Q<sub>t</sub>). In patients undergoing OLV during thoracic surgery, volatile anesthetics have had minimal effects on PaO<sub>2</sub> and Q<sub>s</sub>/Q<sub>t</sub> when changing from two-lung ventilation to OLV (Fig. 18-23).<sup>107</sup>

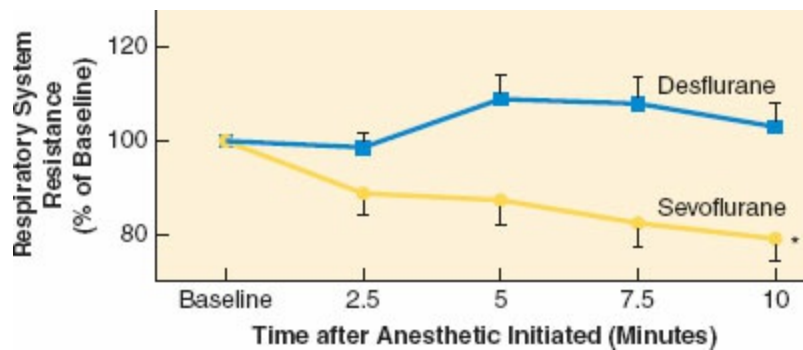

### **Hepatic Effects**

Unlike most intravenous anesthetic drugs, modern-day volatile anesthetics undergo minimal liver metabolism, and because they are excreted primarily via the lungs, it is not surprising that they minimally affect hepatic function.

**12** The various factors that are known to affect drug metabolism, such as age, disease, genetics, and enzyme-inducing agents, have minor effects on the excretion of the volatile anesthetics.

There are two distinct mechanisms by which anesthetics have caused hepatitis; both discussed in [Chapter 46: The Liver: Surgery and Anesthesia](#), on hepatic anatomy, function, and physiology.

Another consideration is convincing evidence that volatile anesthetics can infer organ protection from ischemic injury (discussed earlier in the chapter). When sevoflurane was compared to propofol anesthesia in a prospective, randomized study of 320 patients undergoing CABG surgery, postoperative biochemical markers of hepatic dysfunction were lower after the sevoflurane-based anesthetic.<sup>91</sup>

**Figure 18-22** Changes in respiratory system resistance expressed as a percentage of the baseline recorded after tracheal intubation but prior to administration of sevoflurane or desflurane to the inspired gas mixture. Airway resistance responses to sevoflurane were significantly different from desflurane ( $*p < 0.05$ ). (Adapted from Goff MJ, Arain SR, Ficke DJ, et al. Absence of bronchodilation during desflurane anesthesia: a comparison to sevoflurane and thiopental. *Anesthesiology*. 2000;93:404.)

## Neuromuscular System and Malignant Hyperthermia

The inhaled anesthetics have two important actions on neuromuscular function: (1) they directly relax skeletal muscle through a dose-dependent effect and (2) they potentiate the action of neuromuscular blocking drugs.<sup>108,109</sup> Relaxation of skeletal muscle is most prominent for potent volatile anesthetics above 1.0 MAC, with an effect enhanced by 40% in patients with myasthenia gravis.<sup>110</sup> Conversely, nitrous oxide does not affect skeletal muscle relaxation.

Volatile anesthetic potentiation of neuromuscular blockade has been well documented. For example, the infusion rate of rocuronium required to maintain neuromuscular blockade is 30% to 40% less during isoflurane,

desflurane, and sevoflurane administration compared with propofol, with a similar effect observed with cisatracurium.<sup>109,111</sup> While the mechanism of volatile anesthetic potentiation of the neuromuscular blocking drugs is not entirely clear, it appears to be largely because of a postsynaptic effect at the nicotinic acetylcholine receptor located at the neuromuscular junction. Specifically, at the receptor level, the volatile anesthetics act synergistically with the neuromuscular blocking drugs to enhance their action.<sup>112</sup> The degree of enhancement is related to their aqueous concentration so that at equi-MAC concentrations, the less potent anesthetics (e.g., desflurane and sevoflurane vs. isoflurane) should have a greater inhibitory effect on neuromuscular transmission.<sup>113</sup> However, at equipotent concentrations, desflurane, sevoflurane, and isoflurane acted similarly to enhance the effect of cisatracurium on neuromuscular function.<sup>109</sup> This may relate to structural differences of the benzylisoquinolines versus aminosteroid neuromuscular blocking drugs.

**Figure 18-23** Shunt fraction (**top panel**) and the alveolar–arterial oxygen gradient (**bottom**) immediately before, during, and after one-lung ventilation (OLV) in patients anesthetized with desflurane or isoflurane. Data are means. (Adapted from Pagel PS, Fu JL, Damask MC, et al. Desflurane and isoflurane produce similar alterations in systemic and pulmonary hemodynamics and arterial oxygenation in patients undergoing one-lung ventilation during thoracotomy. *Anesth Analg*. 1998;87:800.)

Malignant hyperthermia is a clinical syndrome of acute, uncontrolled, increased skeletal muscle metabolism resulting in heightened oxygen

consumption, lactate formation, heat production, and rhabdomyolysis. The hallmark findings of MH are a rapidly rising temperature, increasing up to 1°C every 5 minutes along with increasing end-tidal CO<sub>2</sub>, arrhythmias, mixed respiratory/metabolic acidosis, and skeletal muscle rigidity.<sup>114</sup> Susceptibility to MH is an inherited autosomal dominant genetic disorder with reduced penetrance and variable expression. While N<sub>2</sub>O and xenon are considered safe in MH-susceptible patients, all volatile anesthetics serve as triggers for MH in these patients.<sup>115,116</sup>

13

## Genetic Effects, Obstetric Use, and Effects on Fetal Development

The possibility of a health hazard from brief but chronic exposures to volatile anesthetics directly or as waste gases has been sought for several decades, and is probably nonexistent or at best minimal. The Ames test has been applied as a test for mutagenicity or carcinogenicity and has been negative for isoflurane, desflurane, sevoflurane, and N<sub>2</sub>O. Genotoxicity can be inferred by demonstrating sister chromatid exchanges (SCE) in lymphocytes from peripheral blood. Desflurane but not sevoflurane transiently increased the frequency of SCE.<sup>117,118</sup> The clinical implications of these findings are not clear in relation to the negative Ames test. Nonetheless, the National Institute for Occupational Safety and Health has set exposure limits of 25 ppm for N<sub>2</sub>O and 2 ppm for volatile anesthetics. Scavenging systems seem important in limiting anesthesia provider exposure. In a recent study evaluating anesthesia providers working in an unscavenged OR where average sevoflurane exposure was 9 ppm and N<sub>2</sub>O exposure was 119 ppm, SCE were noted at nearly three times the control group, and the SCE effect was reversible after 2 months out of the OR.<sup>119</sup> In contrast, when a scavenging system was in place and exposures were limited to solely sevoflurane with a time weighted average of 0.2 ppm, only minor increases in SCE could be detected from lymphocytes.<sup>120</sup>

Volatile anesthetics can be teratogenic in animals,<sup>121</sup> but do not cause teratogenicity in humans. Mazze and Källén<sup>122</sup> evaluated 5,405 surgeries in 2 million patients and found no increase in teratogenicity. Nitrous oxide decreases the activity of vitamin B<sub>12</sub>-dependent enzymes, methionine synthetase (MS) and thymidylate synthetase. The mechanism appears to be an irreversible oxidation of the cobalt atom of vitamin B<sub>12</sub> by N<sub>2</sub>O; for example, there is a 50% inactivation of MS after exposure to 46 minutes of 70% N<sub>2</sub>O. This might affect the rapidly developing embryo/fetus because MS and thymidylate synthetase are involved in the formation of myelin and the formation of DNA, respectively. Megaloblastic changes in bone marrow are consistently observed in patients exposed to N<sub>2</sub>O for 24 hours, and 4 days of exposure to N<sub>2</sub>O has resulted in agranulocytosis. Furthermore, animals

exposed to 15% N<sub>2</sub>O for several weeks developed neurologic changes including spinal cord and peripheral nerve degeneration and ataxia. A sensory motor polyneuropathy that is often combined with signs of posterior lateral spinal cord degeneration has been described in humans who chronically inhale N<sub>2</sub>O for recreational use.<sup>123</sup>

Uterine smooth muscle tone is diminished by volatile anesthetics in similar fashion to the effects of volatile anesthetics on vascular smooth muscle. There is a dose-dependent decrease in spontaneous myometrial contractility that is consistent among the volatile anesthetics. Desflurane and sevoflurane also inhibit the frequency and amplitude of myometrial contractions induced by oxytocin in a dose-dependent manner.<sup>124</sup> Uterine relaxation/atony can become problematic at concentrations of volatile anesthesia greater than 1 MAC, and might delay the onset time of newborn respiration.<sup>125</sup> Consequently, a common technique used to provide general anesthesia for urgent cesarean sections is to administer low concentrations of the volatile anesthetic, such as 0.5 to 0.75 MAC, combined with N<sub>2</sub>O. This decreases the likelihood of uterine atony and blood loss, especially at a time after delivery when oxytocin responsiveness of the uterus is essential. In some situations, uterine relaxation may be desirable, such as to remove a retained placenta. In this case, a brief, high concentration of a volatile anesthetic may be advantageous.

There has been an ongoing concern about the incidence of spontaneous abortions in operating room personnel chronically exposed to trace concentrations of inhaled anesthetics, especially N<sub>2</sub>O.<sup>126</sup> Early epidemiologic studies suggested that operating room personnel had an increased incidence of spontaneous abortions and congenital abnormalities in offspring. However, subsequent analysis of the data suggests that inaccurate study design, confounding variables, and nonresponders might have led to flawed conclusions.<sup>127</sup> In prospective studies, no causal relationship has been shown between exposure to waste anesthetic gases and adverse health effects, regardless of the presence or absence of scavenging systems. Despite the unproven influence of trace concentrations of the volatile anesthetics on fetal development and spontaneous abortions, concerns for an adverse influence have resulted in the use of scavenging systems to remove anesthetic gases from operating and recovery rooms and have led to the establishment of standards for waste gas exposure.

In terms of neonatal effects from general anesthesia, Apgar scores and acid–base balance are not affected by anesthetic technique, such as spinal versus general.<sup>128</sup> More sensitive measures of neurologic and behavioral function, such as the Scanlon Early Neonatal Neurobehavioral Scale and the Neurologic and Adaptive Capacities Score (NACS) indicate some transient depression of scores following general anesthesia that resolves at 24 hours

after delivery.<sup>128,129</sup>

Neonatal brain development is a complicated yet intricate process of excess neuron generation followed by apoptosis (selective cell death).<sup>130</sup> The “threshold effect” for neurotoxicity has been established in *in vivo* neonatal murine models, with accelerated neuronal apoptosis and degenerative effects noted in the temporal/somatosensory cortices, frontal cortex, and hippocampus related to increasing anesthetic exposure.<sup>130,131</sup> Observed cognitive and behavioral deficits in these models have been associated with disturbances in neuronal circuitry, mitochondrial morphology, and dendritic spine development. In addition, sevoflurane has been demonstrated to produce the least neurodegeneration compared to equipotent exposures of isoflurane and desflurane.<sup>130,132</sup> It is unclear if the findings in rodents can be extrapolated to humans, as the period of peak vulnerability with rapid synaptogenesis in rodents is very brief and easily exposed to an anesthetic. The equivalent period in humans extends from mid-gestation to several years after birth.<sup>133,134</sup> Human retrospective observational studies have demonstrated higher rates of learning disorders and behavioral impairment among children with multiple exposures to anesthesia.<sup>135</sup> Interpretation of these studies is limited by the ability to distinguish between anesthetic-induced neurotoxicity and confounders such as comorbidity, and the stresses of surgery and hospitalization. Prospective trials are currently ongoing and may impact future practice.<sup>136,137</sup>

## Anesthetic Degradation by Carbon Dioxide Absorbers

### Compound A

Sevoflurane undergoes base-catalyzed degradation in carbon dioxide absorbents to form a vinyl ether called *compound A*. The production of compound A is enhanced in low flow or closed circuit breathing systems and by warm or very dry CO<sub>2</sub> absorbents.<sup>138,139</sup> Dessicated barium hydroxide lime produces more compound A than soda lime and this can be attributed to slightly higher absorbent temperature during CO<sub>2</sub> extraction.<sup>140</sup> Dessicated barium hydroxide lime also has been implicated in the heat and fires associated with sevoflurane, discussed later. This absorbent has been removed from the US market.

In patients and volunteers receiving sevoflurane in closed circuit or low-flow delivery systems, inspired compound A concentrations averaged 8 to 24 ppm and 20 to 32 ppm with soda lime and barium hydroxide lime, respectively.<sup>141–144</sup> Total exposures as high as 320 to 400 ppm/hr have had no clear effect on clinical markers of renal function.<sup>145–147</sup> In randomized and prospective volunteer and patient studies, no adverse renal effects from low-

flow (0.5 to 1.0 L/min) or closed circuit sevoflurane anesthesia were detected using both standard clinical markers of renal function (serum creatinine and blood urea nitrogen concentrations) and experimental markers of renal function and structural integrity (proteinuria, glucosuria, and enzymuria).<sup>142-144,146,148-150</sup> In a prospective, multicenter, randomized study in patients with preexisting renal disease, there were no adverse renal effects of long duration, low-flow sevoflurane.<sup>151,152</sup> The majority of countries that have approved sevoflurane for clinical use have no flow restriction, perhaps because of the proven safety of sevoflurane in scientific studies. Pharmacovigilance supports the science; there has not been a single case report of renal injury directly attributable to sevoflurane after nearly two decades of use.

One explanation for the inconsistency between the early rat studies and human studies in terms of renal injury from compound A may be related to species differences in the metabolism of compound A. The biodegradation of compound A to cysteine conjugates and the further action of a renal enzyme called  $\beta$ -lyase on the conjugates can result in formation of a potentially toxic thiol. The  $\beta$ -lyase-dependent metabolism pathway in humans is far less extensive than the  $\beta$ -lyase pathway in rats (8 to 30 times less active).<sup>153</sup> Thus, compared with rats, humans (1) receive markedly lower doses of compound A, (2) metabolize a lower fraction of compound A via the renal  $\beta$ -lyase pathway, and (3) have not suffered renal injury.

### **Carbon Monoxide and Heat**

Carbon dioxide (CO<sub>2</sub>) absorbents degrade sevoflurane, desflurane, and isoflurane to carbon monoxide (CO) when the normal water content of the absorbent (13% to 15%) is markedly decreased to less than 5%.<sup>154-156</sup> **14** The degradation is the result of an exothermic reaction of the anesthetics with the absorbent. There are no clinically useful humidification detectors in current systems that house the CO<sub>2</sub> absorbents on modern day anesthetic machines. Formation of CO is dependent on both the anesthetic molecular structure and the presence of a strong base in the carbon dioxide absorbent.<sup>155</sup> Desflurane and isoflurane contain a difluoromethoxy moiety that is essential for the formation of CO. When studies are conducted with dry CO<sub>2</sub> absorbents maintained at or just above room temperature, desflurane given at just under 1 MAC produced up to 8,000 ppm of CO versus 79 ppm with nearly 2 MAC sevoflurane.<sup>156</sup> In desiccated barium hydroxide, CO production from desflurane was nearly threefold higher than with soda lime. Instances of CO poisoning of patients have been reported in situations where the CO<sub>2</sub> absorbent presumably has been desiccated because an anesthetic machine had been left on with a high FGF passing through the CO<sub>2</sub> absorbent over an

extended period of time.<sup>157–160</sup> In an experimental setting, drying of barium hydroxide with 10 L/min FGF for 24 hours resulted in significant CO production from desflurane, whereas 14 hours of drying did not result in CO production from desflurane.<sup>161</sup>

Higher temperatures of the CO<sub>2</sub> absorbents can promote CO formation. Lower FGFs increase the normal (25 to 45°C) canister temperature. In a laboratory setting where sevoflurane was administered through desiccated barium hydroxide, the exothermic reaction increased canister temperature above 80°C, resulting in significant CO production.<sup>154</sup> Although desflurane produces the most CO with desiccated CO<sub>2</sub> absorbers, the reaction with sevoflurane produces the most heat.<sup>162</sup> The strong exothermic reaction with significant heat production has caused fires and patient injuries.<sup>163–165</sup> Although sevoflurane is not flammable at up to 11% concentrations, other heat-induced degradation products, for example, formaldehyde, methanol, and formate have been identified,<sup>166</sup> and these alone or in combination with oxygen might be flammable at high canister temperatures. An important safety initiative in the United States has led to the removal of barium hydroxide as a CO<sub>2</sub> absorbent from the anesthesia marketplace.

There are newer CO<sub>2</sub> absorbents that do not degrade anesthetics (to either compound A or CO), and they reduce exothermic reactions (Figure 18-24).<sup>167</sup> Although they have a lower CO<sub>2</sub> absorptive capacity than soda lime, their benefit may be substantial. Adoption of these new absorbents into routine clinical practice is consistent with the patient safety goals of our anesthesia society.

## Generic Sevoflurane Formulations

Generic formulations of sevoflurane were introduced into the clinical market in 2006. The methods for synthesizing sevoflurane differ between manufacturers.<sup>168</sup> Although the active ingredient of sevoflurane from different manufacturers is chemically equivalent, the water content in the formulations differs and this accounts for their different resistances to degradation when exposed to a Lewis acid (metal halides and metal oxides that are present in modern-day vaporizers). Adding water to the formulation inhibits the action of Lewis acids to degrade sevoflurane to hydrofluoric acid. Shortly after Abbott Labs introduced sevoflurane to the US market in 1995, the formulation of sevoflurane was changed to contain 300 to 400 ppm of water, based on an adverse experience with hydrofluoric acid formation from their original low water formulation. One generic formulation with a low water content has been shown in clinical and laboratory studies to degrade to toxic and corrosive hydrogen fluoride.<sup>169</sup> Whether these differences in formulation lead to patient safety issues remains to be determined.

**Figure 18-24** Compound A levels produced from three non-desiccated carbon dioxide absorbents during 1 minimum alveolar concentration sevoflurane anesthesia delivered to volunteers at 1 L/min fresh gas flow (mean  $\pm$  SE). Gas samples were taken from the inspired limb of the anesthesia circuit. \*Different from barium hydroxide lime or soda lime ( $p < 0.05$ ). (Adapted from Mchaourab A, Arain SR, Ebert TJ. Lack of degradation of sevoflurane by a new carbon dioxide absorbent in humans. *Anesthesiology*. 2001;94:1007.)

## Anesthetic Metabolism

### Fluoride-induced Nephrotoxicity

The metabolism of anesthetic gases has the potential to adversely affect organs via toxicity from the metabolite. For example, enflurane metabolism results in a well-described injury to renal collecting tubules.<sup>170,171</sup> The nephrotoxicity has been attributed to an increase in plasma fluoride and presents as a renal concentrating defect that is unresponsive to vasopressin and is characterized by dilute polyuria, dehydration, serum hypernatremia, hyperosmolality, elevated blood urea nitrogen, and creatinine. The traditional “fluoride toxicity” hypothesis stated that both the duration of the high systemic fluoride concentrations (area under the fluoride-time curve) and the peak fluoride concentration (peaks above 50  $\mu$ M appear to represent the toxic threshold) were related to nephrotoxicity. Sevoflurane undergoes 5% metabolism leading to transient increases in serum fluoride concentrations without a renal-concentrating defect. The safety of sevoflurane may be the result of a rapid decline in plasma fluoride concentrations because of less availability of the anesthetic for metabolism from a fast elimination compared with enflurane.<sup>172</sup> In addition, renal defluorination of sevoflurane is minimal and may add to the absence of an adverse renal-concentrating effect.<sup>173</sup>

## Clinical Utility of Volatile Anesthetics

### For Induction of Anesthesia

The appeal of mask induction in the adult population centers on the potential

safety and utility of this technique.<sup>174-176</sup> Sevoflurane is potent, poorly soluble in blood, nonpungent, and therefore inhaled easily. Spontaneous ventilation is preserved with a gas induction since patients essentially regulate their own depth of anesthesia (too much sevoflurane would suppress ventilation). Clinical studies indicate that stage two excitation is avoided with high concentrations of sevoflurane. The typical time to loss of consciousness is 60 seconds when delivering 8% sevoflurane via the face mask. Sevoflurane also has been administered by mask as an approach to the difficult adult airway because it preserves spontaneous ventilation and does not cause salivation.<sup>177</sup> Laryngeal mask placement can be successfully achieved 2 minutes after administering 7% sevoflurane via the face mask.<sup>176</sup> The addition of N<sub>2</sub>O to the inspired gas mixture does not add significantly to the induction sequence. The gas induction technique is improved by pretreatment with benzodiazepines and worsened with opioid pretreatment because of apnea.<sup>175</sup> Importantly, patient acceptance of this technique has been relatively high, exceeding 90%.<sup>174</sup>

### **For Maintenance of Anesthesia**

The volatile anesthetics are clearly the most popular drug used to maintain anesthesia. They are easily administered via inhalation, they are readily titrated, they have a high safety ratio in terms of preventing recall, and the depth of anesthesia can be quickly adjusted in a predictable way while monitoring tissue levels via end-tidal concentrations. They are effective regardless of age or body habitus. They have some properties that prove beneficial in the operating room, including relaxation of skeletal muscle, preservation of cardiac output and CBF, relatively predictable recovery profiles, and organ protection from ischemic injury. Some of the drawbacks to the use of the current volatile anesthetics are the absence of analgesic effects, their association with postoperative nausea and vomiting, their potential for carbon monoxide poisoning and hepatitis, their ability to induce neuroapoptosis leading to memory deficits in neonatal animal models, and greenhouse gas effects adding to the potential for global warming.<sup>178-180</sup>

## KEY POINTS

- 1 The ideal intravenous anesthetic would cause hypnosis and amnesia with a rapid onset, minimal cardiovascular and respiratory effects, and rapid metabolism.
- 2 Context-sensitive half-time is defined as the time to achieve a 50% reduction in concentration after stopping a continuous infusion. Context-sensitive half-time demonstrates the influence of the distributive process in governing drug disposition.
- 3 The mechanism by which the unconscious state is attained by propofol is complicated, but primarily occurs via enhancement of GABA inhibitory pathways.
- 4 The rapid and smooth induction and emergence from anesthesia helped transform propofol into an intravenous sedative-hypnotic that is a viable alternative to standard inhalational agents and other intravenous drugs.
- 5 Etomidate is a hemodynamically stable induction medication with a relatively large safety margin. Adrenocortical suppression is a recognized adverse effect of etomidate.
- 6 Ketamine causes “dissociative anesthesia” acting through the *N*-methyl-D-aspartate (NMDA) receptor, and is associated with nystagmus, significant analgesia, and unconsciousness.
- 7 Dexmedetomidine, an  $\alpha_2$  agonist, has been used for ICU sedation in mechanically ventilated patients, for procedural sedation, and as an adjunct to general anesthesia. Dexmedetomidine is unique as a sedative in that it has limited respiratory depressant effects.
- 8 Benzodiazepines are frequently used to produce several clinically desirable effects: anxiolysis, anterograde amnesia, sedation, and hypnosis.
- 9 The mechanism of action of barbiturates involves cortical and brainstem GABA inhibitory pathways, leading to loss of consciousness, as well as respiratory and cardiovascular depression.
- 10 New drugs are being developed in an effort to achieve the ideal intravenous anesthetic with a short duration of action, a short context-sensitive half-time that allows for infusion administration, and minimal adverse effects.

## Pharmacokinetics: General Principles for Intravenous Anesthetics

Traditionally, intravenous anesthetics have been utilized for the induction of anesthesia. Thiopental was introduced into clinical practice in 1934 and was the gold standard for intravenous anesthetics for 50 years. Thiopental had a rapid, smooth onset of sedative and hypnotic effects, predictable pharmacokinetics, and a rapid and smooth emergence. However, thiopental has a long context-sensitive half-time that made it less ideal for use as an infusion. A review article from 1989 stated that the use of intravenous anesthetics for maintenance was unpopular because bolus administration resulted in swings in hemodynamics and anesthetic level.<sup>1</sup> The introductions of anesthetics with shorter durations (midazolam, propofol, remifentanyl) and the development of variable rate infusion pumps allowed for routine use of intravenous anesthetics for maintenance. Combination of these modalities with a depth of anesthesia monitor has been utilized to create a closed-loop automated anesthesia delivery system. Intravenous anesthetics are now a key component of modern anesthesia practice.

**Table 19-1** Properties of the Ideal Intravenous Anesthetic Agent

<p><b><i>Pharmacodynamic/pharmacokinetic properties</i></b></p> <p>Hypnosis and amnesia            Rapid onset (time of one arm–brain circulation)            Rapid metabolism to inactive metabolites            Minimal cardiovascular and respiratory depression            No histamine release or hypersensitivity reactions            Nontoxic, nonmutagenic, noncarcinogenic            No untoward neurologic effects, such as seizures, myoclonus, antanalgesia, neurotoxicity            Other beneficial effects: analgesia, antiemetic, neuroprotection, cardioprotection            Pharmacokinetic-based models to guide accurate dosing            Ability to continuously monitor delivery</p> <p><b><i>Physiochemical properties</i></b></p> <p>Water-soluble            Stable formulation, nonpyrogenic            Nonirritating: painless on intravenous injection            Small volume needed for induction            Inexpensive to prepare and formulate            Antimicrobial preparation</p>

From Hemmings HC. The pharmacology of intravenous anesthetic induction agents: a primer. *Anesthesiol News*. 2010;October:9–16.

**1** No single anesthetic agent is perfect. The characteristics of the ideal intravenous anesthetic agent were described by Hemmings and are outlined in [Table 19-1](#).<sup>2</sup> The ideal intravenous anesthetic would cause hypnosis and amnesia with a rapid onset (time of one arm–brain circulation), minimal cardiovascular and respiratory effects, and rapid metabolism. Propofol has become the new “gold standard” in anesthesia practice, with a rapid onset, rapid recovery after bolus administration from redistribution, and utility as a continuous infusion. Propofol is remarkable for how patients are

awake and oriented after administration with lack of “hangover” effect that was associated with older anesthetics. Added benefits of propofol include its antiemetic properties. Propofol has been used in multiple different settings: (1) induction of anesthesia, (2) maintenance of anesthesia, either with volatile anesthetics or as a component of total intravenous anesthesia (TIVA), and (3) monitored anesthesia care (MAC) sedation for minor procedures. Propofol is not without its problems. It causes hypotension, respiratory depression, pain with injection, and has a prolonged duration with continuous infusion. Prolonged infusion can cause propofol infusion syndrome (PRIS) (association with doses of 4 mg/kg/hr for >48 hours).<sup>3</sup> Future medications will likely improve on our currently available anesthetics.

Intravenous anesthetics have a rapid onset after administration. They rapidly distribute to higher perfused and vessel-rich tissues. Their lipophilicity allows for rapid crossing of the blood–brain barrier. The slight delay between target blood concentration and effect organ (brain) response is known as hysteresis. This delay occurs because of differences between peak plasma concentration and peak drug concentration in the brain. The action of a single bolus injection is terminated by redistribution of the anesthetic to lean tissues such as muscle. This property of intravenous anesthetics is key to understanding their pharmacokinetics in relation to continuous infusion and maintenance. An initial bolus or loading dose of an anesthetic establishes the desired blood concentration of the drug. Redistribution of intravenous anesthetics to nonactive tissues accounts for part of their initial clearance; however, this becomes less important as those tissues equilibrate with the blood. Therefore, the rate of infusion of an intravenous anesthetic for maintenance of anesthesia decreases over the duration of an infusion to maintain the desired blood concentration.

An understanding of the pharmacokinetics of intravenous anesthetics is important to understanding their administration. Following a bolus of an intravenous drug, the plasma concentration over time resembles the curve in [Figure 19-1](#). This graph shows the blood concentration of an intravenous anesthetic (i.e., propofol) after bolus injection. The curve can be explained by a triexponential equation. Essentially, there are three phases that occur after a bolus injection of propofol.<sup>4</sup> The first phase is a rapid distribution phase; propofol rapidly distributes from the plasma to peripheral tissues. The second phase is a slow distribution phase; propofol continues to distribute to other tissues concurrent with return of drug to the plasma from the rapid distribution tissue. The last phase is the terminal phase, or elimination phase, where propofol is removed from the body.

**Figure 19-1** Plasma concentration after bolus injection of an intravenous anesthetic. Decreases in blood concentration occur in three components corresponding to rapid distribution (A), slow distribution (B), and elimination (C). The individual lines associated with each component term are also shown. The triexponential curve represents the algebraic sum of the individual exponential functions. The y-axis intercepts of the curve peel are shown as A, B, and C. These are present as coefficients of the triexponential equation. (Adapted with permission from Struys MMRF, De Smet T, Glen JB, et al. The history of target-controlled infusion. *Anesth Analg.* 2016;122(1):56–69.)

**Figure 19-2** Hydraulic depiction of a three-compartment model.  $r(t)$  represented a drug infusion via a syringe pump adding drug to the blood.  $CA_1$  represents the central

compartment (blood). Administered medication will distribute to the peripheral compartments ( $CA_2$ ,  $CA_3$ ), which affects the drug's concentration in the blood. Ultimately the drug is eliminated by the body, depicted as  $G_1$ . (Adapted with permission from Hughes MA, Glass PS, Jacobs JR. Context-sensitive half time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology*. 1992;76:334–341.)

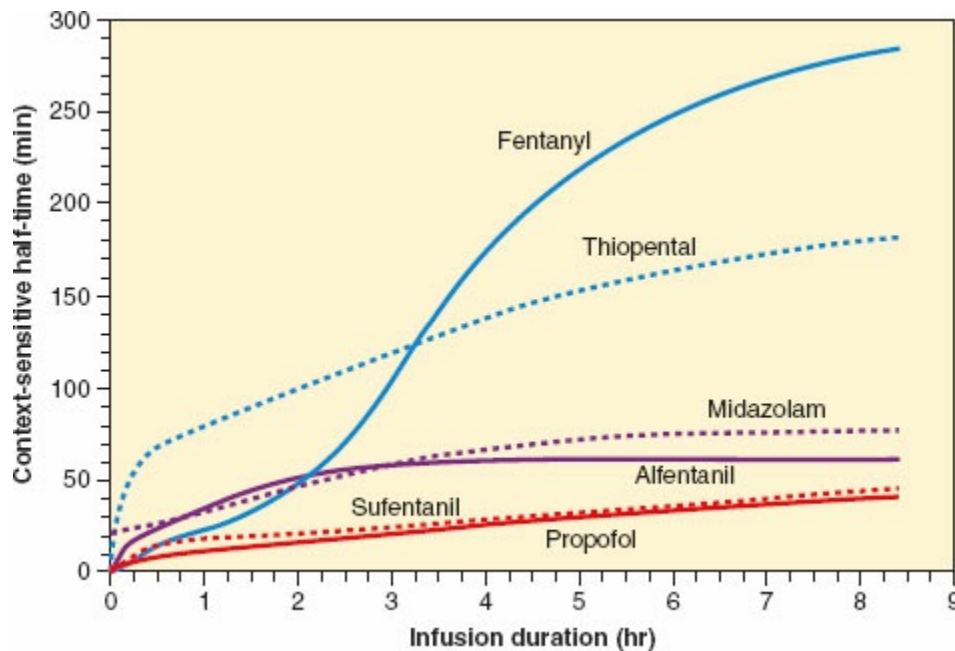

The three-compartment model is used to describe the behavior of an intravenous anesthetic. [Figure 19-2](#) depicts a hydraulic version of the three-compartment model. We will use this model to understand the behavior of a propofol infusion. When propofol is first administered, it fills the central compartment (blood,  $CA_1$ ). The propofol then distributes to peripheral compartments ( $CA_2$ ,  $CA_3$ ), one rapid and the other slow. The distribution of drug to the peripheral compartments and the elimination of propofol ( $G_1$ ) can be matched with an appropriate infusion rate ( $r(t)$ ) that would then allow for maintaining a desired target blood concentration. However, over time, the propofol will begin to accumulate in the peripheral compartments. Less propofol is removed from the central circulation by redistribution to these peripheral compartments. With prolonged time, the contributions of propofol from the peripheral compartments become greater, thus requiring less drug to be infused to maintain target blood concentration. This also leads to a longer time to awakening, and to the concept of context-sensitive half-time.

A concept most are familiar with is elimination half-time ( $t_{1/2}$ ). It is the time it takes for the plasma concentration of a drug to decrease to 50% of its original concentration. This concept works well to describe a one-compartment model for a drug distributed only to the blood, or if the drug is administered only once. In contrast, pharmacokinetic modeling that describes intravenous anesthetics administered by infusion needs to account for multiple compartments, phases of distribution and elimination.

**2** Context-sensitive half-time is defined as the time to achieve a 50% reduction in concentration after stopping a continuous infusion. Context-sensitive half-time demonstrates the influence of the distributive process in governing drug disposition. This refers to both the transfer of drug out of the plasma into peripheral compartments and the reverse process when there is a net transfer of drug back to the central compartment. [Figure 19-3](#) shows the context-sensitive half-time of several anesthetic drugs. In comparison to thiopental, propofol has a much lower context-sensitive half-time. Although the elimination of propofol is prolonged with longer infusions, it is not to the same magnitude as with thiopental. It is the low context-sensitive half-time that allows for propofol to be used as a continuous infusion. Thiopental by comparison has a much longer context-sensitive half-time and is a poor choice to be used for continuous infusion.

The medication that best illustrates the concept of context-sensitive half-time is remifentanyl. Remifentanyl is an ultrashort opioid agonist. It has an ester component in its chemical structure and is eliminated rapidly because of metabolism by nonspecific plasma esterases. Because of these properties, remifentanyl has a context-sensitive half-time that is essentially independent of the duration of the infusion (Fig. 19-4). The brevity of action allows for easy titration and optimal intraoperative analgesia with a quick recovery time. Elimination time of remifentanyl is the same for a 1-hour infusion as it is for a 10-hour infusion (3 minutes for both). The future may yield intravenous anesthetics with similar pharmacokinetic properties to remifentanyl that may allow for the so-called “anesthesia off” switch that our surgical colleagues believe we possess.

These pharmacokinetic principles of intravenous anesthesia are incorporated into target-controlled infusion (TCI) devices. The anesthesiologist sets the target blood or brain concentration on a TCI. This idea is intuitive to an anesthesiologist because this is how we administer inhaled anesthetics because end-tidal concentrations of inhaled anesthetics reflect brain concentration after equilibrium. TCI devices incorporate patient factors (age, sex, height, weight), the amount of drug that has been delivered, and the amount of drug that has accumulated in the tissues, to determine the appropriate infusion rate.<sup>4</sup> The appropriate infusion rate is calculated using these pharmacokinetic models of intravenous anesthetics. The accuracy of these devices relies on the accuracy of the pharmacokinetic model that is used. Because of pharmacokinetic variability between patients, the actual plasma concentration may be different than the set target concentration. The Food and Drug Administration (FDA) cited this lack of precision as an unacceptable risk. These concerns were raised despite extensive use of TCI systems outside the United States with a good safety record.<sup>5</sup>

**Figure 19-3** Context-sensitive half-time of intravenous anesthetics. (Adapted with permission from Hughes MA, Glass PS, Jacobs JR. Context-sensitive half-time in multi-compartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology*. 1992;76:334–341.)

## Propofol

Propofol (2,6-diisopropylphenol) has become one of the most frequently used intravenous anesthetics on the market today (Fig. 19-5; Table 19-2). Its pharmacokinetic profile presents a desirable rapid onset, a predictable context-sensitive half-time, and a rapid emergence from anesthesia. Additionally, a favorable side-effect profile and antiemetic property allow for a wide spectrum of uses, including induction and maintenance of general anesthesia, intensive care unit (ICU) sedation, and as a sedative-hypnotic in a variety of outpatient procedures.

Derivation of the appropriate propofol formulation has always centered around the challenge of managing its lipophilicity and relative insolubility in aqueous solutions. After its introduction in the 1970s in Cremophor EL formulation,<sup>6</sup> it was rapidly withdrawn from the market due to concern for anaphylactic reactions.<sup>7</sup> Nearly a decade later it was reintroduced in its more current form consisting of 1% propofol, 10% soybean oil, 2.25% glycerol, and 1.2% egg phospholipid emulsifier. In the 1990s ethylenediaminetetraacetic acid (EDTA) was added to this formulation to deter microbial growth within the emulsion. The lipid emulsion comes in a familiar milky white consistency, and can be stored at room temperature without any significant degradation.

**Figure 19-4** A simulation of the time necessary to achieve a 50% decrease in drug concentration in the blood after variable length intravenous infusions of remifentanil, fentanyl, alfentanil and sufentanil. Note that the context-sensitive half-time for remifentanil is independent of infusion duration. (Adapted with permission from Egan TD, Lemmens HJ, Fiset P, et al. The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. *Anesthesiology*. 1993;79:881–892.)

## Pharmacokinetics

Propofol is primarily metabolized by the liver, and subsequently its inactive and water-soluble metabolites are excreted by the kidneys. A small amount of unmetabolized propofol is excreted in both urine and feces, but that is considered negligible (< 3%). Despite the primary mechanism of metabolism, liver and kidney disease have not been noted to alter pharmacokinetics of propofol significantly. Also the clearance rate for propofol has been reported to be 20 to 30 mL/kg/min ( $\approx 1.5$  L/min), exceeding average hepatic blood flow (15 mL/kg/min), suggesting that other forms of metabolism and elimination play a significant role. The most common extrahepatic sites of metabolism are the kidneys and lungs, both responsible for up to 30% of the common propofol metabolites, explaining why pharmacokinetics of propofol are relatively consistent across patient populations with different comorbid states.

To truly understand the kinetic properties of propofol, evaluation of multicompartment models is crucial. The distribution of propofol after an initial bolus dose has been described in a variety of kinetic models. In a simple two-compartment model, the blood concentration of propofol drops rapidly with the initial distribution half-life of 2 to 4 minutes. In a three-compartment model propofol has the initial distribution half-life estimated to be 1 to 8 minutes and the secondary slow distribution half-life listed as 30 to 70 minutes. Elimination half-lives for both models are significantly slower, reported in a wider range from 2 to 24 hours. As noted in [Figure 19-3](#),

infusion duration of up to 8 hours maintains a reliable context-sensitive half-life of 40 minutes or less, allowing clinicians to take advantage of the predictable kinetic properties that yield a rapid recovery after initial bolus administration and continuous infusion.

**Figure 19-5** Propofol. 2,6-diisopropylphenol.

**Table 19-2** Propofol

Key Pharmacology	Key Clinical Uses
Primary mechanism: GABA-A receptor agonist	General anesthesia induction and maintenance
Predictable context-sensitive half-time across various comorbidities	Commonly used for TIVA
CNS depressant, neuroprotective, anticonvulsant, decreases CMRO <sub>2</sub> , CBF, and ICP	Conscious and deep sedation, including out-of-operative-room settings
Can be used for EEG burst suppression	Intensive care unit sedation
Cardiovascular: significant decreases in systemic vascular resistance, stroke volume, and cardiac output	Postoperative nausea and vomiting prophylaxis
Pulmonary: respiratory depressant and potent bronchodilator	Safe for use in patients with malignant hyperthermia
Addiction potential: may elicit feelings of well-being or euphoria during emergence	
Side effects: associated pain with injection, propofol infusion syndrome	

CMRO<sub>2</sub>, cerebral metabolic oxygen consumption rate; CBF, cerebral blood flow; ICP, intracranial pressure; EEG, electroencephalogram; TIVA, total intravenous anesthesia.

## Pharmacodynamics

**3** The mechanism by which the unconscious state is attained by induction doses of propofol is complicated and not fully understood. Primarily, it occurs via enhancement of GABA inhibitory pathways.<sup>7</sup> Other neuroreceptors have been linked to propofol activity, including  $\alpha$ -adrenergic receptors and N-methyl-D-aspartate (NMDA) receptors. Alteration of the central cholinergic transmission by propofol may also play a role in achieving a state of unconsciousness.<sup>8</sup> The neurotransmission target is the vast array of interneurons involved within the cerebral cortex, brain stem, and thalamus

that ultimately play a critical role in arousal.<sup>9,10</sup>

Initial low doses of propofol produce sedation, but at increased doses a state of paradoxical excitation may occur, where a patient is disinhibited, has unpredictable movement, broken speech, and is not readily arousable.<sup>11</sup> A further increase in dose of propofol leads to loss of consciousness, apnea, relative relaxation of muscles, loss of brainstem reflexes, and subsequently necessitates airway support.

## Central Nervous System Effects

Similar to other intravenous anesthetics, the changes in electroencephalogram (EEG) pattern with propofol are dependent on the depth of anesthesia achieved. At lower sedative doses, a characteristic increase in  $\beta$ -wave activity is common. After an induction dose, initial stages of general anesthesia are reached, and the EEG pattern often resembles that of deep non-REM sleep, with progressively increased low-frequency and high-amplitude activity. This ultimately means that  $\beta$ -wave activity decreases, with a simultaneous increase in  $\alpha$  and  $\delta$  activity.<sup>12</sup> Burst suppression is marked by periods of electrical inactivity with alternating higher-frequency activity, and is commonly employed as a neuroprotective measure prior to aneurysm clipping. It can be attained at concentrations of propofol (8  $\mu\text{g}/\text{mL}$ ) that are significantly higher than the blood concentrations needed to reach the initial stages of general anesthesia (3  $\mu\text{g}/\text{mL}$ ). A further increase in propofol concentration will lead to an isoelectric EEG pattern.

Neuroprotective effects of propofol are likely multifactorial. Intravenous agents such as propofol lower cerebral metabolic oxygen consumption rate ( $\text{CMRO}_2$ ) and decrease intracranial pressure (ICP) primarily by lowering cerebral blood flow (CBF). At the same time, cerebral perfusion pressure (CPP) may also be lowered, thus this benefit is not without limitations and should be employed carefully. Propofol has specific antioxidant properties, and its function as a free radical scavenger has been hypothesized to play a role in preventing injury during neurodegenerative processes such as stroke and trauma.<sup>13</sup> Other protective mechanisms have been hypothesized, including attenuation of excitotoxic glutamate pathways<sup>14</sup> that lower the likelihood of programmed neuronal apoptosis,<sup>15</sup> and its overall anti-inflammatory effects (e.g., decreasing  $\text{TNF-}\alpha$ ).<sup>16</sup>

Propofol is generally considered an anticonvulsant. At induction doses that reach burst suppression, EEG epileptiform activity is limited.<sup>17</sup> These results have not been reproduced in patients with epilepsy at lower sedative doses.<sup>18</sup> It has also been used successfully to treat status epilepticus, thus it is rarely the anesthetic of choice during induction of anesthesia for ECT because it shortens seizure duration. Contradictory case reports of propofol anesthetics

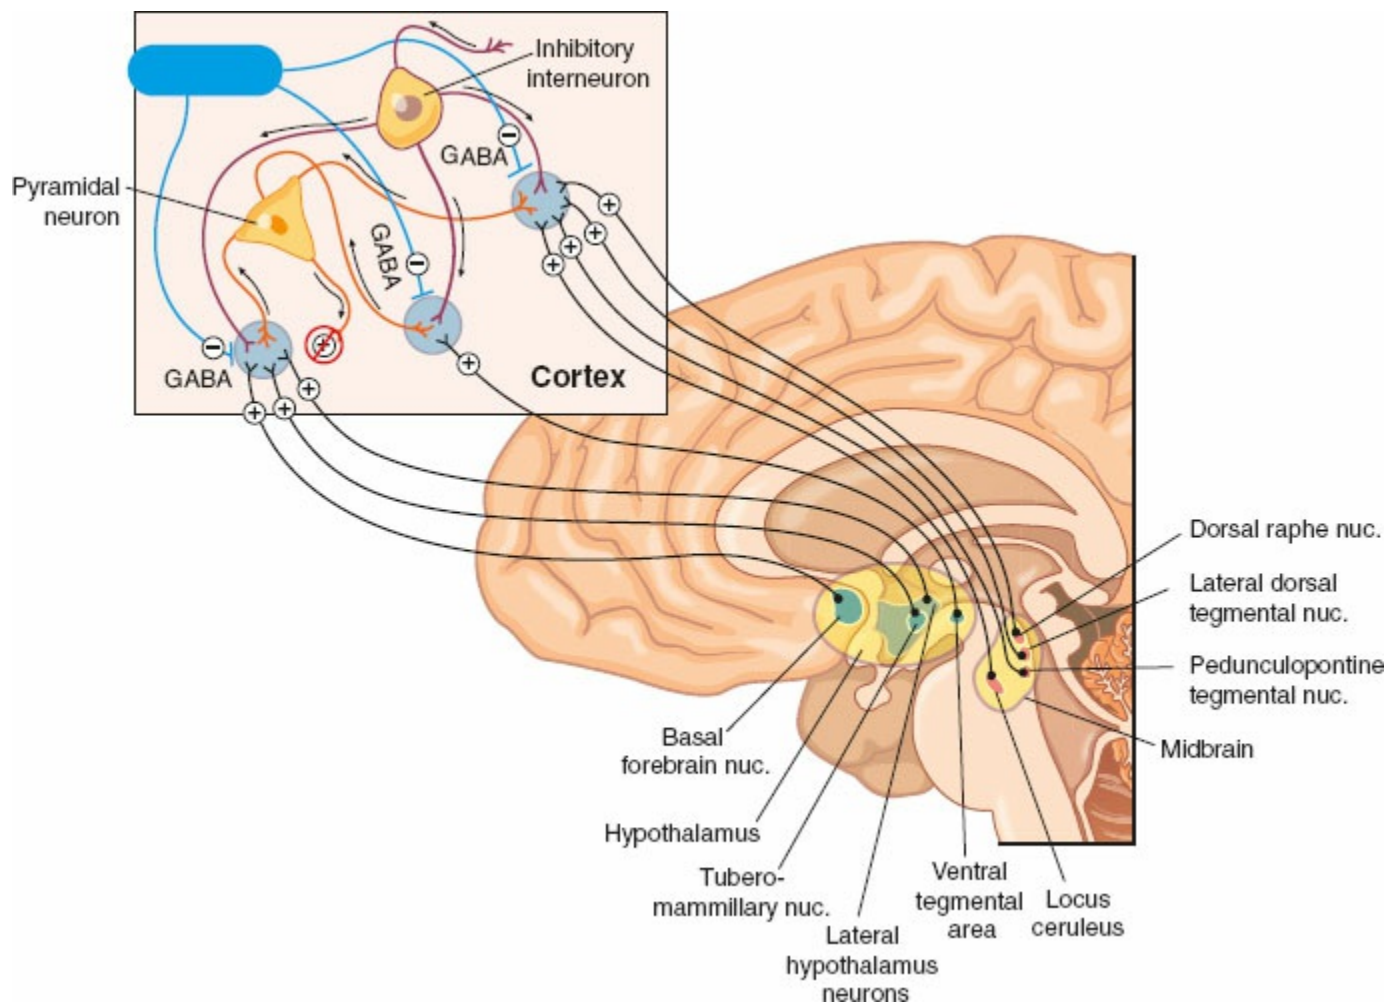

associated with grand mal seizures do exist, but the proconvulsant effects are not well elucidated.

Although not traditionally considered a drug for recreational use, the incidence of propofol abuse has likely increased over the last 10 years, and is by far highest in anesthesia providers with easy access to the drug. In the United States, 18% of academic institutions have reported propofol abuse or diversion in the last decade, with a significant mortality rate among residents.<sup>19</sup> Propofol has properties that allow for addiction; emergence from propofol sedation has been associated with an overall feeling of well-being, and tolerance over time has been documented in the intensive care setting.<sup>20</sup> The Drug Enforcement Agency (DEA) developed a proposed rule to label propofol as a controlled substance in 2010. Interestingly, only fospropofol, a water-soluble prodrug of propofol, is currently on the scheduled substance list.

The loss of consciousness attributed to propofol can be partially reversed by the central cholinomimetic properties of physostigmine.<sup>21</sup> This drug has been used in the treatment of emergence delirium, and presumably the mechanism of propofol reversal is similar. Activation of central cholinergic pathways leads to an overall state of arousal, and likely alters propofol-induced state of unconsciousness (Fig. 19-6).

## **Cardiovascular Effects**

The hemodynamic effects of propofol are dose-dependent and more significant after an induction dose than during a continuous infusion. There is a characteristic drop in systolic and diastolic blood pressure without the expected increase in heart rate. The observed blood pressure drop results from a decrease in cardiac output, stroke volume, and systemic vascular resistance (SVR). Propofol decreases sympathetic activity and leads to indirect arterial vasodilation and venodilation. This effect is enhanced by direct effects on smooth muscle and depressant effects on the myocardium, affecting intracellular calcium balance and influx.<sup>22</sup> The decreased sympathetic tone is also coupled with direct inhibition of the baroreceptor response, leading to a diminished reflex increase in heart rate and a more pronounced hemodynamic effect. Suppression of supraventricular tachycardia has also been reported, and may be a direct result of propofol effects on the heart conduction system.<sup>23</sup>

**Figure 19-6** Propofol's proposed mechanism of action in the central nervous system. Ascending arousal pathways arise from both the thalamus and the midbrain to send excitatory inputs to a pyramidal neuron (orange). A GABAergic inhibitory interneuron (purple) synapses onto this pyramidal neuron. Propofol binds post-synaptically and enhances GABAergic inhibition. Unconsciousness occurs as this enhanced GABAergic inhibition counteracts ascending arousal inputs to the pyramidal neuron and decreases excitatory activity.

## Respiratory System Effects

The respiratory depressant effects of propofol are also dose-dependent. Apnea is relatively common with a higher induction dose, while a typical maintenance dose of propofol results in diminished tidal volumes and increased respiratory rate. There is also a blunted response to hypoxia that may be a direct effect on chemoreceptors, as well as decreased respiratory response to hypercarbia. Propofol is a potent bronchodilator, primarily because of its direct effects on intracellular calcium homeostasis.

## Clinical Uses

The rapid and smooth induction and emergence from anesthesia helped

transform propofol into an intravenous sedative-hypnotic that is a viable alternative to standard inhalational agents and other intravenous drugs. The induction dose in a healthy adult is approximately 1 to 2.5 mg/kg, and loss of consciousness is commonly achieved at corresponding blood concentration close to 3 µg/kg. Induction dose requirement variability is tremendous among patients with different characteristics and comorbidities. Elderly patients typically have prolonged effects and increased sensitivity to propofol because of decreased cardiac output and clearance.<sup>24</sup> On the opposite end of the spectrum, children typically have a larger than average volume of distribution and quicker clearance, resulting in increased propofol requirement on a per kilogram basis.<sup>25</sup> Morbidly obese patients should have lean body weight used when calculating propofol dosing.<sup>26</sup> Patients with chronic alcohol abuse, as expected, have an increased induction dose requirement. An exaggerated hemodynamic response is likely after induction of propofol in patients with cardiovascular disease. Thus, determination of the appropriate propofol induction dose requires careful assessment of premedication administration, patient history, and comorbidity.

Maintenance of general anesthesia with propofol can commonly be achieved with infusions between 100 and 200 µg/kg/min. TIVA with propofol alone—or together with opioids as part of a balanced anesthetic—has been utilized successfully for all types of surgery. One of the major benefits is prevention of postoperative nausea and vomiting (PONV), although the antiemetic properties of propofol can be replicated with subhypnotic concentrations. Maintenance infusions as low as 10 µg/kg/min and blood concentration levels as low as 350 ng/mL have been noted to cause significant decreases in PONV.<sup>27</sup> These levels can be reached after recovery from general anesthesia leading only to minimal sedation, but more commonly intraoperative infusion of propofol is employed as a nausea-sparing technique. Propofol can also be used as the anesthetic of choice in patients with malignant hyperthermia (MH), as it is not a trigger for MH. Maintenance infusion of propofol is also commonly employed when inhalational anesthetics are avoided intentionally or are difficult to administer. One example includes surgery with a shared airway such as rigid bronchoscopy during which administration of inhaled anesthetics may be less predictable. Office based anesthesia is another example where an anesthesia machine may not be readily available.

Sedation with propofol is employed commonly for minor procedures, outpatient surgery, and off-site anesthetics, as well as ICU sedation of mechanically ventilated patients. Typical infusion doses range between 25 and 75 µg/kg/min. Clinical effects of propofol are dose-dependent, and apnea can be avoided with careful titration of infusion rate.

## Side Effects

Pain on injection occurs in approximately 60% to 70% of patients when propofol is administered peripherally alone. Numerous interventions have been tested to minimize this common side effect, with varying levels of success. The most efficacious technique is pretreatment with a local anesthetic such as lidocaine in conjunction with venous occlusion using a tourniquet, or in essence a modified Bier block.<sup>28</sup> Antecubital vein use as an alternative to smaller peripheral vein sites (e.g., hand) has proved to be the most important nondrug technique for minimizing pain on injection.<sup>29</sup> Addition of lidocaine to propofol, or pretreatment with lidocaine without the use of a tourniquet has also been shown to be beneficial. Pretreatment with opioids is commonly performed prior to induction with propofol, and it decreases pain on injection. Techniques to lower free propofol concentration, such as diluting the emulsion and changing the lipid solvent have shown some improvement. Pretreatment with other drugs has shown limited success, including non-steroidal anti-inflammatory drugs (NSAIDs), ketamine, steroids, and  $\beta$ -blockers.<sup>29</sup>

PRIS is an extremely rare, but potentially deadly side effect of propofol that was first described in children in the 1990s and subsequently in adults after its use for sedation in the ICU setting.<sup>30,31</sup> The key clinical characteristics include unexplained metabolic acidosis, hyperkalemia, hyperlipidemia, rhabdomyolysis, hepatomegaly, renal failure and most importantly ECG changes, arrhythmias, and progression to cardiac failure. The pathophysiology of PRIS is not well understood, but may involve mitochondrial toxicity and uncoupling of the intracellular respiration chain, although other hypotheses such as inhibition of fatty acid oxidation have been suggested. Development of clinical symptoms of PRIS is likely dependent on both the infusion dose and duration, but short-duration infusions have been associated with cardiac failure. In 2006, the FDA altered the recommended maximum propofol infusion dose to 4 mg/kg/hr, but it is unclear if the recommendations have altered the frequency of PRIS, and currently the rate of mortality from PRIS is still close to 50%.<sup>32</sup>

**Figure 19-7** Etomidate. Ethyl 3-[(1R)-1-phenylethyl]imidazole-5-carboxylate.

Prolonged infusion of propofol, especially in the ICU setting, has yielded several case reports of production of green urine as a side effect. The likely

etiology may be due to increased extrahepatic metabolism of propofol, and subsequent excretion of these metabolites in urine. Case reports of single-dose propofol causing green urine do exist, but are less common than the typically reported 6 to 64 hours after infusion has started.<sup>33</sup>

## Etomidate

In 1972, etomidate was introduced into anesthetic practice as an induction agent (Fig. 19-7; Table 19-3). It subsequently gained much popularity because of its safe hemodynamic profile. However, it lost some proponents with increased reports of adrenal suppression, pain on injection, thrombophlebitis, PONV, myoclonus, and hiccups. Like most other decisions regarding drug selection, the use of etomidate is the result of a risk/benefit analysis. If hemodynamic stability is of paramount importance, one may choose to induce with etomidate and prepare to manage these unwanted side effects.

### Pharmacokinetics

Etomidate is an imidazole derivative (the D(+) enantiomer) and is not stable in neutral pH solutions. The solvents in its formulation, namely propylene glycol, contribute to veno-irritation and phlebitis that occur frequently. Similar to other induction agents, etomidate has a quick onset of action (“vein to brain”), fast resolution of effect secondary to redistribution, and follows the three-compartment kinetic model. Etomidate’s use as a continuous infusion is limited by its association with adrenal suppression. Etomidate is metabolized in the liver and excreted predominantly by the kidney (approximately 80%) and in bile (approximately 20%). It is largely protein bound (approximately 75%) and thus affected by pathologic conditions and/or drugs that alter serum proteins. Other pharmacokinetic values of etomidate are found in Table 19-4.

**Table 19-3** Etomidate

<b>Key Pharmacology</b>
GABA-A receptor agonist
Hemodynamically stable
Adrenocortical suppression
Postoperative nausea and vomiting
<b>Key Clinical Uses</b>
Hemodynamically stable induction
Cardiac, trauma, and hypovolemic patients

**Table 19-4** Etomidate Pharmacokinetics

Initial distribution half-life	2.7 minutes
Redistribution of half-life	29 minutes
Elimination half-life	2.9–5.3 hours
Volume of distribution	2.5–4.5 L/kg
Induction dose	0.2–0.3 mg/kg

### *Pharmacodynamics and Clinical Uses*

Etomidate binds as an agonist to the GABA-A receptor and thus has an inhibitory influence on the brain. It is a potent vasoconstrictor that reduces CBF, ICP, and CMRO<sub>2</sub>. Because of etomidate's minimal effect on the mean arterial pressure (MAP), CPP is either maintained or increased. Unlike benzodiazepines, etomidate can achieve burst suppression with a concomitant decrease in ICP. However, despite its neurodepressant properties at high doses, etomidate is often associated with epileptogenic activity (excitatory spikes) on EEG. This alone may render etomidate an undesirable induction agent for patients undergoing neurosurgical procedures. The epileptogenic EEG activity is not to be confused with the observable seizure-like, myoclonic movements that often follow an induction dose of etomidate (although excitatory EEG spikes may also be present during this time). Similar to other maintenance intravenous anesthetics, etomidate will increase the latency intervals measured on somatosensory-evoked potentials (SSEPs). Paradoxically, etomidate increases the amplitude of SSEPs, in contrast to the typical effect of other anesthetics. Etomidate is used frequently for electroconvulsive therapy. Unlike the barbiturates (except methohexital), etomidate is proconvulsant and lowers the seizure threshold.

**5** Etomidate is often touted as a hemodynamically stable induction medication with a relatively large safety margin. Etomidate has a minimal or nonexistent effect on MAP, pulmonary artery (PA) pressure, pulmonary artery wedge pressure, central venous pressure (CVP), stroke volume, cardiac index, SVR, and pulmonary vascular resistance (PVR).<sup>34</sup> Etomidate is frequently used for induction of anesthesia in cardiac operating rooms. Etomidate is also used for trauma patients who are hemodynamically unstable and are often hypovolemic.

There are mixed data regarding etomidate's effect on the respiratory system. It is widely believed that etomidate depresses airway reflexes less than propofol (unless co-administered with another sedative/analgesic agent). Etomidate also relaxes the smooth musculature of the pulmonary vasculature system to a similar degree as propofol.

Etomidate is a reasonable choice for MAC sedation because of the preservation of airway reflexes.

## Side Effects

Adrenocortical suppression may be the most significant adverse effect of etomidate. Etomidate inhibits the activity of the enzyme  $11\beta$ -hydroxylase and prevents the conversion of cholesterol to cortisol. It has been postulated that one dose is sufficient to transiently suppress the adrenocortical axis. Some suggest pretreatment with dexamethasone to curtail this effect.<sup>35</sup> Although many studies conclude that there are no direct adverse outcomes following a bolus of etomidate, even in the septic population,<sup>36</sup> other studies propose the opposite.<sup>37</sup> However, most practitioners, in an effort to limit this possibility, will not administer repeat doses or continuous infusions.

**Figure 19-8** Ketamine. (RS)-2-(2-chlorophenyl)-2-(methylamino)cyclohexanone.

## Ketamine

6

Phencyclidine (PCP; angel dust) was long ago noted to have remarkable analgesic and anesthetic effects. Ketamine was discovered in the search for a phencyclidine derivative with similar anesthetic and analgesic properties, but with fewer psychomimetic effects (Fig. 19-8; Table 19-5). Ketamine was described as causing “dissociative anesthesia” in human volunteers in 1965, acting through the NMDA receptor.<sup>38</sup> Key features associated with ketamine administration included marked nystagmus, significant analgesia, and unconsciousness. Emergence from ketamine anesthesia was associated with emergence delirium, hallucinations, and alterations in mood and affect. The use of ketamine as an anesthetic has been limited by its cardiovascular stimulating properties and the disturbing emergence reactions. Interestingly, the NMDA receptor has been found to play a key role in nociception, and low-dose ketamine has an opiate sparing effect in the management of acute pain. The effects of ketamine related to pain can be best described as antihyperalgesic, antiallodynic, or tolerance-protective.<sup>39</sup> More recently, ketamine has gained interest in the treatment of major depression, however its clinical effects are of short duration.<sup>40</sup>

## Pharmacokinetics

Ketamine is an analog of phencyclidine that is a chiral compound and is a

racemic mixture of S and R enantiomers. The S(+) enantiomer of ketamine is three to four times more potent than the R-enantiomer. The S-enantiomer has a shorter duration of action and is cleared more rapidly.<sup>41</sup> Ketamine is bioavailable by multiple routes of administration. Intramuscular (IM) administration has a 93% bioavailability, transnasal administration has 25% to 50% bioavailability, and rectal or oral administration has 16% bioavailability.<sup>42</sup> The high lipid solubility and low protein binding (20%) allow for a rapid uptake of ketamine in the brain, as well as a fairly rapid redistribution. The onset of anesthesia after intravenous administration of ketamine is 30 to 60 seconds, with duration of 10 to 15 minutes. The induction dose of ketamine is 0.5 to 2 mg/kg for intravenous administration and 4 to 6 mg/kg for intramuscular administration. Peak plasma levels averaged 0.75 mg/mL and CSF levels were about 0.2 mg/mL 1 hour after dosing.<sup>43</sup>

**Table 19-5** Ketamine

<b>Key Pharmacology</b>
NMDA receptor antagonist
Cardiovascular stability; increases heart rate and blood pressure
Mild respiratory depression
Side effects: Emergence delirium, hallucinations, nystagmus, increased salivation
Trance-like cataleptic unconscious state ("dissociative anesthesia")
<b>Key Clinical Uses</b>
Anesthesia—intravenous and intramuscular induction
Analgesia
Chronic pain
Depression
Bronchodilator
Procedural sedation, especially in pediatric and burn patients

After intravenous bolus administration, ketamine shows a bi- or triexponential pattern of elimination. The  $\alpha$ -elimination phase (redistribution of ketamine from the central nervous system [CNS] to peripheral tissues) is 11 minutes, and the  $\beta$ -elimination phase is 2.5 hours.<sup>44</sup> Ketamine is metabolized primarily in the liver by cytochrome P-450 enzymes (CYP 3A4 > CYP 2C9 > CYP 2B6). The liver extensively metabolizes ketamine by demethylation to its principal metabolite norketamine. Norketamine is biologically active but only has one-third to one-fifth the activity of racemic ketamine. Norketamine is eliminated by renal excretion. Due to its lipophilicity, ketamine is only partially removed by dialysis.

## Pharmacodynamics

The neuropharmacology of ketamine is complex. Antagonism of the NMDA receptor is primarily responsible for ketamine's specific clinical effects. However, ketamine also has clinical effects at opioid, noradrenergic, cholinergic, nicotinic, and muscarinic receptors.

Ketamine binds preferentially to the NMDA receptors on inhibitory interneurons in the cortex, limbic system, and hippocampus that promote uncoordinated increase in neuronal activity and an active EEG pattern, and produce unconsciousness.<sup>45</sup> Ketamine has been shown to increase the bispectral index (BIS) from 40 to 63 with higher doses of ketamine (0.5 mg/kg) under general anesthesia with propofol and fentanyl.<sup>46</sup>

There are NMDA receptors present on nearly all CNS cells, and especially those cells involved with nociception such as primary afferent nociceptors in the spinal dorsal horn. Ketamine binds to an interchannel site of the NMDA receptor called the phencyclidine (PCP) binding site and decreases channel opening time. Ketamine decreases the amplification of repeated stimulation of the NMDA receptor ("wind up") that is considered an elementary form of CNS sensitization. Antagonism of the channel is more profound if the NMDA channel has been previously opened by glutamate.<sup>47</sup>

Functional MRI has provided some insight into the analgesic pharmacodynamics of ketamine. Volunteers who were subjected to painful heat stimulation showed a typical pattern of pain activation from the thalamus to the insula, to the cingulate, and ultimately to the prefrontal cortex. There was a dose-dependent reduction in these cerebral activation pathways when volunteers were given ketamine. Ketamine has also been found to block signals from the spinoreticular pathway. Activity of the medial thalamic nuclei and medial reticular formation—important relays in nociceptive transmission between the spinal and supraspinal levels—are both depressed.<sup>47</sup>

Ketamine has been found to bind to opioid, noradrenergic, and cholinergic receptors (Fig. 19-9). Ketamine binds to  $\mu$ ,  $\delta$ , and  $\kappa$  opioid receptors; however this does not account for its analgesic effects.<sup>47</sup> The primary analgesic mechanism of ketamine is believed to be in the prevention of developing hyperalgesia.<sup>48</sup> Ketamine causes stimulation of CNS noradrenergic neurons and inhibition of catecholamine uptake, which provokes a hyperadrenergic state (with increased release of norepinephrine, dopamine, and serotonin). Ketamine's effect on noradrenergic neurons is partly responsible for the hypnotic, psychic, and analgesic effects observed. Ketamine also affects CNS cholinergic neurons, and the anticholinergic physostigmine can antagonize the hypnotic effects of ketamine.

## Clinical Uses

## **Anesthesia**

Ketamine administration has been described as causing a dissociative amnestic state. Patients are unconscious with eyes open, maintain spontaneous respiration, and do not react to painful or noxious stimuli.<sup>38</sup> EEG shows a depression of the thalamocortical pathways and concomitant activation of the limbic system. Despite this increased epileptiform activity, there is no clinical evidence of seizure activity or spread of the epileptiform activity to cortical areas. Therefore, ketamine is less likely to cause a seizure and may in fact have CNS protective properties. Ketamine anesthesia is associated with profound analgesia that occurs at subanesthetic levels.

Induction doses of ketamine are 1 to 2 mg/kg, with an onset of 1 minute and a duration of 10 to 20 minutes. Ketamine administration is associated with an increase in heart rate and blood pressure. Ketamine is therefore a good choice for anesthetic induction in the hemodynamically unstable patient. Ketamine has been compared to etomidate in the unstable patient and has the advantage of not causing adrenal suppression.<sup>49</sup> The increased blood pressure and heart rate associated with ketamine may make it unsuitable for some cardiac patients (critical coronary artery disease). An increase in PVR associated with ketamine may make it an unsuitable choice in patients with severe right heart dysfunction.

## **Sedation**

Ketamine has been used to provide sedation to burn patients during wound care. Benefits of ketamine in this patient population include analgesia as well as maintenance of spontaneous respiration and airway reflexes. Ketamine can be administered via intramuscular injection and has been used to provide sedation or anesthesia in uncooperative or hostile patients. Ketamine has also been used in pediatric patients for painful procedures such as reduction and casting of bone fractures in the emergency department.<sup>42</sup>

## **Analgesia**

Ketamine has been extensively studied for its role as an analgesic in the management of acute postoperative pain. Ketamine has been shown to lower pain scores and decrease opiate requirements in postoperative patients. Administration of both a ketamine bolus prior to surgical incision and a ketamine infusion postoperatively has been found to be the most effective use of ketamine for acute pain. The analgesic effects of ketamine are achieved at subanesthetic blood concentrations. Ketamine reduces opiate requirements for postsurgical pain, but it cannot replace opiates altogether. Ketamine is useful in patients who will require high doses of opiates, such as patients on chronic

opiate therapy or patients with a history of opiate abuse.<sup>50</sup>

**Figure 19-9** Ketamine's mechanism of action in the central nervous system. Ketamine binds preferentially to the *N*-methyl-D-aspartate (NMDA) receptors on inhibitory interneurons in the cortex, amygdala, and hippocampus. Unconsciousness results from an uncoordinated increase in neural activity. In the spinal cord, ketamine decreases arousal by blocking NMDA glutamate-mediated nociceptive signals from peripheral afferent neurons in the dorsal-root ganglion to projecting neurons.

The exact mechanism of analgesia provided by ketamine is unclear. The NMDA receptor has been found to be associated with central sensitization and winds up at the spinal cord associated with chronic pain. Studies have suggested that ketamine analgesia occurs by the prevention of hyperalgesia and decreases in central nervous system sensitization that occur with acute pain.<sup>39</sup>

## Chronic Pain

Due to the NMDA receptor role in preventing hyperalgesia, ketamine has also been investigated for the management of chronic pain. Ketamine has been most extensively studied in patients with chronic regional pain syndrome (CRPS). Ketamine administration to patients with CRPS yields a decrease in pain scores and opiate consumption.<sup>51</sup> Unfortunately, these effects are only of

limited duration after ketamine administration. Future studies are required to determine the most effective regimen for ketamine administration in patients with chronic pain. Ketamine has also been used in cancer patients with severe pain. Ketamine is associated with a decrease, but not elimination, of opiate requirements. Unfortunately, the CNS side effects and lack of oral administration limit the application of ketamine in patients with chronic pain.

Intranasal ketamine has been investigated for use in chronic pain. Intranasal ketamine was found to significantly lower the intensity of breakthrough pain in patients with chronic pain when compared with placebo.<sup>52</sup> Intranasal ketamine also decreased pain scores in patients with chronic neuropathic pain.<sup>53</sup> Both studies reported no serious side effects. Intranasal ketamine, in combination with intranasal midazolam, has been used in the management of acute postoperative pain, showing similar efficacy to morphine patient-controlled analgesia (PCA) after spine surgery.<sup>54</sup> Further studies are needed to determine the utility of intranasal ketamine.

## **Depression**

Ketamine has been evaluated as a possible treatment for major depression. Ketamine decreased depression symptoms and suicidal ideation within 1 hour of administration.<sup>55,56</sup> Ketamine as an antidepressant represents a possible novel treatment, and has generated excitement because of poor results with current treatments of depression (slow onset, poor efficacy). The mechanism of ketamine's antidepressant effects remains unclear. Investigations using memantine, an NMDA antagonist, failed to improve depressive symptoms.<sup>57</sup> Therefore, the antidepressant effects of ketamine may not be related to its NMDA antagonism, but to its effect on other CNS receptors (dopamine, adrenergic). Unfortunately, the duration of ketamine's antidepressant effect is short after single administration. Further investigation is required to determine the best regimen in use of ketamine as an antidepressant.<sup>41</sup> Understanding the mechanism of action of ketamine in depression may yield new targets for the treatment of major depression.

## **Side Effects**

### **Central Nervous System**

The major side effect of ketamine is the psychogenic reactions seen with its administration. Patients can experience hallucinations and out-of-body experiences that have been described as frightening. Studies have shown that these symptoms can be reduced with coadministration of benzodiazepines. Ketamine also causes patients to have a lateral gaze nystagmus.<sup>38</sup>

## Cardiovascular

Administration of ketamine is associated with increased heart rate and increased blood pressure. The exact mechanism is unclear, but it is hypothesized that ketamine causes activation of the sympathetic nervous system. Ketamine is one of the few intravenous anesthetics that increase SVR, and therefore it is an attractive option for the induction of anesthesia in patients who are hemodynamically unstable. Ketamine has also been found to cause direct myocardial depression. There are reports of ketamine causing cardiovascular collapse in patients who have been sympathetically depleted.<sup>58</sup> Theoretically, this cardiovascular collapse is due to ketamine's myocardial depression in the absence of sympathetic vasoconstriction due to depleted catecholamines.

## Respiratory

Ketamine maintains spontaneous respiration. Hypoxia can occur, but it is easily treated with supplemental oxygen. Ketamine is also a bronchodilator, although it is not effective as a sole agent for the treatment of bronchospasm.<sup>59</sup> Rather, it is a secondary agent to consider for the management of severe bronchospasm or status asthmaticus. Ketamine does cause increased salivation that may result in laryngospasm.

## Intracranial Pressure/Seizure Issues

Historically ketamine was not recommended in patients with elevated ICP. The excitatory CNS effects of ketamine would increase CMRO<sub>2</sub> and CBF. However, studies have found that ICPs remain normal with ketamine administration in neurosurgical patients with controlled ventilation. In fact, ketamine may be neuroprotective.<sup>60</sup> Ketamine is associated with epileptiform activity on EEG; however, these excitement waveforms are not seen in the cortex, and therefore ketamine seems unlikely to precipitate a seizure.

## Dexmedetomidine

Dexmedetomidine is an  $\alpha_2$ -adrenergic agonist similar to clonidine (Fig. 19-10; Table 19-6). It has seven to eight times greater affinity for the  $\alpha_2$ -adrenergic receptor than clonidine. Introduced into clinical practice in 1999, dexmedetomidine has been used for ICU sedation in mechanically ventilated patients, for procedural sedation, and as a component of general anesthesia. Dexmedetomidine is unique as a sedative in that it has limited respiratory depressant effects.

**Figure 19-10** Dexmedetomidine. (S)-4-[1-(2,2-Dimethylphenyl)ethyl]-3-H-imidazole.

---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

## Pharmacokinetics

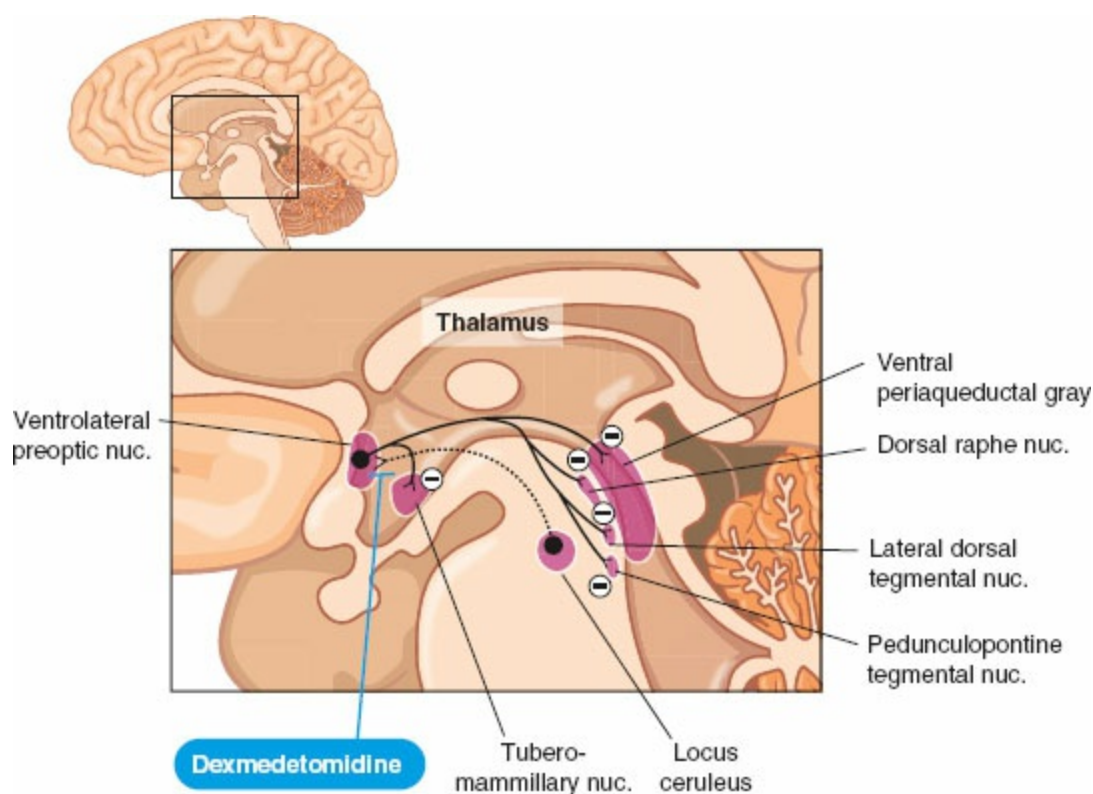

Following intravenous administration, dexmedetomidine exhibits the following pharmacokinetic parameters: a rapid distribution phase with a distribution half-life of approximately 6 minutes; a terminal elimination half-life of approximately 2 hours, and a steady state volume of distributions of approximately 118 L. Dexmedetomidine exhibits linear pharmacokinetics in the dose range from 0.2 to 0.7  $\mu\text{g}/\text{kg}/\text{hr}$  when administered by intravenous infusion for up to 24 hours.<sup>61</sup> The average protein binding is 94% and constant across different plasma concentrations. The fraction of dexmedetomidine bound to plasma protein is significantly decreased in subjects with hepatic impairment compared to healthy subjects.

Dexmedetomidine undergoes almost complete biotransformation with very little unchanged dexmedetomidine in the urine and feces. Biotransformation involves both direct glucuronidation and cytochrome P450-mediated metabolism. The terminal elimination half-life is approximately 2 hours and clearance is estimated to be approximately 39 L/hr. Clearance values for dexmedetomidine are lower in patients with varying degrees of hepatic impairment. Dexmedetomidine pharmacokinetics are not significantly different in patients with severe renal impairment compared to healthy subjects.<sup>62</sup>

## Pharmacodynamics

Dexmedetomidine acts on the  $\alpha_2$ -adrenergic receptors in the spinal cord and brain (Fig. 19-11). Its effects are primarily at the locus coeruleus that activates sleep centers in the brain. Interestingly, the EEG pattern observed in patients receiving dexmedetomidine resembles that of non-REM sleep. Clinically, patients are sedated but easily arousable, and able to follow commands with minimal respiratory depression.<sup>63</sup>

The cardiovascular effects of dexmedetomidine are as expected for an  $\alpha_2$  agonist: bradycardia and hypotension. Compared to placebo, dexmedetomidine causes a 7 mmHg decrease in systolic blood pressure and a decrease in mean heart rate of 1 to 8 bpm.<sup>61</sup>

**Figure 19-11** Dexmedetomidine's mechanism of action in the central nervous system. Dexmedetomidine activates the sleep centers in the brain. Dexmedetomidine binds to  $\alpha_2$  receptors on neurons from the locus coeruleus, inhibiting norepinephrine release (*dashed line*) in the ventrolateral preoptic nucleus. The disinhibited ventrolateral preoptic nucleus reduces arousal of the midbrain, hypothalamic, and pontine arousal nuclei.

## Clinical Uses

**7** Dexmedetomidine has been used to provide sedation for mechanically ventilated patients in the ICU. Patients receiving dexmedetomidine required less rescue sedation with midazolam or morphine versus placebo.<sup>61</sup> Maintenance of spontaneous respiration allows for ICU patients to be extubated while receiving a dexmedetomidine infusion. Dexmedetomidine is

also attractive for ICU sedation in neurosurgery, as patients can participate in neurologic examinations while receiving this medication. Dexmedetomidine has been found to have analgesic properties, and can reduce opiate requirements in ICU patients who are mechanically ventilated. However, a systematic review of controlled trials failed to find sedation superiority when comparing dexmedetomidine to midazolam for ICU sedation.<sup>64</sup>

**Figure 19-12** Midazolam. 8-chloro-6-(2-fluorophenyl)-1-methyl-4*H*-imidazo[1,5-*a*][1,4]benzodiazepine.

Dexmedetomidine can also be used for procedural sedation. Dexmedetomidine has been studied as an agent for sedation during awake fiberoptic intubation.<sup>61</sup> Maintenance of spontaneous ventilation makes this drug useful for this very purpose. Dexmedetomidine can also be used to provide MAC sedation alone or in combination with other medications. Typical administration involves at 0.5 to 1  $\mu\text{g}/\text{kg}$  loading dose over 15 minutes, followed by an infusion of 0.3 to 0.7  $\mu\text{g}/\text{kg}/\text{hr}$ .

Several studies have compared the efficacy of dexmedetomidine to propofol for procedural sedation. In the operating room, dexmedetomidine provided adequate sedation compared to propofol with less hypotension, and better pain scores in the post anesthesia care unit (PACU). However, the onset of sedation was longer with dexmedetomidine, and patients had prolonged sedation and more hypotension in the PACU when compared to propofol.<sup>65,66</sup> Two studies found dexmedetomidine to be inferior to propofol for sedation for upper endoscopy procedures.<sup>67,68</sup>

Although not approved for use in pediatrics, many investigators have evaluated its off-label use in children.<sup>62</sup> Intranasal dexmedetomidine (1  $\mu\text{g}/\text{kg}$ ) has been used for preoperative anxiolysis, with an onset of 25 minutes and duration of 85 minutes. Dexmedetomidine was found to be superior to oral midazolam in ensuring satisfactory levels of sedation; however, its long onset time limits this application. Because it preserves spontaneous respiration, dexmedetomidine has been used in airway procedures such as rigid bronchoscopy. Dexmedetomidine has been used as an adjunct to TIVA during posterior spine fusion surgery, and lowers both propofol and sevoflurane requirements. Dexmedetomidine has been found to have minimal effect on SSEPs and motor evoked potentials (MEPs) during spine surgery.<sup>69</sup>

Dexmedetomidine has been investigated for the prevention of emergence delirium. A meta-analysis found that  $\alpha_2$  agonists (clonidine or dexmedetomidine) decrease emergence delirium when given via the oral, intravenous, or caudal route. Dexmedetomidine given by intravenous bolus or infusion has been shown to decrease emergence delirium, but the optimal dose is unknown. Compared to placebo, dexmedetomidine (0.5 to 1  $\mu\text{g}/\text{kg}$ ) decreases the incidence of emergence delirium from 47% to 2.8%, with slightly prolonged emergence time.<sup>70</sup>

Dexmedetomidine has been investigated as a local anesthetic adjuvant for regional anesthesia. Dexmedetomidine was found to prolong both motor and sensory blocks when administered intrathecally in combination with local anesthetic. Perineural injection of dexmedetomidine as part of a brachial plexus block did extend the duration of the block, but this was not found to be statistically significant. Further studies are needed to define the potential benefit of dexmedetomidine as a local anesthesia adjuvant.<sup>71</sup>

### **Side Effects**

The main adverse reactions of dexmedetomidine are hypotension, bradycardia, dry mouth, nausea, and hypertension. The incidence of bradycardia is reported as high as 40%, and can be managed with atropine, ephedrine, or volume administration.<sup>72</sup> There are case reports of patients who have developed severe bradycardia and cardiac arrest with dexmedetomidine administration.<sup>73</sup> However, in these reports, dexmedetomidine is unlikely to be the only causative agent of these cardiac arrests. Therefore, care should be taken in using dexmedetomidine in patients who will not tolerate bradycardia, or in patients who are receiving medications that cause bradycardia. The bradycardia associated with dexmedetomidine typically occurs after a loading dose. Omitting the loading dose decreases the incidence of bradycardia.<sup>72</sup>

Dexmedetomidine is associated with hypotension that is expected with an  $\alpha_2$ -adrenergic agonist. In healthy volunteers, after a 1  $\mu\text{g}/\text{kg}$  bolus, blood pressure decreased 23% compared to baseline. Infusions of 0.2 to 0.7  $\mu\text{g}/\text{kg}/\text{hr}$  were associated with larger decreases in blood pressure when compared to placebo. Blood pressure returns to baseline within 6 hours of treatment cessation without any apparent rebound effects. There are case reports of dexmedetomidine overdose. Two patients received infusions of 2 or 4  $\mu\text{g}/\text{kg}/\text{hr}$  (instead of 0.2 to 0.4  $\mu\text{g}/\text{kg}/\text{hr}$ ), which caused excess sedation but had minimal effect on hemodynamics.<sup>74</sup> In a 3-year-old child who received an unintentional bolus of 9  $\mu\text{g}/\text{kg}$  of dexmedetomidine, the heart rate, blood pressure, and oxygen saturation were all decreased. However, the child was managed with supplemental oxygen, fluid bolus, and epinephrine infusion,

and recovered to baseline after 7 hours.<sup>75</sup>

## Benzodiazepines

**8** Benzodiazepines—midazolam in particular—are frequently used by anesthesiologists to produce several clinically desirable effects: anxiolysis, anterograde amnesia, sedation, and hypnosis. They can also be used as muscle relaxants and anticonvulsants. Benzodiazepines have a favorable safety profile and can be reversed by flumazenil to manage excessive sedation or respiratory depression.

Midazolam was first discovered in 1976 and is the most widely used benzodiazepine in the perioperative period (Fig. 19-12; Table 19-7). Its use as a premedication and anesthetic is largely due to its quick onset, short elimination half-life, anterograde amnestic effect, and minimal side-effect profile.<sup>76</sup> Midazolam can be administered intravenously, intranasally, orally, rectally, and intramuscularly. This flexibility in route of administration also contributes to its popularity. A 0.5-mg/kg dose of oral midazolam given 30 minutes preoperatively in children yields a reliable anxiolytic and sedative effect without delayed emergence.<sup>77</sup> Some studies have even found a positive behavioral effect 1 week postoperatively in pediatric patients premedicated with oral midazolam.<sup>78</sup> Midazolam is also used as an infusion in the ICU setting. One meta-analysis reported that “infusions of both midazolam and propofol appear to provide similar quality sedation, that extubation time and recovery time is shorter in patients sedated with propofol, and that hemodynamic complications related to either drug regimen are not usually clinically significant.”<sup>79</sup>

**Table 19-7** Benzodiazepines

<b>Key Pharmacology</b>

Induction of anesthesia, hemodynamically stable
Anticonvulsant

### Pharmacokinetics

Benzodiazepines are highly protein-bound and highly lipophilic (Tables 19-8

and 19-9). High protein binding renders a smaller free fraction of the drug available to cross the blood–brain barrier, and high lipophilicity results in a larger volume of distribution. Clinically, less drug is free to cross the blood–brain barrier, but the high lipophilicity results in a rapid-onset of action (the peak effect of intravenous midazolam is within 2 to 3 minutes).<sup>80</sup> Only a fraction of the available CNS binding sites need to be occupied to produce clinical effects. Midazolam’s high lipid solubility, short duration of action, and short context-sensitive half-time allow this drug to be administered as a continuous infusion,<sup>81</sup> unlike other benzodiazepines.

Metabolism of benzodiazepines occurs largely in the hepatic cytochrome P450 system via oxidation and glucuronic conjugation. The metabolized drug is then renally excreted. Some drugs, such as diazepam, have pharmacologically active metabolites (i.e., desmethyldiazepam, 3-hydroxydiazepam) with long elimination half-lives that lead to a prolonged duration of action, especially in patients with renal failure. Drugs that inhibit the cytochrome P450 system can result in prolonged duration of benzodiazepines.

Favorable properties of midazolam are its high rate of hepatic clearance and relatively short elimination half-life. Midazolam has a volume of distribution of 1 to 3.1 L/kg after a single bolus dose, an elimination half-life of 1.8–2.6 to hours (mean approximately 3 hours), and a total clearance of 6.4–11 mL/kg/min.<sup>82</sup> Midazolam’s active metabolite (1-hydroxymidazolam) contributes minimally to its clinical effects (approximately 20% of midazolam’s potency). These properties are influenced by the patient’s age and comorbidities, particularly kidney and liver dysfunction. With continuous infusions of midazolam, the metabolite will accumulate and exert a more pronounced and prolonged effect. Rather than metabolism, redistribution of midazolam results in the termination of its effects.

**Table 19-8** Benzodiazepine Metabolism and Clearance

Drug	Duration	Metabolites	Hepatic Clearance
Midazolam	Short	1-Hydroxymidazolam (mild CNS depressant)	High
Diazepam	Intermediate	Oxazepam and desmethyldiazepam	Slow
Lorazepam	Long	Inactive	Intermediate

**Table 19-9** Benzodiazepine Pharmacokinetics

Drug	Induction Dose (mg/kg)	Duration of Action (min)	Half-Life (min)	Protein Binding (%)	Volume of Distribution (L/kg)	Clearance (mL/kg/min)	Elimination Half-Life (hr)
Midazolam	0.1–0.3	15–20	7–15	94	1–3.1	6.4–11	1.8–2.6
Diazepam	0.3–0.6	15–30	10–15	98	0.7–1.7	0.2–0.5	20–50
Lorazepam	0.03–0.1	60–120	3–10	98	0.8–1.3	0.8–1.8	11–22

## Pharmacodynamics and Clinical Uses

The three most commonly used parenteral benzodiazepines are lorazepam, diazepam, and midazolam. Lorazepam and diazepam are not soluble in water and often cause vein irritation due to the propylene glycol admixture. Alternative formulations are available as a lipid emulsion, but with a decrease in bioavailability. Midazolam is water-soluble and undergoes conformational change in the bloodstream, becoming more lipophilic. Midazolam is manufactured as an acidic formulation that may produce mild local tissue and vein irritation.

Benzodiazepines bind to specific receptor sites that are part of the GABA-A receptor complex. This binding augments the effect of the GABA-A receptor/chloride channel coupling, resulting in increased frequency of chloride channel opening. The resultant hyperpolarization of the cell ultimately leads to neural inhibition. It is this enhanced affinity of the GABA-A receptor for the GABA molecule, and subsequent decreased unbinding that produces the so-called ceiling effect.<sup>83</sup> Benzodiazepines thus have a dose-dependent CNS depressant effect (Table 19-10). For example, at 30% to 50% receptor occupancy, sedation is often produced, while at 20% occupancy one usually only achieves anxiolysis.<sup>84</sup>

The high density of GABA-A receptors in the cerebral cortex helps explain the sedative/hypnotic, anxiolytic, and amnestic capabilities of these drugs. Benzodiazepines also decrease both the CMRO<sub>2</sub> and CBF, while maintaining carbon dioxide responsiveness. They exert little if any effect on ICP. Because of the ceiling effect of benzodiazepines, an isoelectric EEG or burst suppression is not attained. This is in direct contrast to propofol and thiopental, each of which can achieve burst suppression. Thus, the neuroprotectant effect of benzodiazepines is quite limited, but likely not entirely absent. Some investigators have demonstrated that activation of GABA-A receptors, including the specific binding subunits for propofol and midazolam, play a role in the inhibition of neuronal death induced by brain ischemia.

**Table 19-10** Midazolam Dosing by Clinical Use

Premedication: anxiolysis, anterograde amnesia	0.02–0.04 mg/kg IV/IM; 0.4–0.8 mg/kg PO
Induction: hypnosis, amnesia, sedation	0.1–0.2 mg/kg IV
Infusion (in conjunction with volatile anesthetics): hypnosis, amnesia	0.25–1 µg/kg/min

Additionally, benzodiazepines are anticonvulsants and are a first-line

therapy in the management of seizures. They can also be used as muscle relaxants, but this spinal cord-mediated response typically requires supratherapeutic doses.

Benzodiazepines can also have a profound effect on the respiratory system. Upper airway reflexes may be decreased and central respiratory drive is depressed. In the usual premedication dosage, respiratory depression is rarely an issue.; however, if the patient has other comorbidities and/or concurrent opioid use, then adverse respiratory events are more likely to occur.

Benzodiazepines, especially in induction doses, depress the SVR and decrease blood pressure. This effect is quite minimal as there is some preservation of homeostatic reflexes. This response may be more pronounced in the hypovolemic patient. Benzodiazepines are overall regarded as hemodynamically stable induction agents.

### **Side Effects**

Aside from their previously discussed systemic effects, benzodiazepines are associated with limited adverse events. Anaphylaxis is extremely rare following the administration of a benzodiazepine. More frequently described is pain or thrombophlebitis that ensues following intravenous injection, especially diazepam. Propylene glycol is the organic solvent for diazepam and causes the pain associated with injection. In contrast, midazolam is water-soluble, but may also cause burning with injection secondary to its acidic formulation.

### **Barbiturates**

Thiopental is one of the earliest intravenous anesthetics used, discovered in the 1930s and first used on human patients in 1934. It has withstood the test of time as an induction agent because of its favorable pharmacokinetic profile (Fig. 19-13; Table 19-11). In 2011, production of thiopental in the United States ceased, leading to a drastic decrease in intraoperative use. Two major classes of barbiturates, oxybarbiturates and thiobarbiturates, are of anesthetic clinical and historical relevance. Both classes contain a pyrimidine center, and either an oxygen or sulfur molecule at position 2. Used in clinical practice are the thiobarbiturates thiopental (2.5%) and thiamylal (2%), and the oxybarbiturate methohexital (1%). The thiobarbiturate solutions are produced as racemic mixtures, despite unequal potency between their two stereoisomers. Methohexital has two chiral centers and four potential stereoisomers, but not all isomers are included in the final product. Barbiturate solutions are highly alkaline, allowing for formation of water-soluble salts. Addition or reconstitution in acidic solutions leads to

precipitation of these salts, preventing intravenous use. Unlike propofol, barbiturates cannot be stored for an extended period of time at room temperature after reconstitution in solvent. In alkaline solution, thiobarbiturates can be stored up to 2 weeks, and methohexital up to 6 weeks.

**Figure 19-13** Thiopental: (*RS*)-[5-ethyl-4,6-dioxo-5-(pentan-2-yl)-1,4,5,6-tetrahydropyrimidin-2-yl]sulfanide sodium. Thiamylal: 5-Allyl-5-(1-methylbutyl)-2-thioxodihydropyrimidine-4,6(1*H*,5*H*)-dione. Methohexital: 5-hex-3-yn-2-yl-1-methyl-5-prop-2-enyl-1,3-diazinane-2,4,6-trione.

### Pharmacokinetics

Primary metabolism of both barbiturate classes is hepatic, yielding water-soluble inactive metabolites that are subsequently eliminated in urine and bile. Oxidation of thiopental and methohexital to their respective hydroxyl derivatives is the most common form of metabolism.<sup>85</sup> Thiopental has a relatively long elimination half-life (12 hours), and its clearance rate (3 mL/kg/min) is 10-fold longer than that of propofol. Methohexital elimination half-life (4 hours) is also shorter than thiopental, secondary to a more efficient hepatic extraction of the drug (clearance rate 11 mL/kg/min). A negligible percentage of barbiturates is eliminated without metabolism in the urine.

**Table 19-11 Barbiturates**

<p><b>Key Pharmacology</b> GABA-A receptor agonist Prolonged context-sensitive half-time CNS depressant, neuroprotective, anticonvulsant, decreases CMRO<sub>2</sub>, CBF, and ICP EEG burst suppression (thiopental) Cardiovascular: decreases mean arterial pressure, venous vascular tone, and cardiac output Pulmonary: Dose-dependent respiratory depression, does not cause bronchodilation</p> <p><b>Key Clinical Uses</b> Induction of general anesthesia Methohexital used for sedation, premedication, and electroconvulsive therapy Barbiturate coma (thiopental) Thiopental intra-arterial injection can lead to tissue necrosis</p> <p>CMRO<sub>2</sub>, cerebral metabolic oxygen consumption rate; CBF, cerebral blood flow; ICP, intracranial pressure; EEG, electroencephalogram.</p>
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Multicompartment pharmacokinetic models of barbiturates after administration of an induction dose have been described. Similar to other intravenous agents, rapid redistribution into highly perfused compartments accounts for the rapid termination of drug action after a single induction dose. After an extended infusion of thiopental, accumulation in poorly perfused compartments and slow elimination play larger pharmacokinetic roles, resulting in a prolonged context-sensitive half-time and delayed recovery. The long context-sensitive half-time of thiopental after high doses is explained by the drug exhibiting zero-order kinetics. The elimination of thiopental becomes independent of both drug plasma concentration and level of compartmental saturation, and remains constant and defined by the slow rate of clearance.

## Pharmacodynamics

The mechanism of action of barbiturates involves cortical and brainstem GABA inhibitory pathways, leading to loss of consciousness, as well as respiratory and cardiovascular depression. Hypnotic effects of barbiturates are likely enhanced by the inhibition of central excitatory pathways, specifically those mediated by glutamate via NMDA receptors and acetylcholine.

## Central Nervous System Effects

The progression of EEG changes after administration of barbiturates is dose-dependent. Initial low doses can generate a light level of anesthesia often associated with a high-frequency and low-amplitude EEG pattern. With higher doses, both burst suppression and an isoelectric EEG can be attained.<sup>86</sup> Thiopental is generally considered an anticonvulsant, having been used

successfully for treatment of status epilepticus. At smaller concentrations thiopental has been noted to have proconvulsant properties. Methohexital is considered to have significant proconvulsant effects in patients with epilepsy, and is often the agent of choice for induction of anesthesia prior to electroconvulsive therapy.<sup>87,88</sup> The excitatory effects of methohexital are commonly exhibited muscle twitches that occur after an induction dose of the drug.

Barbiturates cause a decrease in  $CMRO_2$  that is dose-dependent, eventually leading to an isoelectric EEG that is associated with up to a 50% decrease in oxygen consumption.<sup>89</sup> A concomitant increase in cerebral vascular resistance leads to decreased CBF and ICP. CPP is often unchanged or even improved, as the decrease in MAP is typically less than the decrease in ICP. Barbiturate CNS effects are considered neuroprotective and in part explained by the decrease in  $CMRO_2$ , although  $CMRO_2$  decreases are not directly proportional to levels of ischemic neuroprotection.<sup>90</sup> Other neuroprotective mechanisms likely play a role, including barbiturate anticonvulsant properties, improved blood flow to ischemic parts of the brain (reverse steal effect), free-radical scavenging, attenuation of excitatory neurotransmitter release and pathways, and membrane stabilization. The reverse steal effect is a result of flow-metabolism coupling. At higher doses, the reduction in oxygen consumption in well perfused areas of the brain leads to decreased flow, with subsequent diversion of blood flow to ischemic areas.

Historically, barbiturate-induced “brain relaxation” has been utilized as a protective strategy during neurosurgery and after head trauma. The clinical benefit after barbiturate administration has been reproduced by other techniques, including cooling (to lower  $CMRO_2$ ) and antihypertensive strategies. Barbiturate neuroprotection is generally considered more effective for focal and incomplete ischemia, rather than global injury. In the setting of comatose cardiac arrest survivors, thiopental loading after cardiac arrest has not been shown to significantly improve outcome.<sup>91</sup> In contrast, thiopental-induced burst suppression and isoelectric EEG prior to potential focal ischemic insult during cardiopulmonary bypass and carotid surgery have been shown to have clinical benefit.

## **Cardiovascular Effects**

The most prominent cardiovascular changes after an induction dose of thiopental are decreases in both MAP and cardiac output. The primary mechanism is reduction of venous vascular tone, followed by peripheral pooling of venous blood and a decrease in venous return.<sup>92</sup> Thiopental also has negative inotropic effects, directly by altering intracellular calcium homeostasis and indirectly by diminishing sympathetic tone. Baroreceptor-

mediated heart rate increase may be impaired by thiopental administration, but a reflex elevation in heart rate of 10% to 30% is still typically present. The negative hemodynamic effects after a thiopental bolus are more pronounced in patients with underlying cardiovascular disease and in hypovolemic states. Induction doses of methohexital are typically associated with a smaller decrease in MAP and larger increase in heart rate than what is described for thiopental.<sup>93</sup>

## **Respiratory System Effects**

Barbiturates cause respiratory depression in a dose-dependent manner, leading to central apnea at deeper stages of anesthesia. After a typical induction dose, apnea is commonly noted after 1 to 1.5 minutes, with ventilatory response to carbon dioxide returning to baseline in approximately 6 minutes. The time course to recovery from respiratory depression is shorter with thiopental than with propofol.<sup>94</sup> Thiopental does not cause as much bronchodilation as propofol or inhalational anesthetics.<sup>95,96</sup> Case reports of laryngospasm and bronchospasm after induction of anesthesia with thiopental exist, and airway reflexes are generally considered to be more preserved compared to induction with propofol.

## **Clinical Uses**

Rapid onset and emergence from a bolus dose of thiopental have made it an ideal induction agent. The typical induction dose is 2.5 to 5 mg/kg, resulting in light stages of anesthesia in 15 to 30 seconds, and deeper stages in 30 to 40 seconds that last for approximately 1 minute. Premedication may decrease the required induction dose by as much as 50%, and nitrous oxide may decrease the required plasma concentration of thiopental by 67%.<sup>97</sup> Patient variability will affect the required induction dose. Unpremedicated healthy children may require a 5- to 6-mg/kg induction dose, and infants may have an even higher requirement.<sup>98</sup> Elderly patients have a lower induction dose requirement, although no significant age-specific difference in plasma concentrations of thiopental were noted to achieve a given hypnotic effect.<sup>99</sup> The necessary reduction in dose is likely due to variation in pharmacokinetic profile of elderly patients, including decreased volume of distribution and slower redistribution times. Obesity also has been noted to lower thiopental induction requirement on a per kilogram basis,<sup>100</sup> but similar to elderly patients, the use of lean body mass to determine induction dose corrects the difference. Numerous comorbid states have been associated with a decrease in induction dose requirement, including liver disease, heart failure, shock, and severe anemia. Methohexital can also be used for induction of anesthesia,

with the typical intravenous induction dose of 1 to 2 mg/kg. It has also been administered rectally in solution form as a sedative in the pediatric population, with the recommended dose of 25 mg/kg.<sup>101</sup>

Thiopental is rarely used as an intravenous infusion for maintenance of general anesthesia because higher doses lead to zero-order kinetics and a slow plasma clearance. The context-sensitive half-time of thiopental is relatively high and results in unpredictable and prolonged recovery from infusion. Methohexital has a shorter elimination half-life than thiopental, and at infusion doses of 50 to 150 µg/kg/min has been used for maintenance of sedation and general anesthesia. Concern for seizure activity after prolonged infusions in susceptible patient populations has minimized this utility. As noted, thiopental infusion for maintenance of barbiturate coma has been utilized in patients with elevated ICP after acute brain injury, although the efficacy of thiopental in preventing long-term brain injury and improving outcomes has been questioned.

### **Side Effects**

Intravenous administration of thiopental is typically not irritating or painful, but if injected outside the vein into subcutaneous tissue it can cause discomfort. Methohexital-induced pain on injection is much more prevalent. Inadvertent arterial administration of thiopental has to be managed promptly, as formation of crystals can lead to decreased flow due to vasospasm and thrombus formation, pain at the arterial site, and possible tissue necrosis. Management includes arterial administration of papaverine, heparinization, and potential arteriodilation by appropriate regional anesthetic technique. Barbiturates are contraindicated in patients with acute intermittent porphyria, as an exacerbation of symptoms may be augmented by their direct effects on hepatic enzymes.

## **New Intravenous Anesthetics**

New drugs are constantly being developed in an effort to achieve the ideal intravenous anesthetic with a short duration of action, a short context-sensitive half-time that allows for infusion administration, and minimal adverse effects. 10

### **Remimazolam**

This investigational drug is a benzodiazepine with a structure and onset time similar to midazolam (Fig. 19-14), and it binds as an agonist to the GABA receptor. It has a rapid offset that follows first-order kinetics at the

recommended doses due to metabolism by tissue esterases (similar to remifentanyl), and thus does not result in accumulation of drug. In addition to organ-independent metabolism, this drug is reversible with flumazenil, further adding to the safety profile. The quick onset and offset offer the potential for use as an infusion. Remimazolam is initially being developed for procedural sedation during procedures such as colonoscopy.<sup>102</sup> It is also being considered for ICU sedation, as many critically ill patients have end-organ dysfunction and would benefit from the organ-independent metabolism of this drug. This drug provides an alternative to propofol by avoiding PRIS and accumulation of drug leading to prolonged sedation. To summarize, remimazolam takes advantage of the hypnotic and amnestic effects of midazolam with a speed and mode of metabolism similar to remifentanyl.<sup>103</sup>

**Figure 19-14** Structural comparison between midazolam and remimazolam.

### **Propofol Formulations**

Propofol is a hydrophobic oil that requires a lipid emulsion as a vehicle of administration. This emulsion, comprised largely of egg yolk lecithin, soybean oil, and glycerol, has several drawbacks. The most common complaint is pain on injection. More serious adverse effects include anaphylaxis, sepsis secondary to microbial contamination of an open vial (despite antimicrobial additives), and PRIS.<sup>104</sup> Many attempts have been made to develop a formulation of propofol that reduces these problems, including (1) to reduce the percentage of lipid in the emulsion, (2) to eliminate the lipid, and (3) to create a prodrug. One major challenge with tailoring the current formulation is that the drug's pharmacokinetics may also be altered.

### **Fospropofol**

Fospropofol is a prodrug of propofol that was produced to reduce or eliminate the adverse effects of the current propofol emulsion. Fospropofol is a water-based solution that yields less pain on injection, less hyperlipidemia, and less risk for bacteremia. Its clinical application as a sedative-hypnotic has been approved for MAC sedation, but not for general anesthesia. A major deterrent

to its use is its delayed onset time and longer elimination time. Although hypotension and respiratory depression may occur less frequently, these reactions still do occur. Fospropofol is also associated with an increase in pruritus and paresthesias.<sup>105</sup> Fospropofol was initially developed as a drug to be used by nonanesthesia medical providers. However, fospropofol is associated with similar respiratory depression as propofol, and practitioners must be able to rescue patients from unintended deep sedation or general anesthesia.

**Figure 19-15** Etomidate, cyclopropyl-methoxycarbonyl metomidate (CPMM), and their metabolites.

### **Cyclopropyl-methoxycarbonyl Metomidate**

Cyclopropyl-methoxycarbonyl metomidate (CPMM), also known as AB700, is an analogue of etomidate that has shown promise in animal studies (Fig. 19-15). It causes less adrenal suppression compared with etomidate. It also is less potent and has a shorter duration of action than etomidate. The investigators of this drug purport its use as a bolus or infusion medication for both sedation and general anesthesia.<sup>106</sup> Although its structure is a derivative of etomidate, its clinical application seems to be more consistent with that of propofol. Some studies have even demonstrated that compared to propofol, CPMM has less drug accumulation and therefore more rapid recovery after prolonged infusion.<sup>106</sup>

### **THR-918661/AZD-3043**

The search for a sedative/hypnotic agent whose effects are terminated in a predictable and consistent time frame regardless of dose or duration of infusion has led to the development of THR-918661/AZD-3043. This medication is a metabolically-labile, positive allosteric modulator of the GABA-A receptor. This investigational drug is water-soluble and rapidly

hydrolyzed by blood and tissue esterases to an inactive carboxylate metabolite.<sup>107</sup> A Phase I clinical trial showed no serious adverse events and a rapid recovery after infusion administration. Further studies will be required to evaluate the potential of THR-918661/AZD-3043 to provide rapid recovery regardless of duration of anesthesia.<sup>108</sup>

## Sedasys

In May 2013, the FDA approved Sedasys, a computer-assisted patient-controlled sedation system that administers propofol for colonoscopies/endoscopies. Patients are monitored with electrocardiography, pulse oximetry, noninvasive blood pressure monitoring, and end-tidal carbon dioxide. Sedation is also further monitored via an earpiece through which the computer tells the patient to squeeze a handset. Based on these parameters, Sedasys will algorithmically adjust the infusion rate of propofol.

An early study of one thousand patients, ASA class 1–3, who used the Sedasys system found fewer episodes of desaturation and improved patient and physician satisfaction.<sup>109</sup> Sedasys affords nonanesthesia providers the ability to conduct procedures that require minimal to moderate sedation with propofol. Healthcare cost savings might theoretically result from removing the anesthesiologist from the cost of the procedure. However, many physicians, especially anesthesiologists, are skeptical of the safety of this patient-controlled system. For example, there are times when deeper planes of anesthesia are needed, yet cannot be provided by Sedasys. Patients may cough or buck or obstruct their airway during the procedure, and nonanesthesia providers may not be sufficiently trained or skilled in airway management. Furthermore, sampling of the end-tidal carbon dioxide may not be accurate secondary to the endoscope physically being near the airway.<sup>110</sup> Interestingly, in March, 2016 the device manufacturer has exited the market for this product.

## KEY POINTS

- 1 Opioids produce analgesia as well as serious side effects. All physicians who prescribe opioids for relief of acute or chronic pain need to know how to use these drugs safely. This requires an in-depth understanding of

the pharmacokinetics and pharmacodynamics of opioids as well as the acquisition of sufficient clinical experience in their use.

- 2 Opioids can be classified according to strength or potency based on the plasma concentrations at which they exert their effects ( $C_{50}$  or the plasma concentration causing a 50% effect). Strong opioids include fentanyl, sufentanil, and remifentanyl. Weak opioids include codeine and tramadol. An intermediate group includes morphine, methadone, oxycodone, and buprenorphine.
- 3 Opioids act through specific opioid receptors on neuronal tissues such as peripheral nerves and neurons in the spinal cord and brain. The most important receptors include the  $\mu$ -opioid receptor (MOR),  $\delta$ -opioid receptor (DOR), and  $\kappa$ -opioid receptor (KOR). For anesthesia and pain relief, the MOR is most important. Opioids also act through nonneuronal pathways, such as those affecting the immune system, which may be of relevance in the treatment of inflammatory pain.
- 4 Endogenous opioid pathways are activated in cases of stress-induced analgesia, placebo-induced analgesia, and conditioned pain modulation (CPM). CPM occurs when pain arising from one focus is decreased by application of a second painful stimulus (pain inhibits pain).
- 5 Opioid-induced hyperalgesia (OIH) is a paradoxical opioid effect whereby pain sensitivity increases during or following escalating opioid treatment. It is also observed postoperatively following the use of a remifentanyl infusion during anesthesia. Greater and more frequent doses of morphine are required to treat postoperative pain. OIH may be treated and prevented by administration of a low dose of ketamine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist.
- 6 The pharmacokinetic characteristics of a drug determine its behavior in the body of a patient. One important pharmacokinetic concept is that of context-sensitive half-time ( $CSt_{1/2}$ ). This is the time needed for the drug's plasma concentration to decrease by 50% from a steady-state concentration. For most opioids, this value is dependent on the duration of drug infusion. For example, for fentanyl the  $CSt_{1/2}$  increases rapidly with the infusion duration. In contrast, the  $CSt_{1/2}$  of remifentanyl is independent of the infusion duration due to its rapid elimination from plasma.
- 7 Opioid metabolism is affected by drugs that interfere with metabolizing cytochrome P450 enzymes, most importantly CYP3A4. Opioid metabolites can be active or inactive. Active metabolites need to be considered when treating patients. For example, the active metabolite of morphine, morphine-6-glucuronide, can accumulate in patients with renal impairment. Genetic variability in the CYP system can have important clinical implications, especially in case of variations in the copies of a

gene coding for the metabolizing enzyme. An example is the enzyme CYP2D6, which catalyzes the conversion of codeine into morphine. Patients with multiple copies of the CYP2D6 gene and who receive codeine will have large plasma morphine concentrations with all related beneficial and adverse side effects.

- 8 Opioid effects are variable among patients. Dosing is optimum when opioids are titrated to the effect. It is also important to take into account the delay between the administration of an opioid and its effect, which is defined as the blood–effect site equilibration half-life, or  $t^{1/2}k_{e0}$ . This will allow proper and timely dosing particularly when anticipating a stressful event (laryngoscopy, intubation, skin incision, etc.) and administering opioids to prevent the occurrence of a large hemodynamic response to these stimuli. Since the  $t^{1/2}k_{e0}$  of morphine is about 90 minutes, it is important to give an initial bolus dose of morphine at least 60 minutes before the end of surgery when using the drug for postoperative pain relief.
- 9 Opioids reduce the requirement of inhalational anesthetics and propofol during anesthesia, which makes rapid awakening from anesthesia possible. Using known pharmacokinetic and pharmacodynamic data it can be determined what doses and plasma concentrations will permit the shortest time to awakening. For example, termination of drug infusions at plasma concentrations of propofol 1.5  $\mu\text{g}/\text{mL}$  and remifentanyl 9.0  $\text{ng}/\text{mL}$  will lead to patient awakening within 6.5 minutes.
- 10 In the perioperative setting careful, slow, infusion of opioids allows the gradual accumulation of arterial  $\text{CO}_2$ , which serves as a respiratory stimulant at the chemoreceptors and lowers the probability of apnea.
- 11 Administration of opioids can potentially lead to life-threatening respiratory depression. The incidence of serious perioperative respiratory events is approximately 0.5% (1 in every 200 patients). In the acute setting risk factors include sleep-disordered breathing, obesity, renal impairment, pulmonary disease, neurologic disorders, and CYP450 enzyme polymorphism. In the pediatric population risk factors include morphine administration in patients with renal impairment, adenotonsillectomy for recurrent tonsillitis, and/or obstructive sleep apnea and codeine use in patients with CYP2D6 gene polymorphism associated with the ultrarapid metabolizer phenotype. In chronic pain patients risk factors included renal failure, sensory deafferentation, and drug–drug interactions.
- 12 The nonspecific opioid receptor antagonist, naloxone, is currently the drug of choice to reverse opioid-induced respiratory depression. The required dose of naloxone depends on the pharmacokinetic and pharmacodynamic properties and the dose of the opioid that needs

reversal. Postoperatively, when there is persistent apnea, opioid concentrations are often just above the threshold for respiratory depression. Intravenous administration of naloxone using incremental doses of 40 to 80  $\mu\text{g}$ , to a cumulative dose of less than 400  $\mu\text{g}$ , may be sufficient for breathing to resume.

- 13 New drugs are being developed that reverse or prevent opioid-induced respiratory depression without affecting analgesia. These drugs include blockers of potassium-channels expressed on oxygen-sensing cells of the carotid bodies and drugs that increase respiratory drive through action at  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors in brainstem respiratory centers involved in rhythmogenesis.
- 14 Apart from respiratory depression, opioids cause a large number of side effects that require attention: nausea, smooth muscle spasms, skeletal muscle rigidity, histamine release, pruritus (especially after spinal administration), miosis, sedation, and dizziness. The cardiovascular side effects of opioids include bradycardia and hypotension but are generally mild at usual clinical doses. However, when combined with anesthetics, even at usual clinical doses, or in severely ill patients, opioids may produce hemodynamic instability, which requires treatment.

## Introduction

Opioids are the most potent painkillers available in modern medicine. Traditionally opioids are used in perioperative care by anesthesiologists and other anesthesia care providers to attenuate autonomic responses to noxious (surgical) stimulation and treat acute postoperative pain. In recent years, however, there has been an exponential increase in the prescription of opioid analgesics by pain specialists and other health-care providers, such as primary care doctors, for treatment of chronic (cancer and noncancer) pain. Consequently, a significant number of patients in developed countries are exposed to these potent drugs that not only produce pain relief but also cause a variety of side effects that range from dizziness, orthostatic hypotension, nausea, and constipation to harmful and potentially lethal effects such as **1** addiction and critical respiratory depression. The “epidemic” of opioid use by nonsurgical patients, coupled with an emphasis on aggressive and effective postoperative pain management for patients undergoing surgery, has resulted in increasingly complex postoperative pain management problems for surgical patients,<sup>1</sup> and an increase in opioid-related complications for patients with pain in general.<sup>2,3</sup> Consequently, expertise in the use of opioids is not only required in the operating room and following surgery in the postanesthesia care unit (PACU) and on the ward, but also when caring for patients with chronic pain in nonsurgical settings. The expertise should cover

all aspects of opioid effects such as pharmacokinetics (PK), pharmacodynamics (PD), and the side effect profile associated with opioid use.

## History

Opium is among the oldest drugs in the world. Fossilized opium poppies have been found in Neanderthal excavation sites dating back to 30000 BC. Many old civilizations, including the Sumerians, Egyptians, Greeks, Romans, and Chinese, used opium for nutritional, medicinal, euphoric, spiritual, and religious purposes. The first written reference to the medicinal use of the opium poppy is described in a Sumerian text dated near 4000 BC. Just over 200 years ago, the German pharmacist and chemist Friedrich Sertürner isolated a stable alkaloid crystal from the opium sap and named it morphine after the Greek god of dreams, Morpheus.<sup>4,5</sup> Morphine was 10-fold more potent than opium and soon replaced it not only for the treatment of severe pain, but also for a myriad of other purposes such as cough and diarrhea. After the invention of the hypodermic syringe in 1853, the Englishman Alexander Wood was the first to inject morphine in a controlled fashion into a patient producing more than a day's sleep.<sup>6</sup> The first reported casualty from morphine occurred shortly thereafter when Wood injected his wife with morphine resulting in a fatal overdose from respiratory depression. Morphine revolutionized the treatment of the wounded in battlefield medicine, but euphoric and addictive properties led to the addiction of thousands of soldiers to morphine during the American Civil War. The synthesis of heroin in 1874 was based on the empirical finding that boiling morphine with specific acids caused the replacement of the two morphine –OH groups by –OCO<sub>2</sub>H<sub>3</sub> producing diamorphine or heroin (Fig. 20-1).

**Figure 20-1** Chemical structure of commonly used opioids.

After the structure of morphine was determined in the 1920s, the synthesis of new morphine-like opioid compounds was based on chemical principles rather than empirical discoveries. In 1937, meperidine (or pethidine) became the first synthetic opioid synthesized on the basis of the central structure of morphine. Since then many synthetic and semisynthetic opioids have been produced, including the clinically important opioid antagonists naloxone and naltrexone, by replacing the N-methyl substituent in morphine with allyl and cyclopropylmethyl groups, respectively (Fig. 20-1).<sup>7</sup>

For clinical use during anesthesia the most important opioids are the **2** fenyloperidines: fentanyl, sufentanil, alfentanil, and remifentanyl. These opioids produce potent analgesia and suppression of cardiovascular responses to noxious stimulation from surgery with predictable PK and PD.

Recently developed opioids include tapentadol and cebranopadol.<sup>8,9</sup> These opioids act simultaneously at multiple receptor systems. Tapentadol activates the  $\mu$ -opioid receptor (MOR) and inhibits the neuronal uptake of noradrenaline.<sup>8</sup> Cebranopadol is an opioid with similar affinities for the MOR and nociception/orphanin FQ receptor (NOP, also known as opioid receptor-like receptor type 1).<sup>9</sup> The continued development of opioids with complex simultaneous actions at multiple target sites is driven by concerns that the side effect profile of potent opioids, which presents a serious risk to patients, needs to be minimized.

## The Endogenous Opioid System

A major breakthrough in the understanding of opioid pharmacology came from a series of discoveries of opioid receptors, endogenous opioid peptides, their encoding genes, and endogenous opioid alkaloids. The endogenous opioid system is composed of a family of structurally related endogenous peptides that act at a four-member opioid receptor family consisting of the MOR,  $\kappa$ -opioid receptor (KOR),  $\delta$ -opioid receptor (DOR), and NOP receptor.<sup>10,11</sup> This opioid system is involved in a variety of regulatory functions including important roles in nociceptive, stress, emotional, and hedonic responses, as well as modulation of thermoregulation, breathing, neuroendocrine function, gastrointestinal (GI) motility, and immune responses.

In rodents, various subtypes of opioid receptors have also been identified, with different pharmacologic functions. For example, at least three MOR subtypes have been described:  $\mu_1$  is predominantly involved in opioid analgesia,  $\mu_2$  is involved in opioid-induced respiratory depression, and  $\mu_3$  is involved in opioid-induced immune suppression.<sup>12,13</sup> The functional validation of most opioid receptor subtypes awaits the development of antagonists with sufficient selectivity to allow a clear differentiation by effect. The endogenous opioid peptides include endorphins, enkephalins, and dynorphins, each of which displays different affinities for MOR, KOR, and DOR.<sup>14</sup>  $\beta$ -endorphins have a high affinity for the MOR, met- and leu-enkephalins for the DOR, and Dynorphin A for the KOR. The recently discovered nociceptin has been identified as a selective endogenous ligand of the NOP receptor,<sup>11</sup> whereas endogenous morphine acts via the  $\mu_3$ -receptor located on immune cells, such as human monocytes.<sup>15</sup>

Opioid receptors are members of the large G-protein-coupled receptor (GPCR) family.<sup>16</sup> GPCRs mediate a cascade of downstream signaling pathways leading to (1) the inhibition of adenylyl cyclase and decreased cyclic AMP, (2) activation of  $\text{Ca}^{2+}$  and  $\text{K}^+$  channels, and (3) activation of mitogen-activated protein kinase/extracellular signal-regulated kinase, protein kinase C, and P13 K/Akt.<sup>17</sup> Interactions between opioid ligands and selective receptors have a number of important clinical effects. Morphine-induced analgesia and respiratory depression are both induced through activation of the MOR and subsequent activation of the adenylyl cyclase/cyclic AMP pathway.<sup>18</sup>

### ***Simultaneous Targeting of Multiple Opioid and Nonopioid Receptors***

Most opioid analgesics act at multiple opioid receptors with different affinities.<sup>19</sup> For example, morphine acts with high affinity at the MOR and with lower affinities at the KOR and DOR. Some opioids act at opioid and

nonopioid receptors. For example, methadone is an MOR agonist and relatively potent antagonist at the *N*-methyl-D-aspartate (NMDA) receptor.<sup>20,21</sup> Antagonism of the NMDA receptor is clinically useful in reducing opioid tolerance and opioid-induced hyperalgesia (OIH) and in chronic pain states leading to pain hypersensitivity.<sup>22</sup>

Tramadol is an analgesic that produces pain relief through MOR agonism and inhibition of the neuronal reuptake of serotonin and noradrenaline,<sup>23</sup> which activate descending controls. Tramadol is a racemic mixture and its opioid action results from the (+)-enantiomer and the active metabolite O-desmethyltramadol (M1), which has a higher affinity for the MOR than its parent compound. The monoaminergic activity is related to the (–)-enantiomer. Since the metabolism of tramadol into its active compound M1 is dependent on the cytochrome P450 system, patients with a reduced CYP2D6 activity will require higher tramadol doses for analgesia.

Tapentadol is a new analgesic agent.<sup>8</sup> In contrast to tramadol, it is one molecule that has a dual mechanism of action. It is active at the MOR at spinal and supraspinal sites. It is also a norepinephrine reuptake inhibitor in the spinal cord, activating  $\alpha_2$ -adrenergic receptors in the spinal cord dorsal horn. The affinity of tapentadol for the MOR is 50-fold lower than that of morphine. However, due to synergy between the two mechanisms of action, tapentadol produces potent analgesia and is useful in the treatment of moderate-to-severe acute and chronic pain. Tapentadol differs from tramadol due to its lack of serotonergic activity resulting in a lower incidence of nausea and vomiting. Tapentadol's low affinity for the MOR may limit its undesirable side effects although its respiratory side effects have not yet been fully studied. Tapentadol produces analgesic effects in chronic neuropathic pain patients by (re)activation of descending inhibitory pathways. In diabetic polyneuropathy patients, conditioned pain modulation (CPM, see below) increased significantly during tapentadol treatment, and was correlated strongly with its analgesic effect.<sup>24</sup>

Cebranopadol is a novel opioid and, like tapentadol, is a single molecule acting at multiple receptor systems, most importantly the MOR and NOP receptors.<sup>9</sup> In various animal models of acute and chronic (neuropathic) pain, cebranopadol produces potent antinociception with a favorable side effect profile. Human studies are currently ongoing.

Finally, nonopioids may also act at opioid receptors. An important example is ketamine, which is an NMDA receptor antagonist with affinity for multiple receptor systems including the opioid receptors.<sup>25</sup> Its anesthetic properties are related to its effect at the NMDA receptors while its analgesic effects are predominantly due to MOR activation.

## Opioid Mechanisms

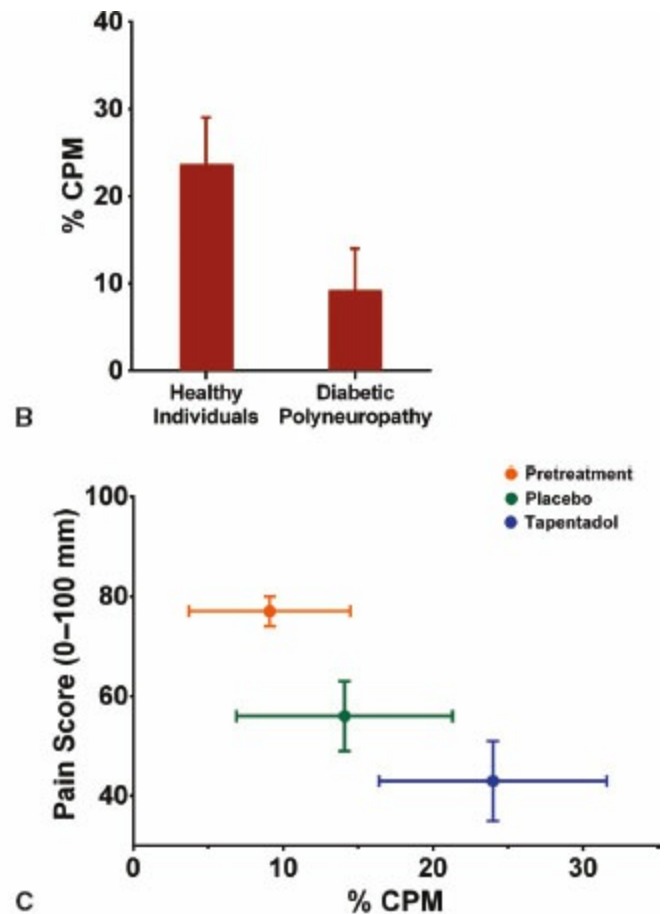

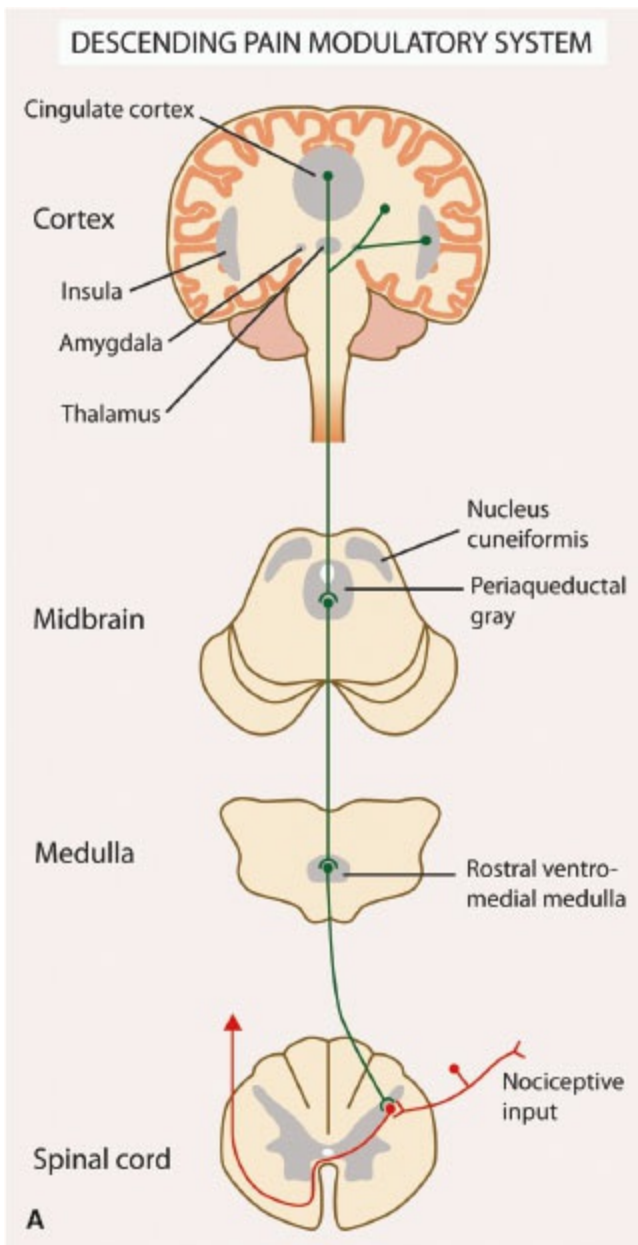

## Central Opioid Analgesia

Whereas nociception is the neural process of encoding and processing of noxious stimuli that can potentially (or actually) damage tissue,<sup>26</sup> pain is the subjective translation of these stimuli into a perception or sensation. Opioids modify both nociception and the perception of a noxious stimulus (emotional coloring of pain). Different types of peripheral sensory nociceptors, often free nerve endings, are stimulated by tissue damage. The resulting pain information is transmitted to the spinal cord by two types of small diameter peripheral afferent fibers: slow conducting, unmyelinated C-fibers (which cause a dull burning pain) and faster, thinly myelinated A $\delta$  fibers (which cause sharp, pricking pain). Both types of primary afferent fibers enter the dorsal horn of the spinal cord and terminate in its superficial layers (lamina I-II). Projection neurons from these laminae give rise to the ascending pathways of the spinothalamic tract. Thalamic nuclei receive the nociceptive inputs and pass the information to key brain pain reception sites such as the periaqueductal gray (PAG), amygdala, and somatosensory cortex. Activation of the MORs extensively located in these higher brain centers stimulates analgesia by activating *descending inhibitory pathways* from the PAG and rostroventral medulla (RVM) that inhibit nociceptive dorsal horn neuron firing in the spinal cord (Fig. 20-2A).<sup>27,28</sup> Opioids also exert actions in the cortex and limbic systems affecting cholinergic systems that lead to changes in arousal and pain perception.<sup>29</sup> Opioid receptors are further abundantly present in the spinal cord dorsal horn at pre- and postsynaptic locations. In the superficial laminae of the dorsal horn, local neuronal circuits process both ascending and descending pain pathways and are regulated by local endogenous opioid circuits.

MOR-induced analgesia and descending inhibitory pathways may be activated not only by exogenous opioids, but also by activation of endogenous opioid systems. Direct electrical stimulation of the PAG and RVM induces analgesia that is reversed by opioid antagonists.<sup>30</sup> The electrically stimulated sites overlap with the opioid receptor sites and with opioid-containing interneurons, linking together the actions of exogenously applied analgesic stimuli and endogenous opioid systems. Three major examples of analgesia driven by the endogenous opioid system are (1) stress-induced analgesia<sup>31</sup>; (2) placebo-induced analgesia<sup>32</sup>; and (3) conditioned pain modulation (CPM).<sup>33</sup>

1. *Stress-induced analgesia.* The endogenous opioid system is activated under stressful conditions, as demonstrated by the delayed onset of pain by soldiers wounded in battle.<sup>34</sup> The same higher brain centers bearing MORs are involved in the implementation of stress-induced analgesia. 4

2. *Placebo-induced analgesia.* The endogenous opioid system also mediates placebo-induced analgesia, a reduction of pain resulting from an expectation of pain relief. Studies using fMRI and PET show activation of the endogenous opioid systems and MORs in the brains of subjects receiving placebo described as an analgesic.<sup>35,36</sup>
3. *CPM.* Formerly known as diffuse noxious inhibitory control, CPM is a condition in which pain arising from a noxious stimulus applied to one part of the body is decreased by application of a second remote noxious stimulus (pain inhibits pain).<sup>24,37,38</sup> CPM is due to activation of descending inhibitory pathways by higher brain centers. An example of CPM from animal physiology is the observation that an imposed nose twitch in a horse attenuates the increase in heart rate induced by painful stimuli.<sup>39</sup> Since naloxone blocks this effect it is assumed that endogenous opioids are released during the nose twitch. In humans, tapentadol is an example of an opioid that induces analgesia through activation of descending pathways (Fig. 20-2B and C).<sup>24</sup>

**Figure 20-2 A:** Simplified diagram of activated descending inhibitory pathways (*green lines*) in response to afferent nociceptive input (*red lines*). Descending inhibition is activated in various higher brain centers, including the rostral ventromedial medulla, periaqueductal gray, amygdala, cingulate cortex, insula, and orbitofrontal cortex. These same areas are involved in Conditioned Pain Modulation (CPM). (From Dahan A, Niesters M, Sarton E. Endogenous modulation of pain is visible in the brain. *Clin Neurophysiol.* 2012;123:642–643). **B:** Reduced or absent CPM responses are present in patients with diabetic polyneuropathy, reflecting inactive descending inhibitory pathways. **C:** Effect of 4-week treatment with the opioid/norepinephrine reuptake inhibitor tapentadol and placebo on CPM and pain scores in patients with diabetic polyneuropathy. (Data from Niesters M, Niesters M, Aarts L, et al. Tapentadol potentiates descending pain inhibition in chronic pain patients with diabetic polyneuropathy. *Br J Anaesth.* 2014;113:148–156.)

## Peripheral Opioid Analgesia

Opioids are also involved in peripheral analgesia by acting directly on sensory neurons ( $A\delta$  and C-fibers) to inhibit pain signal transmission. This is especially important in inflammatory pain. However, the immune system is also widely involved in peripheral analgesia.<sup>40</sup> Opioid receptors are located not only on neurons, but also on immune cells, such as human leukocytes.<sup>41</sup> An insult to a peripheral tissue triggers the local release of many proinflammatory mediators that generate an inflammatory cascade, induce spontaneous nociceptor activity, and sensitize sensory neurons to induce spontaneous pain, allodynia (a nonpainful stimulus is perceived as painful), and hyperalgesia (increased pain sensitivity). Early in the inflammatory process there is an influx of leukocytes into the inflamed area and these cells are a major source of opioid peptides to inflamed sites. Opioid peptides released locally interact with the opioid neuronal receptors to induce analgesia (Fig. 20-3).<sup>42</sup> The inflammatory process also stimulates further opioid receptor upregulation and thereby increases the antinociceptive action of opioid peptides released by immune cells. In aggregate, the inflammatory process not only promotes inflammation and its painful sequelae, but also initiates and sustains a counteracting analgesia driven by endogenous opioids.<sup>43</sup>

**Figure 20-3** Schematic diagram illustrating the role of opioids in analgesia of peripheral

inflammation. Opioid-containing leukocytes are attracted to inflamed tissue by various chemokines and cytokines. Specific upregulated protein facilitates leukocyte migration through the vascular endothelium. In the inflamed tissue leukocytes interact with releasing agents such as corticotropin-releasing factor (CRF), interleukin-1 (IL-1), and norepinephrine (NA) derived from postganglionic sympathetic neurons, to secrete opioid peptides. These bind to peripheral opioid receptors, synthesized in the dorsal root ganglia and transported to peripheral endings of sensory neurons, to mediate analgesia. AR, adrenergic receptor; CRFR, corticotropin-releasing factor receptor; PECAM-1, platelet endothelial adhesion molecule 1; ICAM-1, intracellular adhesion molecule 1; CXCR2, chemokine (C-X-C motif) receptor 2; CXCL1, chemokine (C-X-C motif) ligand 1; CXCL2/3, chemokine (C-X-C motif) ligand 1/2.

### *Opioid-induced Hyperalgesia and Tolerance*

**5** Opioids can induce the paradoxical effect of OIH or an increase in pain sensitivity.<sup>44</sup> OIH may limit the analgesic effects of opioids. During long-term and/or high-dose opioid treatment, rapid opioid dose escalation, or administration of an opioid with rapid onset/offset (e.g., remifentanyl), a paradoxical increase in pain accompanies the treatment escalation.<sup>45,46</sup> The MOR is not a prerequisite for OIH, because there is ample evidence from knockout mice studies (mice devoid of MORs) or studies in mice treated with naloxone or naltrexone that OIH develops in response to exposure to high-dose opioids.<sup>47</sup> There may be various mechanisms for OIH, including activation of the central glutaminergic system, central nitric oxide production, and facilitation of descending pronociceptive systems.

Postoperative patients who have received remifentanyl infusions intraoperatively can have a higher incidence of OIH and need greater doses of morphine for control of postoperative pain than patients receiving nonremifentanyl-based anesthesia. Although animal and human data indicate that all  $\mu$ -opioids may cause OIH there seems to be a gradual difference in prevalence, with most observation of OIH following administration of rapid-acting opioids, such as remifentanyl. In addition, this high incidence of exaggerated pain in surgical patients following remifentanyl infusions may be related to its rapid offset of analgesia. In order to prevent severe pain responses following remifentanyl-based anesthesia, administration of morphine (0.1 to 0.25 mg/kg) 45 to 60 minutes before the end of surgery is advisable, and adding a low-dose ketamine infusion may prevent the development of OIH (dose range: 10 to 30 mg/hr) due to ketamine's NMDA antagonistic properties.

OIH is not the same phenomenon as opioid tolerance. *Acute opioid tolerance* due to tachyphylaxis requires increasing doses of the opioid to reach a specific analgesic end point during the initial hours of opioid treatment.

*Chronic tolerance*, often seen in opioid abusers, occurs over days and manifests as a decreasing analgesic effect, resulting in dose escalation and increasing the likelihood of OIH. In contrast to OIH, opioid receptor–related and postactivation intracellular processes play an important role in the development of tolerance (including  $\beta$ -arrestin–dependent receptor desensitization and internalization, and G-receptor uncoupling).<sup>48,49</sup> Finally, *pseudotolerance* is a phenomenon seen in chronic pain patients due to progression of disease with an increase in the level of nociception often due to destruction of nerves in the tumor region, resulting in neuropathic pain, which is poorly responsive to opioid dose escalation.

## Opioid Pharmacokinetics and Pharmacodynamics

### *Classification of Exogenous Opioids*

Opioids may be classified on the basis of their synthesis, chemical structure, potency, receptor binding, and effect at the opioid receptors. There are *natural* (opiates including morphine), *semisynthetic* (buprenorphine, codeine, etorphine, heroin, hydromorphone, oxycodone, and oxymorphone), and *synthetic* opioids (piperidines: loperamide, meperidine, alfentanil, fentanyl, sufentanil, remifentanil; methadones: methadone, dextro-propoxyphene). Opioid potency ranges from *weak opioids* such as codeine, dextro-propoxyphene, tramadol, and hydrocodone to *strong opioids*, which include etorphine, fentanyl, sufentanil, alfentanil, and remifentanil. Medium potency opioids include morphine, methadone, oxycodone, hydromorphone, and buprenorphine. Irrespective of the “strength” of these agents, all of these agents may potentially produce serious and potentially life-threatening side effects including sedation and respiratory depression, hypotension, and bradycardia. During surgery *strong* opioids are used in high doses while in the postoperative phase medium strength opioids such as morphine or methadone are used for treatment of acute pain. In 1986, the World Health Organization designed a stepwise approach for treatment of chronic cancer pain in which *weak* opioids are prescribed before *strong* opioids ([www.who.int/cancer/palliative/painladder/en/](http://www.who.int/cancer/palliative/painladder/en/)). Opioids may be *full agonists*, which cause the maximum possible effect when activating their receptors. Opioid full agonists at the MOR include morphine, piperidines, and methadone. Opioid *partial agonists*, such as buprenorphine, activate their receptor but cause only a partial or reduced effect. Naloxone and naltrexone are opioid *antagonists*. It is more practical to classify opioids with a rapid onset and offset of action (e.g., remifentanil and alfentanil) versus agents with a slow onset/offset of action (e.g., morphine and buprenorphine). The concept of onset/offset of action will be discussed below.

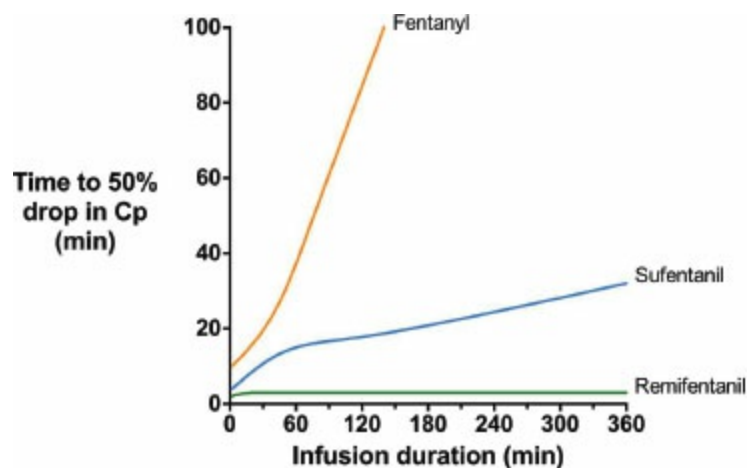

## Opioid Pharmacokinetics

When injected intravenously opioids are rapidly transported to the heart and pulmonary vessels from where they are dispersed to the various organs and tissues. After a standard dose of opioid, the inter-patient variability in plasma concentrations is large (at least 30-fold) and related to various factors including weight-related parameters (lean and fat body mass), organ function (hepatic and renal function), and cardiac output. This variability is manifest in the distribution and elimination constants that describe the PK profile of these drugs, which is also related to their physicochemical properties, such as molecule size,  $pK_a$  (affects the degree of ionization of the molecule and depends on the plasma pH), protein binding (to albumin and  $\alpha_1$ -acid glycoprotein), and lipid solubility. These factors affect the passage of the drug into the brain across the blood–brain barrier, and thereby affect both the opioid’s PK and PD characteristics. For example, a small increase in pH seen with respiratory alkalosis will increase the nonionized form of morphine, fentanyl, sufentanil, and remifentanyl, which subsequently crosses the blood–brain barrier. Different drugs may also affect the blood–brain barrier’s active transport systems that eliminate opioids from the brain. For example, cyclosporine enhances morphine’s analgesic effect but not that of methadone, suggesting that cyclosporine selectively interferes with morphine’s efflux from the brain via specific transporter proteins.

When an opioid is injected into the venous system, there is an initial rapid peak in plasma concentration. Next, the drug rapidly enters multiple organ systems with high blood flow (such as the brain, liver, kidney) from which the plasma drug concentration rapidly drops followed by a slower drop due to redistribution to organs (such as the muscles and later tissues with high fat content) that are less well perfused. These concentration changes over time are often described by noncompartmental PK models. Such models describe the drug’s PK behavior in terms of volume of distribution ( $V_D = \text{drug dose}/\text{steady-state plasma drug concentration}$ ), rapid and slow distribution half-lives, and elimination half-life ( $t^{1/2}_{\text{elim}}$ ). A high  $V_D$  is observed for lipophilic opioids with low protein-binding affinity such as fentanyl ( $V_D = 300 \text{ L}$ ), whereas a low  $V_D$  is observed for remifentanyl and alfentanil, due to a high clearance (remifentanyl) and/or high protein binding. When  $V_D$  is small, clearance is responsible for the drop in plasma concentration and consequently the loss of analgesia, whereas redistribution accounts for loss of analgesic effect in drugs with a high  $V_D$ .

The time needed for the drug’s plasma concentration to decrease by 50%, from a steady-state plasma concentration after the drug infusion has stopped, is called the context-sensitive half-time ( $CSt^{1/2}$ ) (Fig. 20-4).<sup>50,51</sup> A drug has not just one, but many such half-times, depending on the duration of the infusion,

which is the context to which the term applies. For fentanyl, the context-sensitive half-time increases with the duration of the infusion,<sup>50</sup> while for remifentanyl the half-time is independent of the duration because of its rapid clearance (50% drop in plasma concentration is 2 minutes, 75% drop is 8 minutes).<sup>51</sup> In clinical practice, the time to the loss of analgesia depends on the opioid dose, neuronal and receptor kinetic processes, the transport of the opioids from brain to plasma, and the context-sensitive half-time. The time course of a specific effect is difficult to predict for individual patients. For some side effects such as opioid-induced respiratory depression, the prediction of onset or offset of effect is even more complicated due to counteracting forces, such as the respiratory stimulant effects of increased arterial carbon dioxide (CO<sub>2</sub>) and the presence of pain.<sup>52</sup>

**Figure 20-4** Context-sensitive half-times, or the time to a 50% drop in plasma concentration (Cp) versus infusion duration for remifentanyl, fentanyl, and sufentanyl.

### **Metabolism: Which Pathways and Metabolites Are Clinically Relevant?**

**7** Most opioids are metabolized in the liver through either phase I (oxidative and reductive reactions catalyzed by the cytochrome P450 enzyme system) or phase II reactions (conjugation to a specific substrate). Metabolism may occur at other sites as well, such as in the enterocytes of the GI tract, the kidney, or the brain. Excretion of the parent drug and/or metabolites occurs via the kidney and/or via the biliary tract into the gut where some opioids (morphine, buprenorphine) may undergo reuptake of the compound into the bloodstream.

Three aspects of opioid metabolism have clinical importance:

1. Medications that inhibit or induce the CYP450 system may increase or decrease the clinical effect of opioids, respectively, by interfering with their metabolism (Table 20-1).<sup>53</sup>
2. Opioid metabolites may be either active or inactive, which applies not

only to their analgesic effect but also to their unwanted side effects.<sup>54–56</sup>

3. Genetic variability in the CYP system has clinical implications that are discussed in the pharmacogenetics section.

## Morphine

Morphine undergoes rapid metabolism (by UGT2B7, a phase II reaction) in the liver. Within minutes after its administration the two most important hydrophilic metabolites appear in plasma: morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).<sup>54</sup> M3G is the major metabolite and about 60% of morphine is converted into M3G, while just 5% to 10% is converted to M6G. In humans M3G has no analgesic or antianalgesic action. M6G is a full MOR agonist, but at the concentrations observed following morphine administration in a patient with normal renal function its contribution to the overall analgesic effect is minimal.<sup>54</sup> Due to its low lipophilicity, passage of M6G across the blood–brain barrier is slow and consequently limited. In the hepatocytes both M3G and M6G are transported back into the bloodstream via transporter protein MRP3, while a small part is transported into the bile ducts via transporter protein MRP2 (Fig. 20-5).<sup>54</sup> In the gut both glucuronides are deglucuronidated and the resultant morphine molecule is partly absorbed by the enterocytes. Enterocytes are able to metabolize morphine and transport the resultant M3G and M6G and remnant morphine to the bloodstream (the enterohepatic cycle).

Since the morphine-glucuronides are excreted via the kidney, patients with renal failure are at risk for M6G-related side effects.<sup>54,55</sup> Because M6G is a full MOR agonist, these side effects are typical of opioids and, most importantly, include sedation and respiratory depression. In patients with compromised renal function morphine treatment causes M6G to accumulate in high concentrations that may cause loss of consciousness and severe respiratory depression.<sup>54</sup>

## Piperidines

Fentanyl, alfentanil, sufentanil, and remifentanyl are lipophilic opioids that rapidly cross the blood–brain barrier. Fentanyl, alfentanil, and sufentanil are metabolized by the liver, catalyzed by the cytochrome P450 enzyme system.<sup>57,58</sup> *Fentanyl* has a high hepatic extraction ratio with clearance approaching liver blood flow (1.5 L/min). The major metabolite of fentanyl is the inactive compound norfentanyl. *Sufentanil* also has a high hepatic extraction ratio with a clearance of 0.9 L/min. *Alfentanil* is metabolized by CYP3A4 and 3A5 forming the inactive compounds noralfentanil and *N*-phenylpropionamide. The polymorphic expression of the CYP3A5 gene

accounts for the great variability in alfentanil metabolism and clearance.<sup>58</sup> *Remifentanil* contrasts with the other piperidines in that it is not metabolized in the liver.<sup>59</sup> Remifentanil contains a methyl ester side chain (Fig. 20-1) that is metabolized by blood (within the erythrocyte) and tissue nonspecific esterases. This causes a rapid clearance of the drug (context sensitive half-life of 2 minutes) making it the most rapidly acting opioid currently available. Clearance of remifentanil is 3 to 5 L/min, which exceeds liver blood flow affirming its extrahepatic clearance. Remifentanil is usually administered as a continuous infusion since its plasma level decreases by 50% in as little as 40 seconds.<sup>50,59</sup>

**Figure 20-5** Morphine metabolism in the liver and transport of its metabolites into the bloodstream and bile system. Morphine enters the hepatocyte, where it undergoes metabolism by UGT2B7 (a phase II reaction) into morphine-3-glucuronide (not shown) and morphine-6-glucuronide (M6G). These two glucuronides are transported via transporter protein MRP3 (red) back into the systemic circulation and via transporter protein MRP2 (blue) back into the biliary duct system.

## Methadone

Methadone is extensively metabolized to an inactive form by CYP2B6, which is also affected by pharmacogenetic variability.<sup>60</sup> Methadone has a 60% to 95% oral bioavailability, high potency, and a long duration of action. **1** Furthermore, there is considerable variation among recipients in the response to the drug. While methadone has properties which make it attractive for use intravenously as a perioperative analgesic, in a controlled and well-monitored environment, these same properties may prove hazardous when methadone is administered orally for treatment of patients with chronic pain. Large numbers of patient deaths have been attributed to the long, and often unpredictable, duration of action of methadone when administered orally.

## Naloxone

Naloxone is the most valuable and popular nonspecific MOR antagonist.<sup>61</sup> **2** Since it has a low and unpredictable bioavailability after oral intake due to an extensive (>95%) first-pass effect, naloxone is best given via the intravenous route. The most important metabolic pathway of naloxone is glucuronidation into the inactive naloxone-3-glucuronide. Its duration of effect is short, ranging from 15 to 45 minutes, which requires it to be redosed or administered as a continuous infusion when antagonism is required for

long-acting opioids or for patients experiencing an opioid overdose.

## **PKPD Models of Opioid Effect: Which End Point Serves the Clinician Best?**

The PK of a drug describes the time course of dose to concentration; the PD describes the concentration-to-effect relationship; the effect can be any of the desired or undesired drug effects. Pharmacokinetic–pharmacodynamic (PKPD) models are constructed for each drug to enable the clinician to understand and predict the clinical implication of a given dose to a desired effect.<sup>62</sup> These models allow dosing regimens to be constructed on the basis of patient characteristics such as total or lean body weight, gender, age, and other characteristics, making them particularly helpful when treating individual patients. The PK part of such models describes the drug distribution kinetics. This relates to both the parent drug and the possible metabolites. In compartmental models, the concentration–time profiles are described by drug transfer between interconnected hypothetical compartments, mimicking drug absorption, distribution, elimination, and metabolism. The PD part of the model describes the drug concentration–effect relationship. This hypothetical effect compartment is made infinitely small so that it does not influence the drug’s disposition (PK) and is located at the drug’s target organ, such as the muscle endplate for muscle relaxants and the brain for hypnotic drugs. For most opioid effects (such as analgesia, sedation, and respiratory depression) the effect site is located within the central nervous system (CNS) while the effect site for constipation is the GI tract. The delay between the peak drug concentration in the plasma and the peak concentration at the effect site is described by the plasma–effect site equilibration constant  $k_{e0}$  (or its half-life  $t_{1/2k_{e0}} = \ln 2/k_{e0}$ ),<sup>63,64</sup> which is commonly referred to as hysteresis. For the analgesic and respiratory depressive effects of opioids, the hysteresis is determined by the drug’s passage across the blood–brain barrier (the more lipophilic an opioid, the faster the transfer into the brain compartment), receptor kinetics, and neuronal dynamics. The effect site concentration–effect relationship is described by a sigmoid  $E_{\max}$  model<sup>62–64</sup>:

$$\text{Effect} = (C_E/C_{50})^\gamma / [1 + (C_E/C_{50})^\gamma]$$

where  $C_E$  is the drug concentration in the hypothetical effect site,  $C_{50}$  is the measure of drug potency or the effect site or steady-state concentration causing 50% of the effect, and  $\gamma$  is the Hill or steepness parameter. In summary, any PKPD analysis using the above-mentioned descriptions yields PK parameters (volumes of distribution and clearances), as well as PD

parameters related to drug potency ( $C_{50}$ ) and the onset/offset times of the drug ( $t_{1/2k_{e0}}$ ). It is important to understand that PK (volumes of distribution and rate constant) and PD (potency) values vary largely among patients. This is related to differences in physiology, underlying disease, age, weight, ethnicity, and other factors. Thus the clinician should choose a PK/PD set derived from a population of subjects whose characteristics are most similar to the individual they are treating. For example, due to changes in PK and PD behavior, elderly patients display a greater opioid sensitivity<sup>65</sup>; patients with liver or renal insufficiency require adaptation to their dosing; and patients with certain genetic abnormalities may experience unusual responses to opioids (see below).

For most opioids, the target effect when constructing PKPD models has traditionally been the slowing of the frequency components of the electroencephalogram (EEG), quantified by a shift in the 95th percentile of the power spectrum (95% spectral edge frequency). The  $C_{50}$  and  $t_{1/2k_{e0}}$  derived from these studies are useful to compare the potency and onset/offset of opioids. However, since the  $C_{50}$  for EEG effects occurs beyond the normal clinical dose range of opioids, more clinically useful  $C_{50}$  values would include those for the analgesic, respiratory depressive, and sedative effect of opioids. For alfentanil and fentanyl  $C_{50}$  values range from 75 and 1 ng/mL for sedation to 150 and 2 ng/mL for analgesia, respectively.<sup>66,67</sup> This indicates that these clinically relevant effects occur at lower doses than their effects on the EEG. For fentanyl it is of further interest that  $t_{1/2k_{e0}}$  values for analgesia (20 to 40 minutes) and respiratory depression are much longer (15 minutes) than those observed for EEG-slowing (5 to 6 minutes). In [Table 20-2](#) values of  $t_{1/2k_{e0}}$  for the end points of pain relief and respiratory depression are given for various analgesics currently in use.

**Table 20-2** Estimates of Analgesic  $t_{1/2k_{e0}}$  for Clinically Relevant End Points of Pain Relief and Respiratory Depression

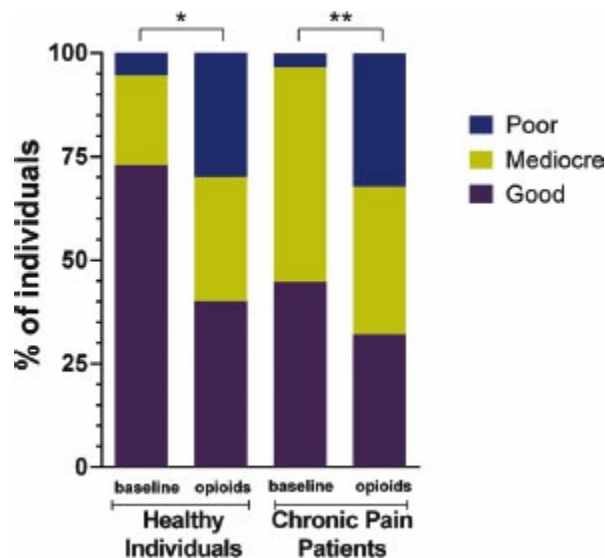

Drug	$t_{1/2k_{e0}}$	End Point Measured
Morphine	1.5 h	Postoperative analgesia
Ibuprofen	0.5 h	Postoperative analgesia
Acetaminophen	1 h	Postoperative analgesia
Morphine (men)	1.5 h	Relief of experimental pain
Morphine (women)	5 h	Relief of experimental pain
Fentanyl	20–40 min	Relief of experimental pain
Alfentanil	1–10 min	Relief of experimental pain
Remifentanyl	1–1.5 min	Relief of experimental pain
Buprenorphine	2.5 h	Relief of experimental pain
S-ketamine	<1 min	Relief of experimental pain
Morphine	1.2 h	Respiratory depression
Buprenorphine	1.5 h	Respiratory depression
Fentanyl	15 min	Respiratory depression
Remifentanyl	0.5 min	Respiratory depression
Naloxone	5–8 min	Relief of respiratory depression

Data from Martini C, Olofsen E, Yassen A, et al. Pharmacokinetic-pharmacodynamic modeling in acute and chronic pain: an overview of the recent literature. *Exp Rev Pharmacother*. 2011;4:719.

### Pharmacodynamics: Pain Relief

In postoperative patients following major orthopedic surgery under general anesthesia, it has been observed that some patients require a morphine dose of 0.02 mg/kg to obtain a visual analog pain score of 30 mm (on a scale from 0, no pain, to 100 mm, most intense pain) or less while others require a dose 40 times as large (0.8 mg/kg).<sup>68</sup> Younger (<40 years) healthy volunteers of normal weight (BMI <25 kg/m<sup>2</sup>) had analgesic responses to a fixed dose of morphine that varied by a factor of 20.<sup>69</sup> This variability is not restricted to morphine, but is observed for all opioids used for treatment of acute, perioperative, and chronic pain, including strong opioids such as fentanyl and remifentanyl. These data suggest that the variability in opioid effect is related to both variability in PK-related parameters (which in turn are attributable to differences in age, weight, body fat and muscle content, renal/liver function, cardiac output, genetic polymorphism in metabolic pathways, and co-medication) and variability in PD-related parameters. These PD differences of opioid sensitivity and pain perception most likely have a genetic origin. To date, no clear genetic basis for variability in morphine or any other opioid PD effect has been demonstrated (for exceptions see the pharmacogenetics section). Recently it was shown that the ability to score pain in a consistent and reliable fashion depends on various factors, including the presence of chronic pain and prior opioid administration (Fig. 20-6).<sup>70,71</sup> This may be

related to changes in brain areas involved in the translation of nociceptive stimuli into a verbal numeric response (a complex cognitive process that requires many steps, including number sensing). In chronic pain patients these changes may be due to neuroplastic changes in the frontal and parietal cortices. Opioids may cause transient effects on cognition and signal processing.<sup>71</sup>

**Figure 20-6** The ability to reliably translate a randomly applied nociceptive stimulus into a numerical pain score (between pain threshold and pain tolerance) is shown in healthy individuals and chronic pain patients, to demonstrate the effects of opioid treatment. Scores are divided into good, mediocre, and poor, reflecting the amount of deviation from an expected pain score. \* $p = 0.015$ , \*\* $p = 0.016$ . (Data from Oudejans LCJ, van Velzen M, Olofsen E, et al. Translation of random painful stimuli into numerical responses in fibromyalgia and perioperative patients. *Pain*. 2016;157:128–136.)

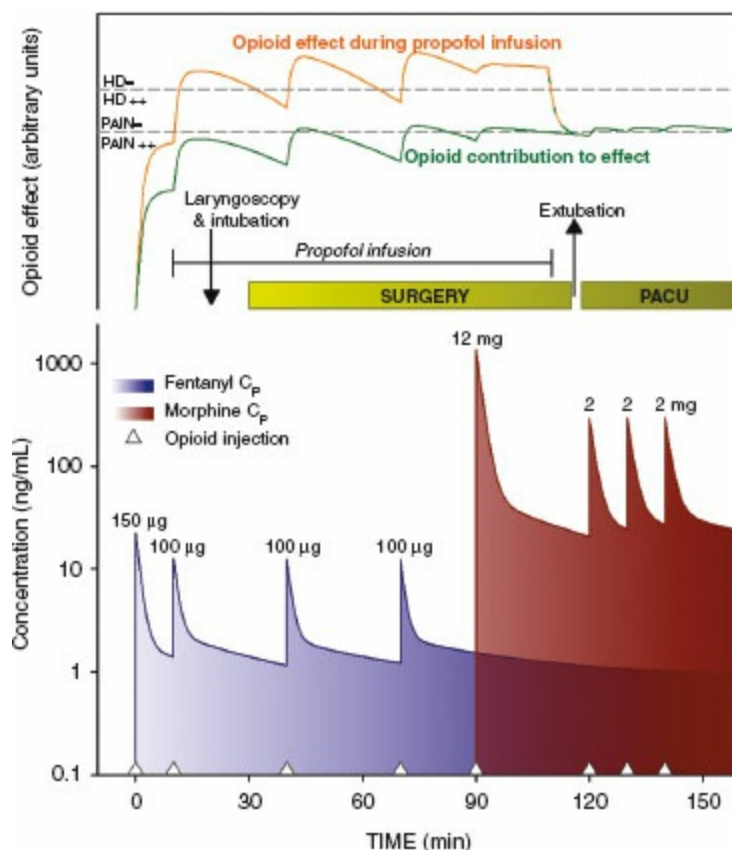

These data indicate that the safest approach to opioid analgesia is one of careful titration to analgesic effect during surgery and in the postoperative period, with acute awareness of the undesirable dose-related side effects. This admonition to carefully titrate the administration of opioids is perhaps even more crucial when administering long-acting opioids orally for the treatment of chronic pain.

During surgery opioids are titrated in doses sufficient to dampen and prevent exaggerated hemodynamic responses to painful surgical stimuli. In the postoperative period (and in chronic pain patients) opioids are usually titrated to the patient's verbal response to pain. This distinction requires not only a difference in administration, but also a difference in vigilance with respect to opioid side effects. During surgery, potent high-dose piperidines (e.g., fentanyl, remifentanyl) are the opioids of choice, while in the postoperative period medium strength opioids (morphine, methadone) are often chosen. During anesthesia one should be aware of hypotension and

bradycardia, a common side effect of strong opioids. In contrast, in the postoperative period the most important side effects to avoid are respiratory depression and severe sedation, while other non-life-threatening side effects impacting patient satisfaction and health costs are nausea/vomiting and loss of bowel motility.

## Morphine

In two studies on the postoperative effects of morphine following major surgery, the average intravenous dose of morphine to reach 50% pain relief was 20 mg. This dose resulted in a plasma concentration of 34 ng/mL and a  $t_{1/2ke0}$  of about 2 hours, although the initial onset of analgesia occurred between 15 and 30 minutes.<sup>72,73</sup> Thus, there is a 1- to 2-hour delay between peak plasma morphine concentration and peak analgesic effect (i.e., hysteresis). Surprisingly, these parameters are not influenced by the patient's age, weight, and gender. Given the long time to peak analgesia, a practical strategy for dosing morphine in adults is to give an initial morphine bolus dose (0.15–0.2 mg/kg) at least 60 minutes before the end of surgery. When the patient is in pain in the postanesthesia care unit (PACU), 2 mg bolus doses at 5- to 10-minute intervals may be given until visual analog pain scores decrease to 30 or less (on a scale from 0 to 100) (Fig. 20-7). At that point, the patient can be started on a patient-controlled analgesia (PCA) pump.

**Figure 20-7** Simulated effect of multiple bolus doses of fentanyl (100 to 150  $\mu$ g) during anesthesia, and morphine during and following anesthesia, on the analgesic and

hemodynamic state of the patient. **Bottom:** An initial dose of morphine (12 mg) is given 30 minutes before the end of surgery followed by three 2-mg doses (at the end of this titration phase the patient can be set on PCA morphine). The *blue* and *red lines* are the simulated fentanyl and morphine plasma concentration ( $C_p$ ). **Top:** The effect profile induced by the two opioids. During anesthesia fentanyl dosing is based predominantly on hemodynamic and other autonomic parameters; in the PACU morphine dosing is based on pain rating. During anesthesia, the combination of fentanyl and propofol (orange line) provides greater analgesia than opioids alone (*green line*). When propofol infusion is terminated the analgesic profile reverts to a lower level (from *orange* via *orange-green* to *green line*). HD indicates that hemodynamic and other autonomic responses are in the normal range, HD++ indicates increased responses (such as high blood pressure, tachycardia, and sweating) due to the surgical stress; PAIN indicates adequate analgesia, PAIN++ indicates pain. The *dotted lines* are the arbitrary divisions between adequate anesthesia and inadequate anesthesia, and adequate analgesia and inadequate analgesia.

Two considerations must accompany every postoperative acute pain plan. First, the postoperative analgesic regimen should be multimodal with morphine (or any other opioid), and combined with opioid-sparing drugs such as acetaminophen and nonsteroidal anti-inflammatory drugs such as diclofenac. Second, some patients require large doses of morphine, yet their pain appears unresponsive to morphine. The cause of such reduced opioid sensitivity is unclear. Irrespective of the cause, it is wise not to continue dosing (see Opioid-induced Respiratory Depression versus Opioid Analgesia) but to add an adjuvant such as the NMDA receptor antagonist ketamine (0.125 mg/kg), or an  $\alpha_2$ -adrenergic receptor agonist, such as clonidine (75  $\mu$ g). Both drugs are analgesics in their own right and enhance morphine's analgesic effect.<sup>74,75</sup> A practical morphine PCA regimen may consist of a 1-mg dose, a 5-minute lockout, and a maximum of 24 mg per 4 hours.

## Fentanyl

Fentanyl is about 100 times more potent than morphine. Like all opioids the analgesic response to intravenous fentanyl is highly variable. Fentanyl's lipophilic structure means it rapidly crosses the blood–brain barrier, as is evident from a characteristic  $\delta$ -wave appearing on the EEG ( $t_{1/2ke0}$  6.5 minutes). However, fentanyl's  $t_{1/2ke0}$  for analgesic effect is longer with values ranging between 10 and 20 minutes<sup>66</sup>; fentanyl's potency ( $C_{50}$ ) for analgesia ranges from 1 to 2 ng/mL.<sup>66</sup> Fentanyl is used during anesthesia to dampen cardiovascular responses to noxious stimulation from laryngoscopy, intubation, skin incision, and surgical stress. On average, the requirements for inhalational anesthetics and propofol are reduced by about 50% when

administering 1.5 to 3  $\mu\text{g}/\text{kg}$  IV fentanyl.<sup>76–78</sup> In fact, by combining fentanyl (or any other potent opioid) with propofol the requirement of both drugs to prevent movement and hemodynamic responses to laryngoscopy and surgical stress is reduced (Fig. 20-7).<sup>77,78</sup> Fentanyl dosing should be repeated at regular intervals in order to maintain a comfortable analgesic state (the dose and frequency are dependent on the patient's weight, dose, type of surgery, etc.). Be aware that a continuous infusion leads to the accumulation of the drug in the body as its 50% context-sensitive half-time increases rapidly with the duration of infusion (Fig. 20-4).<sup>50,51</sup> Similarly, frequent dosing of the drug may cause accumulation. Taking into account the drug's  $t_{1/2k_{e0}}$  fentanyl should be administered 5 to 10 minutes prior to an anticipated painful/stressful event such as laryngoscopy or skin incision (Fig. 20-7).

In the 1980s, high-dose fentanyl was often used in combination with nitrous oxide to provide both analgesia and suppression of consciousness. Although this combination provided excellent hemodynamic stability, it could not assure amnesia. Hence, it is not surprising that this technique has been replaced by the technique of “balanced anesthesia” or total intravenous anesthesia (TIVA) where opioids are combined with sedatives, intravenous anesthetics, and muscle relaxants to assure amnesia, as well as analgesia.

Fentanyl is also used in the treatment of chronic pain. For example, the fentanyl patch is used in a large number of cancer and noncancer chronic pain patients. The transcutaneous delivery of fentanyl ranges from 12 to 100  $\mu\text{g}/\text{hr}$ , although absorption depends on a variety of factors such as skin thickness, subcutaneous fat layer, and subcutaneous perfusion. Peak analgesic effect is reached only after 10 to 12 hours and the effect of one patch lasts 3 to 4 days. Other methods of administration include intranasal fentanyl, sublingual fentanyl, fentanyl lozenges (a solid preparation in the form of a lollipop), mucosal patch—all four methods are used for treatment of breakthrough pain—and iontophoretic transdermal fentanyl applications. The home use of fentanyl in chronic pain patients comes with the danger of misuse and abuse by the patients or by family members or friends. This is a major concern as it leads to an increasing number of opioid fatalities.

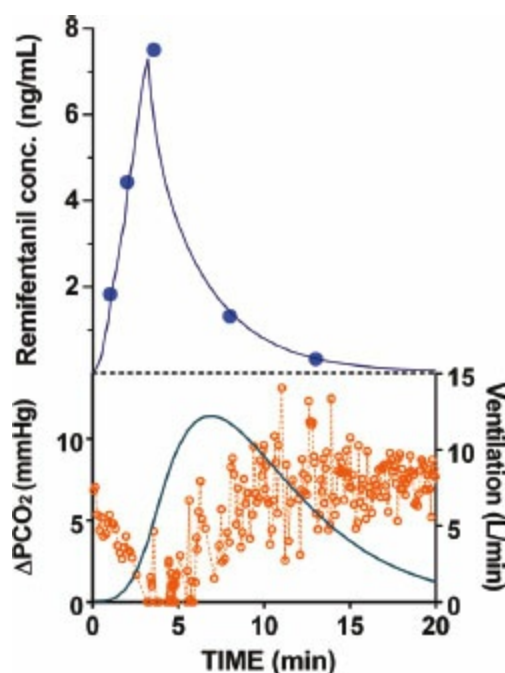

## Sufentanil

Sufentanil is a thienyl derivate of fentanyl and about 10 times more potent than fentanyl; its lipophilicity is two times greater than that of fentanyl. Sufentanil acts selectively at the MOR with a  $C_{50}$  for analgesia of 30  $\text{pg}/\text{mL}$  and  $t_{1/2k_{e0}}$  similar to that of fentanyl. Sufentanil is metabolized in the liver to various inactive and one active compound, desmethyلسufentanil. The latter has 10% of the activity of sufentanil, and since it is produced in minute quantities has no clinical relevance. Sufentanil is used predominantly as an analgesic

during anesthesia, as it produces stable hemodynamics and cardiac output. A sublingual sufentanil PCA system for postoperative pain relief has also been introduced. Compared to other clinically available opioids, sufentanil has a high therapeutic index ( $= LD_{50}/ED_{50}$  where  $LD_{50}$  is the lethal dose in 50% of animals tested, and  $ED_{50}$  the effective dose in 50% of animals tested).

## Remifentanil

Remifentanil, the newest piperidine available for use in humans, differs from the other strong opioids in its rapid onset/offset for all clinical effects including respiration (Fig. 20-8).<sup>79</sup> Indications for its use include anesthesia/surgery, PCA analgesia and sedation in the ICU, diagnostic procedures, and the treatment of obstetric labor pain. The use of remifentanil in spontaneous breathing patients at relatively low infusion rates ( $<0.1$  to  $0.2 \mu\text{g}/\text{kg}/\text{min}$ ) is feasible<sup>52,79</sup> but requires adequate monitoring and skilled personnel to detect and manage an adverse respiratory event.

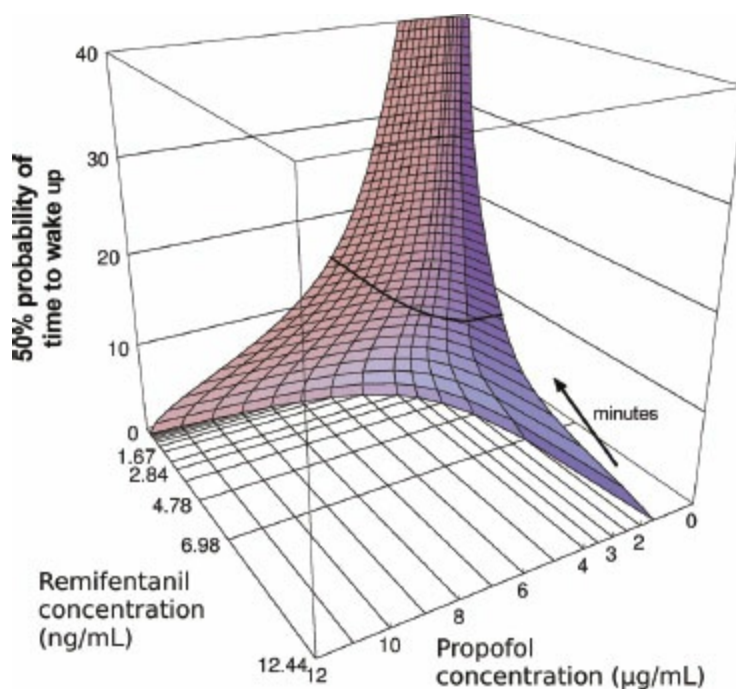

**Figure 20-8** Effect of a short remifentanil infusion on breathing. **Top:** The measured remifentanil plasma concentration (*blue dots*) and the pharmacokinetic data fit (*blue line*). **Bottom:** The increase in end-tidal  $\text{PCO}_2$  ( $\Delta\text{PCO}_2$ , *green line*), the measured inspired ventilation (*orange dots*, each dot is one breath). Note the absence of a delay between the remifentanil plasma concentration and ventilation, and the short delay between changes in the plasma concentration and the end-tidal  $\text{PCO}_2$ . (Data from Olofsen E, Boom M, Nieuwenhuijs D, et al. Modeling the non-steady-state respiratory effects of remifentanil in awake and propofol sedated healthy volunteers. *Anesthesiology*. 2010;212:1382–1395.)

Remifentanil is 100 to 200 times more potent than morphine. Like other

opioids, remifentanil displays large variability in effect among patients. For example, Drover and Lemmens<sup>80</sup> showed that the remifentanil plasma concentration causing a 50% probability ( $C_{P50}$ ) of no clinical response to stimulation (laryngoscopy, intubation, skin incision, and skin closures) varies 50-fold, from 1.5 to 79 ng/mL, during abdominal surgery in patients anesthetized with a nitrous oxide and remifentanil combination. In that study, a clear gender difference in potency of remifentanil was found ( $C_{P50}$  men 4.1 ng/mL, women 7.5 ng/mL). This difference can be accounted for by the difference in surgical stimulation of the prostatectomies versus hysterectomies. Different surgeries produce differences in nociception (i.e., pain) and hemodynamic stress responses, and hence require different dosages to suppress pain and stress. The  $C_{P50}$  varied from 3.8 ng/mL for prostatectomies, 5.6 ng/mL for nephrectomies, and 7.5 ng/mL for abdominal hysterectomies. Like fentanyl, remifentanil causes a reduction in both volatile anesthetic and propofol requirements. Mertens et al.<sup>81</sup> showed that by increasing the remifentanil concentration from 0 to 2 ng/mL the mean propofol concentration required to obtain  $C_{P50}$  for laryngoscopy was reduced from 7 to 3  $\mu\text{g/mL}$ , more than 60% reduction in dose requirement. When combining remifentanil with propofol (TIVA), the remifentanil effect remains variable. When added to a constant propofol plasma concentration of 2  $\mu\text{g/mL}$ , the remifentanil concentration required for suppression of hemodynamic and movement responses during abdominal surgery varies from 3 to 15 ng/mL. Interestingly, at a higher propofol concentration of 4  $\mu\text{g/mL}$ , the variability was reduced to 0 to 5 ng/mL. These data reinforce that opioid dosing requires titration to effect based on careful observation of the clinical response of the patient. Variations in remifentanil infusion rate should be based on an a priori knowledge of the PK and PD properties of the drug, patient characteristics, and, most importantly, hemodynamic responses and nociceptive input during surgery. Between intubation and surgical incision, when there is no stimulation, decreases of 30% to 40% in blood pressure and heart rate are not uncommon unless the remifentanil infusion dose is reduced during that period. Due to its rapid PK activity, the need for an initial remifentanil bolus is rather limited especially when there is ample time between the start of infusion and the first nociceptive stimulus (such as laryngoscopy). If a bolus is required, a slow infusion (given in 1 to 2 minutes) of 0.5 to 1  $\mu\text{g/kg}$  can be used.

The minimum alveolar concentration (MAC) reduction observed with remifentanil use and its very short  $CSt^{1/2}$  (Fig. 20-4) make rapid awakening possible at the end of surgery.<sup>82</sup> For example, after a 3-hour infusion of propofol and remifentanil for abdominal surgery, the shortest time to awakening ( $\approx 7$  minutes) was observed after constant propofol and remifentanil concentrations of 2.5 and 4.8 ng/mL, respectively (Fig. 20-9).<sup>81</sup>

At higher propofol concentrations, but lower remifentanyl concentrations, the time to awakening increases. The occurrence of postoperative pain following remifentanyl “fast-track” anesthesia is frequently reported.<sup>45,46</sup> Postoperative pain scores are higher after a remifentanyl-based anesthesia, and requirements for morphine are increased. This is due to the rapid decrease in opioid concentration causing a rapid decline in analgesic state, possibly combined with OIH. Strategies to counteract this problem include starting morphine administration 30 to 45 minutes before the end of surgery, or a single fentanyl bolus of 50 µg or ketamine 0.125 mg/kg at the end of surgery.<sup>45</sup>

**Figure 20-9** Propofol–remifentanyl interaction on “time to wake up” following anesthesia. Remifentanyl–propofol interaction causing 50% probability of no response to surgical stimulation are given at  $t = 0$  minutes. Next the infusion pumps are switched off causing the decreasing effect site concentrations. The *bold line* on top of the 3D surface represents the 50% probability of return of consciousness. The lowest point represents the optimal propofol–remifentanyl concentration during surgery that gives the minimal recovery time after the pumps are switched off. Note that this occurs at steady-state concentrations of 4.78 ng/mL remifentanyl and 2 µg/mL propofol, and 50% probability of waking up occurs after 7 minutes. (Data from Vuyk J, Mertens MJ, Olofsen E, et al. Propofol anesthesia and rational opioid selection. *Anesthesiology*. 1997;87:1549–1562.)

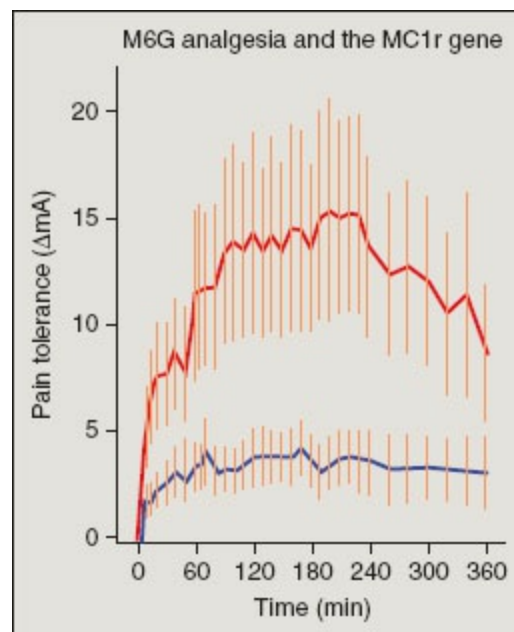

## Pharmacogenetics

Pharmacogenetics describes the relationship between genetic variations and drug response. Variations occur in genes that code for components of the metabolic pathways and transport of the drug across the blood–brain barrier

(affecting PK behavior), and in genes that code for the opioid receptor or proteins in downstream signaling pathways (affecting PD behavior). The existence of a pharmacogenetic effect on PK is well established in opioid pharmacology, whereas an effect of genetic makeup on PD is less certain. For example, the literature on the significance of a specific mutation in the gene coding for MOR, *OPRM1:c.118 A > G* (dbSNP1799971), is equivocal.<sup>83</sup> Some examples of pharmacogenetic variations that influence opioid analgesia are given below.

The gene that codes for the melanocortin-1 receptor, the *MC1r* gene, is involved in the regulation of skin and hair pigmentation and immunomodulation. Sixty percent of redheads have at least two variant alleles of the gene. Animal and human studies indicate that specific mutations in this gene cause a phenotype of red hair, a fair, freckled skin, and an increase in  $\mu$ -opioid analgesia (Fig. 20-10).<sup>84</sup> The exact mechanism by which the *MC1r* gene influences pain pathways and interacts with the opioidergic system remains unknown. Possibly, the inactive MC1r causes a reflex increase in  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ MSH) and ACTH, which may act as the endogenous ligands to MC1r and which may induce neurobehavioral changes. Interestingly, redheads require more midazolam and inhalational anesthetics compared to otherwise pigmented (either blond or dark) individuals.<sup>85</sup>

**Figure 20-10** Analgesic response to morphine-6-glucuronide in volunteers with loss of functional mutations in the melanocortin-1-receptor gene (*red line*) compared to volunteers with an intact gene and blond or dark hair (*blue*). The greater opioid sensitivity is apparent in red heads. (Data from Mogil J, Ritchie J, Smith SB, et al. Melanocortin-1 receptor gene variants affect pain and mu-opioid analgesia in mice and humans. *J Med Genet.* 2005;42:583–587.)

While most CYP isoenzymes display polymorphisms, the genetic variability in the gene coding for CYP2D6 is clinically most important.<sup>58,86</sup> The CYP2D6 isoenzyme of the cytochrome P450 system is highly polymorphic with large variations between individuals in the number of gene copies in their DNA.<sup>86</sup> The rate of metabolism of opioids depends on the number of copies a subject expresses, ranging from ultrarapid metabolizing individuals with multiple copies of the *CYP2D6* gene to poor metabolizing individuals with two nonfunctional alleles of the gene. The more copies of the gene the greater the metabolic power within the CYP2D6 pathway; the reverse is true for individuals without an active copy of the gene.<sup>86</sup> This is important for drugs that rely on CYP2D6 to convert an inactive precursor (prodrug), such as codeine, into the active component of pain therapy (for codeine this is morphine).<sup>87</sup> Patients without an active gene will have no benefit from treatment with codeine. Dangerous circumstances may occur when a patient is an extensive metabolizer and produces large amounts of the active component. There are multiple case reports showing codeine intoxication due to ultrarapid CYP2D6 metabolism (see below). A tragic example reported by Koren et al.<sup>88</sup> describes a normal full-term breastfed neonate that developed lethargy on postnatal day 7 and was found dead 6 days later. His mother had been prescribed 30 mg codeine combined with 500 mg acetaminophen for episiotomy pain (two tablets every 12 hours, reduced to 1 tablet per 12 hours after day 2 because of somnolence and constipation). Postmortem morphine plasma concentrations were 70 ng/mL (normal values for children breastfed by mothers receiving codeine is 0.2 to 2 ng/mL). The mother's milk contained 87 ng/mL morphine (typical mother milk concentrations after repeated codeine dosing is 2 to 20 ng/mL). Genotype analysis revealed that the mother had a 2 × 2 CYP2D6 gene duplication and was classified as an ultrarapid CYP2D6 metabolizer. The clinical picture is that of death due to morphine-induced respiratory depression.

Variations in the *ABCB1* gene, the gene coding for P-glycoprotein, a protein involved in the efflux of xenobiotics from the brain, cause variations in the toxicity of fentanyl. Park et al.<sup>89</sup> monitored the clinical effects (respiration rate) of 2.5 µg/kg intravenous fentanyl in patients under spinal anesthesia and assessed the influence of three single nucleotide polymorphisms in *ABCB1*. They observed an effect of the different genotypes on respiratory depression with an increased risk for a reduction in respiratory rate in certain variant gene combinations. These data are best explained by a lesser efficacy of the variant P-glycoprotein to transport fentanyl away from the brain.

## Opioid-induced Respiratory Depression

## *Mechanisms of Opioid-induced Respiratory Depression*

The drive to breathe is generated in multiple respiratory centers in the brainstem.<sup>90,91</sup> Respiratory neurons receive inputs from various sites in the CNS (cortex, limbic system, hypothalamus, spinal cord), a set of receptors located in the brainstem (central chemoreceptors), and in the carotid bodies (peripheral chemoreceptors). These sensors send information (changes in pH, PCO<sub>2</sub>, and PO<sub>2</sub> of the cerebrospinal fluid and arterial blood) to the brainstem respiratory centers, which appropriately adjust breathing rate and pulmonary tidal volume. For example, acidosis, hypercapnia, and hypoxia will cause hyperventilation, while hypocapnia and alkalosis will reduce minute ventilation. Opioids that activate MORs expressed on respiratory neurons cause a reduction in respiratory rate,<sup>92</sup> while a reduction in tidal volume is caused by the opioid-induced decreased afferent input into the brainstem from peripheral chemosensors.

When an opioid is administered to a patient and the injection rate is sufficiently slow (over minutes) that the depression of the respiratory neurons **10** in the brainstem coincides with the accumulation of arterial CO<sub>2</sub>, the stimulatory effect of the increased CO<sub>2</sub> at the peripheral and central chemoreceptors will offset the decrease in tidal volume and reduced respiratory rate.<sup>52</sup> When just monitoring respiratory rate and oxygen saturation it appears that the opioid injected has no effect on the ventilatory system, but when also monitoring end-tidal (or arterial) CO<sub>2</sub> the opioid effect becomes visible. When a strong opioid that rapidly crosses the blood-brain barrier is injected, a rapid depression of respiratory neurons occurs and there will be no time for gradual CO<sub>2</sub> accumulation, resulting in an apneic patient. An example is given in [Figure 20-8](#), which shows that a rapid short-term infusion of remifentanil causes apnea and hypercapnia.<sup>52</sup> Breathing is restored by a high arterial CO<sub>2</sub> level combined with the rapid drop in brain (effect site) remifentanil concentration. Slowing the speed of injection of this strong opioid allows the accumulation of arterial CO<sub>2</sub>, and apnea will be prevented and the patient will continue to breathe, albeit at a higher arterial PCO<sub>2</sub>.

Apart from their effect on brainstem respiratory neurons (causing central apnea), opioids may increase the collapsibility of the upper airways due to suppression of neurons in the brainstem involved in maintaining the upper airway muscle tone or from the loss of muscle tone related to sedation.<sup>90</sup> Opioids combined with anesthetics do not increase the incidence of upper airway obstruction, but do increase the number of central apneic events.<sup>93</sup> However, any dose of opioid that produces a generalized state of sedation and/or reduced muscle tone will give rise to upper airway collapse, even when the patient is considered awake.<sup>93</sup> Furthermore, depression of the chemo- and arousal reflexes by opioids will cause a delayed and less forceful

response to upper airway obstruction.<sup>90</sup> Recent data indicate that most patients receiving opioids, whether diagnosed with obstructive sleep apnea syndrome or not, develop both central and obstructive apneic events resulting in recurrent hypoxemia during the first three to five nights postoperatively.<sup>94–95</sup> Stone et al.<sup>96</sup> showed that patients on PCA morphine without supplemental oxygen develop recurrent and deep hypoxic events during the first few postoperative nights (Fig. 20-11). While supplemental oxygen results in fewer hypoxic events, it has a serious disadvantage as it masks hypoventilation and early detection of an obstructive respiratory event because the lungs are primed with supplemental oxygen. Use of a pulse oximeter, especially in the presence of supplemental oxygen administration, is not a valid measure of the adequacy of ventilation. An example of the inability to detect an apneic event using pulse oximetry while on supplemental oxygen is given in Figure 20-12. A subject received a remifentanyl bolus causing rapid respiratory depression and a reduction in respiratory rate, both during air and oxygen breathing. Desaturations were detected during air breathing only.<sup>79</sup>

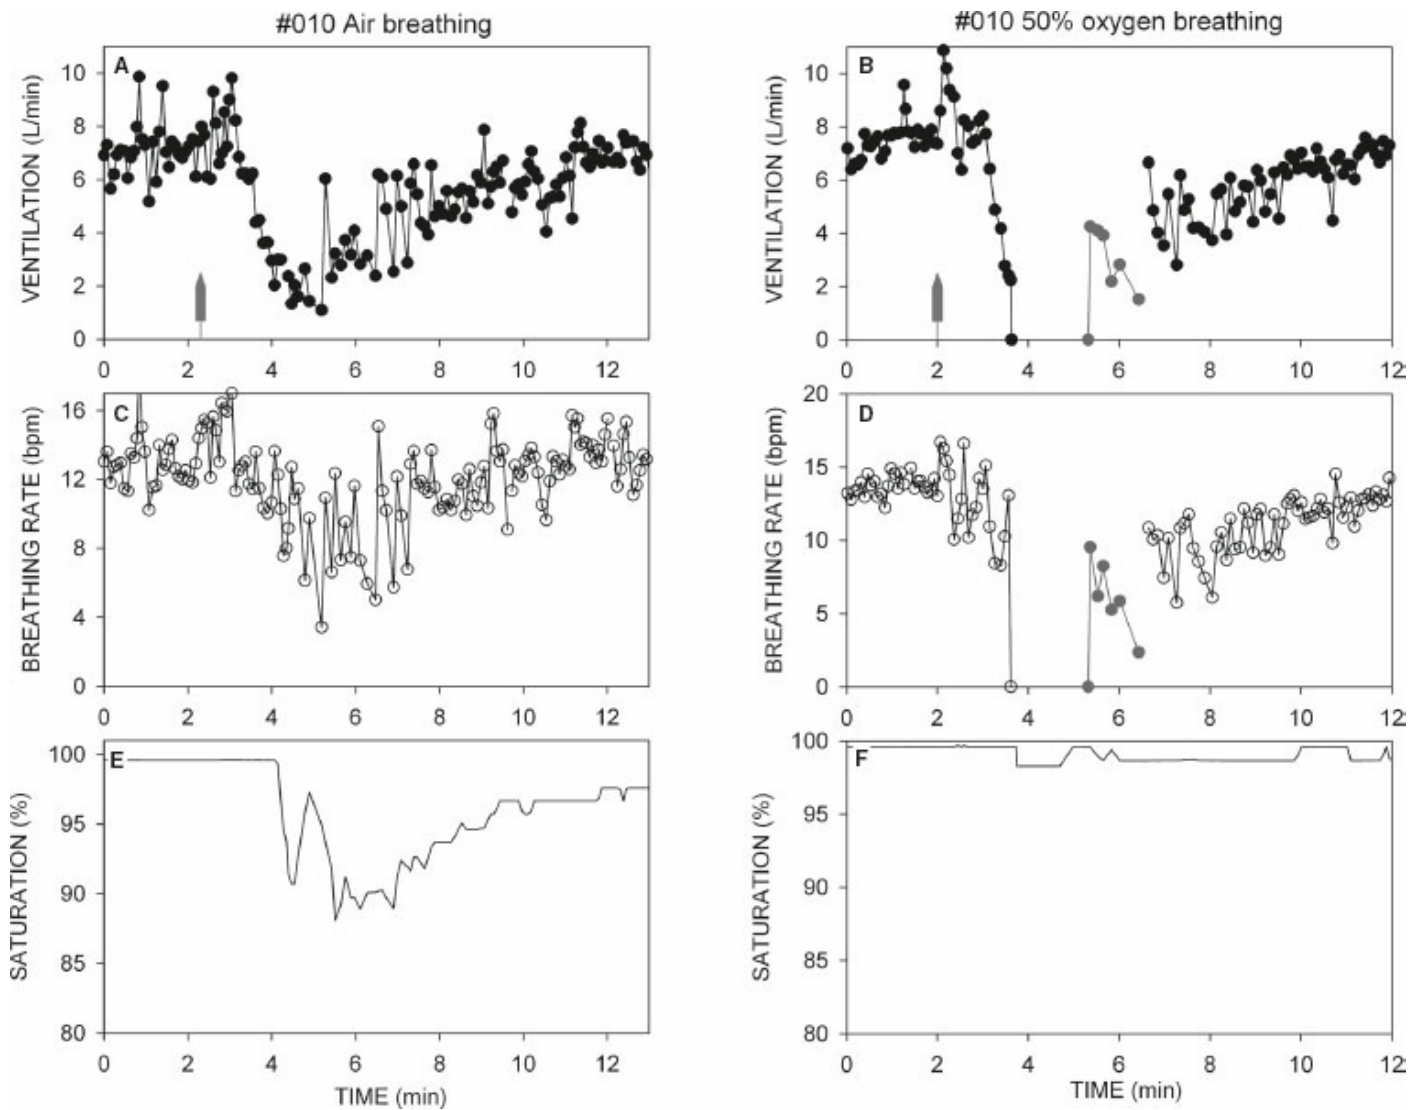

Finally, strong, high-dose opioids, especially when given rapidly, cause skeletal muscle rigidity in thoracic, abdominal, and pharyngeal muscles, all of which can contribute to respiratory insufficiency.<sup>97</sup>

**Figure 20-11** Effect of supplemental oxygen on pulse oximeter values in a postoperative patient on PCA morphine. (Data from Stone JG, Cozine KA, Wald A. Nocturnal oxygenation during patient-controlled analgesia. *Anesth Analg*. 1999;89:104–110.)

### **Incidence and Risk Factors of Opioid-induced Respiratory Depression**

The incidence of respiratory depression from opioid treatment, acute or chronic, is poorly documented. The metrics in the literature defining respiratory depression are inconsistent, the data are predominantly retrospective, and most studies rely on intermittent sampling of data.<sup>90</sup> **11** Thus, a significant number of respiratory depression events from which the patient recovers spontaneously or is rescued by other means are likely missed. A recent systematic review of the literature on postoperative opioid-induced respiratory depression estimates an average incidence of 0.5% with a range of 0.2% to 2%.<sup>90</sup> This would suggest that only one in 200 patients develops a respiratory event from opioids that requires an intervention such as the administration of naloxone. In the case of randomized controlled trials where morphine is used as positive control, the incidence of morphine-induced respiratory depression is many times higher, with hypoventilation (a respiratory rate <8 breaths/minute) occurring in as high as 30% of patients during PCA morphine treatment.<sup>90,98</sup> This suggests that the respiratory depression from opioids frequently goes undetected, and is therefore underreported. The same applies to opioid treatment for chronic pain. Accidental deaths from opioids in chronic cancer pain patients are often falsely attributed to the progression of the underlying disease. Recently, there has been an alarming increase in deaths from accidental opioid overdose among patients being treated for chronic noncancer pain. Unfortunately, no valid data are available on the incidence of opioid-induced respiratory depression in chronic pain patients on strong opioids.

**Figure 20-12** Effect of the administration of 50  $\mu\text{g}$  remifentanyl on ventilation in one subject during air breathing (A, C, and E) and during inhalation of 50% oxygen (B, D, and F). During air breathing the depression in ventilation is apparent from the reduced oxygen saturation (apart from the reduction in ventilation and respiratory rate). During administration of supplemental oxygen the pulse oximeter does not detect the apneic event. Mask ventilation is shown in red. The syringe indicates the time of remifentanyl administration. (Data from Niesters M, Mahajan RP, Aarts L, et al. High-inspired oxygen concentration further impairs opioid-induced respiratory depression. *Br J Anaesth.* 2013;110:837–841.)

Various patient groups are at higher risk for development of opioid-related respiratory depression. These include obese patients, patients with (central or peripheral) hypopneic and apneic periods during sleep, patients with neuromuscular disorders, (premature) neonates, chronic opioid users, and elderly patients.<sup>90</sup> Identification of these high-risk groups may be challenging. For instance, patients with undiagnosed sleep-related breathing disorders often present to the preoperative assessment clinic. A careful history (e.g., looking for daytime somnolence) and physical examination are required to uncover potential heightened opioid-associated respiratory risks. Furthermore

specific questionnaires, such as the STOP-BANG questionnaire for obstructive sleep apnea, should be part of the screening routine in the obese and aging patient population.<sup>99</sup>

Recently, three independent analyses were published on all published cases of respiratory depression related to opioid administration in the pediatric population and in adults in acute and chronic pain.<sup>100–102</sup> From these data specific risk factors could be determined. In the pediatric population risk factors included<sup>100</sup>: morphine administration in patients with renal impairment, causing accumulation of M6G; codeine use in patients with CYP2D6 gene polymorphism associated with the ultrarapid metabolizer phenotype, causing enhanced production of morphine; and opioid use in patients after adenotonsillectomy for recurrent tonsillitis and/or obstructive sleep apnea (respiratory depression may be enhanced by recurrent hypoxic episodes). In chronic pain patients risk factors included renal failure, sensory deafferentation, and drug–drug interactions in which a nonopioid drug affects the metabolism of the opioid through the CYP450 system. One example of the latter is the fact that the polycyclic aromatic hydrocarbons in tobacco smoke induce the CYP system. Patients who use opioids that depend on the CYP system for metabolism and who suddenly quit smoking may then suddenly be exposed to high opioid concentrations in blood.<sup>100</sup> Finally, an underlying risk factor could be detected in just 60% of cases in acute and perioperative pain.<sup>102</sup> These risk factors included sleep-disordered breathing, obesity, renal impairment, pulmonary disease, neurologic disorders, and CYP450 enzyme polymorphism (e.g., the case of opioid-induced respiratory depression in a neonate that died due to high levels of morphine in his mother’s milk has been given above; see the pharmacogenetics section).<sup>88</sup> One particularly well-documented case report of a postoperative lethal opioid-induced respiratory event is given by Lötsch et al.,<sup>103</sup> describing a healthy 26-year, 51-kg female treated with morphine after knee surgery under balanced anesthesia (sevoflurane 2% to 3%, 200- $\mu$ g fentanyl). Following surgery she received four intravenous injections of morphine, with a total dose of 35 mg over 2 hours (almost 0.7 mg/kg). While the patient was comfortable and in no apparent distress directly after the last morphine dose, 40 minutes later the patient had “deep respiratory depression followed by a fatal cardiac arrest.” At that time estimated brain concentrations were about 150 nM, which is above the toxic range for morphine, and highlight the importance of understanding the PK and PD of any opioid. The physicians involved in this case did not take into account the very slow passage of morphine across the blood–brain barrier causing a peak in central effect 1 to 2 hours following peak plasma concentration. And while the onset of analgesia occurred relatively rapidly following the last dose, the fatal respiratory depression occurred 40 minutes later.

## Opioid-induced Respiratory Depression versus Opioid Analgesia

In general, when comparing opioid analgesics it is important to not only anticipate their side effects (respiratory depression), but also assess side effects relative to their analgesic properties. One way to compare opioids in this respect is by constructing so-called safety or utility functions (UFos).<sup>104,105</sup> UFos are constructed by estimating *the difference* in probability of analgesia and respiratory depression from PKPD analyses. The UFO is context-sensitive, that is, it may be defined for various end points, typically analgesia 50% or more, and respiratory depression 50% or less. A negative UFO value indicates that the probability for respiratory depression is larger than the probability for analgesic efficacy (Fig. 20-13A). In Figure 20-13B morphine and fentanyl UFos are compared. For low-dose morphine the probability for respiratory depression exceeds that of analgesia, whereas at higher doses resulting in a plasma concentration ( $C_P$ ) more than 5 ng/mL the probability for analgesia is greater. At high morphine concentrations no difference in probability is apparent as the value of the UFO approaches zero. For fentanyl, an initial positive value at low doses ( $< 0.5$  ng/mL) is followed by a negative effect over the  $C_P$  range 0.5 to 3.0 ng/mL. For these reasons morphine is a better drug for postoperative PCA than fentanyl, when considering analgesia versus respiratory depression. In Figure 20-13C fentanyl UFos are given for individuals who display high fentanyl potency ( $C_{50}$  250 ng/mL) versus individuals who display low fentanyl potency ( $C_{50}$  1,500 ng/mL).<sup>105</sup> Individuals with a high analgesic efficacy display a low probability of respiratory depression, while individuals that respond poorly to fentanyl analgesia have a greater probability of development of respiratory depression. This is an important observation and implies that patients who show limited analgesic effect in response to opioid treatment are better off with other analgesic options (e.g., nerve blocks, intravenous ketamine).

These UFO curves are constructed from data in healthy volunteers. The curves of patients in pain will have a different form, typically more skewed to the left. However, since pain is not a constant in postoperative pain patients or chronic pain patients, the curves shown are still applicable to postoperative patients. Finally, it remains important to stress that a positive value of the UFO does not mean that the opioid does not cause respiratory depression.

## Reversal of Opioid-induced Respiratory Depression

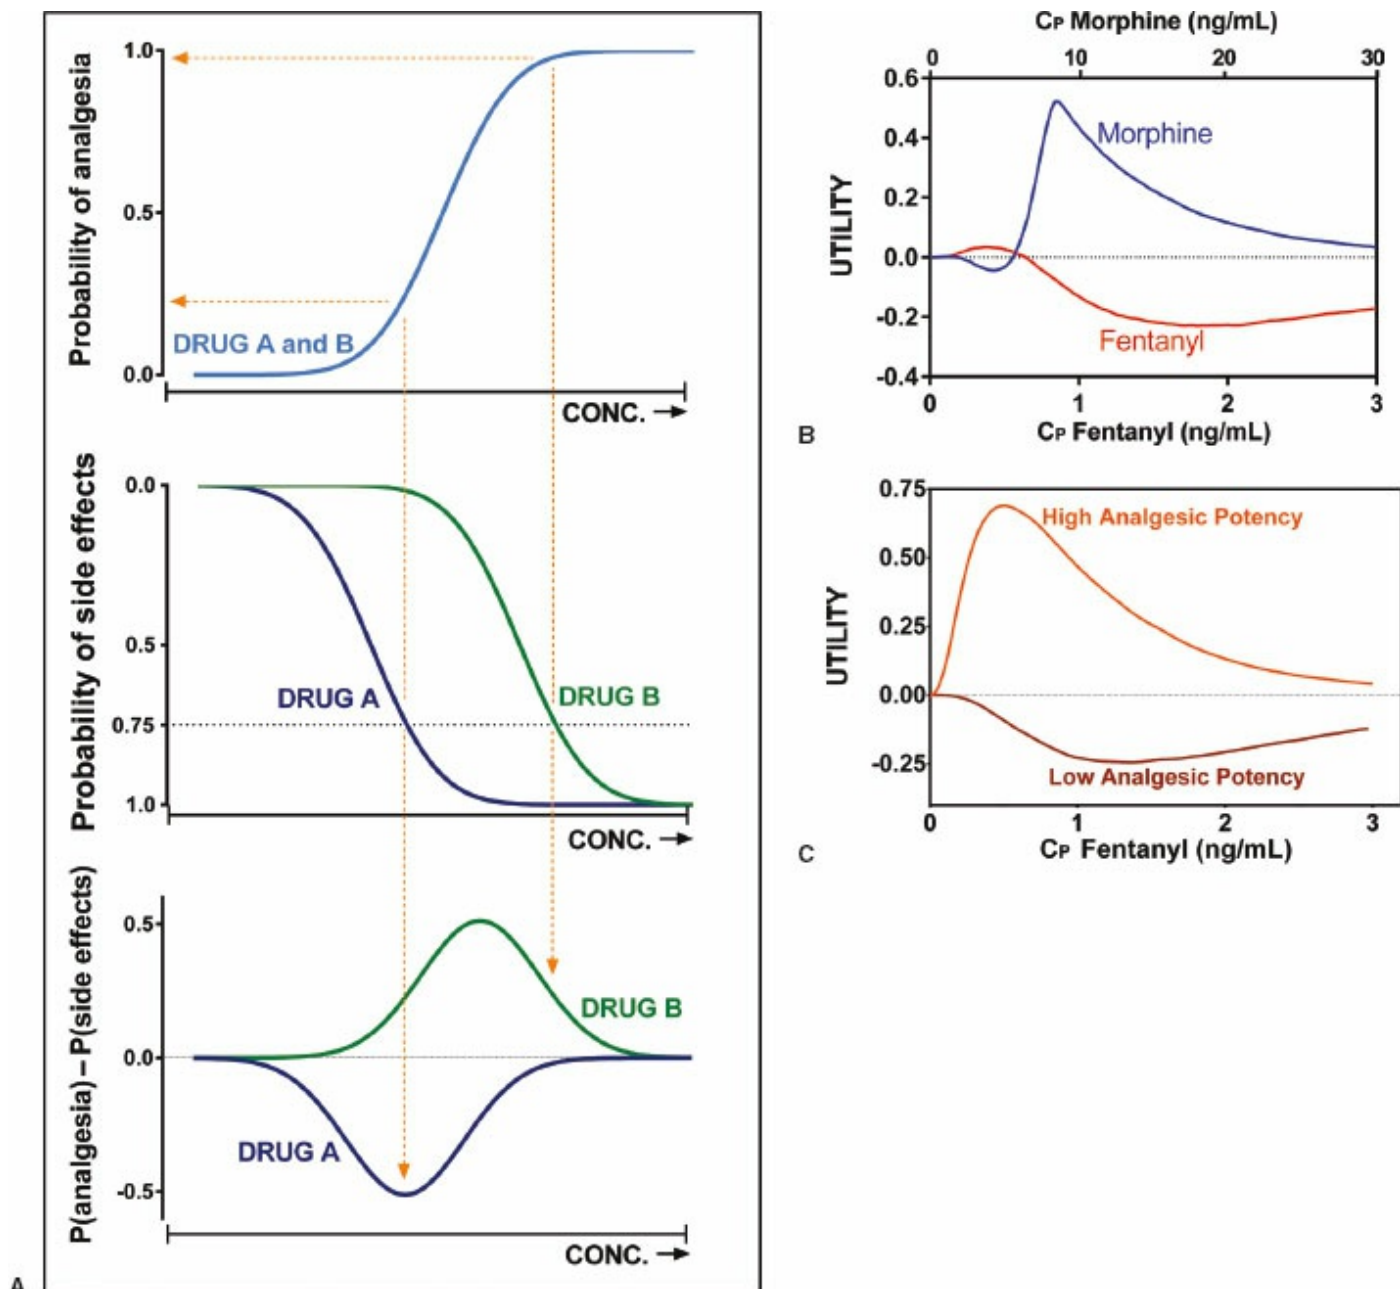

As noted above, the drug of choice in case of life-threatening respiratory depression or the inability to resume spontaneous breathing is naloxone.<sup>61,106</sup> Naloxone is a competitive MOR antagonist causing a parallel rightward shift of the opioid dose–response relationship. An oral MOR antagonist, naltrexone,

is used in the treatment of alcoholism and opioid dependence.<sup>61</sup> Both **12** antagonists are nonspecific, meaning that they antagonize all pharmacologic effects of opioids. The magnitude and duration of reversal of respiratory depression by naloxone depends on the PK and PD profile of the opioid that needs reversal and the administration mode of naloxone (bolus injections vs. continuous infusion).<sup>106,107</sup> Naloxone's onset time ( $t_{1/2ke0}$ ) is 6.5 minutes, indicating that reversal is rapid. But the rate of decay of naloxone in plasma is relatively short ( $t_{1/2elim}$  30 minutes), resulting in "renarcotization" when used to reverse effects from opioids with a longer plasma half-life than naloxone. However, opioid concentrations are often just above the threshold for respiratory depression, and intravenous titration of naloxone 40 to 80  $\mu\text{g}$  bolus doses to cumulative doses of less than 400  $\mu\text{g}$  is often sufficient to restore spontaneous breathing.<sup>90</sup> Respiratory depression from opioids occurs at higher receptor occupancy rates than analgesia. Therefore, analgesia is not compromised with careful titration of naloxone to respiratory effect. Large doses of naloxone, as commonly used in resuscitation, will reverse analgesia immediately and may predispose patients to pain and catecholamine-associated hypertension and cardiac ischemia, if not monitored properly.<sup>61</sup>

The naloxone titration opioid reversal approach is adequate for most opioids, with the exception of opioids with a high affinity for the MOR, such as buprenorphine.<sup>107</sup> In that case, a continuous naloxone infusion (2 to 4 mg/hr) will cause a slow but steady resumption of breathing activity. For remifentanyl the use of bolus naloxone doses in case of respiratory depression is unnecessary. The termination of the infusion will provide a rapid return of spontaneous breathing.

In recent years various drugs have been developed that reverse opioid-induced respiratory depression without affecting analgesia. These drugs stimulate the respiratory system at central (brainstem) and peripheral (carotid body) sites. One of the oldest respiratory stimulants used in clinical practice is doxapram.<sup>108</sup> It inhibits background  $\text{K}^+$  channels (TASK1, TASK3 and the **13** TASK1/2 heterodimer) on oxygen sensing cells in the carotid body. However, doxapram produces various side effects (anxiety/panic attacks, hypertension, tachycardia, sweating, convulsions). A novel  $\text{K}^+$ -channel blocker, GAL021, acting at  $\text{BK}_{Ca}$ -channels, is currently being developed for reversal/prevention of opioid-induced respiratory depression (Fig. 20-14) and possibly sleep-related upper airway obstructions.<sup>109,110</sup> Initial studies show that it does not produce doxapram-like side effects. A respiratory stimulant that acts at central sites is the ampakine CX717.<sup>111</sup> It increases respiratory drive by its action at the AMPA receptor in brainstem respiratory centers involved in rhythmogenesis.

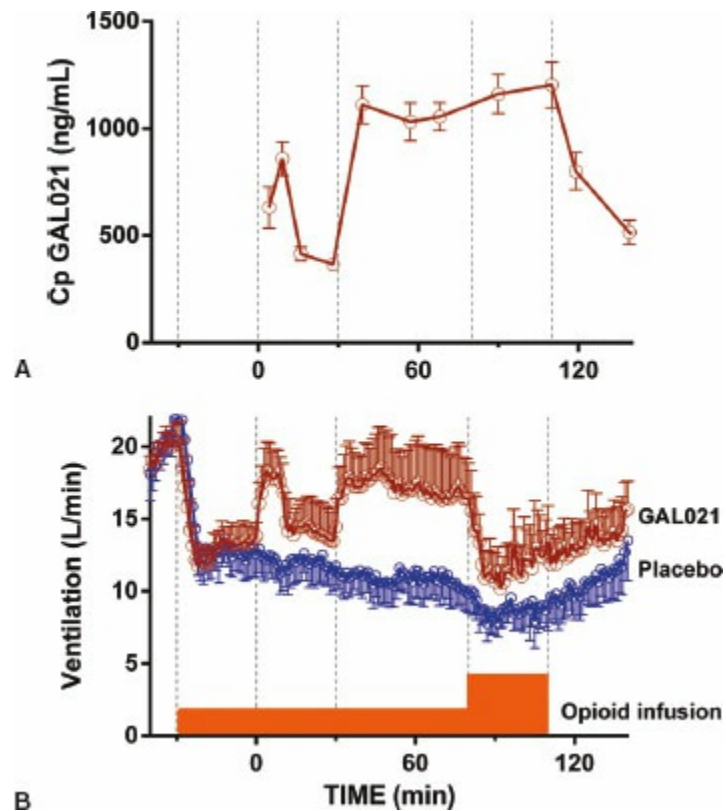

**Figure 20-13** Safety or utility functions. **A:** Construction of two utility functions. Two drugs A and B have similar analgesic potencies (**top**), but differ in their potency to induce side effects (**middle**). The simplified utility is the difference between the probability for analgesia,  $P(\text{analgesia})$ , and the probability for side effects,  $P(\text{side effects})$ . The utility is negative for drug A, but positive for drug B. **B:** Utility functions for morphine and fentanyl. The probability of an analgesic effect greater than 50% minus the probability of side effects greater than 50% is given for the two opioids. **C:** Fentanyl utility functions in individuals with a high and low analgesic response to fentanyl. A high efficacy for analgesia is coupled to a low probability for respiratory depression and vice versa. (Data from C Pharmacotherapy for pain: efficacy and safety issues examined by subgroup analyses. *Pain*. 2015;156:S119–S126.)

## Monitoring

On the ward, patients are monitored less comprehensively than in the

operating room or PACU. On the ward “spot” oxygen saturation measurements by regular nurse visits are insufficient to detect or predict the occurrence of life-threatening respiratory events. A recent study in 833 patients recovering from noncardiac surgery in which continuous oxygen saturation was measured up to 48 hours after surgery showed that hypoxia was common and prolonged. The saturation values recorded in medical records seriously underestimated the presence, duration, and severity of postoperative hypoxemia (21% of patients had oxygen saturation levels < 90% for 10 minutes or more per hour; 8% had saturation levels < 85% for 5 minutes or more per hour, [Fig. 20-15](#)).<sup>112</sup> Apart from cardiopulmonary causes such as ventilation–perfusion mismatch, significant drops in oxygen saturation and tachydysrhythmias do occur when the patient’s breathing system has been compromised for an appreciable period by recurrent central or obstructive apneas (or both) and no arousal occurs. Arousal is a “wake-up” from a state of sleep or sedation, and allows the patient to open his or her throat and hyperventilate to overcome the preceding period of hypoxemia. Arousal is triggered by hypoxia, and depressed by opioids and sedatives. Postoperative respiratory events are often episodic, with arousals and hyperventilation in-between events. This will cause repetitive triggering of the oxygen saturation monitoring alarm and possibly alarm fatigue of the nursing staff. When the alarm is either inactivated or unattended, an arousal failure may occur and is potentially fatal ([Fig. 20-16](#)).<sup>113</sup> Monitors that directly indicate breathing activity are preferable to oxygen saturation monitoring, including monitors that indirectly measure expiratory flow, such as end-tidal carbon dioxide and humidity. The latter device measures the exhaled water content and gives a reliable estimate of breathing frequency.<sup>114</sup> Both monitors will alarm in the event of airway obstruction (flow rate is zero) or reduced breathing rates.

**Figure 20-14** Influence of the BK<sub>Ca</sub>-channel blocker GAL021 on opioid-induced respiratory depression. **A:** GAL021 plasma concentrations. **B:** The reduced ventilation induced by the opioid alfentanil (*orange*), along with the stimulatory effect of GAL021 are both clearly visible. (Data from Roozekrans M, Olofsen E, van der Schrier R, et al. Reversal of opioid-induced respiratory depression by BK-channel blocker GAL021: a pharmacokinetic-pharmacodynamic modelling study in healthy volunteers. *Clin Pharmacol Ther.* 2015;97:641–649.)

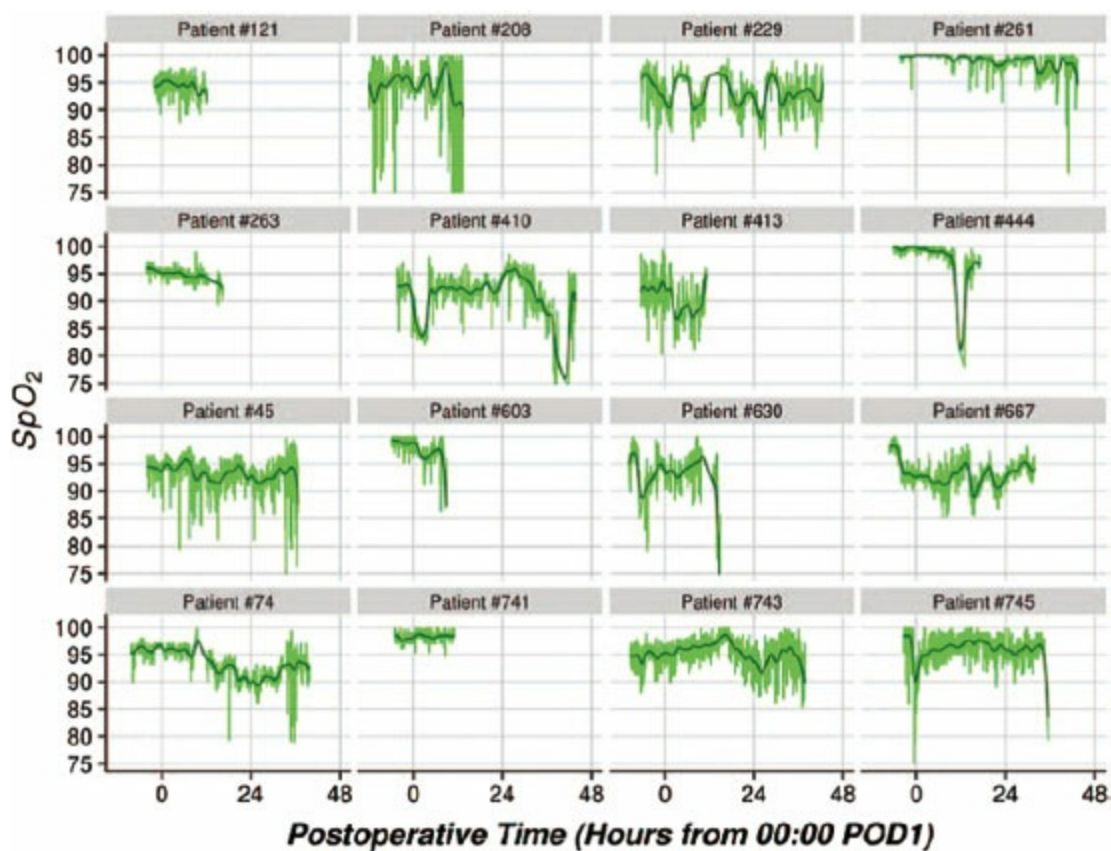

## Other Opioid-related Side Effects

Apart from respiratory depression, opioids produce many other side effects that can cause patient discomfort, as well as potentially serious consequences. Common side effects are nausea and vomiting, delayed gastric emptying, constipation, bowel distension, paralytic ileus, sphincter of Oddi spasm, urinary retention, histamine release, miosis, muscle rigidity, diffuse CNS effects (dizziness, light headedness, sedation, drowsiness, euphoria, dysphoria), cognitive dysfunction (memory loss, inability to concentrate or focus attention), hallucinations, and cardiovascular effects. 14

### Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is a serious side effect from all opioids used in perioperative care. Although inhalation anesthetics contribute significantly to this effect, opioids are the major cause of PONV with an incidence of greater than 50% following balanced 3

anesthesia.<sup>115</sup> Female patients seem more sensitive to opioid-induced PONV (see below). Patient distress from PONV can be so severe that patients may prefer being in pain than being nauseated.<sup>116</sup> Furthermore, retching and vomiting will induce severe pain from the stress it places on recent surgical wounds. Opioids cause PONV by their effects on the chemoreceptor trigger zone (CTZ) in the area postrema of the brainstem, as well as by direct effects on the GI tract.<sup>117</sup> Movement effects (e.g., transport of the patient from the operating room to the PACU) may also contribute to PONV because opioids cause an increased sensitivity of the vestibular system. The CTZ contains opioid, serotonin (5HT<sub>3</sub>), histamine, dopamine (D<sub>2</sub>), and muscarinic acetylcholine receptors.<sup>117</sup> The CTZ, vagal nerve, and vestibular organs all send neural projections to the vomiting center in the medulla. Drugs used in the treatment of PONV include dopamine antagonists (e.g., droperidol), 5HT-antagonists (e.g., ondansetron), and corticosteroids.<sup>115,117</sup> In patients with a known history of PONV or those undergoing surgeries with a known high incidence of PONV, aggressive prevention strategies are used. Such strategies include the use of propofol rather than inhalation anesthetics, the use of regional postoperative analgesia rather than intravenous opioids, and multimodal pharmacologic therapy, including a 5HT-antagonist, a dopamine antagonist, and a steroid given prior to the end of surgery.

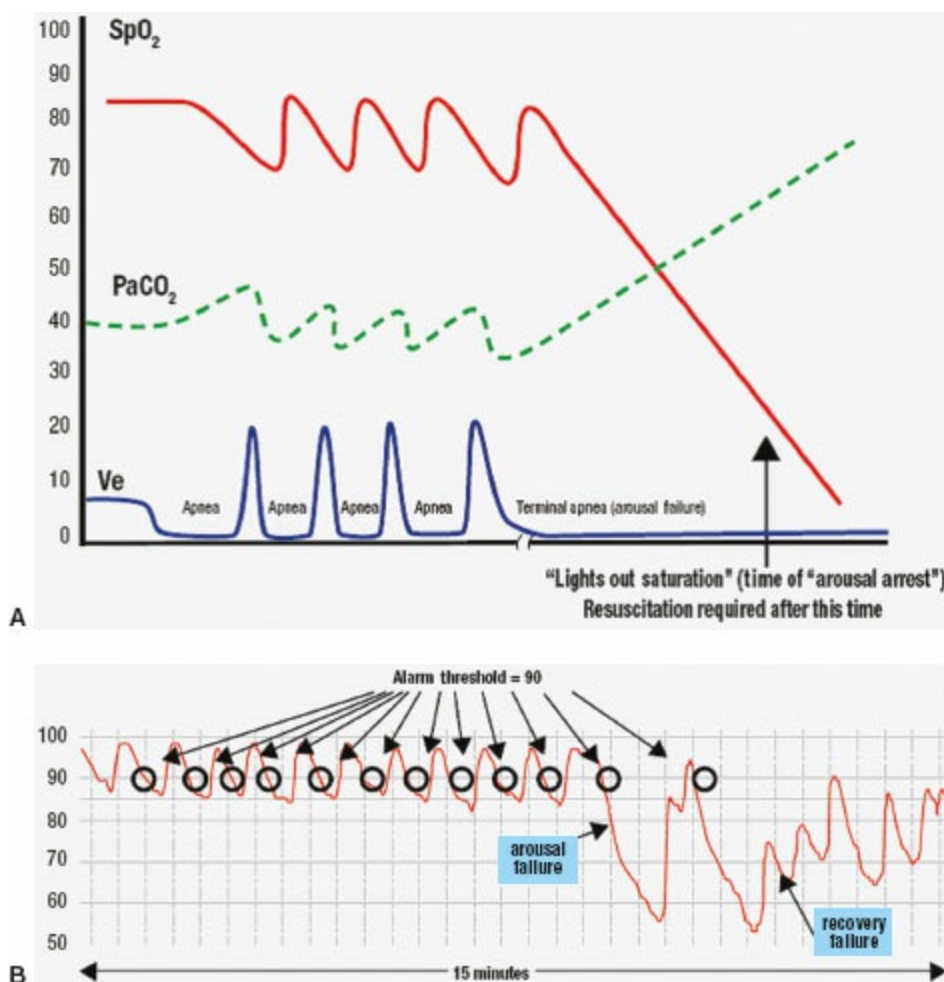

**Figure 20-15** Oxygen saturation tracings of 16 patients following noncardiac surgery. The raw saturation data are shown (*light green*), along with the smoothed estimates (*black lines*). POD is postoperative day. (Data from Sun Z, Sessler DI, Dalton JE, et al.

Postoperative hypoxemia is common and persistent: a prospective blinded observational study. *Anesth Analg.* 2014;121:709–715.)

## Smooth Muscle Effects

Opioid receptors are present in the enteric plexus within the smooth muscle layers of the GI tract. Opioids inhibit intestinal and pancreatic secretion, increase bowel tone, and decrease intestinal propulsive activity.<sup>118</sup> Consequently, opioids cause delayed gastric emptying, constipation, bowel distension, and paralytic ileus. Although opioids affect GI motility from central sites as well, blockade of opioid receptors with opioid antagonists that do not cross the blood–brain barrier (such as methylnaltrexone) will have a favorable effect on GI motility.<sup>119</sup>

Due to spasms of the sphincter of Oddi and common bile duct, opioids may cause acute upper abdominal pain and colic-like complaints.<sup>120</sup> Opioids may also contribute to misinterpretation of perioperative cholangiograms. Naloxone or glucagon can be used for treatment as both cause relaxation of the sphincter muscle.

**Figure 20-16** **A:** Episodic breathing pattern in a hypothetical patient with recurrent obstructive apneic events as might occur during sleep. SpO<sub>2</sub>, oxygen saturation; PaCO<sub>2</sub>, arterial carbon dioxide concentration; Ve, expired minute ventilation. **B:**

Recurrent activation of the saturation alarm in a patient with sleep apnea (alarm threshold set at 90% oxygen saturation). This could possibly lead to alarm fatigue (y-axis = SpO<sub>2</sub>). (Reprinted with permission from Curry JP, Lynn LA. Threshold monitoring, alarm fatigue, and the patterns of unexpected hospital death. *APSF Newsletter Fall 2011*;26:32. Copyright © 2011 Anesthesia Patient Safety Foundation.)

Activated opioid receptors present in the wall of the bladder and ureters can cause acute urine retention.<sup>121</sup> It is most often seen after epidural or spinal opioid administration, with a higher incidence in men than in women. Urine retention is related to the inability of the urethral sphincter muscle to relax while the bladder tone increases. Opioid-induced bladder dysfunction can be treated with opioid antagonists.<sup>122</sup>

### **Cardiovascular Effects**

Opioids affect the cardiovascular system at both central and peripheral sites.<sup>123</sup> Central effects include the activation of vagal nuclei and depression of vasomotor centers in the brainstem. Peripheral effects occur predominantly at high (supraclinical) doses and include direct myocardial depression and both arterial and venous dilatation. Morphine may cause additional cardiovascular effects via the release of histamine. The physiologic consequences are typically mild at clinical doses and include orthostatic hypotension, mild bradycardia, and a moderate reduction of systemic and pulmonary resistance. However, opioids at these doses can induce hemodynamic instability when combined with other drugs such as inhalation anesthetics, propofol, or benzodiazepines, and in severely ill patients (e.g., sepsis). Treatment of hemodynamic instability includes the administration of atropine and vasopressors and intravascular fluid therapy.

### **Remifentanil for Labor Pain**

The primary indications for remifentanil PCA for labor pain are the presence of a condition which contraindicates epidural analgesia, or the unavailability of personnel to place an epidural. One approach is to use remifentanil at bolus doses of 30 µg with a 3-minute lockout period. In case of side effects (respiratory depression, nausea) the bolus dose may be reduced to 20 µg, whereas insufficient pain relief can be managed by increasing the bolus dose to 40 µg. An infusion scheme of 30 µg bolus doses at 3-minute intervals results in plasma concentrations between 2 and 4 ng/mL, and is typically sufficient to relieve the pain of the uterine contraction. Historical clinical studies indicate that while pain scores are not greatly reduced when compared to epidural analgesia, patient satisfaction is higher with remifentanil

PCA.<sup>124,125</sup> However, a recent study performed in over 1,400 parturients showed that patient satisfaction is less with remifentanyl PCA compared to epidural analgesia.<sup>126</sup> With respect to the technique's safety,<sup>126</sup> a recent study reported frequent apneic events and deeper desaturations in women on remifentanyl PCA compared to epidural analgesia.<sup>127</sup> Still, with appropriate monitoring from personnel continuously present in the room with the patient, PCA remifentanyl may be a safe labor analgesic modality in these selected clinical indications.

## Gender Differences

A recent meta-analysis showed that women experience greater effects from opioids than men. This effect is attributed to enhanced opioid sensitivity in women; however, PK differences are equally important.<sup>128</sup> In studies following major abdominal or orthopedic surgery, women demonstrate a greater analgesic effect from PCA opioids than do men, and consequently consume fewer opioids postoperatively. Interestingly, in the first minutes postoperatively, greater morphine opioid efficacy is observed in men; however, this effect is reversed after 30 to 90 minutes. These data are best explained by a sex-related difference in morphine potency (greater in women), coupled with a slower onset/offset of the drug in women (i.e., greater value for  $t_{1/2ke0}$  in women).<sup>69</sup> The slower onset/offset times may be related to a slower passage across the blood–brain barrier or differences in receptor distribution and kinetics between men and women. As a consequence, morphine will take longer to induce adequate analgesia in women, while a speedier effect is observed in men. Due to the lower potency in men, they require multiple additional morphine administrations while women require fewer additional doses. This gender difference persists in older patients (>65 years), although in both sexes the opioid requirements for adequate analgesia are significantly reduced with age due to both PK and PD factors.<sup>65</sup>

Similar to analgesia, there are gender-related differences in opioid-induced respiratory depression and nausea and vomiting, with greater effects observed in women compared to men.<sup>129,130</sup> In a recent study of children undergoing outpatient tonsillectomy, a greater morphine effect was observed in girls compared to boys, including a higher incidence of respiratory depression, nausea, and prolonged stay in the PACU.<sup>131</sup>

## **Conclusion**

## KEY POINTS

- 1 Neuromuscular blocking agents (NMBAs) improve conditions for tracheal intubation and protect against vocal cord damage, improve surgical conditions, and facilitate mechanical ventilation in the operating room and intensive care unit.
- 2 All NMBAs (depolarizing and nondepolarizing) interact with specific sites ( $\alpha$  subunits) of the nicotinic cholinergic receptors and block muscle membrane depolarization, leading to flaccid paralysis.
- 3 Neuromuscular function can be measured (monitored) using neurostimulation. A train of four stimuli at 2 Hz (train-of-four [TOF]) will have four equal muscle contractions at baseline, indicated by a TOF ratio of 1.0 (fourth twitch, T4, equal in amplitude to first twitch, T1). With an increase in nondepolarizing block, the TOF ratio will decrease from 1.0 to 0. This ratio will return to normal with offset of block (recovery). The threshold for minimal recovery is TOF ratio 0.90 or higher.
- 4 Subjective (visual, tactile) evaluation of fade is unreliable, particularly when the TOF ratio is 0.40 or greater. Clinical testing (such as 5-second head-lift, grip strength, vital capacity, tidal volume) is notoriously inaccurate, and despite its wide clinical use, does not exclude residual neuromuscular block. When using subjective and clinical methods of assessment, the incidence of postoperative residual paralysis is 30% to 40%.
- 5 Objective methods of monitoring such as acceleromyography, mechanomyography, or electromyography can eliminate the incidence of residual paralysis and avoid postoperative critical respiratory events.
- 6 Monitoring of facial muscles instead of the adductor pollicis muscle in the hand generally leads to overestimation of neuromuscular function, and increases the incidence of postoperative residual paralysis and postoperative pulmonary complications.
- 7 Upper airway muscles (e.g., genioglossus) are very sensitive to minimal levels of neuromuscular block, and patients may be unable to protect the airway against aspiration even when TOF = 0.90.
- 8 Cholinesterase inhibitors prevent acetylcholine breakdown, and allow competition with nondepolarizing NMBAs for receptor sites. This restores normal neuromuscular transmission, but the reversal of nondepolarizing block is limited (cholinesterase inhibitors have a ceiling effect).
- 9 New selective relaxant binding agents such as sugammadex encapsulate aminosteroid NMBAs and quickly and reliably reverse nondepolarizing block of any depth if administered in sufficient doses that are based on neuromuscular monitoring data.

- 10 The combination of rocuronium (for rapid onset) and sugammadex (for emergent reversal of block) in a failed rapid-sequence induction scenario can be more rapid than spontaneous recovery from succinylcholine (as long as recovery from induction drugs is sufficient and airway patency is restored).

The neuromuscular junction (NMJ) is one of the most comprehensively studied models of neural function.<sup>1</sup> Neuromuscular blocking agents (NMBAs), also called “muscle relaxants” or “paralytics,” have been used in the clinical setting for almost 75 years. Unlike many other classes of drugs used in medicine today, the list of NMBAs is relatively short, and they belong to only two classes: aminosteroidal and isoquinolinium (tetrahydroisoquinoline) compounds. A third class, quaternary amines (gallamine), is no longer in clinical use. Experience with these drugs has taught us the clinical usefulness of NMBAs, and the literature continues to remind us about the huge variability in responses to these drugs among patients. A thorough understanding of the concepts of neuromuscular transmission, of the effects of NMBAs in the normal individual and how these effects might be altered by certain disease states, electrolyte imbalances and interactions with other drugs, and knowledge of how best to monitor the effects of NMBAs, are of **1** paramount importance in providing optimal, safe patient care.

## Physiology and Pharmacology

### *Morphology of the Neuromuscular Junction*

Lower motor neurons, whose cell bodies are located in the ventral horn of the spinal cord and the motor nuclei of cranial nerves, project their axons via the ventral roots to control effector organs (muscles and glands). The somatic motor neurons are typically large-diameter, myelinated, and fast conducting; as the axons approach their endings, they lose their myelin sheaths before branching into terminal fibers. Each terminal fiber supplies a muscle fiber via a specialized connection, the NMJ (or gap). The *NMJ* consists of the presynaptic motor neuron, the postsynaptic muscle fiber, and the intervening 50- to 70-nm gap (synaptic cleft) between the two, which contains the enzyme acetylcholinesterase (Fig. 21-1).

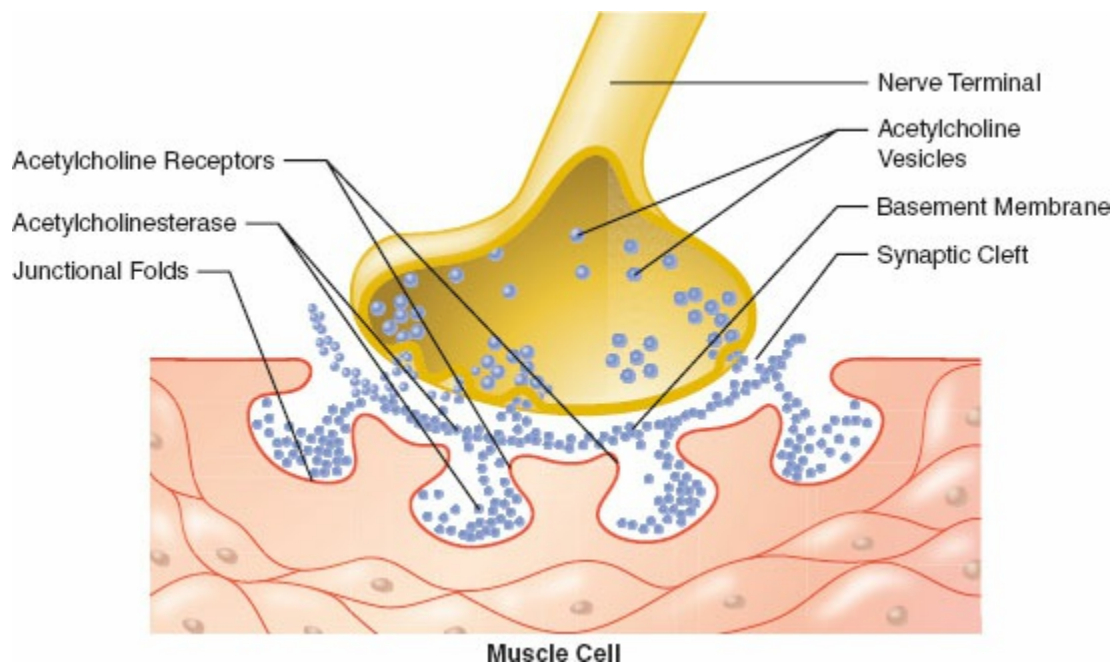

The NMJ has a highly ordered mechanism that converts the electrical signal of the motor nerve (the action potential) into a chemical signal (effected by the release of acetylcholine [ACh]), which in turn is converted into an electrical event (muscle membrane depolarization), leading to a mechanical response (muscle contraction). The *motor unit* consists of the motor neuron and the muscle fiber it innervates. The number of muscle fibers

that each neuron innervates (innervation ratio) determines the precision of the muscle contraction: for muscle groups that require very fine control (e.g., eye or facial muscles), the innervation ratio is close to 1:2 (i.e., 1 nerve innervating 2 fibers). For large muscles that require coarse, powerful movement (thigh or back muscles), the innervation ratio approaches 1:2,000.

Nicotinic muscle-type ACh receptors (muscle-type nAChRs) are located in folds of the postsynaptic muscle membrane in very high concentrations and are not normally found extrasynaptically (see later). More than 90% of all nAChRs in a muscle fiber are located at the synapse, an area that represents less than 0.1% of the total muscle membrane surface area. At birth, the nAChRs are termed “fetal” or “immature” and are comprised of five protein subunits (two  $\alpha$  subunits, one  $\beta$ , one  $\gamma$ , and one  $\delta$  subunit—denoted as  $\alpha_2\beta\gamma\delta$ ), arranged in a rosette with a central transmembrane channel (Fig. 21-2). The initial fetal receptor density is relatively low, approximately 1,000 receptors/ $\mu\text{m}^2$ . After birth, the fetal nAChRs become “mature” or “adult” nAChRs by replacing the fetal  $\gamma$  subunit with an  $\epsilon$  subunit (denoted as  $\alpha_2\beta\delta$ ), and the receptor density increases substantially (10,000 receptors/ $\mu\text{m}^2$ ) (Fig. 21-3). The two  $\alpha$  subunits of the receptor contain the ACh-binding sites (the  $\alpha$ -recognition site).<sup>2</sup> The nAChRs are found preferentially at the endplate, on the crest of the membrane invaginations (folds), and their density decreases markedly outside the junctional area.<sup>3</sup>

## Nerve Stimulation

ACh mediates transmission of an impulse from nerve to muscle. When depolarization of the motor nerve reaches the nerve terminal, voltage-gated  $\text{Ca}^{2+}$  channels open, and the vesicles (quanta) that contain ACh are released by exocytosis from the nerve terminal into the cleft. This release of ACh quanta (each containing 5,000 to 10,000 ACh molecules) is antagonized by hypocalcemia and hypermagnesemia. The  $\text{K}^+$  channels in the nerve terminal area limit the extent of  $\text{Ca}^{2+}$  entry into the terminal, and regulate the transmitter quantal release, initiating nerve membrane repolarization.

**Figure 21-1** Schematic representation of the neuromuscular junction (not drawn to scale).

**Figure 21-2** Nicotinic acetylcholine receptors (nAChRs) termed “fetal” (due to their expression early in development) consist of five subunits: two  $\alpha$  subunits, as well as one  $\beta$ , one  $\gamma$ , and one  $\delta$  subunit (denoted as  $\alpha_2\beta\gamma\delta$ ). During the first 2 postnatal weeks, each postsynaptic motor site is innervated by multiple presynaptic nerve terminals. The  $\alpha$  subunits contain the recognition site for ACh and all neuromuscular blocking agents. (Reprinted with permission from Brull S, Naguib M. Review of neuromuscular junction anatomy and function. In: Mashour GA, Lydic R, eds. *The Neuroscientific Foundations of Anesthesiology*. New York, NY: Oxford University Press; 2011:205–210.)

### **Presynaptic Events: Mobilization and Release of Acetylcholine**

ACh is synthesized in the presynaptic nerve terminal from acetate and

choline, and is divided into two functional pools: the “*immediately available pool*” consists of a small fraction of all ACh available in the nerve terminal. Most of the ACh is contained in the “*reserve pool*” that first must be transported (mobilized) to the area adjacent to the membrane (the *active zone*) and become part of the immediately available pool before it can be released into the cleft. Once nerve depolarization occurs and the intracellular  $\text{Ca}^{2+}$  concentration increases, ACh quanta are released into the synaptic cleft. Released ACh can then bind to the postsynaptic nAChRs to initiate muscle contraction (see later), followed by rapid hydrolysis by acetylcholinesterase into choline and acetic acid; choline then re-enters the presynaptic nerve terminal. ACh can also bind to presynaptic neuronal nAChRs to facilitate ACh mobilization (feedback mechanism).

### Postsynaptic Events

Small quantities of ACh are released spontaneously into the cleft, resulting in small depolarizations (5 mV) of the muscle membrane. These miniature end-plate potentials (MEPPs) may represent the membrane effects of a single ACh quantum. When sufficient ACh quanta are released (200 to 400 quanta, representing 1 to 4 million ACh molecules), the postjunctional muscle membrane depolarization reaches an end-plate potential (EPP) and the excitation–contraction sequence is activated: ACh binds to both recognition sites of the  $\alpha$  subunits of the nAChRs, inducing a conformational change of the receptor that results in the opening of a central channel (pore). The central channel allows  $\text{Na}^+$  influx and  $\text{K}^+$  efflux, resulting in muscle cell membrane depolarization. Voltage-gated  $\text{Na}^+$  channels on the muscle membrane propagate the action potential across the membrane, leading to the development of muscle tension (excitation–contraction coupling).

**Figure 21-3** Nicotinic acetylcholine receptors (nAChRs) termed “adult” (due to their expression later in development) consist of five subunits: two  $\alpha$  subunits, as well as one  $\beta$ , one  $\delta$ , and one  $\epsilon$  subunit (denoted as  $\alpha_2\beta\delta\epsilon$ ). Each postsynaptic adult motor site receives neuronal input from a single motor axon, and the adult nAChRs are restricted in high concentrations ( $10,000/\mu\text{m}^2$ ) in the postsynaptic membrane, but are virtually absent extrasynaptically. As with fetal nAChRs, the  $\alpha$  subunit contains the recognition site for ACh and all neuromuscular blocking agents. (From Brull S, Naguib M. Review of neuromuscular junction anatomy and function. In: Mashour GA, Lydic R, eds. *The Neuroscientific Foundations of Anesthesiology*. New York, NY: Oxford University Press; 2011:205–210.)

### Receptor Up- and Downregulation

When the frequency of stimulation at the NMJ decreases over days (or longer) due to severe burns, immobilization, infection/sepsis, prolonged use of NMBAs in the intensive care unit (ICU), or cerebrovascular accidents (CVAs), the number of immature (fetal) nAChRs increases (*receptor upregulation*) and they extend beyond the NMJ into the adjacent muscle membrane. The immature nAChRs have increased sensitivity to agonists (ACh and succinylcholine [SCh]), and decreased sensitivity to nondepolarizing NMBAs. The channel opening time of the immature nAChRs is up to 10-fold longer than that of mature receptors and may allow systemic release of lethal doses of intracellular  $\text{K}^+$  in response to administration of SCh. *Downregulation* of mature nAChRs occurs during periods of sustained agonist stimulation; for instance, chronic neostigmine use (in patients with myasthenia gravis) or organophosphorus poisoning leads to resistance to SCh but extreme sensitivity to nondepolarizing NMBAs.

### Pharmacologic Characteristics

NMBAs can be classified based on their mode of action: *depolarizing* NMBAs (e.g., SCh) produce muscle relaxation by directly depolarizing the nAChRs. This occurs because SCh (made up of two ACh molecules joined end to end) acts as a “false transmitter,” mimicking ACh. *Nondepolarizing* NMBAs compete with ACh for the two  $\alpha$ -subunits’ (apostrophe) recognition sites, preventing normal nAChR function. Nondepolarizing agents can be classified further according to their chemical structure (benzylisoquinolinium or steroidal) or to their duration of action (short-, intermediate, or long-duration; see later).

*Potency* of a drug is determined by the dose required to produce a certain effect and is calculated from the dose-response sigmoidal curve (Fig. 21-4). For NMBAs, the effect (response) is depression of normal muscle contraction. Thus, a dose that depresses the baseline twitch height by 50% is termed “50%

effective dose” or ED<sub>50</sub>. Most NMBA potencies are expressed as the dose required for 95% depression of the baseline twitch height during nerve stimulation, or ED<sub>95</sub>.

**Figure 21-4** Example of a dose–response relationship. The actual numbers are approximately those for rocuronium. The ED<sub>50</sub> is the dose that produces 50% depression of the control twitch height and ED<sub>95</sub> is the dose that produces 95% depression of the control twitch height.

*Onset of action* (onset time) for all NMBAs is defined as the time from their administration (usually intravenously, IV) until maximal neuromuscular block (disappearance of ST). Onset time is inversely related to dose, and can be affected by its rate of delivery to the site of action (blood flow, speed of injection, etc.), receptor affinity (higher affinity leading to faster onset of action), drug potency (in general, less potent drugs will have a faster onset), mechanism of action (depolarizing vs. competitive), and plasma clearance (metabolism, redistribution).

*Duration of action* until recovery to 25% (DUR 25%) is defined as the time from intravenous (IV) drug administration until spontaneous recovery of ST to 25% of the baseline (normal) strength. The *total duration of action* is defined as the time from drug administration until spontaneous recovery of train-of-four (TOF) ratio to 0.90 (DUR 0.90). Duration of action is directly related to the total dose of NMBA administered. *Recovery index* is defined as the time of spontaneous recovery of ST from 25% to 75% of control (RI<sub>25–75</sub>), a period during which the spontaneous recovery is relatively linear and is not affected significantly by the NMBA dose.

## Depolarizing Neuromuscular Blocking Drugs: Succinylcholine

### Neuromuscular Effects

SCh is the only depolarizing NMBA available clinically (Table 21-1). It has the fastest onset, the shortest duration, and greatest reliability (i.e., narrowest onset variability around the mean) of any NMBA. Because of its molecular similarity to ACh, SCh depolarizes both postsynaptic and extrajunctional receptors, but since it is not degraded by acetylcholinesterases, it depolarizes the muscle membrane for a longer period of time, leading to membrane hyperpolarization and desensitization. This desensitization then leads to flaccid paralysis after the initial receptor activation (which is manifested clinically as muscle “fasciculations”).

1

2

### Characteristics of Depolarizing Blockade

As with all NMBAs, increasing the dose of SCh leads to a progressive decrease in the force of muscle contraction (ST). However, the response to repetitive stimulation (TOF and tetanus patterns—see later) is maintained (*no fade*) because of progressive but equivalent decrease in the force of contractions. Additionally, after a brief period of high-frequency stimulation (tetanus), there is no increase (amplification) in the force of subsequent muscle contractions (*no posttetanic potentiation*—see later; Fig. 21-5). Large doses (>10 times ED<sub>95</sub>) or prolonged (>30 minutes) exposure to SCh, or the presence of abnormal (atypical) plasma cholinesterases (pseudocholinesterase/butyrylcholinesterase deficiency), may lead to dual (or phase II, or nondepolarizing) block. This is characterized by fade of responses to repetitive stimulation and amplification of muscle responses after high-frequency stimulation (posttetanic potentiation—see later), similar to the changes observed during nondepolarizing block (Fig. 21-6).

### Pharmacology of Succinylcholine

The onset of SCh at peripheral muscles (such as the adductor pollicis muscle [APM]) is the fastest of any NMBA (1 to 2 minutes) at equivalent doses. Its ED<sub>95</sub> is approximately 0.30 mg/kg, and at doses of 1.0 to 1.5 mg/kg (3 to 5 × ED<sub>95</sub>), the DUR 25% of SCh is 10 to 12 minutes, but is prolonged beyond 15 minutes with larger doses. Despite paralysis at the APM, the diaphragm (and other central muscles) may start to contract, and spontaneous breathing may resume as fast as 5 minutes after 1 mg/kg SCh administration. SCh is most commonly administered intravenously, but intraosseous, intralingual, and intramuscular routes have been reported if an IV cannot be established. Onset is delayed, particularly with intramuscular administration. Hydrolysis of SCh by pseudocholinesterase (also known as butyrylcholinesterase or plasma cholinesterase) occurs in the plasma, where almost 90% of the IV dose of SCh is hydrolyzed before reaching the NMJ.

**Table 21-1** Pharmacokinetic and Pharmacodynamic Properties of the Depolarizing Neuromuscular Blocking Agent Succinylcholine

Agent*	Succinylcholine
Type (structure)	Depolarizing
Type (duration)	Ultrashort
Potency—ED <sub>95</sub> (mg/kg)	0.25–0.30
Intubating dose (mg/kg)	1.0–1.5
Onset time (min)	1.0–1.5
Clinical duration (min)	7–12
Recovery index (RI <sub>25–75</sub> ) (min)	2–4
Volume of distribution (L/kg)	0.04
Clearance (mL/kg/min)	35
Elimination half-life (minutes)	
• Normal organ function	<1
• Renal impairment	<1
• Hepatic impairment	<1
Maintenance dose (mg/kg)	N/A
Infusion dose (µg/kg/min)	Titrate to ST muscle response
Elimination route/metabolism	Plasma cholinesterase
Active metabolites	No active metabolites (succinylmonocholine has minimal activity)
Side effects	Myalgia; bradycardia/asystole in children or with repeated dosing; dual (phase II) block; anaphylaxis
Contraindications (other than specific allergy)	High K <sup>+</sup> ; MH; muscular dystrophy; children; ACh receptor upregulation pseudocholinesterase deficiency
Comments	Fastest onset, most reliable NMBA for rapid tracheal intubation

\*Agent in current clinical use. The data are averages obtained from published literature and assume there is no potentiation from other coadministered drugs (such as volatile inhalational anesthetics), and the effects are measured at the adductor pollicis muscle. Other factors, such as muscle temperature, mode of evoked response monitoring, type/site of muscle monitoring, etc., will affect the data.

NMBA, neuromuscular blocking agents; ED<sub>95</sub>, effective dose to achieve 95% effect in 50% of patients; K<sup>+</sup>, potassium; MH, malignant hyperthermia; ST, single twitch; ICU, intensive care unit.

**Figure 21-5** Characteristics of depolarizing block. Left: decrease in train-of-four (TOF) amplitude without fade in response to depolarizing agent administration. Right: lack of posttetanic (5 second) potentiation of evoked response. TOF, train-of-four; TOF<sub>c</sub>, control (baseline) TOF; PTF, posttetanic facilitation.

### Side Effects

SCh can induce significant *bradycardia and asystole*, particularly in children, and in any patient after readministration. *Premature ventricular escape beats* are also common; cardiac effects can be attenuated by pretreatment with anticholinergics. Disorganized muscle contractions (*fasciculations*) after SCh are very common (80% to 90% of patients). *Myalgias* are also very common 1

to 2 days postoperatively and can occur in 50% to 60% of patients. Fasciculations have been considered a possible etiology for postoperative myalgia, but systematic reviews have not established a clear relationship. A “defasciculating” pretreatment with a small dose of nondepolarizing NMBA (10% ED<sub>95</sub>) is sometimes used to decrease the incidence of fasciculations and myalgia. However, this technique may render susceptible patients at risk of *regurgitation* and *pulmonary aspiration* because of partial paralysis of pharyngeal muscles. Alternatively, because of large interindividual variability, pretreatment may be ineffective in some patients. If pretreatment is used, the dose requirement for SCh is increased (up to 2 mg/kg). Defasciculation also may be achieved by administering 5 to 10 mg of SCh prior to administering the full SCh dose—this has been termed a “self-taming” dose of SCh, but is rarely used in modern practice. The most effective prophylaxis for myalgia without using nondepolarizing NMBAs is pretreatment with nonsteroidal anti-inflammatory drugs (e.g., aspirin or diclofenac), with a number needed to treat (NNT) of 2.5.<sup>4</sup> Lidocaine and rocuronium pretreatment also decrease the incidence of postoperative myalgia (NNT = 3), but the risk of untoward side-effects such as blurred vision, diplopia, inability to speak, and difficulty in breathing and swallowing likely do not justify this practice (number needed to harm [NNH] <3.5 patients).<sup>4</sup>

**Figure 21-6** Characteristics of nondepolarizing block. Left: progressive decrease in train-of-four (TOF) ratio in response to non-depolarizing agent administration. Right: significant TOF fade and tetanic (5-sec) fade, followed by potentiation of evoked responses (increased amplitude, decreased fade). TOF, train-of-four; TOF<sub>C</sub>, control (baseline) TOF; PTF, posttetanic facilitation.

Although SCh may *increase intragastric pressure*, the lower esophageal sphincter tone is also increased, such that the intragastric-esophageal pressure gradient remains the same; thus, there is no increase in the risk of aspiration from the use of SCh. Normal *intraocular pressure* (IOP) is 12 to 20 mmHg with a diurnal variation of 2 to 3 mmHg, whereas changes in position may induce increases of up to 6 mmHg. In fact, otherwise innocuous settings, such as the

Valsalva maneuver while playing wind instruments, can significantly (+9.2 mmHg) increase IOP (Fig. 21-7).<sup>5</sup> IOP also increases after administration of SCh (up to 15 mmHg increase), but these changes are transient (5 minutes).<sup>6</sup> Pretreatment with an NMBA does not attenuate this increase; lidocaine and sufentanil have been reported to decrease IOP by a mean of 5 mmHg, thus attenuating the IOP increases after SCh.<sup>7</sup>

Despite fears that this SCh-induced increase in IOP may induce extrusion of ocular contents in patients with an “open-globe” injury, clinical practice in thousands of patients has not reported this complication.<sup>8,9</sup> It should be noted that increases in IOP can be significant in the context of inadequate anesthesia and neuromuscular block that allows the patient to cough and perform Valsalva, particularly during laryngoscopy and tracheal intubation. Such settings generate much larger increases in IOP than those associated with SCh administration and must be avoided, particularly in the patient with an open-globe injury.<sup>10</sup>

*Elevation in intracranial pressure (ICP)* from SCh may occur, and this increase is attenuated by defasciculation. Inadequate levels of anesthesia during laryngoscopy and tracheal intubation, however, are much more likely to increase ICP. In a group of patients with head injury, a hypertensive response to laryngoscopy and tracheal intubation was observed in 80% of patients; importantly, in 11% of patients, the increase in ICP was 100% or more.<sup>11</sup>

SCh administration induces a mild elevation in the plasma level of potassium of 0.5 mEq/L; however, severe *hyperkalemia* with attendant cardiac arrest has been reported in cases in which there is proliferation of immature nAChRs (see earlier, Receptor Upregulation). Rare case reports have also associated administration of SCh with fatal hyperkalemia in children receiving oral  $\beta$ -blocker therapy (propranolol).<sup>12</sup> Other settings in which the use of SCh has been associated with hyperkalemia include chronic denervation states (spinal cord injury, prolonged bed rest), major burns, acute renal failure, sepsis, encephalitis, and severe trauma. Pretreatment with a nondepolarizing NMBA prior to SCh administration has not been shown to attenuate the hyperkalemic response. Treatment of hyperkalemia generally consists of hyperventilation, IV calcium chloride, and glucose/insulin to shift potassium intracellularly.

Particularly important is the association between pediatric myotonia and muscle dystrophies, and SCh administration, leading to rhabdomyolysis and fatal hyperkalemia. For this reason, the U.S. Food and Drug Administration (FDA) has a “black box” warning on the use of SCh and, in the pediatric population, SCh should only be used for emergency tracheal intubation. SCh may also trigger lethal *malignant hyperthermia* (MH), especially in patients anesthetized with volatile anesthetics. Some patients (both adults and

children) may exhibit *masseter muscle spasm* after SCh, making intubating conditions difficult. In some cases, particularly in pediatrics, masseter spasm is associated with malignant hyperthermia (MH). SCh can produce *allergic reactions (anaphylaxis)* in about 1 out of 10,000 administrations.

**Figure 21-7** Mean increase in intraocular pressure (IOP) from baseline in response to various procedures and maneuvers. Normal IOP is 10 mmHg. LMA, laryngeal mask airway; ETT, endotracheal tube. (Adapted with permission from Aniskevich S, Brull S, Naguib M. Neuromuscular blocking agents. In: Johnson KB, ed. *Clinical Pharmacology for Anesthesiology*. New York, NY: McGraw-Hill Education, 2015.)

Patients receiving statin therapy may be particularly susceptible to muscle injury from administration of SCh, resulting in high plasma concentrations of myoglobin and creatine kinase, as well as hyperkalemia. However, these changes are likely of limited clinical significance.<sup>13</sup>

## Clinical Uses

SCh is indicated for rapid attainment of optimal intubating conditions and prevention of regurgitation and pulmonary aspiration of gastric contents in patients at risk (those unfasted, with gastroparesis or gastrointestinal obstruction) in the “rapid sequence induction and intubation” (RSII) scenario. In this setting, SCh is the drug closest to the “ideal” NMBA. It has the shortest clinical duration (5 to 10 minutes at 1 mg/kg dose), so most patients will resume some diaphragmatic function before significant apnea-induced hypoxia occurs; it has the shortest onset time (1 minute at 1.5 mg/kg); and it has the highest reliability, with the fewest outliers (patients whose intubating conditions are poor at the time of intubation; [Fig. 21-8](#)). In obese individuals who need RSII, the dose of SCh should be calculated on the basis of actual body weight rather than ideal body weight. Children are more resistant than

adults to the actions of SCh, and the usual dose (see Side Effects) is 1.5 to 2.0 mg/kg (up to 3 mg/kg in infants). In the 2015 Cochrane Database systematic review, the authors found there were no statistically significant differences in intubation conditions between SCh and rocuronium (1.2 mg/kg), but concluded that SCh “was clinically superior as it has a shorter duration of action.”<sup>14</sup>

**Figure 21-8** Neuromuscular blocking agents provide better intubating conditions than high doses of opioids, without hypotension. Hypnotic agent was propofol or thiopental. Intubating conditions are plotted against dose of remifentanyl (in micrograms per kilogram). Results for succinylcholine (Sux), 1 mg/kg (with little opioid) are given for comparison. Hypotension was seen with remifentanyl, 4 µg/kg.

## Contraindications

In the surgical population, the relative risk of MH with SCh administration (vs. without SCh) is 20 times higher when combined with volatile anesthetics.<sup>15</sup> Use of SCh is contraindicated in patients (and their relatives) with a history of MH. Other settings in which SCh is contraindicated include states of receptor upregulation (see earlier) due to potential for lethal hyperkalemia, critical care patients or those immobilized for prolonged periods (e.g., weeks), and patients with pseudocholinesterase deficiency. Patients with pseudocholinesterase (butyrylcholinesterase) deficiency are at risk of unintended intraoperative awareness and recall if they are awakened while paralyzed and neuromuscular monitoring is not used.<sup>16</sup> Approximately 1 in 25 patients may be heterozygous and 1 in 2,500 individuals may be homozygous for the “atypical” deficiency gene, and may require prolonged

(hours) postoperative mechanical ventilation after SCh administration. In patients with renal failure, SCh may be administered if the plasma  $K^+$  is not elevated. Lethal hyperkalemia following administration of SCh has been reported in severely acidotic and hypovolemic patients, and, in these settings, its use is contraindicated. In the intensive care setting, patients can be at increased risk of significant hyperkalemia ( $>6.5$  mmol/L) after receiving SCh because of nicotinic receptor upregulation, particularly if their ICU length of stay at the time of SCh administration was greater than 16 days.<sup>17</sup> Succinylcholine has the potential to induce acute rhabdomyolysis and hyperkalemia followed by ventricular dysrhythmias, cardiac arrest and death after administration to pediatric patients who were subsequently found to have undiagnosed skeletal muscle myopathy, most frequently Duchenne's. For this reason, the U.S. Food and Drug Administration (FDA) has issued a black box warning for the use of succinylcholine in pediatric patients.

## Nondepolarizing Neuromuscular Blocking Agents

### *Characteristics*

Nondepolarizing NMBAs compete with ACh for binding to one or both of the  $\alpha$  subunits of the nAChRs. With repetitive stimulation at frequencies between 0.1 and 2.0 Hz during partial block, muscle contraction fatigue (fade) develops (Fig. 21-6). The degree of fade can be determined with a sequence of four stimuli delivered at a 2-Hz frequency (TOF) by calculating the ratio of the amplitude (strength) of the fourth response (T4) to the amplitude of the first response (T1) of the TOF. This ratio is termed the TOF ratio, or T4/T1. Normal (baseline) TOF ratio is 1.0 (100%).

Another characteristic of nondepolarizing block is the transient amplification of responses that follows a 5-second period of tetanic stimulation (posttetanic potentiation [PTP], or facilitation [PTF]) that lasts about 2 to 3 minutes following tetanic stimulation (see PTP). Unlike depolarizing blockade, which is potentiated by the administration of anticholinesterases, the nondepolarizing block can be antagonized by these agents as long as the depth of block at the time of reversal is not excessive.

### *Pharmacology*

Nondepolarizing NMBAs can be classified as long-, intermediate-, and short-acting, and their duration of action depends on metabolism, redistribution, and elimination (Tables 21-2 and 21-3). They also can be classified based on their chemical structure as aminosteroid (vecuronium, rocuronium, pancuronium, pipecuronium) or benzyloisoquinolinium (mivacurium,

atracurium, cisatracurium, doxacurium) compounds. Nondepolarizing NMBAs are almost always administered IV, because intramuscular delivery leads to very slow and variable absorption and onset of action. Because they are positively charged, nondepolarizing NMBAs are distributed mostly in the extracellular fluid (ECF). Thus, in patients with renal or hepatic failure (who have increased ECF), and in burn patients, who exhibit shorter elimination half-life, larger initial doses may be required.<sup>18</sup>

**Table 21-2** Pharmacokinetic and Pharmacodynamic Properties of Aminosteroid Nondepolarizing Neuromuscular Blocking Agents

Agent <sup>a</sup>	Vecuronium	Rocuronium	Pancuronium	Pipecuronium
Type (structure)	Nondepolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing
Type (duration)	Intermediate	Intermediate	Long	Ultralong
Potency—ED <sub>95</sub> (mg/kg)	0.05	0.3	0.07	0.045
Intubating dose (mg/kg)	0.1	0.6	0.1	0.1
Onset time (minutes)	3–4	1.5–3.0	2–4	4–6
Clinical duration (minutes)	25–50	30–70	60–120	80–140
Recovery index (RI <sub>25-75</sub> ) (minutes)	10–25	8–13	30–45	60
Volume of distribution (L/kg)	0.4	0.3–0.7	0.2–0.3	0.25–0.30
Clearance (mL/kg/min)	5.0	3.0	1.8	2.5
Elimination half-life (min)				
• Normal organ function	65–75	100–250	90–160	90–220
• Renal impairment	Mild increase	100–300	Increased ×2	120–480
• Hepatic impairment	Significant increase	120–400	Increased ×2	—
Maintenance dose (mg/kg)	0.01	0.1	0.02	0.01
Infusion dose (μg/kg/min)	1–2	5–12	20–40 (not recommended)	NA (not recommended)
Elimination route/metabolism	Renal 10%–50%; Hepatic 30%–50%	Renal 30%; Hepatic 70%	Renal 40%–70%; Hepatic 20%	Renal 45%–60%; unchanged 40%
Active metabolites	3-desacetyl-vecuronium	17-desacetyl-rocuronium (minimal)	3-OH-pancuronium; 17-OH-pancuronium	3-desacetyl metabolite
Side effects	Vagal blockade with large doses	Minimal	Vagal block (tachycardia), catecholamine release	Minimal
Contraindications (other than specific allergy)	None	None	Short surgical procedures (<60 minutes); not recommended for continuous infusion	Short surgical procedures
Comments	Not for prolonged ICU administration (myopathy); reversible by sugammadex; elimination half-life halved in late pregnancy; 3-desacetyl metabolite has 60% of the parent compound potency	Pain on injection; easily reversible by sugammadex; elimination half-life prolonged in ICU patients; 17-desacetyl metabolite has 20% activity	Significant accumulation, prone to residual block (3-OH metabolite has 50% activity of pancuronium)	3-desacetyl metabolite has 50% of parent potency; shorter duration of action in pediatrics; can be reversed by sugammadex

<sup>a</sup>Agents in current clinical use. The data are averages obtained from published literature and assume there is no potentiation from other coadministered drugs (such as volatile inhalational anesthetics), and the effects are measured at the adductor pollicis muscle. Other factors, such as muscle temperature, mode of evoked response monitoring, and type/site of muscle monitoring, will affect the data.

Infusion dose (μg/kg/min)	5–8	10–20	1–3	NA (not recommended)
Elimination route/ metabolism	Plasma cholinesterase (70% of succinylcholine rate)	Renal 10%; Hoffman 30%; ester hydrolysis 60%	Hoffman 30%; ester hydrolysis 60%	No metabolism; unchanged excretion in urine (30%–40%) and bile
Active metabolites	No active metabolites	No active metabolites	No active metabolites	No active metabolites
Side effects	Histamine release	Histamine release; laudanosine and acrylates production	None; histamine release at high doses	None
Contraindications (other than specific allergy)	Pseudocholinesterase deficiency	Hemodynamically unstable patients due to histamine release	None	None
Comments	Reversal by cholinesterase inhibitors; mixture of 3 isomers (cis-cis minimal); edrophonium for antagonism more effective during deep block	Organ-independent elimination	Trivial histamine release; minimal plasma laudanosine and acrylate levels	No accumulation; children more resistant, require higher doses; no histamine release; no cardiac effects at 3 × ED <sub>95</sub> dose

<sup>a</sup>Agents in current and <sup>b</sup>anticipated clinical use. The data are averages obtained from published literature and assume there is no potentiation from other coadministered drugs (such as volatile inhalational anesthetics), and the effects are measured at the adductor pollicis muscle. Other factors, such as muscle temperature, mode of evoked response monitoring, and type/site of muscle monitoring, will affect the data.

NA, data not available; ED<sub>95</sub>, effective dose to achieve 95% effect.

### Onset and Duration of Action

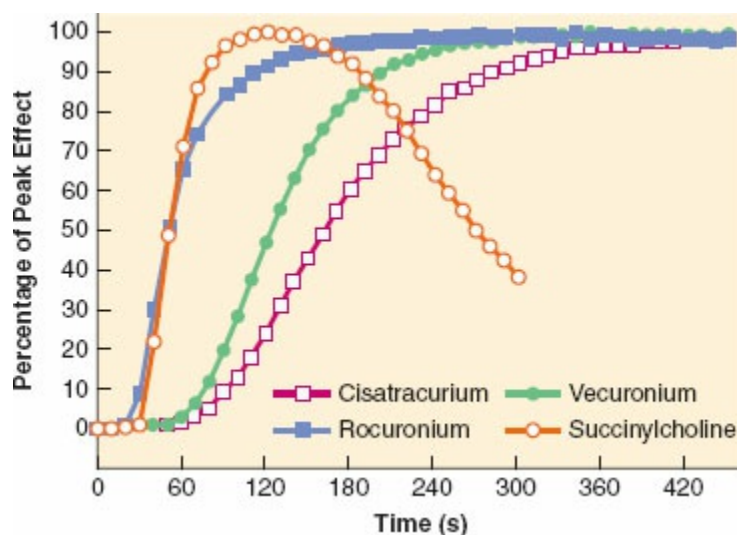

Onset of nondepolarizing NMBAs generally depends on potency; less potent agents such as rocuronium (ED<sub>95</sub> of 0.30 mg/kg) have more molecules per equivalent dose than a potent NMBA such as vecuronium (ED<sub>95</sub> of 0.05 mg/kg); thus, an ED<sub>95</sub> dose of (the less potent) rocuronium will have six times more molecules than an equipotent dose of vecuronium, and the plasma concentration of rocuronium will be greater than that of vecuronium. This greater concentration difference between the plasma and the biophase partly explains the more rapid onset of rocuronium (and SCh), as the rate of

equilibration between blood and the effect compartment (the  $k_{e0}$ ) will be faster (Fig. 21-9). A similar plasma/biophase concentration gradient might be achieved by administering, for instance, six times the ED<sub>95</sub> of vecuronium; although this dose increase will speed up the onset, the much larger dose will also markedly prolong the total duration of action. Typically, a dose of 2 to 3 × ED<sub>95</sub> of a nondepolarizing NMBA is used to facilitate tracheal intubation, whereas only 10% of the ED<sub>95</sub> of a drug will be necessary to re-establish an existing deeper level of block.

## Individual Nondepolarizing Agents

### Aminosteroid Compounds

*Pancuronium* (Table 21-2) is one of the oldest nondepolarizing NMBAs. It is considered a long-acting agent with high predilection for significant accumulation because its main metabolite, 3-OH pancuronium, has 50% of the parent compound potency. DUR 25% is often more than 1 to 2 hours, but it can be prolonged further in renal or hepatic failure, or with repeated administration. Pancuronium has vagolytic effects as well as direct sympathomimetic effects; it blocks norepinephrine presynaptic reuptake. Because of its high potency, it is slow in onset so doses greater than 2 × ED<sub>95</sub> are usually needed for intubation in less than 5 minutes. It has traditionally been used in cardiac surgery, because its vagolytic effects counteract the bradycardic effects associated with high-dose opioid techniques. Anticholinesterase reversal of pancuronium-induced block is much less effective, but the reversal of shallow pancuronium block by the new agent sugammadex (see Selective Relaxant Binding Agents) appears to be effective.<sup>19</sup> Today, many clinicians find pancuronium obsolete because of the significant risk of postoperative residual neuromuscular weakness.

**Figure 21-9** Neuromuscular blockade as a function of time for four neuromuscular

blocking agents. Onset is faster for the less potent succinylcholine and rocuronium than for the more potent vecuronium and cisatracurium. (Adapted with permission from Kopman AF, Klewicka MM, Kopman DJ, et al. Molar potency is predictive of the speed of onset of neuromuscular block for agents of intermediate, short, and ultrashort duration. *Anesthesiology*. 1999;90:425.)

*Pipecuronium* (Table 21-2) is a long-acting aminosteroid NMBA that is currently not used in the United States, but it is still in use in Europe and Asia. It is structurally similar to pancuronium and vecuronium, and its antagonism of residual block by neostigmine is more effective than by edrophonium.<sup>20</sup> Recent data indicate that sugammadex is able to adequately and rapidly reverse pipecuronium-induced moderate block within 5 minutes.<sup>21</sup>

*Vecuronium* (Table 21-2) is an intermediate-duration NMBA that is devoid of cardiovascular effects; because it is more potent than rocuronium, its onset of action is slower. Vecuronium metabolism produces three byproducts (3-OH, 17-OH, and 3,17-(OH)<sub>2</sub> metabolites). The 3-OH (3-desacetyl) metabolite has 60% of the parent compound potency, and its accumulation with large and/or repeated doses in ICU patients likely is responsible for persistent paralysis in the critically ill patient (see Altered Responses to Neuromuscular Blocking Agents). Vecuronium precipitates in the IV tubing if administered immediately after thiopental, but does not precipitate after propofol. It has been reported that vecuronium recovery time may be prolonged significantly in patients with diabetes mellitus.<sup>22</sup> Since the introduction of rocuronium, vecuronium is no longer recommended for RSII.

*Rocuronium* (Table 21-2) is structurally similar to pancuronium and vecuronium. Because of its low potency, the high plasma concentration achieved after bolus administration decreases rapidly, such that its duration of action in patients with normal renal and hepatic function is determined mostly by its redistribution, and not its elimination. Unlike vecuronium, rocuronium metabolites are minimal, with very low neuromuscular blocking activity (17-OH rocuronium), so the risk of accumulation is minimal. In many cases, rocuronium has replaced the use of SCh in the RSII sequence. At doses of 3.5 to 4 × ED<sub>95</sub> (1.0 to 1.2 mg/kg), the onset rivals that of SCh, with similar intubating conditions.<sup>23</sup> The DUR 25%, however, at these doses averages 50 to 70 minutes (with a very wide range).

Similar to vecuronium, rocuronium does not cause significant hemodynamic perturbations and releases no histamine. Allergic reactions have been documented, and the rates of anaphylaxis (in Australia and New Zealand) are higher with rocuronium and SCh than any other NMBAs, whereas cisatracurium has the lowest rate of IgE-mediated anaphylaxis even in patients with previous anaphylaxis to rocuronium or vecuronium.<sup>24,25</sup> Reports from Europe also suggest that the incidence of anaphylaxis following

rocuronium may be higher than with other NMBAs—this propensity having been ascribed in part to sensitization to an antitussive medication, pholcodine, that was previously available in some European countries. A similar increase in the incidence of IgE-mediated sensitization to NMBAs has been described in hairdressers, likely because of repetitive exposure to quaternary ammonium compounds used in cosmetics and hair products.<sup>26</sup> In the pediatric population, whereas both cisatracurium (see Nondepolarizing Neuromuscular Blocking Agents) and rocuronium have been shown to induce mild decreases in pulmonary function, these changes (maximum expiratory flow rate at 10%, MEF10) were more pronounced in patients receiving rocuronium.<sup>27</sup> Interestingly, anaphylaxis to rocuronium has been treated successfully with the new selective relaxant binding agent (SRBA) sugammadex.<sup>28</sup>

Potency of rocuronium appears to be greater in women, in older (60 to 75 years) patients, and in North American than in European patients. In laparoscopic procedures, the duration of neuromuscular block produced by rocuronium is increased by approximately 25%; this increase is attributed to the effects of pneumoperitoneum on hepatic perfusion and blood flow, which may alter the pharmacokinetics of rocuronium.<sup>29</sup> Patients with type II diabetes also have been reported to be at increased risk of residual neuromuscular block following rocuronium exposure.<sup>30</sup> In children, onset is faster and duration of action is shorter, although dose requirements are slightly increased. In patients aged 60 years and older, preadministration of magnesium may shorten its onset without significantly prolonging the duration of action.<sup>31</sup> The ability of sugammadex to reverse rocuronium-induced neuromuscular block, however, is not affected significantly by magnesium administration.<sup>32</sup>

Because of its rapid onset, rocuronium can be used in high doses (1.2 mg/kg) in the RSII setting, particularly in those patients in whom the use of SCh is contraindicated. It must be noted, however, that although the mean onset time at this dose approaches that of SCh (60 seconds), the variability of onset is greater with rocuronium, such that it is more likely that some rare outliers may have poor intubating conditions at the time of attempted laryngoscopy. It also must be borne in mind that after large doses, the DUR 25% is significantly prolonged (>60 minutes), and spontaneous (diaphragmatic) ventilation cannot be relied upon for maintenance of oxygenation in the “cannot-intubate, cannot-oxygenate” (CICO) scenario. In such emergencies, the administration of a large dose (16 mg/kg) of sugammadex may be life-saving, as long as the spontaneous ventilatory drive has not been blocked by the administration of opioids or anesthetics. Administration of high doses ( $4 \times \text{ED}_{95}$ ) of rocuronium has no effect on the corrected QT interval in cardiac patients.<sup>33</sup>

## Tetrahydroisoquinolinium (“Benzylisoquinolinium”) Derivatives

These compounds, ubiquitously called “isoquinolinium” NMBAs, are tetrahydroisoquinolinium derivatives.

*Doxacurium* (Table 21-3) is a long-acting bisquaternary benzylisoquinolinium nondepolarizing NMBA. It is very potent (ED<sub>95</sub> is 0.025 mg/kg), so it is the least rapid in onset (3 to 10 minutes), and also the longest acting (77 to 164 minutes) nondepolarizing NMBA.<sup>34</sup> Doxacurium releases no histamine in doses up to 2.7 times its ED<sub>95</sub>, so is very stable from a cardiovascular standpoint.<sup>35</sup> Its elimination is primarily renal, and its duration of action is prolonged in renal failure<sup>36</sup> and elderly<sup>37</sup> patients. It was used preferentially during long surgical procedures, particularly in cardiac surgery, and in the ICU. Doxacurium is no longer available for clinical use in the United States.

*Atracurium* (Table 21-3) is a bis-benzylisoquinolinium compound of the curare family and is made up of a mixture of 10 optical isomers. It shares, with most of the isoquinolinium compounds, a unique, dual metabolic pathway: a nonenzymatic degradation that is directly proportional with temperature and pH (Hoffman reaction), and a secondary pathway that involves hydrolysis by nonspecific plasma esterases (same enzymes that degrade esmolol, remifentanyl, and oseltamivir). At the usual dose for tracheal intubation (2 × ED<sub>95</sub>), atracurium has a relatively long onset (3 to 5 minutes). Onset can be shortened by increasing the dose, but above 0.5 mg/kg, atracurium induces histamine release, resulting in skin flushing, tachycardia, and hypotension. DUR 25% is intermediate (30 to 45 minutes) and similar to the other intermediate-duration agents, but it is slightly more predictable, likely because of the dual metabolic pathway. Unlike aminosteroid NMBAs, atracurium potency is similar between men and women, and is not affected appreciably by age or organ failure. Allergic reactions have been reported with the same frequency as the other benzylisoquinolinium compounds. The breakdown products, such as laudanosine and acrylates, have no clinical significance at the doses of atracurium used in the clinical setting.

*Cisatracurium* (Table 21-3) was developed in an attempt to reduce atracurium’s propensity for histamine release. It is a potent cis-cis isomer of atracurium, and its onset time is longer than that of atracurium. Because five times less cisatracurium is administered than atracurium at equipotent (ED<sub>95</sub>) doses, cisatracurium does not induce histamine release. For this reason, the plasma concentrations of the metabolite laudanosine are similarly lower when cisatracurium is used.<sup>38</sup> Metabolism is largely independent of liver function, and because the organ-independent Hoffman elimination is the predominant pathway for its elimination, cisatracurium is preferred for use in the ICU setting. The incidence of anaphylactic reactions is similar to that of

atracurium and lower than that of rocuronium and SCh.

*Mivacurium* (Table 21-3) was developed initially as the “ideal nondepolarizing neuromuscular blocking agent” that promised to achieve rapid onset with a duration of action significantly shorter than that of intermediate-duration agents. It consists of three stereoisomers (cis-trans, trans-trans, cis-cis). The cis-cis isomer has a much longer half-life (30 minutes) than the other two isomers (2 to 3 minutes), but it represents only 6% of the mixture, so its overall contribution to the drug’s duration of action is limited. Mivacurium is rapidly hydrolyzed in plasma by butyrylcholinesterases, giving it a duration of action almost twice that of SCh (15 to 20 minutes). Because of its high potency, large doses ( $3$  to  $4 \times \text{ED}_{95}$ ) are needed for good intubating conditions and rapid onset, but at these doses, histamine release is observed. In smaller doses of  $0.2$  mg/kg ( $2.5 \times \text{ED}_{95}$ ), even when combined with propofol and remifentanyl, mivacurium resulted in optimal intubating conditions in only 20% of patients.<sup>39</sup> In order to avoid histamine release when large doses are administered, some have suggested a “split-dose” technique in which a dose of  $0.15$  mg/kg is followed 30 seconds later by  $0.10$  mg/kg.<sup>40</sup> Even with this split administration, however, histamine release can still occur, and clinicians have not adopted the technique widely. When mivacurium is administered for tracheal intubation, four factors increase the probability of achieving excellent conditions: increasing mivacurium dose; opioid coadministration; delaying time to intubation (from 1 minute to 2 minutes); and patient age ( $>70$  years).<sup>41</sup> Because of its rapid metabolism, the differential onset between the central (laryngeal) and peripheral (adductor pollicis) muscles is exaggerated. Thus, if the timing of tracheal intubation is guided by neuromuscular responses of peripheral muscles (e.g., APM), intubating conditions may not be ideal since the central muscles (e.g., the diaphragm) may have started recovering already.

Reversal of mivacurium-induced neuromuscular block is either spontaneous or pharmacologic, using anticholinesterases. Neostigmine also inhibits plasma cholinesterases (that should slow mivacurium metabolism), but these effects are less than the inhibition of acetylcholinesterases, resulting in a “net” reversal of nondepolarizing block. In patients with homozygous butyrylcholinesterase deficiency, the use of mivacurium (and SCh) will result in prolonged neuromuscular paralysis of 2 to 6 hours, so monitoring of neuromuscular function, mechanical ventilation, and appropriate sedation/amnesia are necessary to prevent unintended patient awareness and recall.<sup>42</sup> Administration of whole blood or fresh frozen plasma (each of which contains pseudocholinesterase) is not recommended unless there is another primary indication for the transfusion. Although mivacurium had been withdrawn from the United States market, it recently (2017) has been re-introduced into clinical use.

## Drug Interactions

*Nondepolarizing NMBAs* may have either additive or synergistic effects when combined. Usually, combining two chemically similar drugs with similar duration of action (e.g., atracurium and cisatracurium) results in an additive potency interaction with no effect on total duration. When drugs of different classes are combined (e.g., cisatracurium plus rocuronium), the effects in term of total dose are synergistic, in which, for instance, ED<sub>25</sub> of rocuronium plus ED<sub>25</sub> of cisatracurium may have an ED<sub>95</sub> effect.<sup>43</sup> Combining different drugs with different duration of action is a special case of interaction: when a short-duration drug (mivacurium) is added at the end of a vecuronium-based block, recovery will follow the intermediate (vecuronium) block. In contrast, when vecuronium is added during recovery from mivacurium, the vecuronium recovery will be shorter, similar to that of mivacurium. This apparent paradox is due to the fact that recovery will always follow that of the drug that blocked the majority (70% to 90%) of the receptors (the loading dose drug); the additional, maintenance drug dose is in comparison very small, and only blocks a small proportion (10% to 15%) of the free receptors. Thus, the predominant characteristics of recovery will be those of the loading drug.

Adding *depolarizing and nondepolarizing NMBAs* results in mutual antagonism. For instance, defasciculating doses of a nondepolarizing NMBA prior to administration of SCh will increase the SCh dose requirement and shorten the SCh duration of action.

*Inhalational anesthetic* agents potentiate neuromuscular block (desflurane > sevoflurane > isoflurane > halothane > nitrous oxide), likely by direct effects at the postjunctional receptors. Higher concentration (minimum alveolar concentration [MAC]) and longer agent exposure will potentiate the neuromuscular block to a greater extent. The intravenous agent *propofol* has minimal effect on neuromuscular transmission, although the potency of rocuronium is enhanced after a 30-minute propofol infusion.<sup>44</sup>

*Local anesthetics* can potentiate the effects of both depolarizing and nondepolarizing NMBAs, but are insufficient to significantly shorten the onset time; NMBAs' duration of action can be prolonged due to both pre- and postsynaptic effects in animal studies.<sup>45</sup> In humans, epidurally administered levobupivacaine can significantly prolong the recovery time of vecuronium,<sup>46</sup> but a continuous infusion of IV lidocaine has no impact on the time course of rocuronium-induced neuromuscular block.<sup>47</sup> It is likely that these apparently contradictory effects of local anesthetics on neuromuscular transmission depend more on their plasma concentration rather than the type of local anesthetic.

The new generation of *antibiotics* has little, if any, propensity for prolonging the effects of NMBAs. Older antibiotics, such as streptomycin and

neomycin, that were known to depress neuromuscular function, are used rarely today; the aminoglycosides have limited effects, but they may be involved in the process of ACh release.<sup>48</sup> Hypercarbia, acidosis, or hypothermia, however, may further potentiate the depressant effects of antibiotics in the critically ill patient.

In patients receiving acute administration of *anticonvulsants* (phenytoin, carbamazepine), neuromuscular block is potentiated, whereas chronic administration significantly decreases the duration of action of aminosteroids while having little effect on benzyliisoquinolinium compounds. *Calcium channel antagonists* have clinically insignificant effects on NMBAs;  $\beta$ -*receptor antagonists* appear to delay the onset of rocuronium, whereas *ephedrine* has been shown to hasten the onset of rocuronium, likely by increasing cardiac output.<sup>49</sup>

*Corticosteroids*, particularly when administered in critical illness for prolonged periods in conjunction with neuromuscular blockade, will markedly increase the risk of myopathy (up to 50% of mechanically ventilated patients who receive both drugs may develop myopathy).

## Altered Responses to Neuromuscular Blocking Agents

The use of NMBAs in the *ICU* setting is commonplace. Multiple reports have documented their benefits in facilitating tracheal intubation and maintenance of mechanical ventilation, particularly in patients requiring prone positioning for acute respiratory distress.<sup>50</sup> Short-term infusion of nondepolarizing NMBAs (cisatracurium) in the *ICU* has been shown in systematic reviews to reduce in-hospital mortality and barotrauma from mechanical ventilation, although not having any effect on the incidence of *ICU*-acquired weakness, as long as patients are not hyperglycemic and do not receive corticosteroids.<sup>51,52</sup> Similarly, continuous short-term neuromuscular blockade (<24 hours) after cardiac arrest was associated with improved lactate clearance, functional outcome, and survival.<sup>53</sup> However, when using NMBAs in the *ICU*, it is critical to remember that sedation is paramount in order to provide comfort and amnesia and avoid unintended patient awareness and recall. In addition, continuous neuromuscular block for prolonged periods (days) should be avoided, particularly in patients who receive steroid therapy concurrently. Although initially most reports of persistent paralysis involved aminosteroidal NMBAs, similar complications have been reported after benzyliisoquinolinium compounds as well.<sup>54</sup>

Patients with *neuromuscular disease* may present a particular challenge to the anesthesiologist because of their increased risk of perioperative events, such as pulmonary and cardiovascular complications, residual neuromuscular weakness after administration of NMBAs, and metabolic syndromes such as

MH.<sup>55</sup> In general, neuromuscular diseases can be classified into disorders of neuromuscular transmission, disorders of muscle and muscle membrane, disorders of lipid or glycogen storage, peripheral neuropathies, and disorders of the central nervous system with neuromuscular manifestations (Table 21-4). Patients with neuromuscular disorders have increased sensitivity to depolarizing, and variable sensitivity to nondepolarizing, NMBAs. In addition, because of the increased association with MH and rhabdomyolysis in many of the disorders, the use of SCh should be avoided, whereas the use of nondepolarizing NMBAs should always be guided by objective monitoring, not by subjective or clinical evaluation.

Multiple factors affect the pharmacokinetics of all drugs, including NMBAs. Intraoperative *hypothermia* prolongs the duration of NMBAs by decreasing receptor sensitivity and ACh mobilization, decreasing the force of muscle contraction, reducing renal and hepatic metabolism, and the Hoffman degradation pathway (and therefore prolonging the action of benzylisoquinolinium drugs, such as atracurium and cisatracurium). *Aging* results in decreased total body water and serum albumin concentration, reducing the volume of distribution of NMBAs; decreased cardiac function, glomerular filtration rate, and liver blood flow decrease the rate of NMBA elimination (especially the steroidal compounds). *Acid–base and electrolyte imbalance* affect the duration of action of NMBAs and their metabolism and elimination. Hypokalemia potentiates nondepolarizing block and decreases the effectiveness of anticholinesterases (neostigmine) in antagonizing nondepolarizing block. Hypermagnesemia prolongs the duration of action of NMBAs by inhibition of Ca<sup>2+</sup> channels (both pre- and postsynaptically). Acidosis interferes with the effects of anticholinesterases in reversing a nondepolarizing block. *Hypercarbia* also leads to acidosis and interferes with NMBA antagonism. *Organ dysfunction* (aside from changes induced by aging) affects all NMBAs. All drugs with significant hepatic and renal metabolism (aminosteroids) will be affected and their duration of action prolonged by liver and kidney dysfunction. For this reason, benzylisoquinolinium-class NMBAs are preferred in patients with organ dysfunction (such as critically ill patients in the ICU), since the nonenzymatic Hoffman degradation is less dependent on normal organ function.

## Monitoring Neuromuscular Blockade

### Monitoring and Risk–Benefit Ratio

The introduction of NMBAs into clinical medicine (curare in 1942 and SCh in 1949) has facilitated major advances in medicine. Despite the tremendous advances afforded by NMBAs, these agents have their own set of

complications. Allergic reactions and anaphylaxis, although rare, are significant problems; use of NMBAs without the ability to secure the airway may be lethal; and a substantial minority (30–40%) of patients who receive NMBAs has significant postoperative residual neuromuscular weakness (mis-termed, “residual curarization” since curare is no longer used). Given that there are over 230 million major surgeries performed every year worldwide,<sup>56</sup> the number of patients exposed to potential complications is huge, and appropriate monitoring is a major patient safety issue. Aside from the cost of the monitors and related disposables (electrodes), there are no significant potential complications from monitoring neuromuscular function, so the risk–benefit ratio is heavily in favor of monitoring.<sup>57</sup> Several anesthesiology organizations around the world have recently published best-practice guidelines that recommend neuromuscular monitoring when neuromuscular blocking drugs are administered.<sup>58,59</sup>

**Table 21-4** Sensitivity of Patients with Neuromuscular Disease to Neuromuscular Blocking Agents and Association with Malignant Hyperthermia

Disorder Type	Depolarizing NMBA Sensitivity	Nondepolarizing NMBA Sensitivity	Other Considerations
Neuromuscular transmission disorders <sup>a</sup>	Increased (myasthenia) Avoid use (Lambert–Eaton)	Increased	No increased risk of MH
Muscle and muscle membrane disorders <sup>b</sup>	Avoid use	Increased	No increased risk of MH (myotonic dystrophy, inflammatory myopathy, mitochondrial myopathy, Brody) Increased risk (Duchenne and Becker muscular dystrophy; central core and multiminicore disease; nemaline rod myopathy; King-Denborough and hyperCKemia)
Storage disorders (lipid, glycogen) <sup>c</sup>	Avoid use	Variable, avoid use if possible	Evidence of increased susceptibility to MH
Peripheral neuropathies <sup>d</sup>	Avoid use	Variable, avoid use if possible	No increased risk of MH
Central nervous system disorders with neuromuscular manifestations <sup>e</sup>	Avoid use	Increased	No increased risk of MH

<sup>a</sup>Myasthenia gravis; Lambert–Eaton syndrome.

<sup>b</sup>Duchenne, Becker muscular dystrophy; myotonic dystrophy; central core and multiminicore disease; nemaline rod myopathy; inflammatory myopathy (dermatomyositis, polymyositis); mitochondrial myopathy; King-Denborough syndrome; hypercreatinemia (hyperCKemia); Brody disease.

<sup>c</sup>Carnitine palmitoyltransferase II (CPT II) deficiency; myophosphorylase deficiency (McArdle disease).

<sup>d</sup>Guillain–Barré syndrome; Charcot–Marie–Tooth disease; chronic inflammatory demyelinating and critical illness polyneuropathy; critical illness myopathy.

<sup>e</sup>Postpolio syndrome; Friedreich ataxia; amyotrophic lateral sclerosis.

NMBA, neuromuscular blocking agent; MH, malignant hyperthermia; CK, creatine kinase.

## Stimulator Characteristics

Monitoring involves the stimulation of a peripheral nerve and evaluation of the response (contraction, or twitch) of the innervated muscle. *Nerve stimulators* (also named peripheral nerve stimulators [PNSs]; Fig. 21-10A) have been in use for over 60 years; they are generally battery-operated,

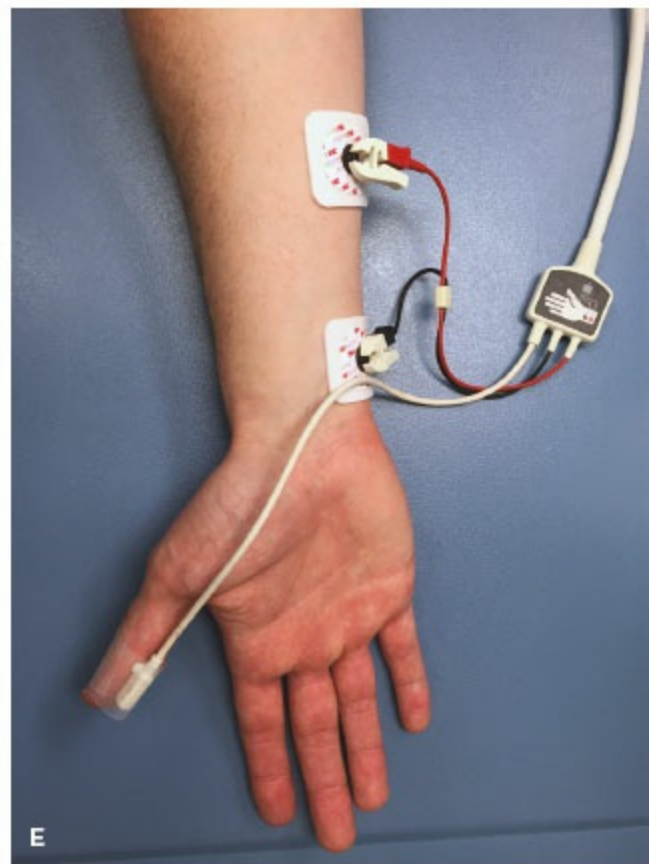

handheld units that provide the stimulus via wires connected to surface (skin) electrodes. Nerve stimulators should not be confused with *neuromuscular monitors* (Fig. 21-10B–E); the monitors not only provide nerve stimulation but also measure the evoked muscle response by using different technologies (see later). Neuromuscular monitors either are battery-operated, handheld devices (Fig. 21-10B,C) or can be incorporated into the anesthesia workstations as modular units (Fig. 21-10D). Nerve stimulators (and the stimulation units of the neuromuscular monitors) deliver a range of currents between 0 and 70 milliamperes (mA). The impulse generated by the nerve stimulator should have a square-wave pattern (i.e., should be monophasic and rectangular), as biphasic pulses may induce repetitive nerve stimulation.<sup>60</sup> The intensity of neurostimulation (charge, in Coulombs, Q) is a product of current (in amperes, A) and the duration of stimulation (pulse width, in seconds).<sup>61</sup> For instance, a charge of 4  $\mu\text{C}$  can be achieved by either using a current stimulus of 20 mA with a pulse width of 200  $\mu\text{sec}$  or a current stimulus of 10 mA with a pulse width of 400  $\mu\text{sec}$ . The current should be constant over the duration of the impulse (which is at least 100  $\mu\text{sec}$  to ensure depolarization of all nerve endings, but less than 300 to 400  $\mu\text{sec}$  to avoid exceeding the nerve refractory period).

The current is delivered via surface (skin) *stimulating electrodes* that have a silver–silver chloride interface with the skin, reducing its resistance. Surface electrodes are preferred to the invasive, transcutaneous needle electrodes. The optimal conducting surface area is circular, with a diameter of 7 to 8 mm; this area provides sufficient current density to depolarize peripheral nerves. Skin can have very high resistance (up to 100,000 Ohms), and “curing” the skin (i.e., placing the electrodes over the abraded, cleansed skin and allowing at least 15 minutes for the silver chloride gel to penetrate the dermis) will decrease skin resistance to below 5,000 Ohms and will ensure delivery of a constant, maximal current.

### Monitoring Modalities

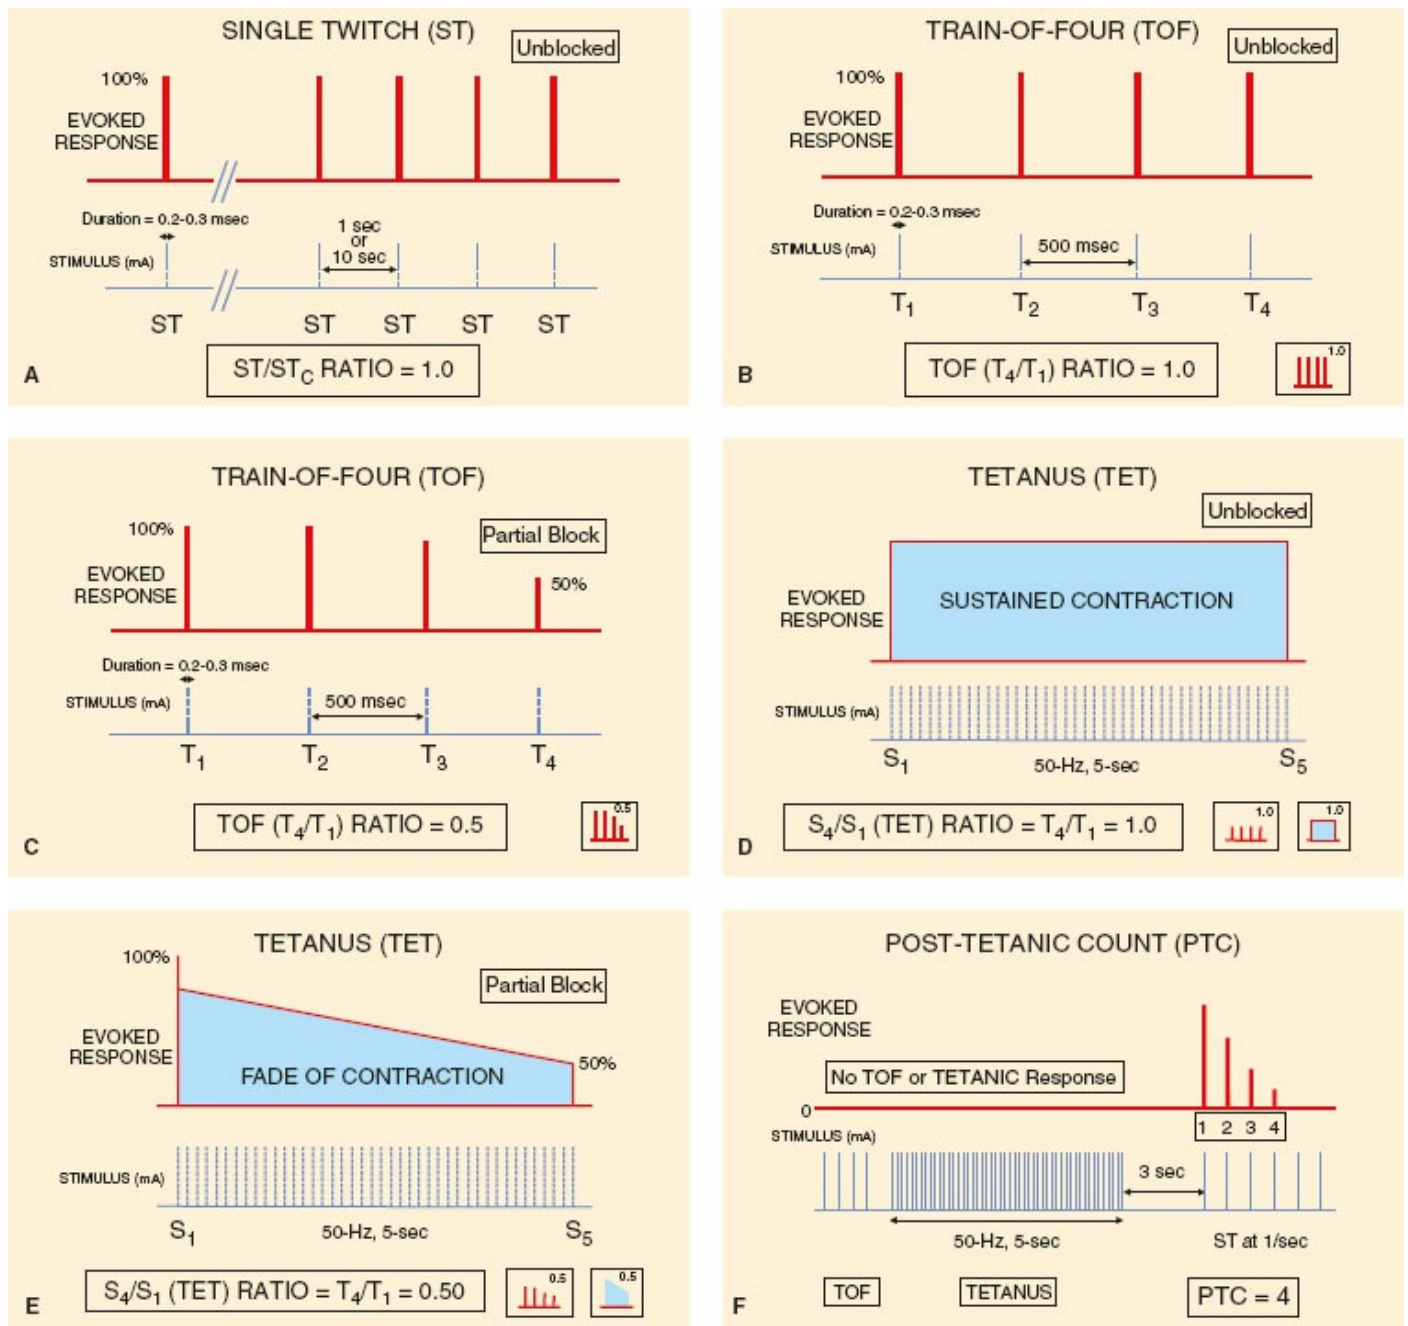

The first nerve stimulators delivered single repetitive stimuli at frequencies between 0.1 and 10.0 Hz. The muscle response was an *ST* to each stimulus (Fig. 21-11A). The frequency of *ST* stimulation should not exceed 0.1 Hz (1 stimulus every 10 seconds), because muscle fatigue may occur with higher stimulation rates. To measure the degree of neuromuscular block, the current intensity is increased progressively (prior to NMBA administration) from 0 mA in 5-to 10-mA steps. The amplitude of the evoked muscle response is plotted over time, and has a sigmoidal shape. Once the amplitude of the muscle response no longer increases as current intensity increases, the response is maximal, and the current required is called “maximal current.”

Increasing the current value by 20% above maximal level ensures that all fibers in the innervated nerve will depolarize despite changes in skin resistance over time; this is termed “supramaximal current.” Because a baseline control value is needed in order to compare the force of contraction over time, ST modality is used clinically to determine onset of neuromuscular block, not its recovery. The characteristics of the various patterns of neurostimulation currently in use clinically are summarized in [Table 21-5](#).

**Figure 21-10 A:** Peripheral nerve stimulator—MiniStim (Life-Tech, now Kimberly-Clark,

Irving, TX). **B:** Acceleromyographic neuromuscular monitor—StimPod (Xavant Technologies, Pretoria, South Africa). **C:** Acceleromyographic neuromuscular monitor—TOF-Watch S (Organon Ltd, Swords, Co. Dublin, Ireland). The TOF-Watch accelerograph recently has been discontinued from manufacture and is no longer available. **D:** Philips NMT Modular Unit (Philips Healthcare, Amsterdam, The Netherlands). **E:** Philips acceleromyographic NMT monitor (Philips Healthcare, Amsterdam, The Netherlands). Electrodes are placed along the ulnar nerve, with the negative (*black*) electrode distal to the positive (*red*) electrode. The accelerometer is taped to the thumb, with the sensor perpendicular to the direction of thumb adduction.

**Figure 21-11** **A:** Single twitch (ST) stimulation. Following establishment of a baseline (control) ST amplitude at supramaximal current (ST<sub>c</sub>), subsequent ST amplitudes are compared to ST<sub>c</sub> (ST/ST<sub>c</sub> ratio). ST is delivered at a frequency of 1 Hz or 0.1 Hz. **B:** Train-of-four (TOF) stimulation pattern. Unblocked state, TOF ratio = 1.0 (100%). Inset

shows the TOF as displayed by a monitor.  $T_1$  = first stimulus in the sequence;  $T_2$  = second stimulus in the sequence;  $T_3$  = third stimulus in the sequence;  $T_4$  = fourth stimulus in the sequence. **C:** TOF stimulation pattern. Partial block, TOF ratio = 0.5 (50%). Inset shows the TOF as displayed by a monitor (TOF ratio = 0.5). **D:** Tetanic stimulation. Unblocked state, no fade between tension at the beginning of the 5-second stimulation ( $S_1$ ) and the end of the stimulation ( $S_5$ ). The ratio of tension at the end of the 5-second stimulation to that at the beginning is the tetanic ratio ( $S_5/S_1$  ratio). Insets show the TOF and the TET as displayed by a monitor (TOF ratio = 1.0; TET ratio = 1.0).  $S_1$  = tetanic tension at the beginning of 5-second TET;  $S_5$  = tetanic tension at the end of 5-second TET;  $S_5/S_1$  = TET ratio. **E:** Tetanic stimulation. Partial blockade, with fade of tension from  $S_1$  to  $S_5$ . The ratio of tension at the end of the 5-second stimulation to that at the beginning is the tetanic ratio ( $S_5/S_1$  ratio). Insets show the TOF and the TET as displayed by a monitor (TOF ratio = 0.5; TET ratio = 0.5). **F:** When there is no muscle response to TOF stimulation, a 5-second tetanic (50 Hz) stimulus is followed, 3 seconds later, by a series of ST stimuli at a frequency of 1 Hz. The number of rapidly fading twitches is counted; the resulting number of twitches is the posttetanic count. A lower posttetanic count (PTC) denotes deeper block.

**Figure 21-11 G:** Double-burst stimulation (DBS<sub>3,3</sub>) consists of a mini-tetanic burst of three stimuli at 50 Hz (D<sub>1</sub>), separated by 750 msec from the second such mini-tetanic burst of three stimuli (D<sub>2</sub>). Top panel depicts the evoked muscle responses to DBS stimuli. Because the stimuli are mini-tetanic, each of the two bursts result in a single (fused) muscle contraction. In the unblocked state, the ratio of the second burst (D<sub>2</sub>) to the first (D<sub>1</sub>) is the DBS ratio (D<sub>2</sub>/D<sub>1</sub>), and is 1.0 (100%). Insets show the TOF and the

DBS<sub>3,3</sub> responses as displayed by a monitor (control TOF ratio = 1.0; DBS<sub>3,3</sub> ratio = 1.0). **H:** DBS<sub>3,3</sub> consists of a mini-tetanic burst of three stimuli at 50 Hz (D<sub>1</sub>), separated by 750 msec from the second such mini-tetanic burst of three stimuli (D<sub>2</sub>). Top panel depicts the evoked muscle responses to DBS stimuli. Because the stimuli are mini-tetanic, each of the two bursts result in a single (fused) muscle contraction. During partial block, the ratio of the second burst (D<sub>2</sub>) to the first (D<sub>1</sub>) is the DBS ratio (D<sub>2</sub>/D<sub>1</sub>), and is less than 1.0 (100%). Insets show the TOF and the DBS<sub>3,3</sub> responses as displayed by a monitor (for instance, when TOF ratio = 0.5; DBS<sub>3,3</sub> ratio = 0.5). **I:** DBS<sub>3,2</sub> consists of a mini-tetanic burst of three stimuli at 50 Hz (D<sub>1</sub>), separated by 750 msec from the second such mini-tetanic burst of two stimuli (D<sub>2</sub>). Top panel depicts the evoked muscle responses to DBS stimuli. Because the stimuli are mini-tetanic, each of the two bursts results in a single (fused) muscle contraction. Because D<sub>2</sub> consists of only two mini-tetanic stimuli, the evoked (fused) muscle response is slightly less than that induced by D<sub>1</sub>. In the unblocked state, the ratio of the second burst (D<sub>2</sub>) to the first (D<sub>1</sub>) is the DBS ratio (D<sub>2</sub>/D<sub>1</sub>), and is 0.8 (80%). Insets show the TOF and the DBS<sub>3,2</sub> responses as displayed by a monitor (control TOF ratio = 1.0; DBS<sub>3,2</sub> ratio = 0.8). **J:** DBS<sub>3,2</sub> consists of a mini-tetanic burst of three stimuli at 50 Hz (lower panel, D<sub>1</sub>), separated by 750 msec from the second such mini-tetanic burst of two stimuli (D<sub>2</sub>). Upper panel depicts the evoked muscle responses to DBS stimuli. Because the stimuli are mini-tetanic, each of the two bursts results in a single (fused) muscle contraction. During partial block, the ratio of the second burst (D<sub>2</sub>) to the first (D<sub>1</sub>) is the DBS ratio (D<sub>2</sub>/D<sub>1</sub>), and is less than 1.0 (100%). Insets show the TOF and the DBS<sub>3,2</sub> responses as displayed by a monitor (for instance, when TOF ratio = 0.5; DBS<sub>3,2</sub> ratio = 0.3).

*TOF* (Fig. 21-11B) stimulation was introduced clinically in 1971, and consists of four sequential ST stimuli (named T1, T2, T3, and T4) delivered at a frequency of 2 Hz.<sup>62,63</sup> Each train is delivered no more frequently than every 15 to 20 seconds to avoid facilitation of subsequent muscle responses. The TOF ratio is calculated by dividing the T4 amplitude by the T1 amplitude. The control TOF ratio (before administration of NMBA) is 1.0 (100%). During a partial nondepolarizing block, the ratio decreases (fades) as the degree of block increases (Fig. 21-11C). There is a well-described relationship between TOF fade and percent (%) postsynaptic receptor occupancy by nondepolarizing NMBAs.<sup>64</sup> Up to 65% to 70% of the nAChRs can be blocked without any apparent fade in the TOF ratio; these receptors make up the “margin of safety” of neuromuscular transmission.<sup>65,66</sup> Once approximately 70% to 75% of the receptors are blocked (occupied), T4 starts to decrease in amplitude, and as the % receptor occupancy increases, fade increases (TOF ratio decreases from 1.0). When 75% to 80% of the receptors are blocked, T4 disappears, so the TOF ratio (T4/T1) becomes 0; at this point, the TOF count (TOFC) is 3, meaning that there are three discernible muscle responses. As the % receptor occupancy increases to 80% to 85%, the TOFC becomes 2, and at

85% to 90% occupancy, T2 disappears (TOFC = 1). Once over 95% of the receptors are blocked, TOFC becomes 0 (Table 21-6).

3

TOF has multiple benefits over ST monitoring: at supramaximal stimulation, T1 and ST amplitudes are the same, so TOF does not require a baseline measurement—all subsequent responses are then measured as a fraction of T1. By eliciting four responses, the clinician sometimes is able to assess the degree of fade subjectively by visual or tactile means, or, more reliably, by counting the number of evoked responses (twitches) of TOF (TOFC). Additionally, the TOF ratio remains consistent over a range of stimulating currents, as long as the stimulating current intensity is at least 10 mA above the threshold current (Table 21-7).<sup>67</sup> This TOF consistency at varying stimulating currents allows this pattern to be used to measure the degree of neuromuscular recovery in patients recovering from anesthesia, as currents of 20 to 30 mA are not associated with the high degree of discomfort of supramaximal 60- to 70-mA stimulation.<sup>68</sup>

**Table 21-5** Characteristics of Various Patterns of Neurostimulation

Pattern	Characteristics
Single twitch (ST)	<ul style="list-style-type: none"> <li>• A "control" ST needs to be established by determining maximal response to increasing stimulus current</li> <li>• Pulse duration is 0.1–0.3 msec (0.2 msec most common)</li> <li>• An increase in maximal current by 20%–30% is needed to establish "supramaximal" current and ensure activation of all muscle fibers and consistent recruitment over time</li> <li>• A single, supramaximal stimulus delivered at a frequency of 1/sec (1 Hz) or 1/10 sec (0.1 Hz)</li> <li>• Frequency higher than 1 Hz affects subsequent muscle response</li> <li>• Range of receptor occupancy detected by ST is narrow, ~75%–95%</li> <li>• Unable to differentiate depolarizing from nondepolarizing block</li> </ul>
Train-of-four (TOF)	<ul style="list-style-type: none"> <li>• Four ST stimuli at a frequency of 2 Hz</li> <li>• No "control" (prerelaxant) muscle response needed</li> <li>• Ratio of fourth to first response is T4/T1 or TOF ratio</li> <li>• "Fade" defined as a weaker fourth response (T4) than the first (T1)</li> <li>• Trains delivered at 15- to 20-second intervals do not induce potentiation of subsequent muscle responses</li> <li>• TOF ratios &gt;0.40 cannot be detected subjectively</li> <li>• Able to differentiate depolarizing from nondepolarizing block</li> <li>• Less painful to measure in awake patients than tetanic (or DBS) stimulation</li> <li>• Can detect degree of block in the range of surgical relaxation, ~70%–100% receptor occupancy</li> </ul>
Double burst stimulation (DBS)	<ul style="list-style-type: none"> <li>• Two mini-tetanic bursts (two or three impulses at 50 Hz in each burst) separated by 750 msec</li> <li>• DBS delivered at 20-second intervals to avoid potentiation of subsequent muscle responses</li> <li>• DBS<sub>3,3</sub> contains 3 mini-tetanic bursts followed by 3 mini-tetanic bursts</li> <li>• DBS<sub>3,2</sub> contains 3 mini-tetanic bursts followed by 2 mini-tetanic bursts</li> <li>• No "control" (prerelaxant) muscle response needed</li> <li>• Ratio of 2nd to 1st muscle response is D2/D1 or DBS ratio</li> <li>• "Fade" defined as a weaker second response (D2) than the first (D1)</li> <li>• Fade of TOF is identical to fade of DBS<sub>3,3</sub></li> <li>• TOF ratios &gt;0.60 cannot be detected subjectively</li> <li>• Able to differentiate depolarizing from nondepolarizing block</li> <li>• Less painful to measure in awake patients than tetanic stimulation, but more painful than TOF</li> <li>• Subjective evaluation of DBS fade superior to TOF fade</li> </ul>
Train-of-four count (TOFC)	<ul style="list-style-type: none"> <li>• Available once T4 of TOF becomes 0</li> <li>• At disappearance of T4, the TOFC = 3</li> <li>• At disappearance of T3, the TOFC = 2</li> <li>• At disappearance of T2, the TOFC = 1</li> <li>• At disappearance of T1, the TOFC = 0</li> <li>• There is a relationship between TOFC and receptor occupancy (blockade)</li> </ul>
Tetanic stimulation (TET)	<ul style="list-style-type: none"> <li>• Common frequency is 50 Hz for 5 seconds</li> <li>• Alternative more demanding TET is 100 Hz for 5 seconds</li> <li>• The 100-Hz TET may be supraphysiologic and can induce fade in normal controls</li> <li>• Able to differentiate depolarizing from nondepolarizing block</li> <li>• May induce direct muscle stimulation</li> <li>• Painful to awake patients</li> <li>• TET fade over 5 seconds is equivalent to TOF fade</li> <li>• TET at intervals less than 3 minutes will enhance (potentiate) subsequent muscle responses</li> </ul>
Posttetanic count (PTC)	<ul style="list-style-type: none"> <li>• TET at 50 Hz for 5 seconds followed 3 seconds later by ST at 1 Hz</li> <li>• More PTC responses indicate less block</li> <li>• Allows assessment of profound block (TOFC = 0)</li> <li>• When PTC = 0, further NMBA administration is not recommended</li> <li>• PTC at intervals less than 3 minutes will potentiate subsequent muscle responses</li> </ul>

*Tetanic stimulation (tetanus; Fig. 21-11D)* describes repetitive stimulation at a frequency above 30 Hz. Below this threshold, repetitive nerve stimuli result in individual, rapid contractions. At frequencies above 30 Hz, the muscle responses become fused into a sustained contraction without fade (tetanic ratio = 1.0). During partial nondepolarizing block, the tetanic contraction gets weaker (fades; Fig. 21-11E). The maximal voluntary muscle contraction is approximately 60 Hz, so frequencies above this level are supraphysiologic and may result in muscle contraction fade even in the absence of NMBAs.<sup>69</sup> The fade of TOF in response to nondepolarizing NMBAs corresponds to the

fade of tetanic stimulation. Tetanus has been studied extensively for durations of 5 seconds, so clinicians should always use 5-second durations to evaluate neuromuscular function—decisions based on tetanic durations shorter than 5 seconds will undoubtedly be inaccurate. When tested during partial nondepolarizing block, the high frequency of tetanic stimulation will cause a temporary increase in the amount of ACh released such that subsequent responses will be increased transiently (period of PTP; Fig. 21-6). Depending on the tetanic frequency, this period of potentiated responses may last 1 to 2 minutes after a 5-second, 50-Hz tetanus, or up to 3 minutes after 100-Hz tetanus.<sup>70,71</sup> The response to stimulation during the period of PTP can be used to evaluate the degree of block when there are no responses to TOF stimulation (i.e., when the TOFC = 0).

**Table 21-6** Relationship between % Receptor Occupancy and Train-of-Four Ratio during Nondepolarizing Block

Percent Receptor Occupancy (%)	First TOF Twitch (T <sub>1</sub> ) (% Baseline)	Fourth Twitch (T <sub>4</sub> ) (% Baseline)	TOF Ratio (T <sub>1</sub> –T <sub>4</sub> Responses)	TOF COUNT (TOFC)
100	0%	0%	0	TOFC = 0
90–95	0%	0%	0 (T <sub>1</sub> = 0)	TOFC = 0
85–90	10%	0%	0 (T <sub>2</sub> = 0)	TOFC = 1
	20%	0%	0 (T <sub>3</sub> = 0)	TOFC = 2
80–85	25%	0%	0 (T <sub>4</sub> = 0)	TOFC = 3
	80%–90%	48%–58%	0.60–0.70	TOFC = 4
	95%	69%–79%	0.70–0.75	TOFC = 4
70–75	100%	75%–100%	0.75–1.00	TOFC = 4
	100%	100%	0.9–1.0	TOFC = 4
50	100%	100%	1.0	TOFC = 4
25	100%	100%	1.0	TOFC = 4

TOF, train-of-four; T<sub>1</sub>, first twitch of TOF; T<sub>2</sub>, second twitch of TOF; T<sub>3</sub>, third twitch of TOF; T<sub>4</sub>, fourth twitch of TOF; TOFC, train-of-four count.

*Posttetanic count* (PTC; Fig. 21-11F), used during periods of profound neuromuscular block, consists of a 5-second, 50-Hz tetanic stimulus, followed 3 seconds later by a series of 15 to 30 ST at a frequency of 1 Hz.<sup>72</sup> The number of posttetanic twitches is inversely proportional to the depth of block: the fewer posttetanic twitches there are, the deeper the block. From a depth of block of PTC = 1 until recovery to a TOFC of 1, intermediate-acting NMBAs require 20 to 30 minutes. PTC can also be used for dosing of sugammadex (See Selective Relaxant Binding Agents).

Studies have shown that visual and tactile (subjective) evaluation of fade to TOF stimulation fail to identify significant degrees of residual block (when the TOF ratio is >0.40).<sup>73</sup> By delivering two (instead of four) intense stimuli (mini-tetanic bursts) separated by 0.75 second, the two fused responses can be evaluated as a direct comparison, instead of comparing the fourth response of TOF to the first. This modality is termed *double burst stimulation* (DBS<sub>3,3</sub>; Fig. 21-11G). The numbers 3,3 signify that each burst contains three stimuli at a

frequency of 50 Hz.<sup>74</sup> Because the two individual bursts are tetanic in frequency, a longer recovery period between successive stimulations is necessary (20 seconds). Using DBS subjectively, clinicians are able to detect fade (Fig. 21-11H) when the TOF is less than 0.60, an improvement over the subjectively detected TOF fade (<0.40). The relationship between TOF ratio and DBS<sub>3,3</sub> ratio is linear and identical between 0.0 and 1.0. In order to further increase the ability to detect small degrees of fade, another pattern of DBS only uses two mini-tetanic stimuli in the second burst—this is called DBS<sub>3,2</sub>, and the baseline control DBS<sub>3,2</sub> ratio is 0.8 when the TOF ratio and DBS<sub>3,3</sub> ratio is 1.0 (Fig. 21-11I).<sup>75</sup> This offset of 0.2 units is maintained as fade progresses (e.g., DBS<sub>3,3</sub> ratio of 0.5 corresponds to a DBS<sub>3,2</sub> of 0.3; Fig. 21-11J).

### Testing and Recording the Response

There are different *modalities* to assess the degree of neuromuscular block, including subjective and objective evaluation and assessment of *clinical criteria*.<sup>76</sup> There are also different *technologies* for measuring the evoked response (objective evaluation). When assessing the degree of block (or state of neuromuscular recovery), it is important to note that most clinicians even today evaluate responses subjectively: by *visual* or *tactile* means.

**Table 21-7** Consistency of the Train-of-Four Ratio in Response to Neurostimulation at Varying Current Intensity at Three Depths of Neuromuscular Block

Depth of Block Classification at 50 mA	TOF Ratio at 20 mA	TOF Ratio at 30 mA	TOF Ratio at 50 mA
TOF ≤ 0.70 (n = 28)	0.500 ± 0.180	0.506 ± 0.170	0.513 ± 0.160
TOF > 0.70, < 0.95 (n = 25)	0.915 ± 0.100	0.906 ± 0.080	0.894 ± 0.070
TOF ≥ 0.95 (n = 30)	0.972 ± 0.060	0.972 ± 0.040	0.995 ± 0.020

TOF, train-of-four; mA, milliamperes; n, number of assessments.

Data from Brull SJ, Ehrenwerth J, Silverman DG. Stimulation with submaximal current for train-of-four monitoring. *Anesthesiology*. 1990;72:629–632.

**Table 21-8** Reliability in Correctly Identifying Presence of Fade in Response to Train-of-Four and Double-Burst Stimulation using Subjective (Visual or Tactile) Methods during Minimal Neuromuscular Block (TOF Ratio = 0.40–0.70).

True-Positives (Correct Identification of Presence of Fade)			
	TOF	DBS <sub>3,3</sub>	DBS <sub>3,2</sub>
Engbaek et al. <sup>74</sup>	—	64%	96%
Drenck et al. <sup>78</sup>	16%	78%	—
Viby-Mogensen et al. <sup>73</sup>	36%	—	—
Gill et al. <sup>79</sup>	16%	69%	—
Ueda et al. <sup>75</sup>	—	73%	96%
Brull et al. <sup>80</sup>	42%	67%	72%

TOF, train-of-four; DBS, double-burst stimulation.

*Subjective* evaluation of neuromuscular function may consist of feeling (tactilely) or observing (visually) the degree of fade to TOF stimulation. Such subjective assessments however are inaccurate (Table 21-8); when the TOF recovers to more than 0.40, clinicians are unable to detect TOF fade reliably. Evaluation of fade to 50-Hz tetanic stimulation is no more precise than evaluation of TOF fade. Subjective detection of fade to DBS or 100-Hz tetanic stimulation may be closer (when TOF < 0.70) to the threshold of adequate recovery (defined as TOF ≥ 0.90), but such evaluations cannot be performed in awakening patients awaiting tracheal extubation due to the pain associated with DBS and tetanic stimulation. The ability to detect fade is not influenced by the observers' experience, and there is also no difference in the ability to detect fade between visual and tactile means.<sup>73</sup> Therefore, clinical decisions based on subjective (qualitative) evaluation of fade likely are incorrect, and do not decrease the risk of oxygen desaturation or need for tracheal re-intubation.<sup>77</sup> This fact is borne out by numerous studies for the past 40 years that continue to document the inability of clinicians to detect TOF fade, leading to a significant incidence of residual postoperative paralysis (Table 21-9).

**Table 21-9** Selected Reports of Postoperative Residual Paralysis, 1979–2016

Study	Long-Acting NMBA	Intermediate-Acting NMBA	Reversal	TOF Threshold	Monitoring Modality	Residual Paralysis	Comments
Viby-Mogensen <i>Anesthesiology</i> 1979;50:539	d-TC Panc Gallam		Yes	0.7	None	42%	The first report to highlight the RNMB problem
Bevan <i>Anesthesiology</i> 1988;69:272	Panc	Atrac Vec	Yes Yes Yes	0.7	Subjective	36% 4% 9%	Less residual paralysis after intermediate-acting NMBAs
Brull <i>Can J Anaesth</i> 1991;38:164	Panc	Vec	Yes Yes	0.7	Subjective	45% 8%	Testing with low current to decrease discomfort
Fawcett <i>Acta Anaesthesiol Scand</i> 1995;39:288		Atrac/Vec Bolus Infusion	Yes Yes	0.7 0.7	Subjective	12% 24%	More RNMB after infusion than bolus
Berg <i>Acta Anaesthesiol Scand Suppl</i> 1997;110:156	Panc	Atrac/Vec	Yes Yes	0.7 0.7	Subjective	26% 5%	Atelectasis associated with RNMB
Debaene <i>Anesthesiology</i> 2003;98:1042		Atrac Vec Roc	No	0.7 0.9	None	16% 45%	RNMB present >4 hrs after single dose
Murphy <i>Anesth Analg</i> 2003;96:1301	Panc	Roc	No No	0.8 0.8	Optional	82% 0%	Postcardiac surgery
Murphy <i>Anesth Analg</i> 2004;98:193	Panc		Yes	0.7 0.9	Subjective	40% 83%	Delayed PACU discharge
		Roc	Yes	0.7 0.9		5.9% 29%	
Baillard <i>Br J Anaesth</i> 2005;95:622		Atrac/Vec/Roc	Yes – in 42% of patients	0.9	60% of patients	3.5%	Less RNMB with reversal and when monitoring was used
Cammu <i>Anesth Analg</i> 2006;102:426		Atrac/Cis/Miv/ Roc Outpatients Inpatients	In 26% In 25%	0.9	Clinical (49% of cases)	38% 47%	One of 320 inpatients required reintubation in PACU; subjective assessment did not decrease incidence of residual paralysis
Murphy <i>Anesthesiology</i> 2008;109:389		Roc	Yes	0.9	AMG Subjective	5% 30%	AMG lowers RNMB risk
Butterly <i>Br J Anaesth</i> 2010;105:304		Vec/Cis	Yes	0.9	Subjective	22%	Less RNMB with cisatrac

(continued)

Murphy <i>Anesthesiology</i> 2011;115:946		Roc	Yes	0.9 0.9	AMG Subjective	15% 50%	AMG monitoring lowers RNMB
De Souza <i>Rev Bras Anesthesiol</i> 2011;61:145		Roc Atrac	Yes Yes	0.9 0.9	Clinical	10% 10%	Pediatric population (3 mos–12 yo); improper reversal (too deep or too shallow) in 46% of roc and 25% of atrac patients
Cammu <i>Anaesth Intensive Care</i> 2012;40:999		Atrac/Roc/Miv	None Neo Sgx	0.9	Subjective (38% of cases)	15% 15% 2%	Body mass index was an independent predictor of desaturation in PACU
Norton <i>Rev Esp Anesthesiol Reanim</i> 2013;60:190		Roc/Cis	Yes	0.9	Optional	30%	CRE present in 51% of patients with RNMB; airway obstruction, severe hypoxemia, and respiratory failure all higher in RNMB patients
Ledowski <i>Indian J Anaesth</i> 2013;57:46		Not specified	None Neo Sgx	0.9	Subjective	16% 13% 3%	RNMB associated with atelectasis and pneumonia
Esteves <i>Eur J Anaesthesiol</i> 2013;30:243		Atrac/Cis/Roc/ Vec	Yes (67% of patients)	0.9	Subjective	26%	Incomplete recovery more frequent after reversal than no reversal (31% vs. 17%)

Kotake <i>Anesth Analg</i> 2013;117:345	Roc	None Neo Sgx	0.9	Clinical	13% 24% 4%	RNMB as high as 9% with Sgx without monitoring
Pietraszewski <i>Anaesthesiol Intensive Ther</i> 2013;45:77	Roc	None	0.9	Not used	44%	Incidence of RNMB was 44% in elderly and 20% in young patients
Fortier <i>Anesth Analg</i> 2015;121:366	Roc	Yes	0.9	Optional	64%	Incidence of RNMB was 56% on PACU arrival
Xara <i>Arch Bronconeumol</i> 2015;51:69	NMBAs used in 66% of patients	Yes	0.9	Optional	18%	CRE more common (46%) in patients with RNMB
Ledowski <i>Anesthesiol Res Pract</i> 2015;2015:410	Atrac/Roc/Vec	Yes (48% of patients)	0.9	Optional (used in 23% of patients)	28%	RNMB after neo reversal was twice as high as no reversal in pediatric patients
Brueckmann <i>Br J Anaesth</i> 2015;115:743	Roc	Yes—Neo Yes- Sgx	0.9 0.9	Subjective	43% 0%	OR discharge shorter in Sgx-treated patients
Aytac <i>Braz J Anesthesiol</i> 2016;66:55	Atrac/Roc/Vec	Yes—Neo (66% of patients)	0.7 0.9	Clinical	15% 43%	82% of patients with SpO <sub>2</sub> ≤ 90% had a TOF ≤ 0.90; 43% of patients with TOF < 0.70 required airway support

NMBA, neuromuscular blocking agent; TOF, train-of-four; d-TC, d-tubocurarine; Panc, pancuronium; Gallam, gallamine; RNMB, residual neuromuscular block; Atrac, atracurium; Cis, cisatracurium; Vec, vecuronium; Roc, rocuronium; Miv, mivacurium; PACU, postanesthesia care unit; AMG, acceleromyography; CRE, critical respiratory events; Sgx, sugammadex; OR, operating room.

The limitations of subjective evaluation extend to intraoperative management of the depth of block. Clinicians may consider that intraoperative management based on subjective evaluation of the depth of block (determined by the TOFC) may be more reliable than the evaluation of residual block (determined by TOF fade) performed prior to tracheal extubation. Unfortunately, such subjective evaluation of TOFC also is prone to significant overestimation of the degree of neuromuscular recovery (and underestimation of the depth of block).<sup>81,82</sup> All available data support the conclusion that subjective evaluation of neuromuscular function is inadequate in guiding intraoperative NMBA management or in detecting sufficient neuromuscular recovery to prevent residual neuromuscular paralysis and the occurrence of critical respiratory events.

*Clinical testing* has been advocated for decades; tests such as grip strength, vital capacity, tidal volume, head-lift, or leg-lift (despite their continued use) are notoriously poor at detecting residual fade. It should be noted that none of the currently used clinical signs require sufficient muscle function to allow clinicians to identify residual neuromuscular weakness. The negative inspiratory force (NIF) of  $-20$  cm H<sub>2</sub>O often (and incorrectly) used as an indicator of neuromuscular recovery<sup>83</sup> is less than 25% of the normal NIF of 90 cm H<sub>2</sub>O (Table 21-10). In fact, none of the clinical tests has a sensitivity above 0.35 (general weakness); specificity above 0.89 (5-second sustained grip); a positive predictive value above 0.52 (sustained tongue depressor test); or negative predictive value above 0.66 (general weakness).<sup>84</sup> Even the often-used test of 5-second head-lift has the same poor predictive value: a majority of volunteers were able to maintain head lift for more than 5

seconds at a TOF ratio of 0.5. The best clinical test, the ability to resist removal of a tongue blade from clenched teeth, cannot be used in patients whose tracheas are still orally intubated.<sup>85</sup>

4

For decades, investigators have shown that regardless of the NMBA used, over 40% of patients managed intraoperatively by clinical criteria or subjective evaluation had residual paralysis (TOF <0.90) when tested objectively in the PACU (Table 21-9). This is significant, since postoperative mortality was increased 90-fold if patients who had residual paralysis required unplanned tracheal reintubation and ICU care postoperatively.<sup>77</sup> Given that postoperative pulmonary complications are relatively common in patients with residual neuromuscular block, objective monitoring of adequacy of reversal prior to tracheal extubation is strongly recommended.

**Table 21-10** Relationship between Various Clinical Signs and Peak Inspiratory Force in Healthy Awake Volunteers during Partial Neuromuscular Block

Parameter	Peak Inspiratory Force (cm H <sub>2</sub> O)
Control (no neuromuscular block)	-90
5-second head lift	-53
Effective swallowing	-43
Patent airway without jaw lift	-39
Glottic closure against Valsalva maneuver	-30
Vital capacity > 33% of control	-20

At baseline, volunteers could generate a peak inspiratory force of -90 cm H<sub>2</sub>O and perform all maneuvers. Following partial paralysis, the ability to maintain a patent airway (-39 cm H<sub>2</sub>O) and swallow effectively (-43 cm H<sub>2</sub>O) was not assured even when the peak inspiratory force was -30 cm H<sub>2</sub>O.

Zwiers A, van den Heuvel M, Smeets J, et al. Assessment of the potential for displacement interactions with sugammadex: a pharmacokinetic-pharmacodynamic modelling approach. *Clin Drug Investig.* 2011;31:101-111; data from Pavlin EG, Holle RH, Schoene RB. Recovery of airway protection compared with ventilation in humans after paralysis with curare. *Anesthesiology.* 1989;70:381-385.

*Objective evaluation* involves the actual recording, processing, and measurement of responses (electrical or mechanical) of muscles-to-nerve stimulation. *Electromyography (EMG)* is one of the oldest methods of measuring neuromuscular transmission. For EMG monitoring, a peripheral nerve (usually the ulnar nerve) is stimulated via surface (skin) electrodes, and the action potential generated at the innervated muscle (the APM) is measured. Measurement of the evoked response may involve the area under the curve of the muscle action potential, the peak-to-baseline, or the peak-to-peak amplitude of the signal. The stimulating electrodes should be placed along a peripheral nerve to avoid direct muscle stimulation (that is not subject to NMBA-induced blockade). One of the recording electrodes is placed on the belly of the monitored muscle (close to the location of the NMJ), and the second on the muscle's insertion point. Clinically, the ulnar nerve/APM

combination is used most frequently because APM is the sole hand muscle on the radial side of the hand that is innervated by the ulnar nerve—decreasing the chance of direct muscle stimulation. Other muscles of the hand that can be monitored include the first dorsal interosseous (FDI) and the abductor digiti minimi (ADM) muscles. Although there are minor differences in the time course of relaxation and recovery between the hand muscles, the differences are clinically insignificant. A limitation of EMG is that the response is very sensitive to electrical interference (e.g., diathermy).

*Mechanomyography (MMG)*, like EMG, is one of the standards of measurement of neuromuscular function that records the force of muscle contraction. With MMG (and EMG), the ulnar nerve is innervated, and the force of thumb (APM) adduction is measured via an interfaced force transducer. Although a majority of studies have used MMG for research, MMG monitors are no longer available clinically because of their cost, large size, and difficulty of use. In order to obtain accurate and consistent results, the monitored arm has to be immobilized, pre-tension has to be measured and applied as a control value, and strict temperature parameters have to be maintained, as MMG is sensitive to temperature fluctuation.

*Acceleromyography (AMG)* has been the most commonly used method of measuring muscle function in the past two decades. AMG consists of an accelerometer mounted to a moving muscle (usually the thumb) that measures the acceleration in response to nerve stimulation (the ulnar nerve; [Fig. 21-10B,C,E](#)). The technology is based on Newton's Second Law of Motion,  $F = m \cdot a$ , in which the force of APM contraction is proportional to the thumb acceleration (since mass remains unchanged). Although it is the most commonly used monitor, it has several major limitations that prevent it from becoming the "gold standard of care." The AMG setup can be simple, but is relatively time consuming, if performed properly; the thumb must be allowed to move freely throughout surgery—any arm or hand movement may change the direction of thumb adduction or the baseline, necessitating recalibration, because calibrated and noncalibrated measurements are not interchangeable<sup>86</sup>; AMG monitors cannot be used in procedures that require the patient's arms to be tucked under the surgical drapes unless the arm is protected in a specifically designed tube<sup>87</sup>; and during recovery from neuromuscular block, AMG-derived TOF values are less precise than EMG values and overestimate the extent of EMG-derived recovery.<sup>88,89</sup> Baseline (prerelaxant) TOF values measured with AMG are generally greater than 1.0 (100%), and may in fact be as high as 147%. This overshoot necessitates "normalization"—or calculation of the percent recovery of the TOF as a function of the higher TOF ratio prior to tracheal extubation.<sup>90</sup> Newer AMG-based monitors employ three-dimensional accelerometers to improve consistency and reliability, but most of the rest of the limitations remain.

Measurement of displacement (*kinemyography [KMG]*) is a form of mechanomyography in which an electrical current is generated by bending of a mechanosensor (metallic strip). The molded strip is placed in the groove between the thumb and index finger; ulnar nerve stimulation produces APM contraction and bends the strip, generating a current. KMG is simple to use, but the results obtained are not interchangeable with those obtained with other technologies. For instance, a TOF ratio of 0.90 measured with KMG is equivalent to an EMG-obtained TOF ratio of 0.80. The limits of agreement between the two technologies, moreover, can be as low as 0.65 or as high as 1.0.<sup>91</sup> Another limitation is that KMG (similar to AMG) needs a freely moving thumb, and is very susceptible to arm or hand movement that will change the baseline and therefore introduce inaccuracy in subsequent measurements. Nevertheless, KMG is accepted as a valuable monitor in daily clinical practice.

### **Differential Muscle Sensitivity**

It has long been appreciated that NMBAs do not affect all muscles at the same time, nor produce the same depth of relaxation. It is also important to note that NMBAs are administered in order to produce good intubating conditions, vocal cord paralysis, abdominal muscle relaxation, or diaphragmatic immobility. Yet, clinicians do not monitor laryngeal muscles, abdominal muscles, or the diaphragm. Understanding the relationship between the response of the different muscles to the effects of NMBAs is therefore clinically important.

The APM is monitored most commonly (subjectively or objectively). Being a peripheral muscle, the onset time at the APM is delayed compared to centrally located muscles, where blood flow (and thus drug delivery) is greater. However, the APM is more sensitive to nondepolarizing NMBAs, so recovery is delayed in comparison to central muscles (diaphragm, laryngeal muscles; [Fig. 21-12](#)). Even monitoring of similar peripheral muscles can induce error: stimulation of the ulnar nerve produces flexion of the fifth finger as well as APM contraction. However, the recovery of the fifth finger contraction occurs more rapidly than at the APM, so making clinical decisions based on recovery of the fifth finger will overestimate the degree of recovery at other muscles ([Table 21-11](#)).

**Figure 21-12** Approximate time course of twitch height after rocuronium, 0.6 mg/kg, at different muscles. Larynx, laryngeal adductors (vocal cords); CS, corrugator supercilii muscle (eyebrow); Abd, abdominal muscles; OO, orbicularis oculi muscle (eyelid); GH, geniohyoid muscle (upper airway); AP, adductor pollicis muscle (thumb).

When the patient’s arms are not available for intraoperative monitoring, clinicians will often monitor facial muscles: innervation of the facial nerve and evaluation of contractions of the eye muscles, either the orbicularis oculi or the corrugator supercilii. However, the time course of recovery is not the same for these two facial muscles: the orbicularis oculi moves the eyelid and have a recovery time course similar to the APM. In contrast, the eyebrow muscle, the corrugator supercilii, has a time course similar to the central muscles, the laryngeal adductors (Fig. 21-12).

6

Less commonly, monitoring of neuromuscular blockade takes place using the flexor hallucis brevis in the lower extremity, which produces contraction of the great toe. The time course of this muscle is similar to that of the APM.

### Electrode Placement

For monitoring the APM, stimulating electrodes are placed along the ulnar nerve, on the volar surface of the forearm. The distal (negative) electrode is placed 2 cm proximal to the wrist crease, and the proximal (positive) electrode is placed along the ulnar nerve, 3 to 4 cm proximal to the negative electrode (Fig. 21-10E).

A common clinical practice is to place the stimulating electrodes on the face and to monitor the eyelid (orbicularis oculi) muscle. Improper placement of electrodes on the temple and lower jaw may lead to direct muscle stimulation and false assessment of neuromuscular recovery. In fact, current clinical practice of monitoring “eye muscles” has been shown to result in a fivefold increased risk of postoperative residual paralysis.<sup>92</sup> Placement of the stimulating electrodes just lateral to the eye or along the zygomatic arch, as

done most commonly in the clinical setting, may activate other facial muscles and confound assessment. The facial nerve is best stimulated at the anterior portion of the mastoid process, as the nerve exits the cranial vault, with the second electrode in front of the ear. Even with optimal electrode positioning, however, muscle responses can be elicited despite complete block due to direct muscle stimulation. Neurostimulation of the posterior tibial nerve along the medial malleolus produces flexion contraction of the great toe. The time course of neuromuscular block monitored at the great toe is similar to that at the APM.

### **Monitoring and Clinical Applications**

Knowledge of time course for onset, duration, and recovery of neuromuscular block of NMBAs is important for optimal patient care. A current definition of “adequate” recovery is also important, as the *threshold of adequate recovery* has changed over the past 30 years. Currently, the recovery of a calibrated, normalized TOF ratio to 0.90 or more is considered the threshold (minimum requirement) for full recovery of neuromuscular function. At this level of recovery, most of the respiratory and other motor functions have returned to the prerenalaxant state. Conversely, postoperative pulmonary function test (PFT) values (forced vital capacity and peak expiratory flow) can be decreased by 20% in patients who experience residual neuromuscular block.<sup>93</sup> Similarly, impairment in the ability to swallow and resultant aspiration of pharyngeal fluids can be observed in healthy volunteers who had achieved TOF ratios as high as 0.90 (Fig. 21-13).<sup>94</sup> Respiratory muscle weakness (measured by maximum inspiratory and expiratory pressures, forced vital capacity, and forced expiratory volume in 1 second) was noted following major abdominal surgery, and the presence of residual neuromuscular paralysis was not ruled out until an acceleromyographic TOF ratio threshold of at least 1.0.<sup>95</sup> For these reasons, this threshold (TOF  $\geq$  0.90) should be the minimum accepted level of neuromuscular function, particularly in the elderly, in patients with pulmonary disease, or patients at risk of pulmonary aspiration.<sup>96</sup>

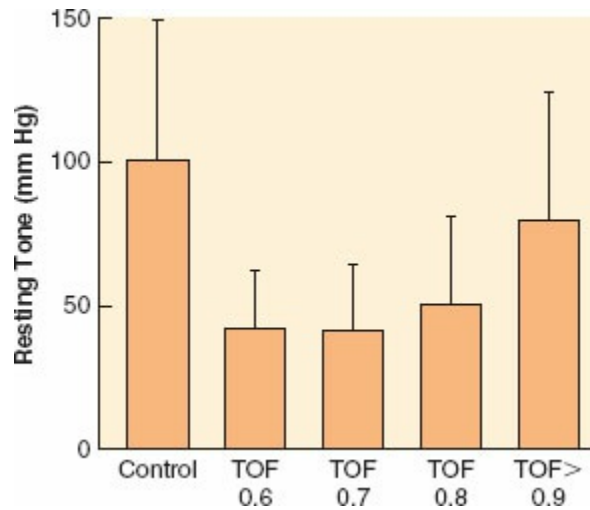

**Table 21-11** Suggested Management of Neuromuscular Blockade According to Monitoring

Site	Modality	Response	Interpretation	Comments
<b>Prediction of Tracheal Intubating Conditions</b>				
Any site	Single twitch, TOF	Present	Adequate conditions not met	Deep blockade is required for intubation
Corrugator supercilii	Single twitch, TOF	Absent	Adequate conditions likely	Corrugator supercilii reflects vocal cords and diaphragm
Adductor pollicis	Single twitch, TOF	Absent	Adequate conditions likely only if high dose given	Adductor pollicis is more sensitive than vocal cords and diaphragm
Flexor hallucis (foot)	Single twitch, TOF	Absent	Adequate conditions likely only if high dose given	Foot muscles are sensitive and block late
<b>Intraoperative Conditions</b>				
Adductor pollicis	PTC	1–2	Deep blockade	Return of diaphragm movements possible, no TOF response at adductor pollicis
Corrugator supercilii	TOF	1–2	Deep blockade	Return of abdominal tone possible, no TOF response at adductor pollicis
Adductor pollicis	TOF	1–2	Moderate blockade	Usually sufficient for most procedures
Corrugator supercilii	TOF	4, with or without fade	Moderate to shallow blockade	Difficult to interpret without adductor pollicis data
Adductor pollicis	TOF	4, with or without fade	Shallow blockade	Additional relaxation might be needed

<b>Management of Recovery</b>				
Adductor pollicis	PTC	0	Wait or sugammadex 16 mg/kg	Sugammadex after rocuronium or vecuronium only
Adductor pollicis	PTC	1–2	Wait or sugammadex 4 mg/kg	
Corrugator supercilii	TOF	1–2	Wait or sugammadex 4 mg/kg	
Adductor pollicis	TOF	2	Wait or sugammadex 2 mg/kg	
Corrugator supercilii	TOF	4, with or without fade	Wait or correlate with adductor pollicis or sugammadex 4 mg/kg	Corrugator supercilii recovers early Correlation with adductor pollicis preferable
Hypothenar eminence (fifth finger)	TOF	4, with or without fade	Observe thumb motion	Adductor pollicis recovers later
Adductor pollicis	TOF, visual or tactile	4, with fade	Wait or neostigmine 0.04–0.05 mg/kg or sugammadex 2 mg/kg	Neostigmine: After any nondepolarizing agent
Adductor pollicis	TOF, visual or tactile	4, without fade	Wait or neostigmine 0.020 mg/kg	
Adductor pollicis	DBS, visual or tactile	Fade	Wait or neostigmine 0.02–0.05 mg/kg	Less neostigmine needed if no TOF fade
Adductor pollicis	DBS, visual or tactile	No fade	Wait or neostigmine 0.020 mg/kg	DBS fade detected when TOF ratio = 0.6
Adductor pollicis	TOF, quantitative	TOF ratio <0.90	Wait or neostigmine	Neostigmine 0.04–0.05 mg/kg if TOF ratio <0.4; 0.02 mg/kg if TOF ratio >0.4
Adductor pollicis	100 Hz TET	No fade	No reversal necessary	100 Hz TET fade detected when TOF ratio = 0.8–0.9
Adductor pollicis	TOF, quantitative	TOF ratio ≥0.9	No reversal necessary	Full recovery

TOF, train of four; PTC, posttetanic count; DBS, double burst stimulation; TET, 5-sec tetanic stimulation.

Actual management depends on patient, surgical procedure, and previous response to neuromuscular blocking agents. \*See Table 21-12 for classification of depth of neuromuscular block.

**Figure 21-13** Upper esophageal resting tone in volunteers given vecuronium. Train-of-four (TOF) ratio was measured at the adductor pollicis muscle. Statistically significant decreases compared with control were found at all levels of paralysis until TOF ratio >0.9. (Adapted from Eriksson LI, Sundman E, Olsson R, et al. Functional assessment of the pharynx at rest and during swallowing in partially paralyzed humans: Simultaneous videomanometry and mechanomyography of awake human volunteers. *Anesthesiology*. 1997;87:1035.)

For assessing the quality of intubating conditions, monitoring of central muscles (or peripheral muscles with time course similar to central muscles) is paramount. When the dose of nondepolarizing NMBA is sufficiently large to offset the relative resistance of central muscles, onset at the laryngeal muscles will be faster than at the APM because of greater blood flow (and drug delivery; [Fig. 21-12](#) and [Table 21-11](#)).

A special clinical challenge presents when surgery requires an *intense (profound) or deep level of intraoperative block* (see Reversal of Intense (Profound) Neuromuscular Block) ([Table 21-12](#)). This can be accomplished with larger doses of nondepolarizing NMBAs, but at the expense of markedly prolonging the duration of block, and increasing the likelihood of residual neuromuscular block and its complications. If a level of block that prevents diaphragmatic movement is required, the depth of block can be monitored with PTC—a PTC of 1 or 2 should be sufficient for most surgeries. At this level of block, reversal may be achieved with a medium dose of sugammadex (4 mg/kg). In contrast, spontaneous recovery of at least a TOFC of 2 or 3 should have occurred before attempting pharmacologic reversal with anticholinesterases (see Reversal of Neuromuscular Blockage). Patients managed with deep intraoperative block are at particular risk for postoperative residual paralysis, which is associated with an increased risk of silent aspiration, hypoxemia, need for reintubation, and prolonged stay in the postanesthesia care unit (PACU).<sup>76</sup>

It should also be noted that *monitoring of the depth of anesthesia* using the bispectral index (BIS monitor) may be affected by muscle activity. The BIS

monitor is sensitive to changes in EMG activity, and the BIS values in awake, paralyzed volunteers decreased in response to neuromuscular paralysis to levels associated with general anesthesia (BIS values of 44 to 47).<sup>97</sup> The effect of NMB on depth of anesthesia monitors, however, remains controversial. Although one report suggested that both BIS and the spectral entropy levels (Entropy) may remain unchanged after sugammadex reversal of rocuronium block,<sup>98</sup> others have reported increases in the numerical values of BIS and Entropy during reversal of rocuronium-induced block by sugammadex (and neostigmine).<sup>99,100</sup>

## Reversal of Neuromuscular Blockade

### *Anticholinesterase Agents*

Blocking or inhibiting the breakdown of ACh at the NMJ results in an increase in the available pool of ACh at the synaptic cleft and better chances of competing with the nondepolarizing NMBA for binding to the receptor's  $\alpha$ -subunit; this binding of ACh to nAChR results in normal transmission. There are three clinically available acetylcholinesterase inhibitors (anticholinesterase agents) in clinical use today: neostigmine, edrophonium, and pyridostigmine. These cholinesterase inhibitors are quaternary compounds and do not cross the blood–brain barrier in sufficient concentrations to have central effects. Their duration of action, at equivalent doses, is similar (60 to 120 minutes), but onset of action is fastest for edrophonium, intermediate for neostigmine, and longest for pyridostigmine. Physostigmine, another cholinesterase inhibitor, is a tertiary amine, but because it crosses the blood–brain barrier (and has central effects), it is not used for pharmacologic reversal of neuromuscular block. Edrophonium, similar to all cholinesterase inhibitors, is ineffective in reversing deep block, and it is used infrequently as a first-line agent, unless other agents are unavailable (see Drug Shortages and Clinical Impact). Because of its longer onset time than neostigmine, pyridostigmine is used rarely in anesthesia practice to antagonize neuromuscular block; it is used most often as an oral cholinesterase inhibitor for the treatment of myasthenia gravis. Neostigmine is the most frequently used anticholinesterase agent today, although a new, more effective agent recently has been approved in the United States (see Selective Relaxant Binding Agents).

**Table 21-12** Classification of Depth of Nondepolarizing Neuromuscular Block Based on Subjective and Objective Criteria

Depth of Block	Posttetanic Count (PTC)	Train-of-Four Count (TOFC)	Subjective Train-of-Four (TOF) Ratio	Measured (Actual) Train-of-Four (TOF) Ratio
Intense (profound) block	0	0	0	0
Deep block	≥1	0	0	0
Moderate block	NA	1–3	0	0
Light (shallow) block	NA	4	Fade present	0.1–0.4
Minimal block	NA	4	No fade	>0.4 but <0.90
Full recovery	NA	4	No fade	≥0.90–1.00

NA, data not available.

Modified from Fuchs-Buder T, Claudius C, Skovgaard LT, et al. 8th International Neuromuscular Meeting: Good clinical research practice in pharmacodynamic studies of neuromuscular blocking agents II: the Stockholm revision. *Acta Anaesthesiol Scand*. 2007;51:789–808.

## Neostigmine

All cholinesterase inhibitors, including neostigmine, block acetylcholinesterases and result in increased concentrations of ACh at the NMJ, increasing the size and duration of EPPs, and facilitating normal neuromuscular transmission. Neostigmine's inhibitory effects are concentration dependent, and at higher concentrations ( $>2.5 \times 10^{-5}\text{M}$ ) it may have a direct action to block the ACh receptor.<sup>101</sup> Because acetylcholinesterase is blocked at all cholinergic synapses, all cholinesterase inhibitors have significant parasympathomimetic effects. For this reason, they are generally coadministered with either glycopyrrolate (which has a slower onset of action similar to neostigmine) or atropine (which has a more rapid onset of action similar to edrophonium). Neostigmine as a reversal agent has a ceiling effect, and may be limited in its ability to antagonize the neuromuscular block beyond neuromuscular function equivalent to a TOF ratio of 0.6. Increasing the dose beyond 70 µg/kg is not recommended, as this dose may induce neuromuscular dysfunction. Similarly, administration of even small doses of neostigmine (30 µg/kg) at a time when recovery of neuromuscular function is almost complete may produce upper airway collapse and may decrease the activity of the genioglossus muscle.<sup>102</sup>

In the pediatric population, residual neuromuscular block can be associated with serious complications, and NMBA reversal with neostigmine is routine in many settings. However, there are currently few if any data on the effectiveness or safety of routine neostigmine use in the pediatric population.<sup>103</sup>

### *Factors Affecting Reversal*

The rate of cholinesterase inhibitor-aided recovery depends on several factors: *depth of neuromuscular block* at the time of pharmacologic reversal; *dose of cholinesterase inhibitor*; *type of NMBA* (long-acting vs. intermediate-acting);

*patient age; anesthesia type* (total intravenous anesthesia [TIVA] vs. inhalational anesthesia). When administered at a *deep degree of block*, such as PTC of 1 or 2, duration of neostigmine-induced reversal (to a TOF  $\geq 0.90$ ) may be over 50 to 60 minutes, with a very wide range of recovery times of 46 to 312 minutes.<sup>104</sup> When administered at this level of deep block (PTC of 1 to 2), 23% of patients receiving neostigmine required more than 60 minutes for full recovery.<sup>105</sup> The literature suggests that reversal should not be attempted at a deep level of block for at least two reasons. First, studies have shown that “early” reversal (5 minutes after vecuronium or rocuronium administration when the TOF count is 0) does not confer any advantage over reversal at TOF count of 3 or 4: total recovery time was similar and independent of the timing of neostigmine administration.<sup>106</sup> Second, it is known that neostigmine-induced recovery is characterized by an initial rapid (and partial) recovery, followed by a later slower recovery (Fig. 21-14). If neostigmine is administered at a deep block, the initial rapid recovery will occur during a blind period, when no responses are possible (or visible), followed by a slow and prolonged recovery at shallower depths of block. The time course of this slower phase will occur during recovery of TOF ratio when subjective evaluation of residual fade is inadequate (TOF of 0.4 to 0.9), and when the patient is at increased risk of critical respiratory events due to premature tracheal extubation. On the other hand, if neostigmine reversal is administered later (or is effected with sugammadex), once spontaneous recovery progresses to a TOFC of 3 or 4, the initial rapid recovery from neostigmine will effect a return of TOF ratio toward normal, followed by a slower and later recovery to TOF of 1.0.<sup>107</sup>

It should also be mentioned that clinical practice sometimes differs from what scientific data show. Attempts at pharmacologic reversal using doses of neostigmine larger than 70  $\mu\text{g}/\text{kg}$  or using a combination of cholinesterase inhibitors (e.g., neostigmine plus edrophonium) in an attempt to hasten pharmacologic reversal should be avoided. Cholinesterase inhibitors inhibit cholinesterases, and once they are 100% inhibited, no additional dose or type of inhibitor will be able to further increase the concentration of ACh at the NMJ to facilitate normal neuromuscular transmission. At this point, additional cholinesterase inhibitors may actually block the ACh receptors, leading to neuromuscular weakness.<sup>101</sup>

8

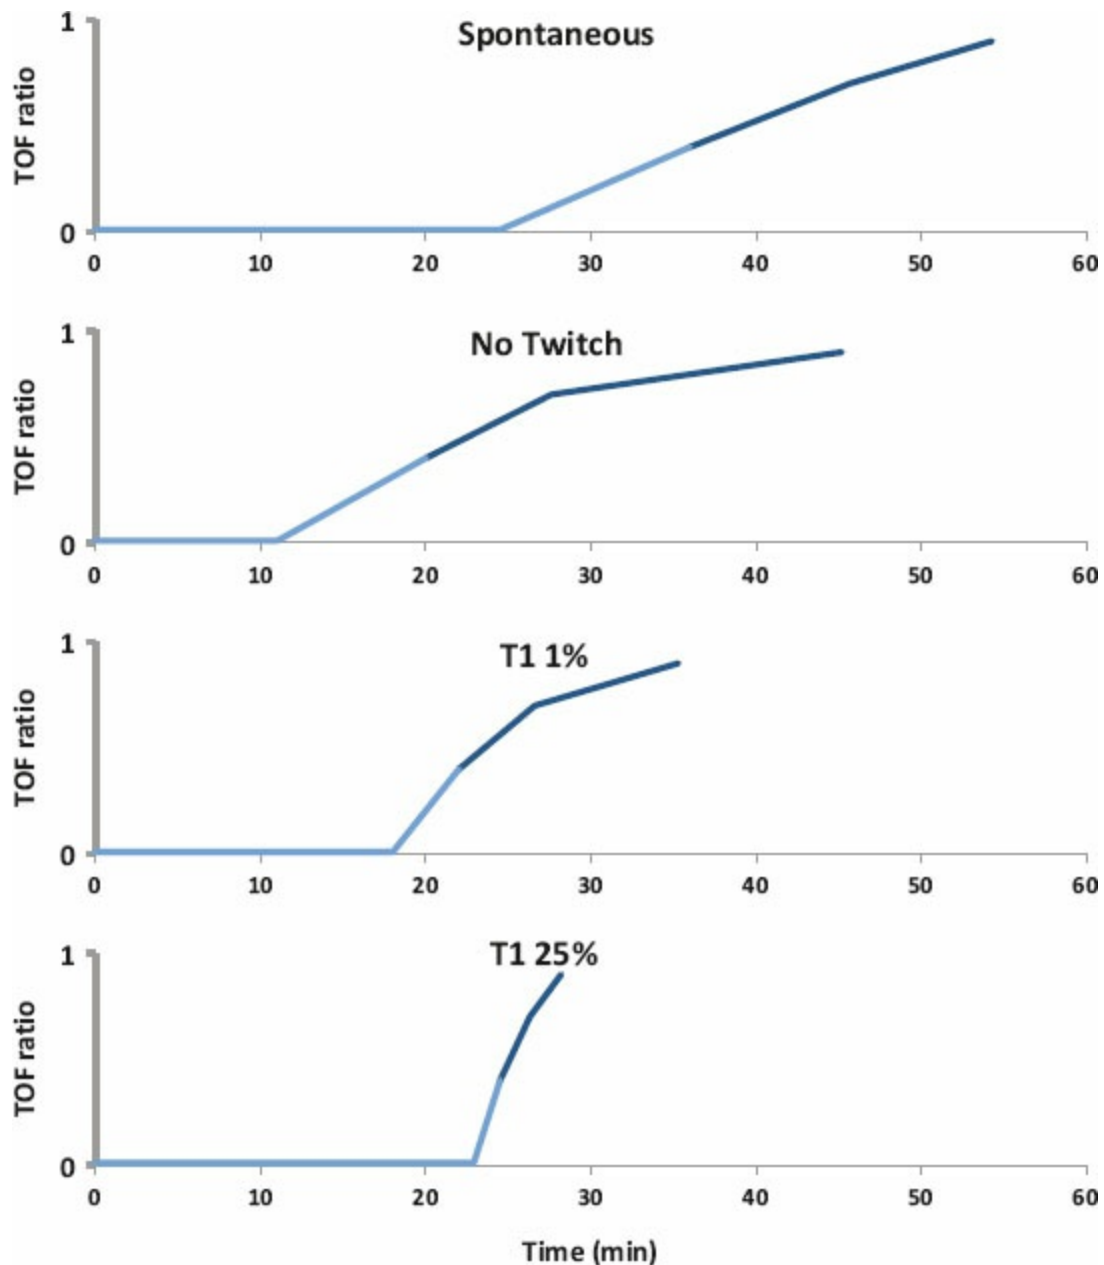

Most *inhalational anesthetic agents* potentiate neuromuscular block to varying degrees (desflurane > sevoflurane > isoflurane > halothane > nitrous oxide), whereas intravenous anesthetic techniques (for instance, based on propofol and/or opioid) will have minimal, if any, NMBA potentiation effects. When neostigmine 70  $\mu\text{g}/\text{kg}$  is administered to antagonize a *moderate* degree of block (tactilely determined TOFC of 1), a dose of  $2 \times \text{ED}_{95}$  of rocuronium requires an average of 8.6 minutes (range 5 to 19 minutes) for

recovery to TOF of 0.9 during propofol-maintained anesthesia; the same dose of rocuronium requires 28.6 minutes (range 9 to 76 minutes) during sevoflurane-based anesthesia.<sup>108</sup> However, even during anesthetic techniques that do not potentiate NMBAs (such as nitrous oxide/propofol-based anesthesia), neostigmine reversal from a tactile-guided TOFC of 3 to recovery of TOF = 0.9 may require 17 minutes (range 8 to 46 minutes).<sup>109</sup>

The speed of reversal from *light* and *minimal* nondepolarizing block is markedly increased by neostigmine, as is the effectiveness of this reversal. Reversal of atracurium (during nitrous oxide/enflurane anesthesia) from T1 values of 40% to 50% of control (TOFC of 4 with fade) to TOF at least 0.70 using neostigmine 20 µg/kg required 4.5 minutes (range 3 to 8 minutes). When the neostigmine dose was increased to 40 µg/kg and 80 µg/kg (a dose that is currently not recommended for use, regardless of the depth of neuromuscular block), the recovery times were 3.0 (range 2 to 5) minutes and 2.3 (range 1 to 4) minutes, respectively, a statistically (and clinically) insignificant change.<sup>110</sup> The authors concluded that neostigmine 20 µg/kg is the optimum dose when atracurium-induced *light* (shallow) block is antagonized. A similar dose of neostigmine (20 µg/kg) was found effective in reversing rocuronium-induced *minimal* block.<sup>111</sup>

These data emphasize that the time from neostigmine (or any cholinesterase inhibitor) administration until full recovery (TOF  $\geq 0.90$ ) depends on the number of molecules of nondepolarizing NMBA in the body, the NMBA duration (long- vs. short-acting), factors affecting the NMBA elimination from the body, and the dose of neostigmine administered. In turn, the number of NMBA molecules in the body at the time of reversal depends on the total dose of NMBA administered during the case; the total duration of continuous (or intermittent) NMBA administration; and the time between the last NMBA dose and neostigmine administration. These factors underscore and explain why neostigmine-induced reversal of deep block may take upwards of 300 minutes, as recovery from this depth of block is mostly driven by spontaneous recovery.

Reversal of *minimal* neuromuscular block (TOF ratio of 0.40 and 0.60) to a TOF of 0.9 using neostigmine 10, 20, and 30 µg/kg during TIVA was reported to be shorter than spontaneous recovery.<sup>112</sup> Reduced doses of neostigmine (20 µg/kg) were required to reach reversal (TOF of  $\geq 0.90$ ) from a TOF ratio of either 0.4 or 0.6 with a 100% probability in the setting of atracurium-induced block during TIVA anesthetic.<sup>112</sup>

**Figure 21-14** Time from injection of rocuronium until recovery to train of-four (TOF) ratio of 0.9 in adults. Reversal with neostigmine was either spontaneous or neostigmine was administered 5 minutes after rocuronium (no twitch), or at 1% twitch recovery (T1 1%), or at 25% twitch recovery (T1 25%). The TOF ratio is indicated against time until a TOF ratio of 0.9 was reached (end of the line). Time is shorter when neostigmine is given at T1 25%, than it is at reappearance of T1. This strategy also minimizes duration of blind paralysis (*dark blue segment*), when the TOF ratio is between 0.4 and 0.9 and fade is difficult to detect by visual or tactile means. (Data from Bevan JC, Collins L, Fowler C, et al. Early and late reversal of rocuronium and vecuronium with neostigmine in adults and children. *Anesth Analg.* 1999;89:333–339.)

The TOF data were nonnormalized acceleromyographic ratios.<sup>112</sup> The AMG-based recovery times to a TOF ratio of 1.0 (complete recovery) are equivalent with the measurements obtained with MMG or EMG monitors to a TOF ratio of 0.90.<sup>113</sup> Similar results were reported using rocuronium; during TIVA-based anesthetic and EMG monitoring, a rocuronium-induced block was

antagonized from a TOF ratio of 0.50 with various doses of neostigmine. The recovery time to a TOF ratio of 0.90 was 2.0 minutes (range 2 to 4 minutes) after neostigmine 40 µg/kg.<sup>114</sup> Low-dose neostigmine (10 µg/kg) administered to antagonize shallow atracurium block (TOF 0.6 to 0.9) during desflurane anesthesia required 5 minutes (range 3 to 8 minutes).<sup>115</sup> Compared with spontaneous recovery, neostigmine 10 µg/kg effected a faster recovery to TOF of 0.9. It should be pointed out, however, that the conclusion that neostigmine 10 µg/kg is effective in antagonizing this level of block is based on data from 12 patients; outlier patients who might require significantly longer recovery times are likely. For instance, a 2016 study found that even at a threshold TOFC of 4 (TOF ratio  $\geq 0.20$ ), neostigmine was not a 100% reliable antagonist of rocuronium-induced nondepolarizing block.<sup>116</sup>

Given the well-known variability in patient responses to NMBAs, we must ensure that there are no outlier patients who require unexpectedly long times for adequate neuromuscular recovery. Since there are no data to unequivocally demonstrate the reliability of a 10 µg/kg dose of neostigmine for reversal of light or minimal neuromuscular block, neostigmine doses of less than 20 µg/kg cannot be recommended.

Regardless of when administered, neostigmine-induced reversal is always faster than spontaneous recovery. Larger doses of neostigmine will also be more effective than lower doses in effecting neuromuscular block reversal—within the dose ranges in which neostigmine is effective (i.e., at doses less than the maximum 60 to 70 µg/kg). Although there is no difference in the speed of recovery induced by neostigmine among the intermediate-acting nondepolarizing NMBAs, reversal is prolonged when used with long-acting agents such as pancuronium.<sup>117,118</sup> Age also affects neostigmine-induced speed of reversal, being faster (and likely more complete) in children than in adults, and slower in the elderly.<sup>106</sup> Finally, drugs and conditions that potentiate the effect of nondepolarizing NMBAs will also prolong neostigmine-induced recovery: volatile anesthetics, aminoglycoside antibiotics, magnesium, opioids (because of the hypercarbia and acidosis they induce), and hypothermia.

### *Other Effects*

Neostigmine (and the other anticholinesterases) induce vagal stimulation, so anticholinergic agents are usually coadministered. Atropine is faster in onset than glycopyrrolate, produces more tachycardia, and crosses the blood–brain barrier. For these reasons, glycopyrrolate is generally preferred. It is slower in onset and induces less tachycardia; for these reasons, it is preferred especially in patients with coronary artery disease. Neostigmine has been associated with prolongation of cardiac repolarization (prolonged corrected QT interval, QTc), which may trigger malignant ventricular arrhythmias (torsade de pointes).<sup>119</sup> Other side effects of neostigmine include increased

salivation and bowel motility; although the anticholinergic agents are effective in preventing salivation, their effects on bowel motility are limited. Several recent meta-analyses of the effects of neostigmine on postoperative nausea and vomiting (PONV) in adult patients have not been able to conclusively show a connection.<sup>120,121</sup> When sugammadex- and neostigmine-induced pharmacologic reversal of neuromuscular block were compared with regard to incidence of PONV in adults, avoidance of neostigmine only slightly and transiently reduced PONV, but antiemetic and analgesic consumption was similar.<sup>120</sup> In the pediatric population, a recent systematic review of the literature has found no study that satisfied the inclusion criteria to determine whether neostigmine should be used routinely to reverse neuromuscular blockade, or to determine whether the use of neostigmine is associated with an increased incidence of nausea and vomiting.<sup>103</sup>

As previously noted, halogenated anesthetics potentiate neuromuscular block, and when continued after administration of neostigmine, they will prolong time to full reversal (TOF >0.90). Similarly, treatment with magnesium sulfate will slow neostigmine-induced spontaneous recovery.<sup>122</sup>

It is well known that administration of neostigmine to subjects who had not received any nondepolarizing NMBA may result in a significant reduction in the peak tetanic muscle contraction and severe tetanic fade; these effects persist for about 20 minutes, while the ST is slightly potentiated.<sup>123</sup> Similarly, an atracurium-induced neuromuscular block that corresponded to a TOF ratio of either 0.50 or 0.90 was established, followed by the administration of two doses of neostigmine 2.5 mg each, given 5 minutes apart. The effect of neostigmine on the depth of block was monitored with TOF and tetanic stimuli.<sup>124</sup> The first neostigmine dose antagonized the block, whereas the second 2.5-mg dose diminished tetanic height and increased tetanic fade, although it had minimal effects on the TOF measurement.

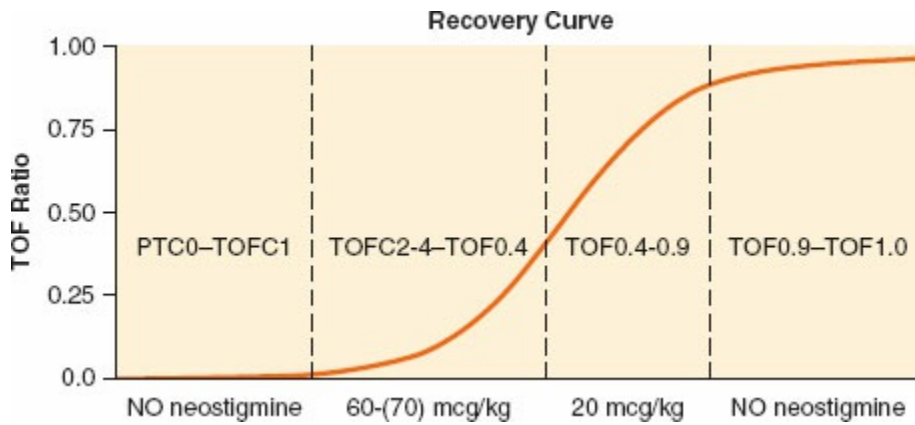

More significant effects on respiratory function were reported when neostigmine was administered after full recovery from neuromuscular block; there was a significant impairment of the upper airway dilator ability as a result of impaired genioglossus muscle and diaphragmatic function.<sup>102,125,126</sup> It should be noted that the preceding should not be interpreted as an argument in favor of omitting pharmacologic reversal; neostigmine-induced recovery is always faster than spontaneous recovery. The only remaining variable is the appropriateness of neostigmine administration as it relates to timing and dose.<sup>127</sup> The typical recovery curve for NMBAs (or any drug) is depicted in [Figure 21-15](#). After administration of an intubating dose of a nondepolarizing NMBA, the depth of block may be profound ([Table 21-12](#)). At this depth of block, neostigmine will be ineffective, and should not be administered.

At the other extreme of this recovery curve, once the objectively measured

TOF ratio is above 0.9 (full neuromuscular recovery), neostigmine reversal is unnecessary; in fact, if administered, it may induce respiratory muscle and diaphragmatic weakness. Full reversal (doses of neostigmine of 60 to 70  $\mu\text{g}/\text{kg}$ ) should be administered once the TOFC is at least 3 (preferably, 4) and when the TOF ratio is less than 0.4 (fade is present on subjective evaluation). In the absence of quantitative monitoring to ensure full recovery, even TOFCs of 4 without fade (determined subjectively) should prompt pharmacologic reversal. However, in these circumstances, doses of neostigmine of 20 to 30  $\mu\text{g}/\text{kg}$  are sufficient to reliably assure satisfactory return of neuromuscular function within approximately 10 minutes (Fig. 21-15). While these guidelines may offer the clinician some broad parameters for improving the efficacy of pharmacologic reversal using cholinesterase inhibitors based on subjective evaluation of neuromuscular function, an optimal reversal strategy can only be assured if clinical decisions are based on quantitative assessment of the depth of neuromuscular block (see Monitoring Neuromuscular Blockade). As already noted, subjective (tactile, visual) assessment and clinical testing are inadequate substitutes for objective (quantitative) monitoring.

### ***Drug Shortages and Clinical Impact***

Drug shortages have existed for decades, but the number of drugs on the shortage list and the duration of shortages have increased significantly in the last decade.<sup>128</sup> There are several reasons for drug shortages, including the scarcity of raw materials, industry consolidation that trims redundant manufacturers, inconsistent and variable manufacturing quality control, and discontinuation of older drugs by manufacturers in favor of newer, more profitable alternatives. In 2011, the U.S. Food and Drug Administration (FDA) published revised guidance on “marketing of unapproved drugs” and established “an orderly approach for removing unapproved drugs from the market.” Neostigmine was one of the drugs that had not been FDA approved. A proprietary, FDA-approved preparation of neostigmine methylsulphate was later marketed as Bloxiverz (Eclat Pharmaceuticals, Chesterfield, MO). Following FDA approval, the manufacturing company requested that the FDA remove all unapproved (generic and much cheaper) neostigmine formulations from the market; currently, Bloxiverz is the only available neostigmine preparation, at a price at least six times as much as its “unapproved” predecessors. Other pharmaceutical companies are authorized distributors of Bloxiverz. In many clinical settings, the disappearance from the market of generic (and much less expensive) neostigmine has forced clinicians to seek alternative cholinesterase inhibitors, including edrophonium.

**Figure 21-15** Neuromuscular blocking agent recovery curve and recommendations for pharmacologic (neostigmine) reversal of neuromuscular block. Typical recovery curve for a nondepolarizing neuromuscular blocking agent (NMBA), from maximal depth of block (PTC = 0) to full recovery (TOF ratio = 1.0). Dosing recommendations for administration of cholinesterase antagonism (neostigmine) are shown on the x-axis at four depths of neuromuscular block. TOF, train-of-four; PTC, posttetanic count; PTC0, posttetanic count of 0; TOFC, train-of-four count; TOFC1, train-of-four count of 1.

## Edrophonium

Edrophonium is an anticholinesterase agent that is used clinically for reversal of nondepolarizing neuromuscular block. It is much faster in onset and to peak antagonism (1 to 2 minutes) than neostigmine (7 to 11 minutes) or pyridostigmine (12 to 16 minutes).<sup>129</sup> Edrophonium is also less effective as an antagonist than neostigmine, as it forms ionic (and much weaker) bonds with the acetylcholinesterase enzyme, rather than the stronger, covalent bonds that neostigmine forms.<sup>130</sup> Its elimination half-life is 33 to 110 minutes, and 67% of the dose is excreted renally. Because of its lower affinity for acetylcholinesterases, edrophonium should only be used to antagonize a shallow block (TOFC of 4). The usual dose of edrophonium is 0.50 mg/kg (approximately  $4 \times \text{ED}_{95}$ ).

Edrophonium's duration of antagonism (66 minutes) is similar to that of neostigmine (76 minutes), but shorter than that of pyridostigmine.<sup>129</sup> Doses of 0.75 mg/kg provide minimal increases in efficacy over the 0.5 mg/kg dose.<sup>131</sup> Because of its propensity to induce bradycardia and its more rapid onset of action than neostigmine, edrophonium is usually administered in conjunction with atropine (as Enlon-Plus). The administration of the combination drug in divided doses over several minutes, as opposed to rapid bolus administration, will result in a lower peak plasma concentration of both agents, and will minimize the potential for bradycardia (from edrophonium) or tachycardia (from atropine).

## Selective Relaxant Binding Agents

## Sugammadex

1 Sugammadex is an FDA-approved gamma-cyclodextrin that has been developed as an selective relaxant binding agent (SRBA).<sup>132,133</sup> It is an eight-membered ring with a central cavity that perfectly encapsulates the steroid nucleus of steroidal intermediate-acting NMBAs (rocuronium > vecuronium >> pancuronium/pipecuronium)<sup>21</sup>—but has no

9 affinity for any of the other depolarizing or nondepolarizing NMBAs. Binding to rocuronium is extremely tight, with no clinically relevant dissociation (dissociation constant estimate of 0.055  $\mu\text{mol/L}$ ).<sup>134</sup> Binding to vecuronium is one-third as tight, but because a dose of vecuronium has 6 times fewer molecules than an equivalent rocuronium dose, the effectiveness of reversal is similar for the two drugs. The affinity for pancuronium may be lower than for other aminosteroids, although successful reversal with sugammadex (4 mg/kg) from reappearance of the second TOF twitch (T2) has been accomplished in less than 3 minutes ( $\pm 1.5$  minutes).<sup>19</sup> Once sugammadex is administered intravenously, the rapid and complete binding to rocuronium (and vecuronium) occurs in the plasma, and the concentration of free plasma NMBA decreases rapidly. This decrease in plasma concentration of free NMBA leads to an increased concentration gradient between the biophase (NMJ) and plasma, resulting in movement of free NMBA back into the plasma. This movement of free NMBA from the NMJ back into plasma will occur as long as the concentration of free (unbound) sugammadex is sufficiently high. When this occurs, there is normalization of neuromuscular function (pharmacologic reversal).

### Pharmacology

Sugammadex is highly water soluble and initial studies have shown it to be devoid of the side effects associated with the use of cholinesterase inhibitors and muscarinic antagonists.<sup>135</sup> The molecular weight of sugammadex is 2,178 daltons (Da), while that of rocuronium is 610 Da. Because the sugammadex/rocuronium complex occurs in a 1:1 molar ratio, 3.57 mg of sugammadex is required to bind to 1 mg of rocuronium. The 1:1 tight binding properties confer sugammadex significant advantages. The speed of reversal is dose dependent, and in general, larger sugammadex doses will hasten recovery. In doses of 2 mg/kg, sugammadex will antagonize both rocuronium and vecuronium from a TOFC of 2 to TOF of 0.9 in 2 to 4 minutes, a recovery that is significantly shorter than that induced by neostigmine.<sup>136–139</sup> When the level of neuromuscular block is deep (Table 21-12), larger sugammadex doses of 4 mg/kg are needed for recovery to TOF of 0.9, and the recovery time for sugammadex (geometric mean of 2.9 minutes) is significantly faster than the recovery following neostigmine (geometric mean of 50.4 minutes).<sup>105</sup>

Reversal from profound block, such as that encountered during a failed RSII scenario in which mask ventilation is not possible (cannot-intubate-cannot-oxygenate [CICO]) requires doses of 16 mg/kg of sugammadex.<sup>140</sup> In this emergent situation, reversal of high-dose rocuronium with high-dose sugammadex is faster than spontaneous recovery from SCh for failed RSII (Fig. 21-16).<sup>141</sup> The rescue from CICO events can be effected as long as the induction agents and opioids administered do not interfere with spontaneous ventilation, and airway instrumentation has not caused airway swelling. Sugammadex (in rhesus monkey) also rapidly and effectively antagonizes the main metabolite of vecuronium, 3-desacetyl vecuronium, at a dose (0.5 to 1.0 mg/kg) that is lower than that required for reversal of vecuronium.<sup>142</sup>

### *Pharmacokinetics*

The volume of distribution in adults approximates the ECF compartment. Metabolism of sugammadex is very limited, and it is eliminated primarily via renal excretion.<sup>143</sup> The sugammadex/rocuronium (or vecuronium) complex is also almost completely excreted by the renal route; its elimination half-life is approximately 100 minutes. In patients with severe renal impairment, both sugammadex and the sugammadex/rocuronium complex may be effectively removed with hemodialysis using a high-flux dialysis method.<sup>144</sup>

Current recommendations suggest waiting for 24 hours before repeating administration of rocuronium after sugammadex reversal of NMB. However, recent studies have shown that earlier readministration of rocuronium for re-establishment of neuromuscular block may be acceptable if a high dose of sugammadex has not been used (see Re-establishment of Block after Sugammadex Reversal).

### *Side Effects and Safety*

Sugammadex is biologically inactive and does not have affinity for any known receptors; therefore, it is devoid of hemodynamic side effects. It has been tested for its predilection to bind hundreds of different compounds, and only toremifene, flucloxacillin, and fusidic acid have been found to bind to sugammadex.<sup>134</sup> *Oral contraception* may be affected, equivalent to missing one daily oral dose, and alternative means of birth control are recommended for a week after exposure to sugammadex. While the use of most cholinesterase antagonists (neostigmine, pyridostigmine) has been associated with prolongation of the QTc interval and with an increased risk of malignant arrhythmias (torsade de pointes), such an effect has not been associated with use of sugammadex, even in high doses.<sup>119</sup>

One of the major side effects associated with sugammadex administration has been the potential for *hypersensitivity reactions*. The perioperative

prevalence of anaphylactic reactions is estimated to be between 1:3,500 and 1:20,000 procedures, with an associated mortality of up to 9%.<sup>145</sup> The main agents responsible for perioperative anaphylaxis are NMBAs, latex, antibiotics, hypnotics, opioids, and colloids. In a 2014 review, 15 cases of hypersensitivity to sugammadex were identified. In 93.3% of these cases, most of which met the World Anaphylaxis Organization criteria for anaphylaxis, the reactions occurred within the first 4 minutes after sugammadex administration.<sup>146</sup> For diagnosis of hypersensitivity reactions during general anesthesia, an elevated acute serum tryptase level is highly predictive of immunoglobulin-E (IgE)-mediated anaphylaxis.<sup>147</sup> Cardiovascular collapse following administration of sugammadex has been treated successfully with high-dose epinephrine and fluid resuscitation.<sup>148</sup>

The effects of sugammadex on *coagulation* have been investigated, and bleeding events within 24 hours of surgical procedures were reported in 2.9% of patients receiving sugammadex, compared with an incidence of postoperative bleeding of 4.1% in patients not exposed to the drug.<sup>149</sup> Compared with patients not exposed to sugammadex, increases of 5.5% in activated partial thromboplastin time (aPTT) and 3.0% in prothrombin time (PT) were observed 10 minutes after sugammadex administration; these values returned to baseline within 60 minutes.<sup>149</sup> In patients with a history of *pulmonary disease*, bronchospasm has an incidence similar to other drugs. Administered at a TOFC of 2, sugammadex 2 mg/kg rapidly and effectively reverses rocuronium in *renal failure* patients (creatinine clearance <30 mL/min) as quickly as in control patients ( $2 \pm 0.7$  minutes vs.  $1.65 \pm 0.63$  minutes, respectively).<sup>150</sup> Deep neuromuscular block (PTC of 1 to 2) induced by rocuronium was reversed with sugammadex 4 mg/kg to full recovery (TOF >0.9) within a median of 3.1 minute (95% CI of 2.4 to 4.6 minutes) in renal patients (creatinine clearance <30 mL/min) versus patients with normal renal function (1.9 minutes, 95% CI of 1.6 to 2.8 minutes).<sup>151</sup> During mild intraoperative *hypothermia* (34.5°C to 35.0°C), sugammadex reversal of rocuronium-induced block was prolonged minimally (<1 minute).<sup>152</sup> Although certain antibiotics may potentiate postoperative neuromuscular block, administration of antibiotics prior to sugammadex reversal did not affect recovery time from rocuronium-induced block.<sup>153</sup> Sugammadex has been marketed in Europe since 2009 without changes in its safety profile.

**Figure 21-16** Duration of action of neuromuscular blockade with succinylcholine 1 mg/kg (Sux), and rocuronium 1.2 mg/kg followed 3 minutes later by sugammadex 16 mg/kg (Roc-sug). T10 and T90: Duration to 10% and 90% first twitch recovery, respectively. Bars indicate standard deviation. (Data from: Lee C, Jahr JS, Candiotti KA, et al. Reversal of profound neuromuscular block by sugammadex administered three minutes after rocuronium. *Anesthesiology*. 2009;110:1020–1025.)

### Clinical Use

Sugammadex is indicated for reversal of steroidal NMBA, particularly rocuronium and vecuronium. Because it binds to the NMBA in a 1:1 molecular ratio, the recommended sugammadex dose is dependent on the depth of neuromuscular block. For immediate reversal of profound block (PTC = 0; [Table 21-12](#)), such as that achieved with 1.2 mg/kg rocuronium in the RSII scenario, a dose of sugammadex 16 mg/kg is recommended; for reversal of deep block (PTC = 1 to 2), a dose of 4 mg/kg is recommended; and for reversal of moderate block (TOFC of 1 to 2), the recommended dose is 2 mg/kg. In a dose of 1.0 mg/kg, sugammadex reverses rocuronium block from a TOFC of 4 in 2 minutes, whereas a dose of 0.5 mg/kg from the same depth of block requires 8 minutes.<sup>154</sup> In all these scenarios, reversal of block is typically accomplished in 2 to 3 minutes, as long as the sugammadex dose is sufficient to bind all of the free NMBA molecules in the plasma. In the morbidly obese patient, the dose of sugammadex has been calculated based on ideal body weight plus 40%. Alternatively, pooled analyses have indicated that recommended sugammadex doses based on actual body weight (in patients with BMI  $\geq 30$  kg/m<sup>2</sup>) provided rapid and reliable recovery from neuromuscular block, and that no dosing adjustments were required.<sup>155</sup>

High-dose rocuronium for RSII and sugammadex-induced reversal may currently provide “near-ideal” neuromuscular block management without significant side effects: optimal intubating conditions with rocuronium, and rapid and effective reversal of block with sugammadex. In addition, such a drug combination may be preferable in clinical scenarios of CICO, as reversal of rocuronium with sugammadex may be quicker than waiting for

spontaneous recovery of SCh.<sup>141</sup>

10

The *reliability* of sugammadex in reversing aminosteroid NMBA blockade has been documented, provided that sugammadex is administered in sufficient doses to encapsulate all NMBA molecules (see Sugammadex Pharmacology). However, as with any drug, there is a small but significant variability in patient response to sugammadex. A recent literature review<sup>156</sup> has documented that rare prolonged recovery times may occur after reversal with low doses (2 mg/kg) of sugammadex (up to 12 minutes,<sup>157</sup> with intermediate (4 mg/kg) doses (up to 22.3 minutes,<sup>158</sup> and even after high (16 mg/kg) doses (up to 16.6 minutes).<sup>159</sup> In special population groups such as the elderly (patients  $\geq 75$  years old); those with pulmonary, cardiac or renal disease; or those with body mass index (BMI) 40 or more—reversal to TOF 0.90 or more also can be prolonged.<sup>139,144,157,160,161</sup>

When used in the obese patient in suboptimal doses of 1 to 2 mg/kg, reanalysis has been reported.<sup>162</sup> In pediatric patients, a suboptimal dose of sugammadex also can lead to recurrent or residual paralysis.<sup>163</sup> Similar reports of reoccurrence of rocuronium-induced block (recurarization) after sugammadex reversal have been reported with administration of magnesium (60 mg/kg) for treatment of atrial fibrillation.<sup>164</sup> In contrast, when administered in adequate doses, the efficacy of sugammadex in reversing moderate and deep neuromuscular block was not affected by the administration of magnesium.<sup>165</sup> Importantly, if no neuromuscular monitoring is used intraoperatively, there is a significant risk of residual weakness (incidence of TOF  $< 0.9$  as high as 9.4% of patients) even with administration of sugammadex 2 to 4 mg/kg.<sup>166,167</sup> Therefore, monitoring neuromuscular function to determine the appropriate dose of sugammadex and minimize the risk of residual block is strongly recommended.

The *effectiveness* of sugammadex-induced reversal of neuromuscular block was compared with that of neostigmine. The EMG activity of the diaphragm (EMGdi), as well as the tidal volume and oxygen saturation (PaO<sub>2</sub>) were increased after sugammadex reversal compared with neostigmine, suggesting a more complete and faster recovery of the diaphragmatic ACh receptors.<sup>168</sup> A similar advantage of sugammadex over neostigmine reversal is reported as improved physiologic and nociceptive postoperative recovery, as well as superior patient satisfaction with recovery and anesthetic care.<sup>169</sup> Sugammadex-induced reversal was also associated with a lower incidence of PONV and with a reduced risk of pulmonary complications in elderly patients.<sup>170</sup>

One of the limiting factors to the wide adoption of sugammadex into routine clinical practice has been its relatively high acquisition cost; as of 2010, approximately \$85, \$170, and \$506, for the 2 mg/kg, 4 mg/kg, and 16 mg/kg dose, respectively, for a typical 75-kg patient.<sup>171</sup> The cost of the drug

in relation to the increased OR efficiency gained with its use (anesthesia OR time decreased from 144 minutes to 120 minutes) remains to be determined.<sup>172</sup>

### *Special Clinical Situations*

#### **Reversal in Patients with Neuromuscular Disorders**

It is well known that patients with neuromuscular disorders may be at increased risk of complications from residual neuromuscular block. The use of sugammadex may be advantageous in such clinical situations, given its pharmacology and its rapid and predictable effects. Rapid and effective reversal of rocuronium-induced block without block reoccurrence has been reported in myotonic dystrophy and spinal muscular atrophy patients.<sup>173</sup> In patients with myasthenia gravis, judicious use of NMBAs is advocated; patients are generally resistant to the effects of SCh, although they are more sensitive to the effects of nondepolarizing NMBAs, particularly in more advanced disease states. For this reason, neuromuscular blocking drugs are generally avoided, and a deep inhalation anesthetic plus a regional anesthetic block are preferred. Since the introduction of sugammadex, multiple reports have documented the safety of NMBA reversal in patients with myasthenia gravis, both in elective and in emergency surgery that required RSII.<sup>174–176</sup>

#### **Reversal of Intense (Profound) Neuromuscular Block**

Laparoscopic and robotic surgical procedures present a particular challenge for both surgeons and anesthesiologists. Insufflation of the abdomen with carbon dioxide (pneumoperitoneum) facilitates the surgical procedure by allowing the surgeon a better field of vision. However, high pneumoperitoneum pressures (12 to 15 mmHg) that improve surgical exposure are associated with greater physiologic derangements (hypotension, tachycardia) and increase postoperative shoulder pain.<sup>177</sup> The hemodynamic effects of high-pressure pneumoperitoneum can be attenuated by decreasing the insufflation pressures (8 to 10 mmHg), but such maneuvers may worsen surgical exposure.

One way to address both surgical need (better exposure) and anesthesiologist need (maintenance of hemodynamic stability) is to achieve a profound level of neuromuscular block of the abdominal musculature, thereby allowing better surgical exposure at lower intra-abdominal pressures. These goals can be achieved by administering NMBAs in sufficient doses to obtain a PTC of 0 (Table 21-12). However, at the end of the surgical procedure, recovery from such an intense block is prolonged (60 minutes or more), and pharmacologic reversal with cholinesterase inhibitors (neostigmine) is contraindicated. Theoretically, all the ideal goals could be achieved by

establishing intraoperative profound neuromuscular block (PTC of 0) with an aminosteroid NMBA (rocuronium) that would maximize surgical exposure at low intra-abdominal pressure (8 to 10 mmHg), followed by rapid (<5 minutes) and complete neuromuscular reversal with sugammadex. The literature on the actual benefits of such an approach, however, remains divided (Table 21-13). Some authors have shown that the enlargement of the surgical space (measured as the distance from the sacral promontory to the trocar) achieved with deep block was minor, and of “unknown clinical significance.”<sup>178</sup> Others have shown that deep neuromuscular block reduced the intra-abdominal pressure requirements by up to 25%, particularly in younger females.<sup>179</sup> Deep neuromuscular block improved surgical conditions during laparoscopic hysterectomy, improved surgical field scores (rated by the surgeon), and prevented unacceptable surgical conditions.<sup>180</sup> Similar benefits of improved surgical conditions (scored on a five-point surgical rating scale) were described during retroperitoneal laparoscopies performed with deep neuromuscular block, and without adversely affecting the patients’ perioperative cardiopulmonary conditions.<sup>181</sup> Although deep block facilitated surgical field visibility and prevented involuntary patient movement,<sup>182</sup> the benefits of deep block do not appear to be significant during low-pressure pneumoperitoneum.<sup>183</sup> Finally, the utility of moderate neuromuscular block (Table 21-12) in optimizing surgical conditions also has been investigated. A recent systematic review found that moderate block improved surgical conditions during open radical retropubic prostatectomy as well as laparoscopic cholecystectomy, nephrectomy, and prostatectomy.<sup>184</sup>

Until a clear and reproducible definition of surgical field exposure/visibility is developed, the interaction between intra-abdominal pressure and depth of block will likely remain controversial (Table 21-13).

### **Re-establishment of Block after Sugammadex Reversal**

A specific clinical situation may occur when rapid re-establishment of neuromuscular block is needed after the patient has already received sugammadex. The drug’s package insert recommends that at least 24 hours lapse before an aminosteroid NMBA is administered to patients who received sugammadex-induced reversal of neuromuscular block. Such a period would allow sufficient elimination of sugammadex via the renal route. In a recent report, rocuronium 1.0 mg/kg was administered 19 minutes after reversal with sugammadex; 3.5 minutes later, T1 was still present, and an additional 30 mg resulted in good intubating conditions. At the end of surgery, recovery was again facilitated with sugammadex, with return of normal neuromuscular function.<sup>185</sup> Similarly, a total dose of rocuronium between 0.6 and 1.2 mg/kg was sufficient to re-establish neuromuscular block when administered 12 to 465 minutes after sugammadex reversal.<sup>186</sup> Alternatively, depolarizing

(succinylcholine) or nondepolarizing (benzylisoquinolinium) agents can be administered in usual doses to re-establish neuromuscular block after sugammadex.

**Table 21-13** Summary of Randomized Trials Investigating the Relationship between Depth of Neuromuscular Block, Pneumoperitoneal (Intra-abdominal) Pressure and Outcome

Author	Surgery Type (number of patients)	NMBA Used	Depth of Block	IAP	Surgical Field Assessment	Results	Comments
Chassard <i>Anesth Analg</i> 1996;82:525	Laparoscopy (porcine model)	Atrac	No NMB vs. NMB	0–15 mmHg (incrementally)	Measured abdominal wall elastance	Elastance $3.98 \pm 1.6$ (no NMBA) vs. $3.86 \pm 1.4$ mmHg (with NMBA)	High intrathoracic pressures not affected by NMBA
Williams <i>Anaesthesia</i> 2003;58:574	Laparoscopic gynecologic surgery (n = 40)	Atrac	None (spontaneous breathing) vs. NMB	15 mmHg	End point was ease of trocar insertion in spontaneously breathing LMA vs. ETT + NMBA patients	IAP was higher in the LMA group	Surgical duration was greater in the ETT/ NMBA group
Lindekaer <i>J Vis Exp</i> 2013	Laparoscopic surgery (n = 15, pilot study)	Roc	Deep NMB vs. no NMB	8 mmHg vs. 12 mmHg	Measured intra-abdominal space as distance from the promontory to skin at the 8 and 12 mmHg pressures with no NMB and with deep NMB	Intra-abdominal space at 8 mmHg IAP with NMB was comparable to space at 12 mmHg without NMB	Using NMB to maintain steady surgical conditions while reducing IAP with deep NMB "may improve patient outcome."
Dubois <i>Eur J Anaesthesiol</i> 2014;31:430	Laparoscopic hysterectomy (n = 102)	Roc	Deep NMB (TOFC $\leq 2$ ) vs. shallow NMB (spontaneous recovery)	Stable at 13 mmHg	Surgeon subjective rating on 1 (excellent) to 4 (unacceptable) scale	"A trend towards higher scores was demonstrated in shallow NMB group"	21 patients in shallow NMB and 34 patients in deep NMB group had excellent surgical field
Martini <i>Br J Anaesth</i> 2014;112:498	Retroperitoneal laparoscopy (n = 24)	Atrac/mivac Roc	Moderate NMB (TOF 1–2) vs. deep NMB (PTC 1–2)	Standard	Subjective assessment by surgeon, SRS (1–5 scale), with 1 = extremely poor conditions and 5 = optimal conditions. Video images of working space evaluated post-hoc by anesthesiologists and surgeons.	In moderate NMB, 18% of SRS scores were 1–3; in deep NMB, 99% of SRS scores were 1–3. Mean SRS = 4.0 in moderate NMB, and 4.7 in deep NMB.	Deep NMB improves quality of surgical conditions over moderate NMB. Poor agreement between surgeons and anesthesiologists in scoring video images.

Staeher-Rye <i>Anesth Analg</i> 2014;119:1084	Laparoscopic cholecystectomy (n = 48)	Roc	Moderate (spontaneous recovery) vs. deep (PTC = 0–1)	8 mmHg	4-point scale (1 = best) and surgical space conditions at dissection of gallbladder (0–100, where 0 = optimal and 100 = unacceptable)	Optimal conditions in 7/25 (28%) of deep NMB and 1/23 (4%) of moderate NMB	Deep NMB associated with marginal improvement in surgical space.
Blobner <i>Surg Endosc</i> 2015;29:627	Laparoscopic cholecystectomy (n = 57)	Roc	No NMB vs. "deep" NMB (TOFC = 0)	–	Assessed with Visual Analogue Scale (VAS)	In no NMB group, 48% of patients had events that impaired procedure. Only 4% of patients in deep NMB had events.	Surgeons requested additional roc in 40% of no NMB group patients, and 0% in deep NMB group.
Vlot <i>Surg Endosc</i> 2015;29:2210	Laparoscopy (porcine model) (n = 16)	–	Not specified	0 mmHg 5 mmHg 10 mmHg 15 mmHg	Working-space dimensions evaluated objectively using computed tomography (CT)	NMB had no effect on abdominal dimensions and laparoscopic working space.	Prestretching improved surgical condition.
Van Wijk <i>Acta Anaesthesiol Scand</i> 2015;59:434	Laparoscopic cholecystectomy (n = 20)	Roc	Lowest IAP that provided adequate surgical conditions in: no NMB vs. deep NMB (PTC <2)	No NMB IAP = 12.75 ± 4.5 vs. deep NMB IAP = 7.20 ± 2.5 mmHg	Not specified	25% lower IAP in deep NMB patients	Younger patients and females benefit more from deep NMB.
Vlot <i>J Pediatr Surg</i> 2015;50:465	Laparoscopy (porcine model)	Not specified	Not specified (block vs. no block)	8–10 mmHg	Working-space volume, anterior- posterior distance, and symphysis-to- diaphragm distance	Increasing IAP to 8 mmHg (from 0 mmHg) increased all surgical field parameters.	Prestretching the abdominal wall by a first insufflation improved surgical field. NMB had no effect on working space.
Madsen <i>Acta Anaesthesiol Scand</i> 2015;59:441	Gynecologic laparoscopy (n = 14, cross-over study)	Not specified	Deep NMB vs. no NMB	8 mmHg 12 mmHg	Surgical field: distance from sacral promontory to trocar (objective assessment)	At 12 mmHg, deep NMB increased surgical space by 0.33 cm; at 8 mmHg, surgical space increased by 0.3 cm.	Deep NMB had better surgical conditions during suturing of fascia.
Yoo <i>PLoS ONE</i> 2015;10:e0135412	Robot-assisted radical prostatectomy (n = 67)	Atrac Roc	Moderate NMB (TOFC 1–2) vs. deep NMB (PTC 1–2)	8 mmHg	Subjective assessment by surgeon (1–5 scale)	Highest IOP after 1 hr of steep head- down position: 23.3 mmHg in moderate NMB vs. 19.8 mmHg in deep NMB group	IOP was the primary parameter of interest.
Madsen <i>Eur J Anaesthesiol</i> 2016;33:341	Laparoscopic hysterectomy (n = 99)	Roc	8 mmHg and deep NMB (PTC 0–1) vs. stan- dard 12 mmHg and moderate NMB	Low (8 mmHg) vs. standard (12 mmHg)	Not specified	Deep NMB and low pressure reduce postoperative pain.	Shoulder pain more frequent in moderate NMB group (60%) than deep NMB + low IAP (28.6%)
Kim <i>Medicine (Baltimore)</i> 2016;95:e2920	Laparoscopic colorectal surgery (n = 61)	Roc	Deep NMB (PTC 1–2) vs. moderate NMB (TOFC 1–2)	Titrated to maintain "operative field" by surgeon	Subjective by surgeon	Deep NMB IAP lower (9.3 mmHg) than moderate NMB (12 mmHg)	VAS pain scores lower, bowel function recovery faster in deep NMB group
Gurusamy <i>Cochrane Database Syst Rev</i> 2014:CD006930 <sup>a</sup>	Laparoscopic cholecystectomy (21 studies, n = 1,092 patients)			Low pressure (<12 mmHg) vs. standard pressure (12–16 mmHg)		Laparoscopic cholecystectomy can be performed successfully in 90% of low pressure group.	No evidence is currently available to support the use of low pres- sure pneumoperi- toneum in low-risk patients undergoin- g laparoscopic cholecystectomy.
Madsen <i>Acta Anaesthesiol Scand</i> 2015;59:1 <sup>a</sup>	Abdominal and gynecologic surgery (15 studies, n = 998 patients)		Deep NMB vs. moderate NMB			Good to excellent surgical conditions can be achieved without NMB. Deep NMB is recommended in laparoscopic cholecystectomy, nephrectomy, and prostatectomy.	Good evidence that optimized surgical conditions can be achieved with deep NMB in laparoscopic cholecystectomy, hysterectomy, nephrectomy, prostatectomy

<sup>a</sup>These studies are systematic reviews of the literature investigating the effects of intra-abdominal pressure or depth of neuromuscular block on surgical conditions and patient outcome.  
NMBA, neuromuscular blocking agent; IAP, intra-abdominal pressure; SRS, surgical rating scale; NMB, neuromuscular block; atrac, atracurium; roc, rocuronium; LMA, laryngeal mask airway;

**Figure 21-17** Calabadiion 2 (**A**), the second-generation cucurbituril receptor, features a cavity with naphthalene walls and binds with high affinity to steroidal (**B**;  $K_a = 0.53\text{--}3.4 \times 10^9 \text{ M}^{-1}$ ) and benzyliisoquinoline ( $K_a = 4.8 \times 10^6 \text{ M}^{-1}$ ) neuromuscular-blocking agents. (Adapted from Haerter F1, Simons JC, Foerster U, et al. Comparative effectiveness of calabadiion and sugammadex to reverse nondepolarizing neuromuscular-blocking agents. *Anesthesiology*. 2015;123(6):1337–1349.)

### Calabadiion

A cucurbit[n]uril derivative, calabadiion-1 has been reported to inactivate both steroidal and benzyliisoquinoline nondepolarizing NMBAs by encapsulation.<sup>187</sup> However, its binding affinity toward rocuronium is less than that of sugammadex. A new compound, calabadiion 2, was developed that has 89 times greater affinity for rocuronium than sugammadex, and a higher molar potency (Fig. 21-17).<sup>188</sup> In vivo experiments (in rats) report that calabadiion 2 also has a very high affinity for cisatracurium, a property that sugammadex lacks. Interestingly, SCh can be administered safely and effectively after administration of calabadiion 2 if rapid reanalysis is required.<sup>188</sup> Similar to sugammadex, the calabadiion-NMBA complex is eliminated unchanged via the renal route.

### Conclusion

After a relatively long period in which few pharmacologic advances were made with regard to NMBAs or their antagonists, the last decade has witnessed the introduction of a new and much more effective antagonist of aminosteroidal NMBAs, sugammadex. Current work suggests that newer, and even more effective, broad-spectrum encapsulating agents are being developed that could potentially reverse the actions of all NMBAs, aminosteroids and benzyliisoquinolinium compounds alike. It is hoped that these advances in pharmacology will be paralleled by similar advances in perioperative monitoring that will increase the anesthesiologist's ability to provide optimal care and improve patient safety.

## KEY POINTS

- 1 Local anesthetics provide anesthesia and analgesia by blocking the transmission of pain sensation along nerve fibers.
- 2 The key target of local anesthetics is the voltage-gated sodium channel. The binding is intracellular and is mediated by hydrophobic interactions.
- 3 The degree of nerve blockade depends on both drug concentration and volume.
- 4 Most clinically relevant agents contain a lipid-soluble benzene ring connected to an amide group and are categorized as either aminoesters or aminoamides based on their chemical linkage.

- 5 Potency is related to lipid solubility and physiochemical properties of the agent. In general, more potent agents are more lipid-soluble.
- 6 Clinical use of local anesthetics may be increased by addition of epinephrine, opioids, and  $\alpha_2$ -adrenergic agonists. The value of alkalization of local anesthetics appears to be debatable as a clinically useful tool to improve anesthesia.
- 7 The rate of local anesthetic system absorption depends on the site of injection, the dose, the drug's intrinsic pharmacokinetic properties, and the addition of a vasoactive agent.
- 8 Systemic toxicity from the clinical use of local anesthetics is an uncommon occurrence. Patients with cardiovascular collapse from bupivacaine, ropivacaine, and levobupivacaine may be especially difficult to resuscitate; however, intravenous lipid infusion is an effective new therapy.

**1** Local anesthetics block the conduction of impulses in electrically excitable tissues. One of the important uses is to provide anesthesia and analgesia by blocking the transmission of pain sensation along nerve fibers. The molecular target of these agents is specific and the interaction has been extensively studied. Existing clinical applications are numerous and continue to expand. A comprehensive understanding of the mechanisms and the physiochemical properties of these agents will optimize the therapeutic potential and avoid complications associated with inadvertent systemic toxicity.

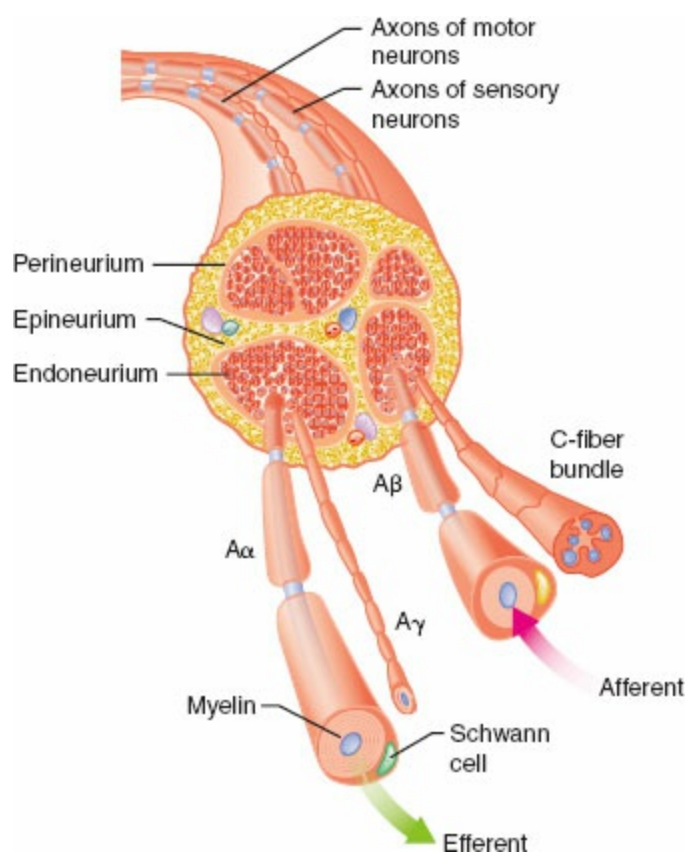

## Mechanisms of Action of Local Anesthetics

### Anatomy of Nerves

Local anesthetics are used to block nerves in the peripheral nervous system (PNS) and central nervous system (CNS). In the PNS, nerves contain both afferent and efferent fibers, which are bundled into one or more fascicles and organized within three tissue layers.<sup>1</sup> Individual nerve fibers within each fascicle are surrounded by the *endoneurium*, a loose connective tissue containing glial cells, fibroblasts, and blood capillaries. A dense layer of collagenous connective tissue called the *perineurium* surrounds each fascicle. A final layer of dense connective tissue, the *epineurium*, encases groups of fascicles into a cylindrical sheath (Fig. 22-1). These layers of tissue offer protection to the surrounded nerve fibers and act as barriers to passive diffusion of local anesthetics.<sup>2</sup>

Nerves in both the CNS and PNS are differentiated by the presence or absence of myelin sheath. Myelinated nerve fibers are surrounded by

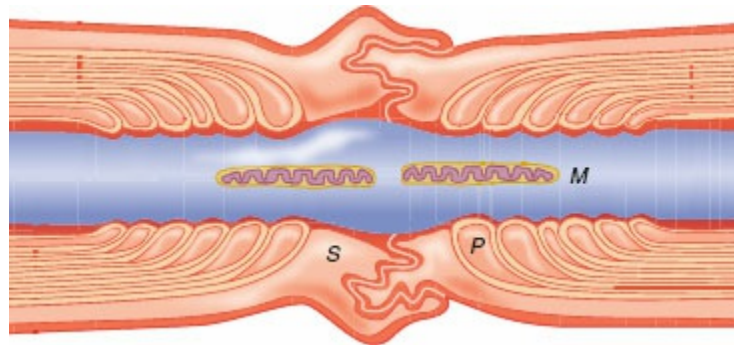

Schwann cells in the PNS and by oligodendrocytes in the CNS. The cells form a concentrically wrapped lipid bilayer sheath around the axons that cover the length of the nerve.<sup>3</sup> The myelin sheath is interrupted at short regular intervals by specialized regions called *nodes of Ranvier*, which contain densely clustered protein elements essential for transmission of neuronal signals (Fig. 22-2).<sup>4</sup> As electrical signals are renewed at each node, nerve impulses move in myelinated fibers by saltatory conduction. In contrast, there are no nodes of Ranvier in nonmyelinated nerve fibers. Although these nerve fibers are similarly encased in Schwann cells, the plasma membrane does not wrap around the axons concentrically. Several nerve fibers may be simultaneously embedded within a single Schwann cell (Fig. 22-3).<sup>1</sup>

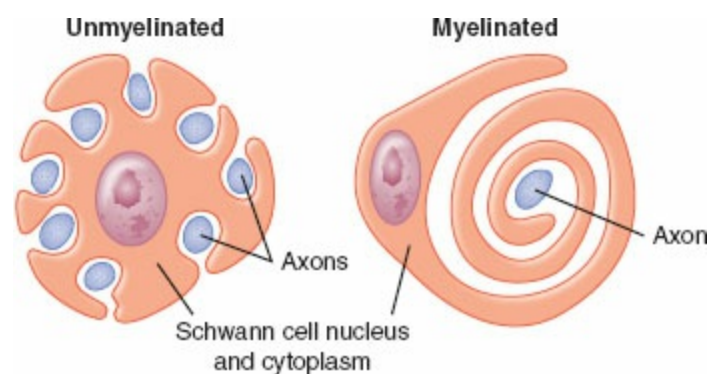

**Figure 22-1** Schematic cross-section of a typical peripheral nerve. The epineurium, consisting of collagen fibers, is oriented along the long axis of the nerve. The perineurium is a discrete cell layer, whereas the endoneurium is a matrix of connective tissue. Both afferent and efferent axons are shown. Sympathetic axons (not shown) are also present in mixed peripheral nerves. (Adapted with permission from Strichartz GR. Neural physiology and local anesthetic action. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. Philadelphia, PA: Lippincott-Raven; 1998:35.)

Nerve fibers are commonly classified according to their size, conduction velocity, and function (Table 22-1). In general, nerve fibers with cross-sectional diameter greater than 1  $\mu\text{m}$  are myelinated. Both a larger nerve size

and the presence of myelin sheath are associated with faster conduction velocity.<sup>5</sup> Nerve fibers with large diameters have better intrinsic electric conductance. Myelin improves the electrical insulation of nerve fibers and permits more rapid impulse transmission via saltatory conduction. Large-diameter myelinated fibers, many of which are classified as A fibers, are typically involved in motor and sensory functions in which speed of nerve transmission is critical. In contrast, small-diameter nonmyelinated C fibers have slower conduction velocity and relay sensory information such as pain, temperature, and autonomic functions.

## **Electrophysiology of Neural Conduction and Voltage-gated Sodium Channels**

Transmission of electrical impulses along the cell membrane forms the basis of signal transduction along nerve fibers. Energy necessary for the propagation and maintenance of the electric potential is maintained on the

cell surface by ionic disequilibria across the semipermeable cell membrane.<sup>6</sup> The resting membrane potential, approximately  $-60$  to  $-70$  mV in neurons (the extracellular electric potential is, by convention, defined as zero, and the intracellular potential is thus negative relative to it), is derived predominantly from a difference in the intracellular and extracellular concentrations of potassium and sodium ions. Neurons at rest are more permeable to potassium ions than sodium ions because of potassium leak channels; therefore, membrane potential is closer to the equilibrium potential of potassium ( $E_K -80$  mV) than that of sodium ( $E_{Na} +60$  mV). The ion gradient is continuously regenerated by protein pumps, cotransporters, and channels via an adenosine triphosphate–dependent process.

Electrical impulses are conducted along nerve fibers as action potentials. They are brief, localized spikes of positive charge, or depolarizations, on the cell membrane caused by rapid influx of sodium ions down its electrochemical gradient.<sup>7</sup> An action potential is initiated by local membrane depolarization, such as at the cell body or nerve terminal by a ligand–receptor complex. When a certain charge threshold is reached, an action potential is triggered and further depolarization occurs in an “all-or-none” fashion.<sup>8</sup> The spike in membrane potential peaks around  $+50$  mV, at which point the influx of sodium is replaced with an efflux of potassium, causing a reversal of membrane potential, or repolarization. The passive diffusion of membrane depolarization triggers other action potentials in either adjacent cell membranes in *nonmyelinated* nerve fibers or adjacent nodes of Ranvier in *myelinated* nerve fibers, resulting in a wave of action potential being propagated along the nerve. A short *refractory period* that ensues after each action potential prevents the retrograde spread of action potential on previously activated membranes.<sup>7</sup>

**Table 22-1** Classification of Nerve Fibers

Classification	Diameter (μm)	Myelin	Conduction (m/s)	Location	Function
Aα, Aβ	6–22	+	30–120	Afferents/efferents for muscles and joints	Motor and proprioception
Aγ	3–6	+	15–35	Efferent to muscle spindle	Muscle tone
Aδ	1–4	+	5–25	Afferent sensory nerve	Pain Touch Temperature
B	<3	+	3–15	Preganglionic sympathetic	Autonomic function
C	0.3–1.3	–	0.7–1.3	Postganglionic sympathetic Afferent sensory nerve	Autonomic function Pain Temperature

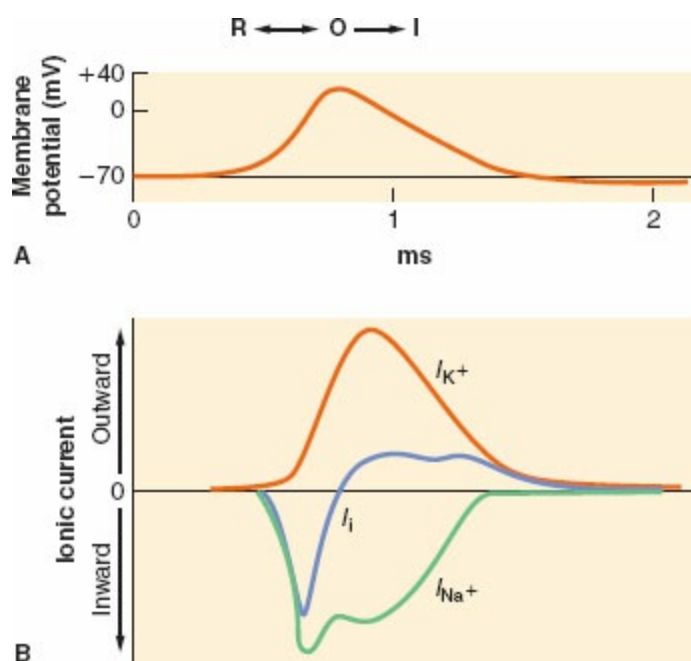

The flow of ions responsible for action potentials is mediated by a variety of channels and pumps, the most important of which are the voltage-gated sodium channels. They are essential for the influx of sodium ions during the

rapid depolarization phase of the action potential and belong to a family of channel proteins that also includes voltage-gated potassium and voltage-gated calcium channels. Each voltage-gated sodium channel is a complex made up of one principal  $\alpha$ -subunit and one or more auxiliary  $\beta$ -subunits.<sup>9</sup> The  $\alpha$ -subunit is a single-polypeptide transmembrane protein that contains most of the key components of the channel function. They include four homologous  $\alpha$ -helical domains (D1 to D4) that form the channel pore and control ion selectivity, voltage-sensing regions that regulate gating function and inactivation, and phosphorylation sites for modulation by protein kinases.  $\beta$ -subunits are short polypeptide proteins with a single transmembrane domain. They are linked to  $\alpha$ -subunits by either noncovalent or disulfide bonds; although they are dispensable for channel activity, evidence suggests that they perhaps play a role in modulation of channel expression, localization, and function.

In the absence of a stimulus, voltage-gated sodium channels exist predominantly in the resting or closed state (Fig. 22-4). On membrane depolarization, positive charges on the membrane interact with charged amino acid residues in the voltage-sensing regions (S4).<sup>10</sup> This induces a conformational change in the channel, converting it to the open state. Sodium ions rush through the opened pore, which is lined with negatively charged residues. Ion selectivity is determined by these amino acid residues; changes in their composition can lead to increased permeability for other cations, such as potassium and calcium.<sup>11</sup> Within milliseconds after opening, channels undergo a transition to the inactivated state. Depending on the frequency and voltage of the initial depolarizing stimulus, the channel may undergo either fast or slow inactivation. Slow or fast inactivation refers to the duration in which the channel remains refractory to repeat depolarization before resetting to the closed state. Fast inactivation completes within a millisecond and is sensitive to the action of local anesthetics. It is mediated by a short mobile intracellular polypeptide loop connecting domains D3 and D4 that closes the channel from inside the cell via a hinge-lid mechanism.<sup>12</sup> A triad of highly hydrophobic amino acids (isoleucine, phenylalanine, and methionine [IFM]) appears to be an important structural determinant of fast activation; disrupting the loop or changing the hydrophobicity of the amino acids abrogates fast inactivation.<sup>13,14</sup> Slow activation, lasting seconds to minutes, is distinct from fast activation. It is resistant to the action of local anesthetics and its mechanism is less well understood. It often occurs after prolonged depolarization and is believed to be important in regulating membrane excitability.

Nine isoforms of voltage-gated sodium channels (Nav 1.1 to Nav 1.9) have been identified; each relates to a unique  $\alpha$ -subunit subtype (Table 22-2). Each isoform varies slightly in its channel kinetics, such as threshold of activation and mode of inactivation, and its sensitivity to blocking agents like

tetrodotoxins and local anesthetics. Cell and tissue expression of individual isoforms may be quite specific; for instance, Nav 1.2 is found almost exclusively in the CNS, whereas Nav 1.6 is restricted to nodes of Ranvier in both CNS and PNS.<sup>15</sup> Likewise, several isoforms could be present on a single cell type; both Nav 1.8 and Nav 1.9 have been found in small- to medium-sized neurons in dorsal root ganglia that are connected to A $\delta$  and C fibers. Whether individual isoforms each have a separate and defined role remains to be seen; however, clues to their function may be inferred from studies of several inherited diseases that have been associated with sodium channelopathies. Hyperexcitability of Nav 1.7 has been implicated in several painful disease states, such as primary erythromelalgia and paroxysmal extreme pain disorder.<sup>16,17</sup> Conversely the null mutation of Nav 1.7 is linked to a rare genetic condition in which otherwise normal individuals have severely impaired perception to pain.<sup>18,19</sup>

## Molecular Mechanisms of Local Anesthetics

**2** Local anesthetics block the transmission of nerve impulses by targeting the function of voltage-gated sodium channels. Several local anesthetics can also bind to other receptors like voltage-gated potassium channels and nicotinic acetylcholine receptors and their amphipathic nature may enable them to interact with plasma membranes. However, it is widely accepted that local anesthetics induce anesthesia and analgesia through direct interactions with the sodium channels. Other molecules with local anesthetic properties, such as tricyclic antidepressants and anticonvulsants, may likewise interact with voltage-gated sodium channels; however, it is unclear if they act through similar mechanisms. Therefore, the following discussion is limited to the “traditional” set of local anesthetic molecules.

Local anesthetics reversibly bind the intracellular portion of voltage-gated sodium channels (Fig. 22-5). Early experiments with giant squid axons demonstrated that a derivative of lidocaine with a permanent positive charge and that cannot cross the plasma membrane (QX-314) blocks ion current through voltage-gated sodium channels only with intra-axoplasmic injections, but not with external application.<sup>20</sup> Subsequent mutational analyses have supported this observation and identified specific sites on the channel involved in drug recognition.<sup>21</sup> Several hydrophobic aromatic residues (a phenylalanine at position 1,764 and a tyrosine at position 1,771 in Nav 1.2) located within an  $\alpha$ -helix (S6) of domains 1, 3, and 4 are essential for drug binding (Fig. 22-6). They line an inner cavity within the intracellular portion of the channel pore and span a region about 11 Å apart, roughly the size of a local anesthetic molecule. Changes in either residue severely reduce the binding affinity. Another hydrophobic amino acid (an isoleucine at position 1,760), located near the outer pore opening, also influences the dissociation of local anesthetics from the channel by antagonizing the release of drugs

through the channel pore.

Application of local anesthetics typically produces a concentration-dependent decrease in the peak sodium current.<sup>22,23</sup> Termed *tonic blockade*, this refers to the reduction in the number of sodium channels for a given drug concentration present in the open state at equilibrium. In contrast, repetitive stimulation of the sodium channels often leads to a shift in the steady-state equilibrium, resulting in a greater number of channels being blocked at the same drug concentration. This is termed *use-dependent blockade*—its exact mechanism is incompletely understood and has been the subject of many competing hypotheses. One popular theory, the *modulated-receptor theory*, proposes that local anesthetics bind to the open or the inactivated channels more avidly than the resting channels, suggesting that drug affinity is a function of a channel's conformational state. An alternate theory, the *guarded-receptor theory*, assumes that the intrinsic binding affinity remains essentially constant regardless of a channel's conformation; rather, the apparent affinity is associated with increased access to the recognition site resulting from channel gating. Experimental evidence so far has been inconclusive.

**Figure 22-5** Diagram of the bilayer lipid membrane of conductive tissue with the sodium channel spanning the membrane. Tertiary amine local anesthetics exist as both neutral base (N) and protonated, charged form (NH<sup>+</sup>) in equilibrium. The neutral base (N) is more lipid soluble, preferentially partitions into the lipophilic membrane interior, and easily passes through the membrane. The charged form (NH<sup>+</sup>) is more water soluble and binds to the sodium channel at the negatively charged membrane surface. Both forms can affect the function of the sodium channel. The N form can cause membrane expansion and closure of the sodium channel. The NH<sup>+</sup> form will directly inhibit the sodium channel by binding with a local anesthetic receptor. The natural “local anesthetic” tetrodotoxin (TTX) binds at the external surface of the sodium channel and has no interaction with the clinically used local anesthetics. (Adapted with permission from Strichartz GR. Neural physiology and local anesthetic action. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. Philadelphia, PA: Lippincott-Raven; 1998:35.)

**Figure 22-6** Diagram of the local anesthetic binding site, depicting a hydrophobic pocket within the sodium channel pore. (Adapted with permission from Ragsdale DS, McPhee JC, Scheuer T, et al. Molecular determinants of state-dependent block of Na<sup>+</sup> channels by local anesthetics. *Science*. 1994;265:1724.)

### Mechanism of Nerve Blockade

Local anesthetics block peripheral nerves by disrupting the transmission of action potentials along nerve fibers. To get to its site of action, principally the voltage-gated sodium channels, local anesthetics have to reach the targeted nerve membrane. This entails the diffusion of drugs through tissues and the generation of a concentration gradient. Even with close proximity of deposition, only about 1% to 2% of injected local anesthetics ultimately penetrate into the nerve.<sup>24</sup> As discussed earlier, the perineural sheath encasing nerve fibers appears to be an important determinant; nerves that have been desheathed *in vitro* require about a 100-fold lower local anesthetic concentration (in the 0.7–0.9 mM range for lidocaine) than nerves *in vivo* (the typical 2% lidocaine used clinically is equivalent to 75 mM concentration). Although it may vary with anatomic location and nerve physiology, functional block typically occurs within 5 minutes of injection in rat sciatic nerves, and this time course corresponds to the peak in the intraneural drug absorption.

**3** The degree of nerve blockade depends on the local anesthetic concentration and volume. For a given drug, a minimal concentration is necessary to effect complete nerve blockade. It reflects the potency of the local anesthetics and the intrinsic conduction properties of nerve fibers, which

in turn likely depend on the drug's binding affinity to the ion channels and the degree of drug saturation necessary to halt the transmission of action potentials. Accordingly, individual types of nerve fibers differ in their minimal blocking concentration, such that some A fibers are blocked by lower drug concentrations than C fibers.<sup>25</sup> Likewise, the pattern of stimulation (tonic vs. use-dependent blockade) influences the degree of conduction failure; repetitive stimulations, which can lead to a shift in steady-state equilibrium of blocked sodium channels, are associated with higher conduction failure than tonic stimulation at a given drug concentration.<sup>26</sup>

Of equal importance as drug concentration is the local anesthetic volume. A sufficient volume is needed to suppress the regeneration of nerve impulse over a critical length of nerve fiber. According to the model of decremental conduction (Fig. 22-7), as membrane depolarization from an action potential passively decays with distance along nerve fibers, the presence of local anesthetics decreases the ability of adjacent membrane or successive nodes of Ranvier to regenerate the impulse.<sup>27</sup> Transmission stops once the membrane depolarization falls below the threshold for action potential activation. If the exposure distance is inadequate, action potentials can “skip” over blocked segments and resume nerve conduction. In contrast, exposure over a long segment of nerve to even a relatively low drug concentration can still result in gradual extinction of impulse by decremental decay.

Not all sensory and motor modalities are blocked equally by local anesthetics. It has long been observed that application of local anesthetics produces an ordered progression of sensory and motor deficits, starting commonly with the disappearance of temperature sensation, followed in order by proprioception, motor function, sharp pain, and finally light touch. Termed *differential blockade*, historically this had been thought to be related simply to the diameter of the nerve fibers, with the smaller fibers inherently more susceptible to drug blockade than larger fibers.<sup>28</sup> However, although the “size principle” of differential blockade is consistent with many experimental findings, it is not universally true. Larger, myelinated A $\delta$  fibers (believed to mediate sharp pain) are preferentially blocked over small, nonmyelinated C fibers (dull pain). Furthermore, within the C fibers are fast and slow components of impulse transmission, each with distinct susceptibilities to drug blockade.<sup>29</sup> These observations argue against a purely pharmacokinetic mechanism as the sole explanation for differential blockade.

**Figure 22-7** Diagram illustrating the principle of decremental conduction block by local anesthetic at a myelinated axon. The first node of Ranvier at left contains no local anesthetic and gives rise to a normal action potential (*solid curve*). If the nodes succeeding the first are occupied by a concentration of local anesthetic high enough to block 74% to 84% of the sodium conductance, then the action potential amplitudes decrease at successive nodes (amplitudes are indicated by *interrupted bars* representing three increasing concentrations of local anesthetic). Eventually, the impulse decays to below-threshold amplitude if the series of local anesthetic-containing nodes is long enough. Propagation of the impulse is then blocked by decremental conduction, even though none of the nodes are completely blocked. Concentrations of local anesthetics that block more than 84% of the sodium conductance at three successive nodes prevent any impulse propagation at all. (Adapted with permission from Fink BR. Mechanisms of differential axial blockade in epidural and spinal anesthesia. *Anesthesiology*. 1989;70:851.)

More likely, explanations may additionally be found in the intrinsic excitatory properties of the nerve fibers, namely, the patterned expression of ion pores and channels on the cellular membrane. Indeed, sodium channel isoforms  $Na_v$  1.7 and  $Na_v$  1.8 are highly expressed on the dorsal root ganglia, and have been shown to have distinct sensitivities to lidocaine.<sup>30</sup> Similarly, experiments with large pore, nonspecific cation channels, the transient receptor potential channel subfamily V (TRPV1) and member A1 (TRPA1), suggest that they can be activated by lidocaine and other local anesthetics.<sup>31,32</sup> Because these transient receptor potential channels are found predominantly on sensory neurons mediating specific stimulus modalities, their activation may selectively facilitate entry of local anesthetics, thereby resulting in the observed progression of sensory, autonomic, and motor blockade.

## Pharmacology and Pharmacodynamics

### *Chemical Properties and Relationship to Activity and Potency*

**4** Most clinically relevant local anesthetics consist of a lipid-soluble, aromatic benzene ring connected to an amide group via either an amide or an ester moiety. The type of linkage broadly defines them into two

categories, the *aminoesters* and the *aminoamides*, and affects how they are metabolized. Aminoesters are hydrolyzed by plasma cholinesterases and aminoamides are degraded by hepatic carboxylesterases. Some metabolites of aminoesters, such as *para*-aminobenzoic acid, can induce immunologic reactions and are responsible for the slightly greater incidence of severe allergic reactions associated with aminoesters. Other than these characteristics, physiochemical properties of both aminoesters and aminoamides are similar and are mainly determined by their dissociative constant, lipophilic makeup, and spatial arrangement of the molecule.

The tertiary amide on local anesthetics can accept a proton at low affinity; thus, these compounds are classified as weak bases. In aqueous solution, local anesthetics are in constant equilibrium between the protonated cationic form and the lipid-soluble neutral form. The ratio of the two forms depends on the  $pK_a$  or the dissociation constant of the local anesthetics and the surrounding pH (Table 22-3). A ratio with high concentration of the lipid-soluble form favors intracellular entry, as the cellular membrane restricts passage of the cationic form, but not the lipid soluble form.<sup>2</sup> Clinically, the proportion of the lipid-soluble form can be increased by alkalization of local anesthetic solution and thus accelerate the onset of action. Once inside the cell, equilibrium is reestablished between the cationic and the neutral forms, and experimental findings have shown that the cationic form is principally responsible for blockade of sodium channels.<sup>33</sup>

By far the most important physiochemical property of local anesthetics is their lipophilicity. Lipid solubility of local anesthetics is conferred by the composition of alkyl substitution on the amide and the benzene groups. In the laboratory, lipid solubility is measured by the partition coefficient in a hydrophobic solvent, octanol, and compounds with high octanol:buffer partition coefficient are more lipid soluble.<sup>34</sup> A positive correlation exists between the potency of the local anesthetics and their octanol:buffer partition coefficient; highly lipid-soluble agents are more potent and tend to have a longer duration of action than ones that are less lipid soluble.<sup>35</sup> The lipophilic property of local anesthetics may act at two levels. The first is at the level of cellular entry as greater lipid solubility facilitates passage through the lipid membrane barriers. The second is at the level of binding to the sodium channels. Detailed crystallographic findings show that local anesthetics bind to a hydrophobic pocket within the sodium channels and suggest that ligand binding may be mediated primarily by hydrophobic and van der Waals interactions (Fig. 22-6).<sup>21</sup>

The correlation between local anesthetic potency and lipophilicity is **5** generally observed in vitro; however, it may be less exact in vivo. Compared with experimental setups using isolated nerves, many other factors may influence the potency of local anesthetics on nerves in situ.<sup>36</sup> Highly

lipid-soluble agents may be sequestered into surrounding adipose cells and myelin sheaths. Local anesthetics cause vasodilation, which in turn could alter regional drug redistribution.<sup>37,38</sup> Finally, mounting evidence suggests that some local anesthetics can enter certain neurons via nonspecific cation channels, thereby circumventing the membrane barrier altogether.<sup>31</sup> Hence, relative potency of local anesthetics has been determined clinically for different applications, and these values are listed in [Table 22-4](#).

Finally, anesthetic activity and potency are affected by the stereochemistry of the local anesthetic molecules. Many older drug preparations exist as racemic mixtures; that is, enantiomeric stereoisomers are in equal proportion. Newer agents, namely, ropivacaine and levobupivacaine, are available as specific enantiomers. They were initially developed as less cardiotoxic alternatives to bupivacaine. Although the desired improvement in the safety index has been generally supported in clinical studies, this is at the expense of a slight decrease in potency overall and shorter duration of action compared with racemic mixtures.<sup>39,40</sup> The underlying mechanism has not been defined. Topographic features at the channel-binding site are likely to play a key role in stereoselectivity of local anesthetics.

**Table 22-3** Physicochemical Properties of Clinically Used Local Anesthetics

Local Anesthetic	pK <sub>a</sub>	Percent Ionized (at pH 7.4)	Partition Coefficient (Lipid Solubility)	Percent Protein Binding
<b>Amides</b>				
Bupivacaine <sup>a</sup>	8.1	83	3,420	95

## 6 Additives to Increase Local Anesthetic Activity

## Epinephrine

Reported benefits of epinephrine include prolongation of local anesthetic block, increased intensity of block, and decreased systemic absorption of local anesthetic.<sup>41</sup> Epinephrine's vasoconstrictive effects augment local anesthetics by antagonizing inherent vasodilating effects of local anesthetics, decreasing systemic absorption and intraneural clearance, and perhaps by redistributing intraneural local anesthetic.<sup>41,42</sup>

Direct analgesic effects from epinephrine may also occur via interaction with  $\alpha_2$ -adrenergic receptors in the brain and spinal cord,<sup>43</sup> especially because local anesthetics increase the vascular uptake of epinephrine.<sup>44</sup> The clinical effects of the use of epinephrine are listed in [Table 22-5](#). The smallest dose is suggested because epinephrine combined with local anesthetics may have toxic effects on tissue,<sup>45</sup> the cardiovascular system,<sup>46</sup> peripheral nerves, and the spinal cord.<sup>41</sup>

## Alkalinization of Local Anesthetic Solution

Local anesthetic solutions are alkalinized in order to hasten onset of neural block.<sup>47</sup> The pH of commercial preparations of local anesthetics ranges from 3.9 to 6.5 and is especially acidic if prepackaged with epinephrine.<sup>48</sup> Because the  $pK_a$  of commonly used local anesthetics ranges from 7.6 to 8.9 ([Table 22-3](#)), less than 3% of the commercially prepared local anesthetics exist as the lipid-soluble neutral form. As previously discussed, the neutral form is believed to be important for penetration into the neural cytoplasm, whereas the charged form primarily interacts with the local anesthetic receptor within the sodium channel. Therefore, the rationale for alkalinization was to increase the ratio of local anesthetic existing as the lipid-soluble neutral form. However, clinically used local anesthetics cannot be alkalinized beyond a pH of 6.05 to 8 before precipitation occurs<sup>48</sup> and these pH values will only increase the neutral form to about 10%.

**Table 22-5** Effects of Addition of Epinephrine to Local Anesthetics

	Increase Duration	Decrease Blood Levels (%)	Dose/Concentration of Epinephrine
<b>Nerve Block</b>			
Bupivacaine	+/-	10–20	1:200,000
Lidocaine	++	20–30	1:200,000
Mepivacaine	++	20–30	1:200,000
Ropivacaine	--	0	1:200,000
<b>Epidural</b>			
Bupivacaine	+/-	10–20	1:300,000–1:200,000
Levobupivacaine	+/-	10	1:200,000–1:400,000
Chloroprocaine	++		1:200,000
Lidocaine	++	20–30	1:600,000–1:200,000
Mepivacaine	++	20–30	1:200,000
Ropivacaine	--	0	1:200,000
<b>Spinal</b>			
Bupivacaine	+/-		0.2 mg
Lidocaine	++		0.2 mg
Tetracaine	++		0.2 mg

++, overall supported; --, overall not supported; +/-, inconsistent.

Data from Liu SS. Local anesthetics and analgesia. In: Ashburn MA, Rice LJ, eds. *The Management of Pain*. New York: Churchill Livingstone; 1997:141; and Kopacz DJ. A comparison of epidural levobupivacaine 0.5% with or without epinephrine for lumbar spine surgery. *Anesth Analg*. 2001;93:755.

Clinical studies on the association between alkalinization of local anesthetics and hastening of block onset have shown an improvement of less than 5 minutes compared with commercial preparations.<sup>47,49</sup> Furthermore, results from a study in rats indicate that alkalinization of lidocaine may also decrease the duration of peripheral nerve blocks if the mixture contained no epinephrine.<sup>50</sup> Together, alkalinization of local anesthetics appears limited as a clinically useful adjuvant to improving anesthesia.

## Opioids

Opioids have multiple central and peripheral mechanisms of analgesic action (see [Chapter 20](#)). Spinal administration of opioids provides analgesia primarily by attenuating C-fiber nociception<sup>51</sup> and is independent of supraspinal mechanisms.<sup>52</sup> Coadministration of opioids with central neuraxial local anesthetics results in synergistic analgesia.<sup>53</sup> An exception to this analgesic synergy is chloroprocaine, which appears to decrease the effectiveness of opioids coadministered epidurally.<sup>54</sup> The reason is unclear, but the mechanism does not seem to involve direct antagonism of opioid receptors.<sup>55</sup> Nonetheless, clinical studies support the practice of central neuraxial coadministration of local anesthetics and opioids for prolongation and intensification of analgesia and anesthesia.<sup>53</sup>

The discovery of peripheral opioid receptors initially generated much interest in the use of opioids as adjuvants to local anesthetics for peripheral nerve blockade.<sup>56</sup> However, although some studies have reported favorable outcomes for such coadministration, others have failed to demonstrate any

increased efficacy.<sup>57</sup> A problem that has plagued many studies is the lack of adequate controls for differentiating the analgesic effects of opioids acting peripherally versus a more central mechanism resulting from systemically absorbed opioids. Nonetheless, recent carefully designed trials have shown that some opioids, namely, buprenorphine, may enhance and prolong postoperative analgesia better than either local anesthetics alone or local anesthetics administered with intramuscular buprenorphine.<sup>58,59</sup> Finally, cumulative evidence does not support the use of intra-articular coadministration of local anesthetic and opioid for postoperative analgesia.<sup>60</sup>

## **β<sub>2</sub>-Adrenergic Agonists**

α<sub>2</sub>-Adrenergic agonists can be a useful adjuvant to local anesthetics. α<sub>2</sub>-Specific agonists such as clonidine produce analgesia via supraspinal and spinal adrenergic receptors.<sup>61</sup> Clonidine also has direct inhibitory effects on peripheral nerve conduction (A and C nerve fibers).<sup>62</sup> Thus, addition of clonidine may have multiple mechanisms of action depending on the type of application. Preliminary evidence suggests that coadministration of an α<sub>2</sub>-agonist and local anesthetic results in central neuraxial and peripheral nerve analgesic synergy,<sup>63</sup> whereas systemic (supraspinal) effects are additive.<sup>64</sup> On average, clonidine improves the duration of analgesia by about 2 hours, regardless of whether an intermediate- or long-acting local anesthetic is used.<sup>65</sup> Overall, results from clinical trials indicate that clonidine can enhance local anesthetic effects when used for intrathecal and epidural anesthesia and peripheral nerve blocks.<sup>65,66</sup>

## **Steroids**

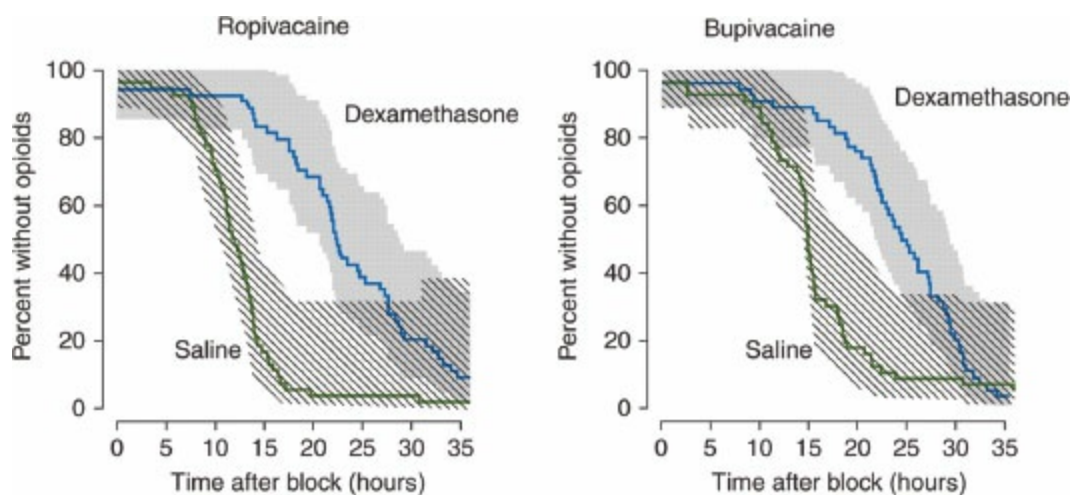

Potent glucocorticoid injections have been widely used for the treatment of chronic low back pain caused by radiculopathy. Experiments in animals using extended-release preparations of local anesthetics have found that addition of dexamethasone to the mixture prolongs the conduction block after peripheral nerve application.<sup>67,68</sup> The duration of the blockade is associated with the potency of the glucocorticoid activity and appears to be steroid receptor dependent and locally mediated.<sup>69</sup> Clinical reports of the use of dexamethasone as an adjuvant to local anesthetics have shown similar prolongation of anesthesia after brachial plexus blockades<sup>70,71</sup> and intravenous regional anesthesia.<sup>72</sup> Combined with intermediate- to long-acting local anesthetics, dexamethasone extends the duration of analgesia by approximately 50% after supraclavicular<sup>70</sup> or interscalene approaches<sup>71</sup> to the brachial plexus block (Fig. 22-8). Although initial laboratory data show no evidence of increased neurotoxicity from use of dexamethasone as compared with other adjuvants, our current understanding of its mechanism of action

and potential side effects remains incomplete.<sup>73</sup>

## Liposomes

Commercially available preparations of liposomal bupivacaine are designed to provide sustained release of encapsulated bupivacaine after a single administration. Currently, such preparations are approved for local infiltration of surgical wounds after bunionectomy and hemorrhoidectomy.<sup>74,75</sup> Compared with placebo controls, liposomal bupivacaine reduced cumulative pain score, increased time to first opioid use, and required less rescue analgesia. However, in trials with active comparators (i.e., plain bupivacaine), there was no statistically significant difference among the cumulative pain scores across the treatment groups.<sup>76,77</sup> A direct comparison based on equivalent content of the bupivacaine (1.33%) showed that the addition of a liposomal formulation extends the block duration by a modest 14% (240 minutes vs. 210 minutes for liposomal bupivacaine and 1.33% bupivacaine, respectively).<sup>78</sup>

**Figure 22-8** Addition of dexamethasone to either ropivacaine or bupivacaine increases the duration of analgesia after interscalene brachial plexus block. Data are shown as the Kaplan–Meier survival density estimates, with the shaded region representing the 95% confidence interval. (Reprinted with permission from Cummings KC, Napierkowski DE, Parra-Sanchez I, et al. Effect of dexamethasone on the duration of interscalene nerve blocks with ropivacaine or bupivacaine. *Br J Anaesth.* 2011;107:446.)

In animal models, perineural infiltration of liposomal bupivacaine was associated with tissue inflammation and myotoxicity.<sup>78</sup> The degree of myotoxicity was comparable to that of 0.5% bupivacaine, although the inflammation due to liposomal bupivacaine persisted for much longer duration. There was no evidence of local neurotoxicity or CNS or cardiac toxicity.<sup>79</sup> Clinically, most frequently reported untoward effects of liposomal bupivacaine were nausea and pyrexia.<sup>80</sup>

## Pharmacokinetics of Local Anesthetics

Plasma concentration of local anesthetics is a function of the dose administered and the rates of systemic absorption, tissue distribution, and drug elimination. Elevated levels may produce unintended effects in other electric-sensitive systems, most importantly, the cardiovascular system and the CNS. Having a thorough understanding of the factors involved would enable one to maximize the local anesthetic potential while avoiding possible complications arising from systemic local anesthetic toxicity.

### Systemic Absorption

**7** Decreasing systemic absorption of local anesthetics increases their safety margin in clinical uses. The rate and extent of systemic absorption depends on the site of injection, the dose, the drug's intrinsic pharmacokinetic properties, and the addition of a vasoactive agent. The vascularity of the tissue markedly influences the rate of drug absorption, such that deposition of local anesthetics in vessel-rich tissues results in higher peak plasma levels in a shorter period of time. Accordingly, the rate of systemic absorption is greatest with intercostal nerve blocks, followed in decreasing order by caudal and epidural injections, brachial plexus block, and femoral and sciatic nerve blocks (Table 22-6). Thus, the same amount of local anesthetics injected would result in unequal peak plasma levels depending on the site of drug delivery.

For a given site of injection, the rate of systemic absorption and the peak plasma level are directly proportional to the dose of local anesthetic deposited. This relationship is nearly linear (Fig. 22-9) and independent of the drug concentration and the speed of injection.<sup>81</sup>

The rate of systemic absorption differs with individual local anesthetics. In general, more potent lipid-soluble agents are associated with a slower rate of absorption than less lipid-soluble compounds (Fig. 22-10). Sequestration into lipid-rich compartments may not be the only explanation. Local anesthetics exert direct effects on vascular smooth muscles in a concentration-dependent manner. At low concentrations, more potent agents appear to cause more vasoconstriction than less potent agents, thereby decreasing the rate of vascular absorption.<sup>38</sup> At high concentrations, vasodilatory effects seem to predominate for most local anesthetics.

**Table 22-6** Typical  $C_{max}$  after Regional Anesthesia with Commonly Used Local Anesthetics

Local Anesthetic	Technique	Dose (mg)	$C_{max}$ ( $\mu\text{g/mL}$ )	$T_{max}$ (min)	Toxic Plasma Concentration ( $\mu\text{g/mL}$ )
Bupivacaine	Brachial plexus	150	1.0	20	3

## Distribution

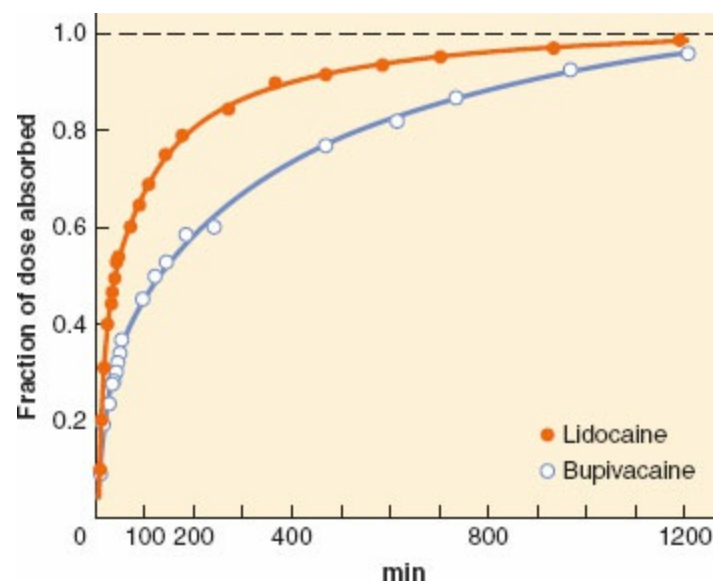

Systemic absorption of local anesthetics leads to rapid distribution throughout the body. The steady-state drug concentration in plasma can be readily derived from the apparent volume of distribution ( $VD_{ss}$ ; Table 22-7); however, regional differences in local anesthetic concentrations are seen among individual organ systems. The pattern of distribution is largely dependent on organ perfusion, the partition coefficient between compartments, and plasma protein binding.<sup>82</sup> Organs that are well perfused, such as the heart and the brain, have higher drug concentrations. Unfortunately, they are also the organs most seriously affected by local anesthetic toxicity.

**Figure 22-9** Increasing doses of ropivacaine used for wound infiltration result in linearly increasing maximal plasma concentrations ( $C_{max}$ ). (Data from Mulroy MF, Burgess FW, Emanuelsson B-M. Ropivacaine 0.25% and 0.5%, but not 0.125%, provide effective wound infiltration analgesia after outpatient hernia repair, but with sustained plasma drug levels. *Reg Anesth Pain Med.* 1999;24:136.)

## Elimination

The metabolic pathway for clearance of local anesthetics is primarily determined by their chemical linkage. Aminoesters are hydrolyzed by plasma cholinesterases and aminoamides are transformed by hepatic carboxylesterases and cytochrome P450 enzymes. Severe liver disease may slow the clearance of aminoamide local anesthetics and significant drug levels may therefore accumulate.<sup>83</sup>

**Figure 22-10** Fraction of dose absorbed into the systemic circulation over time from epidural injection of lidocaine or bupivacaine. Bupivacaine is a more lipid-soluble and more potent agent with less systemic absorption over time. (Adapted from Tucker GT, Mather LE. Properties, absorption, and disposition of local anesthetic agents. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain.* Philadelphia, PA: Lippincott-Raven; 1998:55.)

**Table 22-7** Pharmacokinetic Parameters of Clinically Used Local Anesthetics

Local Anesthetic	VD <sub>ss</sub> (L/kg)	CL (L/kg/h)	T <sub>1/2</sub> (hours)
Bupivacaine	1.02	0.41	3.5
Levobupivacaine	0.78	0.32	2.6

Pharmacokinetics of the enantiomers of bupivacaine following intravenous administration of the racemate. *Br J Clin Pharmacol*. 1994;38:125.

## Clinical Pharmacokinetics

The primary benefit of understanding the systemic pharmacokinetics of local anesthetics is the ability to predict the peak plasma level ( $C_{\max}$ ) after the agents are administered, thereby avoiding the administration of toxic doses (Tables 22-6, 22-8, and 22-9). Nonetheless, pharmacokinetics are difficult to predict in any given circumstance because both physical and pathophysiologic characteristics will affect the individual pharmacokinetics. There is some evidence for increased systemic plasma levels of local anesthetics in the very young and in the elderly owing to decreased clearance and increased absorption<sup>84</sup>; however, the correlation of systemic blood levels between the dose of local anesthetic and weight is often inconsistent (Fig. 22-11).<sup>85</sup> Effects of gender on clinical pharmacokinetics of local anesthetics have not been well defined,<sup>86</sup> although pregnancy may decrease clearance.<sup>87</sup> Pathophysiologic states such as cardiac and hepatic disease will alter expected pharmacokinetic parameters (Table 22-10), and lower doses of local anesthetics should be used for these patients. As expected, renal disease has little effect on pharmacokinetic parameters of local anesthetics (Table 22-10). All of these factors should be considered when using local anesthetics and minimizing systemic toxicity, the commonly accepted maximal dosages (Table 22-9) notwithstanding.

**Table 22-8** Relative Potency for Systemic Central Nervous System Toxicity by Local Anesthetics and Ratio of Dosage Needed for Cardiovascular System: Central Nervous System (CVS:CNS) Toxicity

Agent	Relative Potency for CNS Toxicity	CVS:CNS

## Clinical Use of Local Anesthetics

There are a myriad of uses of local anesthetics in the modern practice of anesthesia. They all take advantage of their ability to attenuate or block pain and other noxious stimuli. When applied topically to the skin, a eutectic mixture of lidocaine and prilocaine reduces the sharp, painful sensation associated with needle insertion and intravenous catheter placement, particularly in the pediatric population. In the awake patient, aerosolized benzocaine and viscous lidocaine directed at the mucosal surface can help blunt the protective reflex responses associated with airway instrumentation (see [Chapter 28](#)). In addition, lidocaine can be given intravenously to decrease the incidence and the severity of pain associated with propofol administration (see [Chapters 19, 31](#)). Likewise, intravenous lidocaine may also help to reduce the hemodynamic response to tracheal intubation and extubation.<sup>88,89</sup>

By far the most common application, local infiltration of the dermis, provides quick onset of anesthesia suitable for a broad variety of minor superficial procedures. The clinical profile of some commonly used agents is listed in [Table 22-9](#). For a wider and greater area of coverage, a regional anatomic approach to anesthesia and analgesia can be used. This can be accomplished either by intravenous administration of local anesthetics to a limb under pneumatic compression (Bier block) or by direct application of local anesthetics to individual peripheral nerves (nerve blocks). Local anesthetics can be deposited centrally near the nerve roots, either intrathecally in the lumbar cistern or epidurally in the thoracic, lumbar, and caudal regions of the spine (see [Chapter 35](#)). Alternatively, injections can be made peripherally at the plexus, such as at the brachial or lumbar plexus block or on the nerve fibers (see [Chapter 36](#)). The duration of the anesthesia and analgesia is dependent on the type of local anesthetics

used, though it can be extended with continuous infusion through an indwelling catheter.

**Table 22-10** Effects of Cardiac, Hepatic, and Renal Disease on Lidocaine Pharmacokinetics

	VD <sub>ss</sub> (L/kg)	CL (mL/kg/min)	T <sub>1/2</sub> (hours)
Normal	1.32	10.0	1.8
Cardiac failure	0.88	6.3	1.9
Hepatic disease	2.31	6.0	4.9
Renal disease	1.2	13.7	1.3

VD<sub>ss</sub>, volume of distribution at steady state; CL, total body clearance; T<sub>1/2</sub>, terminal elimination half-life.

## Toxicity of Local Anesthetics

### Systemic Toxicity of Local Anesthetics

#### Central Nervous System Toxicity

Local anesthetics readily cross the blood–brain barrier and, as a result, CNS toxicity can occur with systemic absorption or inadvertent intravascular injections. The effects on the CNS are determined by the plasma concentration of the local anesthetics (Table 22-11). At low plasma concentration, mild disturbances to the sensory systems appear. As the plasma concentration increases, CNS excitation and seizure activities predominate. If the plasma concentration is sufficiently large or the increase is rapid, the CNS excitation may progress to generalized CNS depression and coma, leading to respiratory depression and arrest.<sup>90</sup>

The potential for CNS toxicity correlates directly with the potency of local anesthetics (Tables 22-4 and 22-8).<sup>90</sup> Highly potent lipid-soluble agents such as bupivacaine can cause CNS toxicity at doses that are a fraction of those of less potent agents. The potential for CNS toxicity is further modified by other factors. For example, a decrease in protein binding and clearance of local anesthetics, systemic acidosis, hypercapnia, and hypercarbia can all increase the risk for CNS toxicity. Conversely, coadministration of CNS depressive agents, such as barbiturates and benzodiazepines, may decrease the likelihood for seizures.<sup>91</sup>

Clinical reports suggest that CNS toxicity associated with the use of local anesthetics in regional anesthesia is uncommon. Surveys from France and the United States of over 280,000 cases involving regional anesthesia show an incidence of seizures of approximately 1/10,000 with epidural injections and

7/10,000 with peripheral nerve blocks.<sup>92,93</sup> The higher incidence of CNS toxicity resulting from peripheral nerve blocks may be due to differences in practice or, perhaps, decreased clinical awareness. Nonetheless, in an analysis of closed malpractice claims in the United States from 1980 to 1999, epidural anesthesia (primarily obstetrical) constituted all of the cases of death or brain damage resulting from unintentional intravenous injection of local anesthetic.<sup>94</sup>

**Table 22-11** Dose-Dependent Systemic Effects of Lidocaine

Plasma Concentration (µg/mL)	Effect
1-5	Analgesia
5-10	Lightheadedness Tinnitus Numbness of tongue
10-15	Seizures Unconsciousness
15-25	Coma Respiratory arrest
>25	Cardiovascular depression

### Cardiovascular Toxicity of Local Anesthetics

**8** In general, systemic cardiovascular toxicity is seen at a plasma concentration far greater than that for CNS toxicity. The potential for cardiovascular toxicity, like that for CNS toxicity, correlates closely with the potency, or lipid solubility, of local anesthetics (Tables 22-4 and 22-8). However, although all local anesthetics can cause hypotension, dysrhythmias, and myocardial depression, more potent agents (bupivacaine, ropivacaine, and levobupivacaine) are predisposed to devastating outcomes, such as fatal cardiovascular collapse and complete heart block (Fig. 22-12).<sup>95</sup>

Among the potent long-acting agents, ropivacaine and levobupivacaine may have a safer cardiovascular toxicity profile than bupivacaine. In animal models, both ropivacaine and levobupivacaine appear to exhibit 30% to 40% less cardiovascular toxicity than bupivacaine on a milligram-to-milligram basis (Fig. 22-13)<sup>34,90,96</sup>; however, in human studies, that difference appears less striking (Fig. 22-14).<sup>97,98</sup> Detailed electrophysiologic studies with isolated heart muscles and cultured cardiomyocytes support the view that *S*(-)-bupivacaine (levobupivacaine) is generally less potent than *R*(+)-bupivacaine in blocking both the cardiac action potential<sup>99</sup> and binding of voltage-gated sodium channels during the inactivated stage.<sup>100</sup> Likewise for ropivacaine, evidence suggests that the propyl side chain renders it less cardiodepressive than the larger butyl side chain of bupivacaine.<sup>101</sup>

The underlying pathophysiology responsible for local anesthetic-induced

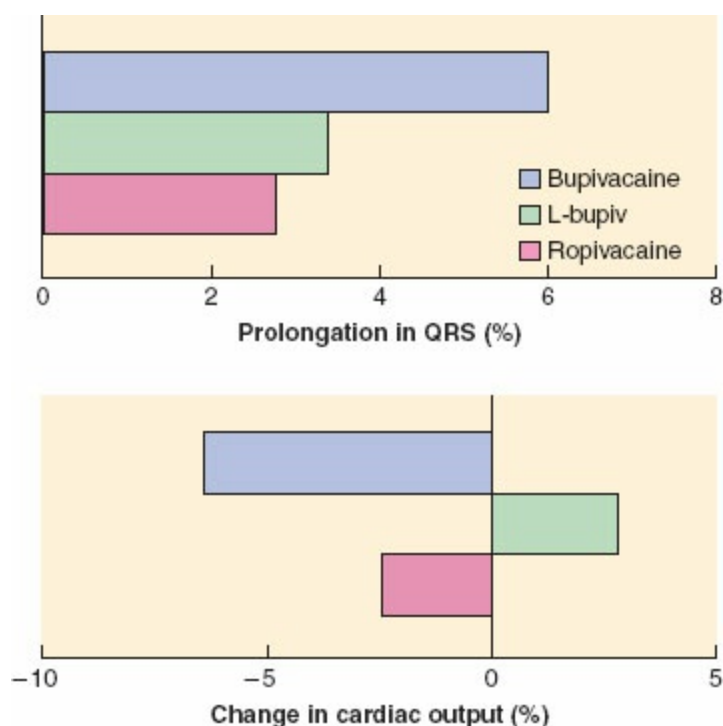

cardiovascular collapse has not been fully established. Although local anesthetics can directly cause major disturbances to the heart, their effects on other components of cardiovascular systems may be just as important. For example, systemic bupivacaine has been shown to impair regulation by the CNS of the cardiovascular system. Disruption to the arterial baroreflex in the brainstem by bupivacaine can lead to attenuation of the heart rhythm response to changes in blood pressure.<sup>102,103</sup> Local anesthetics also act on smooth muscle endothelium surrounding blood vessels. In the periphery, vasoconstriction occurs at subclinical doses and vasodilation at higher doses.<sup>104</sup> In the pulmonary vasculature, however, increasing local anesthetic concentrations produce marked pulmonary artery hypertension.<sup>105</sup> The increase in the pulmonary vascular resistance occurs prior to any significant decrease in the cardiac output, suggesting that the result is a primary effect of local anesthetic intoxication, rather than secondary to a decline in cardiac contractility.

**Figure 22-12** Success of resuscitation of dogs after cardiovascular collapse from intravenous infusions of lidocaine, bupivacaine, levobupivacaine (L-bupiv), and ropivacaine. Success rates were greater for lidocaine (100%) compared to ropivacaine (90%), levobupivacaine (70%), and bupivacaine (50%). Required doses to induce cardiovascular collapse were greater for lidocaine (127 mg/kg) compared to ropivacaine (42 mg/kg), levobupivacaine (27 mg/kg), and bupivacaine (22 mg/kg). (Data from Groban L, Deal DD, Vernon JC, et al. Cardiac resuscitation after incremental overdose with lidocaine, bupivacaine, levobupivacaine, and ropivacaine in anesthetized dogs. *Anesth Analg.* 2001;92:37.)

**Figure 22-13** Serum concentrations in sheep at each toxic manifestation for bupivacaine, levo (L)-bupivacaine, and ropivacaine. Both levobupivacaine and ropivacaine required significantly greater serum concentrations than bupivacaine. (Data from Santos AC, DeArmas PI. Systemic toxicity of levobupivacaine, bupivacaine, and ropivacaine during continuous intravenous infusion to nonpregnant and pregnant ewes. *Anesthesiology*. 2001;95:1256.)

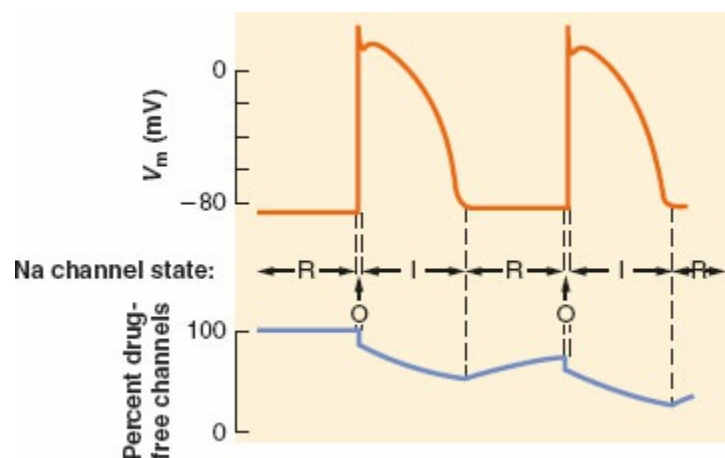

**Figure 22-14** Mild prolongation in QRS interval and change in cardiac output after intravenous infusions of bupivacaine (103 mg), levobupivacaine (L-bupiv; 37 mg), and ropivacaine (115 mg) in healthy volunteers. (Data from Knudsen K, Beckman Suurkula M, Blomberg S, et al. Central nervous and cardiovascular effects of i.v. infusions of ropivacaine, bupivacaine and placebo in volunteers. *Br Anaesth*. 1997;78:507; and Stewart J, Kellett N, Castro D. The central nervous system and cardiovascular effects of levobupivacaine and ropivacaine in healthy volunteers. *Anesth Analg*. 2003;97:412.)

Elevated concentrations of local anesthetics have been shown to delay cardiac electrical conductivity and decrease cardiac contractility. Although all local anesthetics disturb the cardiac conduction system via a dose-dependent

block of sodium channels (seen clinically as a prolongation of the PR interval and duration of the QRS complex), several features unique to bupivacaine seem to potentiate its cardiotoxicity. First, bupivacaine has an inherently greater affinity for binding resting and inactivated sodium channels than lidocaine.<sup>106</sup> Second, although all local anesthetics bind sodium channels during cardiac systole and dissociate during diastole (Fig. 22-15), the dissociation of bupivacaine during diastole occurs more slowly than lidocaine. This slow rate of dissociation prevents a complete recovery of the channels at the end of each cardiac cycle (at the physiologic heart rate of 60 to 80 beats/min), thereby leading to an accumulation and worsening of the conduction defect. In contrast, lidocaine fully dissociates from sodium channels during diastole and little accumulation of conduction delay occurs (Fig. 22-16).<sup>106,107</sup> Finally, bupivacaine exerts a greater degree of direct myocardial depression than less potent agents (Fig. 22-17).<sup>90,101</sup>

Current understanding of the molecular mechanisms underlying local anesthetic cardiac toxicity is limited. It is widely accepted that local anesthetics bind and disrupt the normal function of the heart-specific voltage-gated sodium channel,  $Na_v$  1.5, in cardiac myocytes; however, there appear to be other intracellular targets as well. Local anesthetics have been shown to antagonize the currents of other cations, primarily calcium and potassium.<sup>106</sup> The degree of antagonism between bupivacaine and less potent agents appears to differ, and that difference may contribute to the severity in the disturbance of the cardiac membrane potentials. Lastly, individuals and experimental animal models with L-carnitine deficiency exhibit an increased susceptibility to local anesthetic-associated cardiac toxicity, suggesting that local anesthetics can affect mitochondrial function and fatty acid metabolism.<sup>108,109</sup>

**Figure 22-15** Diagram illustrating the relationship between cardiac action potential (*top*), sodium channel state (*middle*), and block of sodium channels by bupivacaine (*bottom*). Sodium channels are predominantly in the resting form during diastole, open transiently during the action potential upstroke, and are in the inactive form during the

action potential plateau. Block of sodium channels by bupivacaine accumulates during the action potential (systole), with recovery occurring during diastole. Recovery of sodium channels results from dissociation of bupivacaine and is time-dependent. Recovery during each diastolic interval is incomplete and results in accumulation of sodium channel block with successive heartbeats. R, resting form; O, open form; I, inactive form. (Adapted with permission from Clarkson CW, Hondegham LM. Mechanisms for bupivacaine depression of cardiac conduction: fast block of sodium channels during the action potential with slow recovery from block during diastole. *Anesthesiology*. 1985;62:396.)

**Figure 22-16** Heart rate–dependent effects of lidocaine and bupivacaine on velocity of the cardiac action potential ( $V_{max}$ ). Bupivacaine progressively decreases  $V_{max}$  at heart rates above 10 beats/min because of accumulation of sodium channel block, whereas lidocaine does not decrease  $V_{max}$  until heart rate exceeds 150 beats/min. (Adapted with permission from Clarkson CW, Hondegham LM. Mechanisms for bupivacaine depression of cardiac conduction: Fast block of sodium channels during the action potential with slow recovery from block during diastole. *Anesthesiology*. 1985;62:396.)

### Treatment of Systemic Toxicity from Local Anesthetics

The best practice for managing systemic local anesthetic intoxication starts with vigilance and prevention. Elevated plasma levels of local anesthetics can occur by inadvertent intravascular injections or systemic absorption. The risk for intravascular injections can be reduced by using a local anesthetic test dose (about 3 mL), frequently aspirating the injectate for signs of blood return, and dividing the dose of the local anesthetics.<sup>91,110</sup> Understanding the drug’s pharmacokinetic profile and having a good knowledge of the anatomy in the area of local anesthetic injection may help predict the rate of tissue absorption, and thus avoid toxic systemic accumulation. Heart rate and rhythm, blood pressure, and oxygenation should be monitored at all times. Early CNS toxicity may be manifested by tinnitus or excessive sedation.

**Figure 22-17** Plasma concentrations required to induce myocardial depression in dogs administered bupivacaine, levobupivacaine (L-bupiv), ropivacaine, and lidocaine.  $dP/dt_{max}$ , 35% reduction of inotropy from baseline measure; %EF, 35% reduction in ejection fraction from baseline measure; CO, 25% reduction in cardiac output from baseline measure. (Data from Groban L, Deal DD, Vernon JC, et al. Does local anesthetic stereoselectivity or structure predict myocardial depression in anesthetized canines? *Reg Anesth Pain Med.* 2002;27:460.)

The treatment of suspected systemic local anesthetic toxicity is primarily supportive. Administration of local anesthetic should cease immediately. Oxygenation and ventilation should be maintained and the airway, if necessary, must be secured. This is necessary not only as a standard part of resuscitation but also to prevent further exacerbation of local anesthetic toxicity by hypoxemia, hypercapnia, and acidemia.<sup>91</sup> In many cases, with proper airway management and reversal of acidosis, more serious complications of local anesthetic intoxication can be avoided, especially in cases involving less potent agents.

Local anesthetic-induced seizure activity can vastly increase the body's metabolism and the resultant metabolic acidosis may make resuscitation more difficult. Prolonged seizures should therefore be suppressed. Benzodiazepines, such as midazolam or diazepam, have been shown to raise the seizure threshold in animals and are the preferred agents for preventing and terminating seizures. Hypnotic agents, such as propofol and thiopental, may not be best suited for terminating local anesthetic-induced seizures, because at significant doses, they can potentiate the myocardial depression exerted by the causative agent.<sup>110</sup> If seizure activity is prolonged, succinylcholine or other neuromuscular blockers can be administered not only to facilitate pulmonary ventilation but also to disrupt muscular activity and reduce the consequent metabolic demand. However, it is important to note that muscle relaxants do not reduce the electrical excitation in the CNS and cerebral metabolic stress may continue unabated.

Mild myocardial depression and systemic vasodilation can be corrected with sympathomimetic agents such as ephedrine or epinephrine. Pending cardiovascular collapse from severe cardiac dysrhythmias should prompt

immediate initiation of cardiopulmonary resuscitation. For ventricular fibrillation and cardiac arrest, electrocardioversion and pharmacologic means should be attempted to restore sinus rhythm. Epinephrine, in small initial doses, and amiodarone are the preferred agents. Calcium channel and  $\beta$ -adrenergic receptor blocking drugs can worsen myocardial function and are best avoided.<sup>110</sup> Historically, emergent cardiopulmonary bypass was considered the only effective life-saving measure for otherwise fatal dysrhythmias and cardiac collapse resulting from local anesthetic cardiac toxicity.<sup>111,112</sup> However, evidence is accumulating to support the use of an intravenous infusion of lipid emulsion to hasten the return of normal cardiac function. Studies in animals have demonstrated efficacy of a lipid infusion in reversing bupivacaine-induced asystole.<sup>113,114</sup> Subsequent clinical reports have described successful resuscitation using lipid emulsions in individuals with local anesthetic-induced cardiac arrest.<sup>115,116</sup> The lipid emulsion may act as a plasma “sink” to absorb tissue-bound local anesthetics via partition principles.<sup>117</sup> Alternatively, the lipids may provide a usable energy source to bypass the impediment on the cardiac mitochondria.<sup>118</sup> A summary of the American Society of Regional Anesthesia and Pain Medicine practice advisory on treatment of local anesthetic systemic toxicity is listed in [Table 22-12](#).

**Table 22-12** Practice Advisory on Treatment of Local Anesthetic Systemic Toxicity

For Patients Experiencing Signs or Symptoms of Local Anesthetic Systemic Toxicity	
1	<b>Get Help</b>
2	<b>Initial Focus</b> Airway management: ventilate with 100% oxygen Seizure suppression: benzodiazepines are preferred Basic and advanced cardiac life support
3	<b>Infuse 20% Lipid Emulsion</b> Initiate intravenous bolus of 1.5 mL/kg over 1 minute Continue infusion at 0.25 mL/kg/min for at least 10 minutes after the return of cardiac function If cardiovascular instability continues, consider repeating the bolus and increasing the infusion to 0.5 mL/kg/min Up to 10 mL/kg over 30 minutes is the recommended upper limit for initial dosing
4	<b>Avoid</b> vasopressin, calcium channel blockers, beta blockers, or local anesthetics
5	<b>Alert</b> the nearest facility having cardiopulmonary bypass capability
6	<b>Avoid</b> propofol in patients having signs of cardiovascular instability

Adapted from Neal JM, Barnards CM, Butterworth JF, et al. ASRA practice advisory on local anesthetic systemic toxicity. *Reg Anesth Pain Med.* 2010;35;152.

## Neural Toxicity of Local Anesthetics

In addition to their systemic effects, direct application of local anesthetics can result in histopathologic changes consistent with neuronal injury. The causative mechanisms remain speculative, but studies in animals and tissue cultures show evidence of demyelination, Wallerian degeneration, dysregulation of axonal transport, disruption of the blood–nerve barrier, decreased blood flow to the vasa nervorum, and loss of cell membrane integrity.<sup>119,120</sup> The degree of neural injury appears to correlate with possible intraneural placement of local anesthetic, as well as the drug concentration and the duration of exposure to the local anesthetics. Intrafascicular injections result in more histologic changes than either extrafascicular or extraneural placement, with the latter associated with the mildest damage.<sup>121</sup> In large concentrations, all clinically important local anesthetics can produce dose-dependent abnormalities in nerve fibers; however, in clinically relevant concentrations, they appear generally safe.<sup>122,123</sup>

The significance of these experimental findings is unclear, because clinical injury is rare. A systematic review of approximately 2.7 million centrally administered local anesthetic neuraxial blocks determined an occurrence of radiculopathy at approximately 0.03% and of paraplegia at approximately 0.0008%.<sup>124</sup> Furthermore, direct intraneural injections of local anesthetics per se do not invariably lead to detectable neurologic symptoms.<sup>125</sup> Nonetheless, there have been clinical scenarios in which a greater propensity for nerve injury has been described. The use of microcatheters with a high concentration of lidocaine for continuous spinal anesthesia has been associated with an increased incidence of radiculopathy and cauda equina syndrome.<sup>126</sup> Likewise, chloroprocaine, used until the early 1980s for epidural and intrathecal injections, has been linked to prolonged sensory and motor deficits, possibly due to toxic effects of the preservative, sodium bisulfite.<sup>127</sup> Although the clinical use of local anesthetics appears to be safe, it behooves the practitioner to be mindful of their potential deleterious effects on nerves.

### ***Transient Neurologic Symptoms after Spinal Anesthesia***

Prospective randomized studies reveal a 4% to 40% incidence of transient neurologic symptoms (TNSs), including pain or sensory abnormalities in the lower back, buttocks, or lower extremities, after lidocaine spinal anesthesia<sup>128,129</sup> (see [Chapter 35](#)). These symptoms have been reported with other local anesthetics as well ([Table 22-13](#)), but have not resulted in permanent neurologic injury.<sup>128</sup> Increased risk of TNSs is associated with lidocaine, the lithotomy position, and ambulatory anesthesia, but not with baricity of solution or dose of local anesthetic.<sup>128,129</sup> The potential neurologic etiology of this syndrome coupled with known concentration-dependent toxicity of lidocaine led to concerns over a neurotoxic etiology for TNSs from

spinal lidocaine.

However, evidence for a direct linear relation between nerve toxicity and symptoms is scant. Although the concentration of local anesthetics may be a strong factor for determining nerve injury, such as with cauda equina syndrome, there does not appear to be a dose relation in TNSs. The incidence of TNSs is similar when there is a 10-fold difference in the concentration of lidocaine utilized (0.5% and 5%).<sup>130</sup> Furthermore, a study comparing volunteers with and without TNSs after lidocaine spinal anesthesia shows no abnormalities detectable by routine electrophysiologic testing, such as electromyography, nerve conduction, or somatosensory-evoked potentials. Finally, effective treatment for TNS includes nonsteroidal anti-inflammatory agents and trigger point injections. These are regimens more effective for alleviating myofascial pain than for neuropathic pain.<sup>128</sup> Overall, there is little evidence to support a neurotoxic etiology for TNSs.<sup>128</sup> Other potential etiologies for TNSs include patient positioning, sciatic nerve stretch, muscle spasm, and myofascial strain.<sup>128</sup>

### **Myotoxicity of Local Anesthetics**

As with neural toxicity, local anesthetics can also cause histopathologic changes in skeletal muscle. Myotoxicity can result from most local anesthetic agents in clinically relevant concentrations<sup>131</sup> and manifest clinically as muscle pain and dysfunction. Histopathologic studies show hypercontracted myofibrils, followed by lytic degeneration of striated muscle sarcoplasmic reticulum, and diffuse myonecrosis (Fig. 22-18). The changes are drug-specific (tetracaine and procaine produce the least injury; bupivacaine the most) and both dose- and duration-dependent,<sup>132</sup> and seem to affect the young more than the old.<sup>133</sup> Experimental evidence points to disturbances in the oxidative function of mitochondria and dysregulation of intracellular calcium homeostasis as possible subcellular pathologic mechanisms.<sup>134</sup> In cell cultures, these disruptions appear to be diminished with coapplication with erythropoietin or *N*-acetylcysteine.<sup>135,136</sup> It remains to be seen if these agents may become clinically useful or necessary, because most myotoxic injuries are subclinical and appear entirely reversible.<sup>132</sup>

**Figure 22-18** Skeletal muscle cross-section with characteristic histologic changes after continuous exposure to bupivacaine for 6 hours. A spectrum of necrobiotic changes can be encountered, ranging from slightly damaged vacuolated fibers and fibers with condensed myofibrils to entirely disintegrated and necrotic cells. The majority of the myocytes are morphologically affected. In addition, marked interstitial and myoseptal edema appears within the sections. However, scattered fibers remain intact. (Reprinted with permission from Zink W, Graf B. Local anesthetic myotoxicity. *Reg Anesth Pain Med.* 2004;29:333–340.)

**Table 22-13** The Incidence of Transient Neurologic Symptoms (TNSs) Varies with Type of Spinal Local Anesthetic and Surgery

Local Anesthetic	Concentration (%)	Type of Surgery	Approximate Incidence of TNSs (%)
Lidocaine	2–5	Lithotomy position	30–36
	2–5	Knee arthroscopy	18–22
	0.5	Knee arthroscopy	17
	2–5	Mixed supine position	4–8
Mepivacaine	1.5–4	Mixed	23
Procaine	10	Knee arthroscopy	6
Bupivacaine	0.5–0.75	Mixed	1
Levobupivacaine	0.5	Mixed	1
Prilocaine	2–5	Mixed	1
Ropivacaine	0.5–0.75	Mixed	1

### Allergic Reactions to Local Anesthetics

Untoward reactions to local anesthetics are relatively common, but true immunologic reactions are rare. The immune-mediated hypersensitivity reaction may be type I (immunoglobulin E) or type IV (cellular immunity). Type I hypersensitivity reactions can result in anaphylaxis and potentially be life-threatening, but fortunately, the incidence is estimated to be less than 1%

of all reported cases. Type IV hypersensitivity reactions are delayed-type reactions mediated by T lymphocytes.<sup>137,138</sup> The symptoms can manifest within 12 to 48 hours of exposure and most commonly present as contact dermatitis (dermal erythema, pruritus, papules, and vesicles). The vast majority of reported hypersensitivity reactions have been associated with aminoester agents, likely due to their metabolism to *para*-aminobenzoic acid, which is a recognized allergen. Preservatives, such as methylparaben and metabisulfite that are present in many local anesthetic preparations, may also trigger allergic responses. Evaluation with skin-pricks, intradermal injections, or subcutaneous provocative dose challenges are recommended for individuals with suspected local anesthetic allergy (see also [Chapter 9](#)).<sup>139</sup>

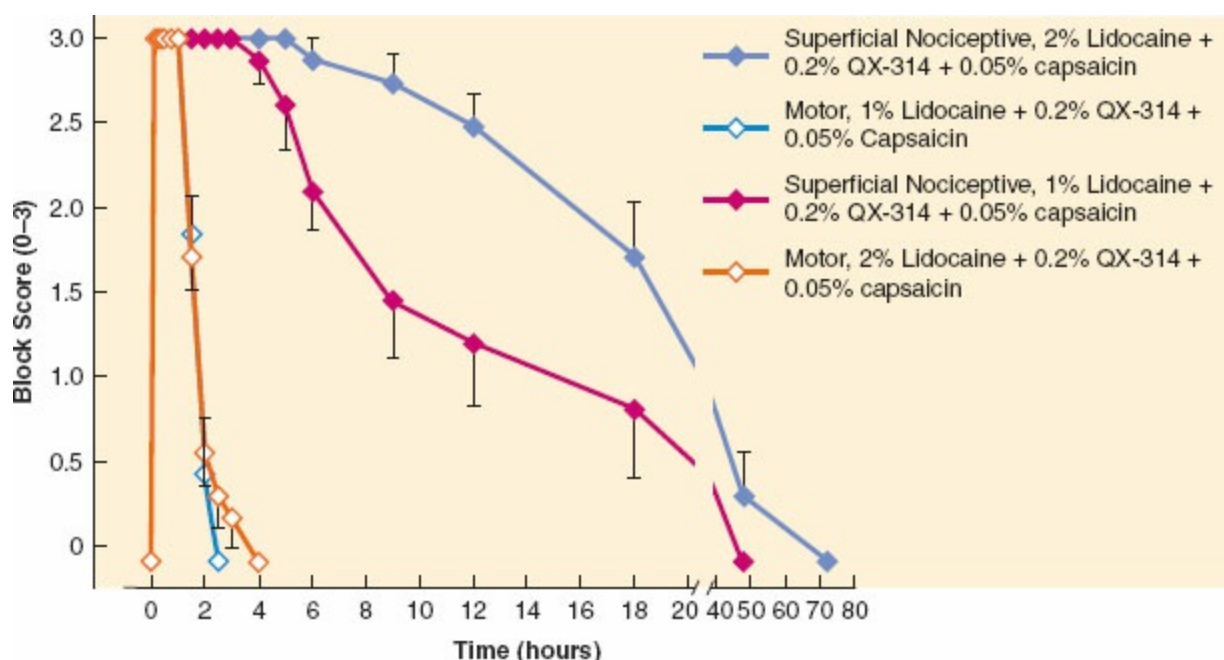

## Future Therapeutics and Modalities

Properties of ideal local anesthetics include selectivity for nociception, long duration of action, and absence of systemic and local tissue toxicities. Efforts to improve local anesthetics have benefitted from a better understanding of the molecular nature of pain. The identification of sodium channel isoforms and their associated channelopathies have focused much attention to developing molecules with specific channel selectivity.<sup>140</sup>

One of the new classes of molecules is the site 1 sodium channel blockers. They belong to a group of potent paralytic neurotoxins that reversibly antagonize voltage-gated sodium channels. In contrast to local anesthetics, they bind to the channel  $\alpha$  subunit extracellularly and have select affinity for channel isoforms.<sup>141</sup> Neosaxitoxin is a well-characterized member of this group and shares the same binding region on the channel outer pore (designated as site 1) as tetrodotoxin. Injected subcutaneously, neosaxitoxin produced hypoesthesia of a modest duration.<sup>142</sup> However, in combination with bupivacaine and epinephrine, neosaxitoxin extended the duration of hypoesthesia almost five-fold compared to bupivacaine alone (median duration 50 vs. 10 hours, respectively,  $p = 0.007$ ).<sup>143</sup> Systemic adsorption can result in a dose-dependent decrease in respiratory and skeletal muscle strength<sup>144</sup>; however, due to its relatively poor affinity for the cardiac sodium channel ( $\text{Na}_v 1.5$ ), cardiac outputs were maintained and no significant cardiac arrhythmias or arrests were seen with systemic infusion.<sup>144</sup> Finally, there was scant evidence of either myotoxicity or neurotoxicity with local injections.<sup>145</sup>

Another promising development toward long-lasting, selective analgesia focuses on modulating large-pore TRPV1 and TRPA1 to facilitate entry of impermeant sodium channel blocker into nociceptor neurons.<sup>146</sup> As discussed previously, TRPV1 and TRPA1 are membrane channels belonging to the transient receptor potential family. In response to heat, capsaicins, or other noxious stimuli, these channels permit passage of large, nonspecific cationic

molecules into the cell. The strategy exploits the finding that their presence is restricted to primary sensory nociceptor neurons. Application of membrane impermeable local anesthetic, such as the permanently charged lidocaine QX-314, results in selective blockade of those sensory, but not motor or autonomic, neurons.<sup>147</sup> In animal studies, coadministration of capsaicin and QX-314 on sciatic nerves produced a long-lasting sensory block with minimal motor deficit.<sup>147</sup> The addition of lidocaine further prolonged the duration of the block at the expense of an initial short and concomitant period of nonselective motor block.<sup>148</sup> However, the duration of the sensory block was much longer than the motor block, leading to a differential blockade of approximately 16 hours (Fig. 22-19). Many questions remain to be addressed before proceeding to volunteer studies. Nonetheless, if the laboratory findings are validated clinically, such combinations will be an invaluable addition to the use of local anesthetics for anesthesia and analgesia.

**Figure 22-19** Comparison of the duration of nociceptive (*blue closed diamonds*) and motor (*blue open diamonds*) blockade produced by triple application of 1% lidocaine/capsaicin/QX-314 (*red diamonds*) or 2% lidocaine/capsaicin/QX-314 (*orange open diamonds*). Grading was as follows: 3, complete block; 2, partial block; 1, minimal block; 0, baseline. (Reprinted with permission from Binshtok AM, Gerner P, Oh SB, et al. Coapplication of lidocaine and the permanently charged sodium channel blocker QX-314 produces a long-lasting nociceptive blockade in rodents. *Anesthesiology*. 2009;111:127.)

#### Summary of Patient Preparation

## KEY POINTS

- 1 The goals of a preoperative evaluation are to reduce patient risk and morbidity associated with surgery and anesthesia, prepare the patient medically and psychologically, and also promote efficiency and reduce costs.
- 2 The anesthesiologist is responsible for assessing the medical condition of the patient and developing the anesthesia plan of care. The American Society of Anesthesiologists (ASA) published basic standards for preoperative care, as well as an updated practice advisory for preanesthesia evaluation that details evidence-supported recommendations.
- 3 It is important for the evaluation to be complete, accurate, and clear, not only to allow the information to be relayed to others who may care for the patient perioperatively but also for medicolegal purposes.
- 4 The preoperative evaluation serves as a screening tool to anticipate and avoid airway difficulties or problems with anesthetic drugs. In addition to the history and physical examination, previous anesthesia records should be reviewed and contraindications to specific drugs, such as succinylcholine, nitrous oxide, or volatile agents, should be sought.
- 5 A review of the patient's medication list, including over-the-counter and herbal preparations, should investigate potential drug interactions and potential indications for stress dose steroid coverage. The anesthesiologist should be aware of the patient's allergies and previous drug reactions, including the possibility of latex allergy.
- 6 When evaluating the patient with hypertension, diabetes mellitus, or obesity, it is important to determine the presence of end-organ damage, such as cardiovascular disease.
- 7 Exercise tolerance is a significant predictor of cardiac risk. Multiple specialty groups have contributed to formal guidelines for the perioperative cardiovascular evaluation and management of patients undergoing noncardiac procedures. The algorithms provide useful guides for further testing and evaluation.
- 8 Preoperative laboratory tests should be ordered on the basis of positive findings from the history and physical examination or from anticipated physiologic disturbances during surgery, such as blood loss.
- 9 Optimization of the patient's health status prior to surgery includes clear instruction regarding fasting times as well as which medications to continue until the time of surgery. In general, most medications for hypertension or cardiac disease should be continued, and consideration should be given to initiating  $\beta$ -blocker therapy before the day of surgery in appropriate patients who are at risk for cardiac adverse events. The

need for subacute bacterial endocarditis prophylaxis should be anticipated. Likewise, drugs for asthma or chronic obstructive pulmonary disease should be continued or administered prophylactically. Medications taken for the treatment of esophageal reflux should be continued or initiated for those patients with untreated symptoms. For diabetic patients, oral hypoglycemic agents should often be held, but patients requiring insulin will need to continue to take adjusted doses.

- 10 Although preoperative sedation is generally limited to drugs given immediately prior to anesthesia, the administration must be carefully planned to allow optimal effect and avoid operating room delays.

## Introduction

**1** The goals of a preoperative evaluation are to reduce patient risk and morbidity associated with surgery and anesthesia, prepare the patient medically and psychologically, and promote efficiency and support cost-effectiveness. As we continue to expand our care at the extremes of age, we are held accountable for high-quality standards while we work to reduce costs. The Joint Commission (TJC) requires that all patients receive a preoperative anesthetic evaluation. The American Society of Anesthesiologists (ASA) web site contains the ASA Basic Standards for Preanesthetic Care that outline the minimum requirements for a preoperative evaluation, as well as the updated Practice Advisory for Preanesthesia Evaluation.<sup>1</sup> The most recent ASA Practice Guidelines can be found at <https://www.asahq.org/quality-and-practice-management/standards-and-guidelines>. Conducting a preoperative evaluation is based on the premise that it will modify patient care and improve outcome. Armed with such knowledge preoperatively, the anesthesiologist can prepare the patient as well as formulate an anesthetic plan that avoids dangers inherent in various disease states. Furthermore, preoperative evaluations may reduce both costs and surgery cancellation rates, increasing resource utilization in the operating room (OR).<sup>2</sup> This notion assumes that evaluations are done by anesthesiologists or other health care providers familiar with anesthesia, surgery, and perioperative events.

The preoperative evaluation has several components. It should include a review of the medical record as well as performance of a history and physical examination pertinent to the patient and planned procedure. On the basis of the history and physical examination, the appropriate diagnostic tests and preoperative consultations should be obtained. Through these, the anesthesiologist determines whether the patient's preoperative condition can be improved prior to surgery and develops the appropriate anesthetic care plan. Finally, the process is used to educate the patient about anesthesia and the perioperative period, answer all questions, and obtain informed consent.

The first part of this chapter outlines clinical risk factors pertinent to patients scheduled for anesthesia and surgery as well as the use of various tests to assess comorbid conditions. The second part discusses preoperative preparation. The chapter provides only an overview of the preoperative management process; for more details, the reader is referred to chapters focusing on specific organ systems.

## Changing Concepts in Preoperative Evaluation

In the past, patients were typically admitted to the hospital a day prior to surgery, enabling the anesthesia team to perform the preoperative evaluation, order relevant laboratory tests or medications, and ensure that the patient was ready for surgery the next day. Currently, a minority of elective patients comes to the OR as inpatients. Older patients are increasingly scheduled for more complex procedures, and there also is more pressure on the anesthesiologist to reduce turnover time between cases. Although others may have seen the patient previously in a preoperative evaluation clinic, the first time that the anesthesiologist performing the anesthetic sees the patient may be just prior to surgery. Thus, only a short time may exist to develop the doctor—patient relationship, engender trust, and answer questions. Under such conditions, it is often impossible to alter medical therapy immediately preoperatively. However, preoperative screening clinics are becoming more effective and clinical practice guidelines are becoming more prevalent. Information technology helps the anesthesiologist to preview the upcoming patients who will be anesthetized. Preoperative questionnaires and computer-driven programs have become alternatives to traditional information retrieval. Finally, when anesthesiologists take responsibility for ordering preoperative laboratory tests, cost savings occur and cancellations of planned surgical procedures become less likely. In this setting, clear and efficient communication between the preoperative evaluation clinic and the anesthesiologist performing the anesthesia are critical.

## Approach to the Healthy Patient

Standardization of best clinical practices may be enhanced by process control procedures. In this regard, the preoperative evaluation form can serve as the basis for formulating the best anesthetic plan tailored to the patient. It **3** should aid the anesthesiologist in identifying potential complications, increase consistency in best-care practices, and serve as a medicolegal document. Because it is more common today for the preoperative evaluation to be completed in a clinic by another physician or health professional who may not personally perform the anesthesia and because regulatory agencies

such as the TJC demand better documentation, the form's design must ensure that the information obtained is complete, concise, and legible. In hospitals with electronic medical records, legibility is rarely an issue. One report investigating the quality of preoperative evaluation forms across the United States rated them in three categories: informational content, ease of use, and ease of reading.<sup>3</sup> Their results revealed a surprisingly high percentage of forms missing important information. [Table 23-1](#) offers one example of the pertinent areas of focus for a preoperative evaluation organized in a systems format.

*Patient Diagnosis and Planned Procedure.* One obviously important detail is the nature of the illness or injury necessitating surgery, as it will both determine the clinical urgency of the proposed operation and influence the available time and depth of the preoperative evaluation. True emergency procedures require a more abbreviated evaluation and are associated with higher anesthetic morbidity and mortality. The approach to urgent procedures is less well defined. For example, ischemic limbs require surgery soon after presentation, but can usually be delayed for 24 hours for further evaluation. The anesthesiologist and surgeon must weigh the risk of morbidity of operative delay against the benefits of establishing associated diagnoses that can influence patient management. [Table 23-2](#) shows one classification of operative urgency, though individual hospitals may have their own definitions. The indication for the surgical procedure may also have implications for other aspects of perioperative management. For example, the presence of a small bowel obstruction has implications regarding the risk of aspiration and the need for a rapid sequence induction. Similarly, the extent of a lung resection will dictate the need for further pulmonary testing and perioperative monitoring. Patients undergoing carotid endarterectomy may require a more extensive neurologic examination as well as additional testing to rule out coronary artery disease (CAD). The planned procedure also dictates patient positioning and whether blood products will be necessary. Frequently, obtaining such information will require communication with the surgeon and the OR team, enhancing both patient safety and OR efficiency.

**Table 23-1** Preanesthetic Evaluation Screen

<b>Diagnosis/Procedure</b> Anesthetic/surgical history MH/adverse reactions Airway difficulty  <b>Airway</b> Difficult airway, sleep apnea Examination: Teeth, Mallampati class, mouth opening, chin length, neck size and mobility  <b>Central Nervous System</b> Stroke, seizures, syncope, ↑intracranial pressure, altered mental status, headaches, neuromuscular disease, spinal cord injury, weakness, paresthesias, psych disorder  <b>Infectious</b> HIV, MRSA, VRE, influenza, TB, foreign travel	<b>Age/Gender/Height/Weight</b> Allergies/adverse reactions Medications Over the counter/herbals, illicit drugs  <b>Cardiovascular</b> Congenital heart disease, hypertension, coronary artery disease, heart failure, cardiomyopathy, valvular disease, syncope, dysrhythmia, pacemaker, vascular disease, angina, dyspnea, orthopnea, exercise tolerance  <b>GI/Hepatic</b> Liver disease, hepatitis, nausea/vomiting, reflux, bowel obstruction, EtOH use  <b>Renal</b> Insufficiency, failure, dialysis  <b>Hematology</b> Anemia, coagulopathy, sickle cell, chemotherapy, transfusions	<b>Vital Signs</b> NPO status IV access/invasive monitors Advance directives  <b>Pulmonary</b> URI/bronchitis/pneumonia, tobacco, asthma, COPD, cough, dyspnea, sleep apnea, O <sub>2</sub> /inhaler/steroid use, pneumothorax, ventilator settings, endotracheal tube size/depth  <b>Endocrine/Metabolic</b> Diabetes, thyroid disease, rheumatoid arthritis, steroid use  <b>Other</b> Pregnancy, weeks of gestation Trauma history

MH, malignant hyperthermia; NPO, nothing by mouth; IV, intravenous; URI, upper respiratory infection; COPD, chronic obstructive pulmonary disease; EtOH, ethanol; HIV, human immunodeficiency virus; MRSA, methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococci; TB, tuberculosis.

**Response to Previous Anesthetics.** The ability to review previous anesthetic records is particularly helpful for detecting the presence of a difficult airway, a history of malignant hyperthermia (MH), and the individual’s response to surgical stress and specific anesthetics. The patient should be questioned regarding any previous personal or familial difficulties with anesthesia. A patient’s report of an “allergy” to anesthesia should raise suspicion for MH. A diagnosis of MH susceptibility will affect the anesthetic regimen and bring into question the appropriateness of outpatient surgery.

**Table 23-2** Classification of Urgency of Surgical Procedures

Classification of Operation	Description	Optimal Timing	Example
Emergency	Life, limb, or organ-saving	<6 h	Ruptured aortic aneurysm Major trauma to thorax, abdomen Acute increase in intracranial pressure
Urgent	Conditions threaten life, limb, or organ	6–24 h	Perforated bowel Compound fracture Eye injury
Time sensitive	Stable, but requires intervention	Days to weeks	Tendon, nerve injuries Cancer procedures
Elective	Procedure planned at patient or surgeon convenience	Up to 1 yr	All other procedures that can be planned in advance

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. *Circulation*. 2014;130:e278–e333.

Although not life-threatening, persistent nausea and vomiting after a previous surgery may be the patient’s most negative and lasting memory. There are multiple predictors of postoperative nausea and vomiting (PONV), including type of surgical procedure, anesthetic agents, and patient factors (Table 23-3). One report predicting postoperative nausea and vomiting after

*inhalation* anesthesia identified four risk factors: female gender, prior history of motion sickness or postoperative nausea, nonsmoking, and the use of postoperative opioids. The Apfel simplified risk score predicts PONV with 0, 1, 2, 3, or 4 risk factors as 10%, 20%, 40%, 60%, and 80%, respectively.<sup>4</sup> The investigators suggested prophylactic antiemetic therapy when two or more risk factors are present while using volatile anesthetics.<sup>5</sup> However, armed with this knowledge preoperatively, the anesthesiologist is also able to tailor the anesthetic or possibly avoid the most likely causes of PONV: volatile anesthetics, nitrous oxide, and postoperative opioids altogether.<sup>6</sup>

**Table 23-3** Risk Factors for PONV in Adults

Evidence	Risk Factors
Positive overall	Female sex History of PONV or motion sickness Nonsmoking Younger age (<50 yr) General (vs. regional) anesthesia Volatile anesthetics and nitrous oxide Postoperative opioids Duration of anesthesia Type of surgery: cholecystectomy, laparoscopic, gynecologic
Conflicting	ASA status Menstrual cycle Anesthesia provider's experience Muscle relaxant reversal

PONV, postoperative nausea and vomiting; ASA, American Society of Anesthesiologists. Adapted from Gan TJ, Diemunsch P, Habib AS, et al. Consensus guidelines for the management of postoperative nausea and vomiting. *Anesth Analg*. 2014;118:85–113.

In children, Eberhart et al.<sup>7</sup> identified four independent predictors of postoperative vomiting (POV): duration of surgery longer than 30 minutes, age above 3 years, history of POV in patient or family, and strabismus surgery. Based on the presence of 0, 1, 2, 3, and 4 factors, the risk of POV was 9%, 10%, 30%, 55%, and 70%, respectively.

**Medications/Allergies.** The history should include a complete list of medications, including over-the-counter and herbal products (Table 23-4), to define a preoperative medication regimen, anticipate potential drug interactions, and provide clues to underlying disease. A complete list of drug allergies, including previous reactions, should be obtained, as well as an inquiry concerning reaction to latex.

**Table 23-4 Herbal/Dietary Supplements and Drug Interactions**

Brand Name	Common Uses	Pharmacologic Effects and Drug Interactions
Ephedra	Weight loss aid Bacteriostatic Antitussive	Increased HR and BP, enhanced sympathomimetic effects with other sympathomimetics Potential arrhythmias with digoxin or halothane, hypertension with oxytocin
Feverfew	Migraine prophylaxis Antipyretic	Inhibits platelet activity and increases bleeding Rebound headache with sudden cessation
GBL, BD, GHB ( $\gamma$ -butyrolactone)	Bodybuilding Weight loss aid Sleep aid	Illegally distributed drugs Death, seizures, unconsciousness Bradycardia, slowed respirations
Garlic	Lower cholesterol, BP Antioxidant	Inhibition of platelet aggregation, potential for increased bleeding
Ginger	Antinausea Antispasmodic	Potent inhibitor of thromboxane synthetase; may increase bleeding time
Ginkgo	Blood thinner	May enhance bleeding in patients on anticoagulant or antithrombotic therapy
Ginseng	Energy level enhancer Antioxidant	May inhibit platelet aggregation and increase bleeding Decreased blood glucose
Goldenseal	Diuretic Anti-inflammatory Laxative	Functions as an oxytocic May worsen edema and/or hypertension
Kava-kava	Anxiolytic	Potentiates sedative effects of anesthetics May cause hepatotoxicity
Licorice	Treats gastritis/ulcers  Treats cough/bronchitis	Glycyrrhizic acid in licorice may cause high blood pressure, hypokalemia, edema Contraindicated in many chronic liver conditions, renal insufficiency
St. John's wort	Treats depression, anxiety	May prolong effects of anesthesia
Valerian	Mild sedative, anxiolytic	May potentiate sedative effects of anesthetics
Vitamin E	Slow aging  Promotes wound healing	May increase bleeding, particularly in conjunction with other anticoagulant and antithrombotic drugs Can cause BP problems

HR, heart rate; BP, blood pressure; GBL, gamma butyrolactone; GHB, gamma-hydroxybutyrate. Adapted from the ASA Physician Brochure: What You Should Know About Your Patients' Use of Herbal Medicines and Other Dietary Supplements, 2003. [www.ASAhq.org](http://www.ASAhq.org).

If the patient presents on the day of surgery, the anesthesiologist should determine when the patient last ate and drank as well as note the sites of pre-existing intravenous cannulas and invasive monitors. Once the general issues are completed, the preoperative history and physical examination can focus on specific systems.

## Screening Patients Using a Systems Approach

### Airway

At the forefront of every anesthesiologist's mind is concern about the patient's airway. The anesthesiologist needs to recognize the potential for difficulty in maintaining a patent airway with a mask, a laryngeal mask airway, or in the ability to place an endotracheal tube when the patient is under general anesthesia. The ability to review previous anesthetic records is especially useful in uncovering an unsuspected "difficult airway" or to confirm previous uneventful tracheal intubations, noting whether the patient's body habitus or airway anatomy has changed in the interim. Patients should be questioned

about their ability to breathe through their nose, whether there is suspected or diagnosed obstructive sleep apnea (OSA), and whether they have orthopnea. Evaluation of the airway involves examination of the oral cavity, including dentition, determination of the thyromental distance, assessment of the size of the patient's neck and potential tracheal deviation or masses, as well as evaluation of their ability to flex the base of the neck and extend the head. For trauma patients or patients with severe rheumatoid arthritis (RA) or Down syndrome, assessment of the cervical spine is critical. The presence of symptoms or signs of cervical cord compression should be assessed. In some instances, radiographic examination may also be required.

The Mallampati classification is the standard for assessing the relationship of the tongue size relative to the oral cavity (Table 23-5),<sup>8</sup> although by itself the Mallampati classification has a low positive predictive value in identifying patients who are difficult to intubate.<sup>9,10</sup> Intubation involves multiple steps: flexion of the lower neck, extension of the upper neck, opening the mouth to insert the laryngoscope, and displacing the tongue forward and down into the submandibular space to expose the glottis. Therefore, a multifactorial approach to predicting intubation difficulty, as shown in Table 23-6, has proven to be more helpful. One must distinguish factors that predict a difficult intubation and factors that predict a difficult mask airway. For example, the absence of teeth clearly makes laryngoscopy less difficult, but at the same time can make mask ventilation more challenging.

**Table 23-5** Modified Mallampati Airway Classification System

Class	Direct Visualization, Patient Seated
I	Full view of soft palate, uvula, tonsillar pillars
II	Soft palate and upper portion of uvula
III	Soft palate
IV	Hard palate only

Modified with permission from Mallampati RS, Gatt SP, Gugino LD, et al. A clinical sign to predict difficult tracheal intubation: A prospective study. *Can Anaesth Soc J.* 1985;32:429–434.

**Table 23-6** Components of the Airway Examination That Suggest Difficult Tracheal Intubation

1. Long upper incisors
2. Prominent "overbite"
3. Inability to protrude the mandibular incisors anterior to maxillary incisors
4. Distance between incisors is <3 cm when mouth is fully opened
5. Uvula not visible when tongue is protruded with patient sitting
6. Shape of palate highly arched or very narrow
7. Mandibular space noncompliant
8. Thyromental distance <3 fingerbreadths
9. Neck short or thick
10. Limited range of motion of head and neck

Clinical context and judgment determine which of the components apply to a particular patient.

Modified from the Task Force on Difficult Airway Management. Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologist Task Force on Management of the Difficult Airway. *Anesthesiology*. 2003;98:1269–1277.

## Pulmonary System

A screening evaluation should include questions regarding the history of tobacco use, dyspnea, exercise tolerance, cough, wheezing, bronchodilator or steroid use, recent upper respiratory tract infection, stridor, and snoring or sleep apnea. Physical examination should assess respiratory rate, chest excursion, use of accessory muscles, nail color, and the patient's ability to carry on a conversation or to walk without dyspnea. Auscultation can detect decreased breath sounds, wheezing, stridor, or crackles. For the patient with positive findings, see the section later on the preoperative evaluation of the patient with known pulmonary disease.

## Cardiovascular System

6

When screening a patient for cardiovascular disease prior to surgery, the anesthesiologist is most interested in recognizing signs and symptoms of uncontrolled hypertension and unstable cardiac disease such as myocardial ischemia, congestive heart failure, valvular heart disease, and significant cardiac dysrhythmias. Symptoms of cardiovascular disease should be carefully sought, particularly the characteristics of dyspnea, chest pain, or syncope, as well as exercise tolerance. Certain populations of patients, such as the elderly, women, or diabetics, may present with more atypical features. The presence of unstable angina has been associated with a high perioperative risk of myocardial infarction (MI).<sup>11</sup> The perioperative period is associated with a hypercoagulable state and surges in endogenous catecholamines, both of

which may exacerbate the underlying process in unstable angina, increasing the risk of acute infarction. The patient should be questioned about symptoms of clinically important valvular disease, such as angina, dyspnea, syncope, or congestive heart failure, that would require further evaluation. Importantly, the anesthesiologist must identify patients who have undergone placement of a coronary artery stent or an implantable cardiac device to be able to coordinate perioperative management with the cardiologist (see section on cardiovascular disease).

The anesthesiologist should also be familiar with the American Heart Association (AHA) web site (<http://www.heart.org/>) and its links to the latest

AHA statements and guidelines for health professionals. Here one can find the most recent recommendations regarding the specific patients and procedures that require subacute bacterial endocarditis prophylaxis.<sup>12</sup>

The examination of the cardiovascular system should include blood pressure evaluation, measuring both arms when appropriate. The anesthesiologist should consider the effects of preoperative anxiety and review resting blood pressure measurements. However, according to one study, the admission blood pressure was the best predictor of heart rate and blood pressure response to laryngoscopy.<sup>13</sup> Auscultation of the heart is performed, specifically listening for a murmur radiating to the carotids suggestive of aortic stenosis, abnormal rhythms, or a gallop suggestive of heart failure. The presence of bruits over the carotid arteries warrants further workup to determine the risk of stroke. The extremities should be examined for peripheral pulses to exclude peripheral vascular disease or congenital cardiovascular disease.

## Neurologic System

Neurologic system assessment in the apparently healthy patient can be accomplished through simple observation. The patient's ability to answer health history questions practically indicates a normal mental status. Questions can be directed regarding a history of stroke, symptoms of cerebrovascular disease, seizures, pre-existing neuromuscular disease, or nerve injuries. The neurologic examination may be cursory in healthy patients or extensive in patients with coexisting disease. Testing of strength, reflexes, and sensation may be important in patients for whom the anesthetic plan or surgical procedure may result in a change in condition.

## Endocrine System

Each patient should be questioned for a history or symptoms of endocrine diseases that may affect the perioperative course: diabetes mellitus, thyroid

disease, parathyroid disease, endocrine-secreting tumors, and adrenal cortical suppression.

## Evaluation of the Patient with Known Systemic Disease

### *Cardiovascular Disease*

Recent clinical practice guidelines have established definitions applicable to the planned procedure and the perioperative risk of major adverse cardiac events (MACE), including death and MI. A low-risk procedure is defined as having a less than 1% incidence of MACE, whereas a high-risk procedure carries a risk of more than 1%. In the preoperative evaluation, a clinical history of cardiovascular disease, diabetes mellitus, and cerebrovascular disease support an elevated risk of MACE. Consistently, advanced age is independently associated with an increased risk of MACE and ischemic stroke. Prior MIs appear associated with both postoperative MI and 30-day mortality, which, in turn, are related to the timing of the initial MI.<sup>14</sup> Recent clinical practice guidelines support delaying noncardiac surgery at least 60 days after an MI in the absence of coronary intervention. Importantly, recent MI within 6 months of noncardiac surgery appears to be a risk factor for perioperative stroke.<sup>15</sup>

**Table 23-7** American Society of Anesthesiologists (ASA) Physical Status (PS) Classification

ASA PS class 1	Normal healthy patient. No organic, physiologic, biochemical, or psychiatric disturbance
ASA PS class 2	Mild-to-moderate systemic disease that is well controlled and causes no organ dysfunction or functional limitation (e.g., treated hypertension)
ASA PS class 3	Severe systemic disease of at least one organ system that does cause functional limitation (e.g., stable angina)
ASA PS class 4	Severe systemic end-stage disease of at least one organ system that is life threatening with or without surgery (e.g., congestive heart failure or renal failure)
ASA PS class 5	Moribund patient who has little chance of survival but is submitted to surgery as a last resort (resuscitative effort; e.g., ruptured aortic aneurysm)
ASA PS class 6	A declared brain-dead patient whose organs are being removed for donor purposes
Emergency operation (E)	Any patient in whom an emergency operation is required

Modified from American Society of Anesthesiologists: New classification of physical status. *Anesthesiology*. 1963;24:111.

The preoperative evaluation of the patient with known or suspected cardiovascular disease is focused on two areas: identification of clinical risk indices and preoperative cardiac testing. The goals are to define risk; identify which patients will benefit from further testing; determine whether perioperative  $\beta$ -blockade, interventional therapy, or even surgery would be beneficial before the planned procedure; and form an appropriate anesthetic plan. Multivariate risk indices, based on epidemiologic statistical methods, can add value in predicting MACE. Historically, these have included the ASA physical status index (Table 23-7) and the Goldman Cardiac Risk Index.

The Revised Cardiac Risk Index (RCRI) is an update of the Goldman Cardiac Risk Index and is a validated method to assign perioperative risk using readily available clinical variables.<sup>16</sup> In a population of 4,315 patients aged 50 years and older undergoing elective, major noncardiac procedures, six independent predictors of complications were identified and included in the RCRI: high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine greater than 2 mg/dL. Cardiac complications rose with an increase in the number of risk factors present. Rates of major cardiac complications with 0, 1, 2, or 3 of these factors were 0.5%, 1.3%, 4%, and 9%, respectively, in the derivation

cohort, and 0.4%, 0.9%, 7%, and 11%, respectively, among 1,422 patients in the validation cohort (Table 23-8). Figure 23-1 shows the rate of major cardiac complications for patients in each ASA class according to the type of procedure performed.

Surgical groups have also developed cardiac and surgical risk calculators. The American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP) Myocardial Infarction and Cardiac Arrest (MICA) risk-prediction calculator is a multivariate risk assessment tool for perioperative cardiac arrest and MI (<http://www.surgicalriskcalculator.com/miorcardiacarrest>).<sup>17</sup> The ACS NSQIP Surgical Risk Calculator uses current procedural terminology codes and 21 patient-specific variables for prediction of several groups of outcomes.<sup>18</sup>

**Table 23-8** Revised Cardiac Risk Index (RCRI)

Risk Factors	RCRI Risk Assessment	Event Rate (%)
Ischemic heart disease	Low (0 factor)	0.5
Congestive heart failure	Low (1 factor)	1.3
Cerebrovascular disease	Intermediate (2 factors)	3.6
Diabetes mellitus treated with insulin	High (3 or more factors)	9.1
Serum creatinine >2 mg/dL		
High-risk surgery (intraoperative, intrathoracic, or suprainguinal vascular)		

Modified from Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective evaluation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100:1043–1049.

Finally, the additional laboratory measurement of biomarkers (e.g., brain natriuretic peptide or N-terminal brain natriuretic peptide and C-reactive protein levels) may increase prediction accuracy.<sup>19,20</sup> For example, the preoperative measurement of elevated brain natriuretic peptide levels appears significantly associated with MACE in vascular patients within 30 days of surgery.<sup>21</sup>

Although all of these indices provide information to assess the probability of complications and provide an estimate of risk, the cardiovascular risk factors in any individual patient first need to be defined; then a plan for anesthesia and perioperative management can be prescribed.

In patients with symptomatic coronary disease, the preoperative evaluation may reveal a change in the frequency or pattern of anginal symptoms. Certain populations of patients—for example, the elderly, women, or diabetics—may present with more atypical features. The presence of

unstable angina has been associated with a high perioperative risk of MI.<sup>11</sup>

In virtually all studies, the preoperative presence of active congestive heart failure is a major risk factor for increased perioperative cardiac morbidity.<sup>22,23</sup> Clinical evidence of heart failure includes symptoms of dyspnea, limited exercise tolerance, and orthopnea; as well as physical signs of jugular venous distention, crackles, third heart sound, and peripheral edema. A chest x-ray reveals pulmonary edema or vascular redistribution. Significantly reduced left ventricular ejection fraction (e.g., <30%) appears to be an independent risk factor for adverse perioperative outcome and long-term mortality.<sup>24</sup> Another study suggests that asymptomatic systolic or diastolic dysfunction is associated with increased 30-day cardiovascular perioperative risk.<sup>25</sup> Optimization of ventricular function and treatment of pulmonary edema are both important prior to elective surgery. Because the type of perioperative monitoring and treatment may be different, clarifying the cause of heart failure is important (e.g., nonischemic cardiomyopathy or cardiac valvular insufficiency and/or stenosis).

Patients with known valvular heart disease can be effectively managed during the perioperative period to limit morbidity. The 2014 AHA/ACC Guideline for the Management of Patients with Valvular Disease supports the use of preoperative echocardiography in patients with moderate or severe valvular stenosis or regurgitation with no echocardiography studies within 1 year, or worsening clinical status.<sup>26</sup> Valvular interventions (e.g., repair or replacement) may be indicated before elective noncardiac surgery depending on the symptoms or severity of disease. Understanding the severity of stenotic or regurgitant valvular disease, coupled with an intraoperative monitoring and management plan, may reduce the risk of perioperative congestive heart failure and respiratory failure.

Adults with a prior MI almost always have CAD. Traditionally, risk assessment for noncardiac surgery was based on the time interval between the MI and surgery, which was based on older data that demonstrated an increased incidence of reinfarction if the MI was within 6 months of surgery.<sup>27</sup> The importance of the intervening time interval may no longer be valid in the current era of interventional therapy and improvements in perioperative care. Although many patients with an MI may continue to have myocardium at risk for subsequent ischemia and infarction, other patients may have their critical coronary stenoses either totally occluded or widely patent, with no such risk. For example, the use of percutaneous transluminal coronary angioplasty, thrombolysis, and early coronary artery bypass grafting (CABG) has changed the natural history of the disease. Therefore, patients should be individually evaluated from the perspective of their risk for ongoing ischemia.

**Figure 23-1** Cardiac risk (percent of patients expected to have major cardiac complications) by Revised Cardiac Risk Index (RCRI) class and type of surgical procedure. Bars represent rate of major cardiac complications in RCRI classes I to IV (based on patients with 0, 1, 2, or more risk factors, respectively) according to the type of procedure performed. Note that, by definition, patients undergoing abdominal aortic aneurysm (AAA), thoracic, and abdominal procedures were excluded from class I. In all subsets except patients undergoing AAA, there was a statistically significant trend toward greater risk with higher-risk class. See text for details. (Reproduced with permission from Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100:1043.)

## Identifying Patients at Risk for Atherosclerotic Cardiac Disease

For those patients without overt cardiac symptoms, the probability of CAD varies with the type and number of atherosclerotic risk factors present. Peripheral arterial disease has been shown to be associated with CAD in multiple studies.<sup>28</sup>

### Diabetes Mellitus

Diabetes mellitus is a common disease with a pathophysiology that affects multiple organ systems. Complications of diabetes mellitus are frequently the cause of urgent or emergent surgery, especially in the elderly. Diabetes accelerates the progression of atherosclerosis, so it is not surprising that diabetics have a higher incidence of CAD than nondiabetics as well as a high incidence of both silent MI and myocardial ischemia.<sup>29</sup> Eagle et al.<sup>30</sup> demonstrated that diabetes is an independent risk factor for perioperative cardiac morbidity, and as mentioned earlier, diabetes requiring insulin treatment is a risk factor in the RCRI. The duration of the disease and presence of associated end-organ dysfunction may also alter the overall cardiac risk. Autonomic neuropathy has been reported as the best predictor of

silent ischemia.<sup>31</sup> Because these patients are at very high risk for a silent MI, a preoperative electrocardiogram (ECG) should be obtained to examine for the presence of Q waves.

### *Hypertension*

Hypertension has also been associated with an increased incidence of silent myocardial ischemia and infarction.<sup>29</sup> Hypertensive patients who have left ventricular hypertrophy and are undergoing noncardiac surgery are at a higher perioperative risk than nonhypertensive patients.<sup>32</sup> Investigators have suggested that the presence of a strain pattern on ECG suggests a chronic ischemic state.<sup>33</sup>

Aggressive treatment of blood pressure is associated with reduction in long-term MI risk. The new 2014 Guideline for the Management of High Blood Pressure by the Eighth Joint National Committee recommends treatment for an elevated systolic blood pressure 150 mmHg or higher, or diastolic blood pressure above 90 mmHg in patients 60 years or older, and to treat systolic blood pressure above 140 mmHg and diastolic blood pressure above 90 mmHg in patients younger than 60 years.<sup>34</sup> However, there are no such guidelines to suggest a safe upper blood pressure limit when a patient presents for surgery with significant hypertension. There is little association reported between elevated blood pressures (up to 180 mmHg systolic or up to 110 mmHg diastolic) and postoperative outcomes. However, such patients are prone to perioperative myocardial ischemia, ventricular dysrhythmias, and lability in blood pressure. It is less clear in patients with blood pressures above 180/110 mmHg, as no absolute evidence exists that postponing surgery will reduce risk.<sup>35,36</sup> Although the literature suggests that elective surgery should be delayed if the diastolic pressure is above 110 mmHg, this study demonstrated no major morbidity in that small group of patients.<sup>37</sup> Thus, in the absence of end-organ changes, such as renal insufficiency or left ventricular hypertrophy with strain, the benefits of optimizing blood pressure must be weighed against the risks of delaying surgery.

### *Metabolic Syndrome/Tobacco*

“Metabolic syndrome” is a disorder comprising a group of risk factors that includes high blood pressure, atherogenic dyslipidemia (high triglyceride and low high-density lipoprotein cholesterol concentrations), high fasting glucose concentration, and central obesity. Metabolic syndrome has been associated with higher rates of cardiovascular, pulmonary, and renal perioperative events, as well as wound infections.<sup>38</sup>

Tobacco is also associated with the increased probability of developing CAD, although it has not been shown to independently increase perioperative

cardiac risk.

### **Importance of Surgical Procedure**

The surgical procedure influences the scope of required preoperative evaluation by suggesting the range of physiologic changes that may occur during the perioperative period. Few data exist defining the surgery-specific incidence of complications. Peripheral procedures are associated with an extremely low incidence of morbidity and mortality,<sup>39</sup> whereas major open vascular procedures are associated with the highest incidence of complications. Eagle et al.<sup>40</sup> published data from the Coronary Artery Surgery Study (CASS) on the incidence of perioperative MI and mortality by procedure for patients with known CAD treated preoperatively either medically or with CABG. Their data found that high-risk procedures included major vascular, abdominal, thoracic, and orthopedic surgery.

### **Importance of Exercise Tolerance**

Exercise tolerance remains one of the most important predictors of perioperative risk for noncardiac surgery, and helps define the need for further testing and invasive monitoring. An excellent exercise tolerance, even in patients with stable angina, suggests that the myocardium can be stressed without failing. Alternatively, if patients experience dyspnea associated with chest pain during minimal exertion, the probability of extensive CAD is high, and is associated with greater perioperative risk. In addition, these patients are at risk for developing hypotension with ischemia and, therefore, may benefit from preoperative coronary intervention therapy, revascularization, or more intensive intraoperative monitoring.<sup>41</sup> Exercise tolerance can be assessed with formal treadmill testing or with a questionnaire that assesses activities of daily living (Table 23-9). Patient-reported poor exercise tolerance (i.e., inability to walk four blocks or climb two flights of stairs) appears to be an independent predictor of serious perioperative complications.<sup>42</sup> The likelihood of a serious adverse event is inversely related to the number of blocks that can be walked. Therefore, there is good evidence to suggest that minimal additional testing is necessary if the patient is able to describe a good exercise tolerance.

### **Indications for Further Cardiac Testing**

Multiple algorithms have been proposed to determine which patients require further cardiovascular testing. As described previously, the risk associated with the proposed surgical procedure influences the decision to perform further diagnostic testing and interventions. With the reduction in

perioperative morbidity, it has been suggested that extensive cardiovascular testing is not always necessary.

The algorithm to determine the need for testing in a patient at risk for CAD proposed by the ACC/AHA Task Force was updated in 2014<sup>15</sup> and is based on available evidence and expert opinion that integrates clinical history, surgery-specific risk, and exercise tolerance (Fig. 23-2). In the first step, the clinician evaluates the urgency of the surgery and the appropriateness of a formal preoperative assessment. Next, one determines if the patient has undergone a recent revascularization procedure or coronary evaluation. Those patients with unstable coronary syndromes should be identified and appropriate treatment instituted. Finally, the decision to perform further testing depends on the interaction of the clinical risk factors, surgery-specific risk, and functional capacity. For patients at high risk, both exercise tolerance and the extent of the surgery are taken into account to determine the need for further testing. Most importantly, no preoperative cardiovascular testing should be performed if the results will not change perioperative management.

**Table 23-9** Estimated Energy Requirement for Various Activities

1 MET	Daily self-care Eat, dress, or use the toilet Walk indoors around the house Walk a block or two on level ground at 2–3 mph or 3.2–4.8 km/h Do light work around the house, like dusting or washing dishes
4 METs	Climb a flight of stairs or walk up a hill Walk on level ground at 4 mph or 6.4 km/h Run a short distance Do heavy work around the house, like scrubbing floors or lifting or moving heavy furniture Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football
>10 METs	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing

MET, metabolic equivalent.

## Electrocardiogram

A preoperative 12-lead ECG can provide important information about the patient’s heart rhythm as well as evidence for left ventricular hypertrophy and prior MI. Abnormal Q waves in high-risk patients are highly suggestive of

a past MI. It has been estimated that approximately 30% of MIs occur without symptoms (“silent infarctions”) and can only be detected on screening ECGs, with the highest incidence occurring in patients with either diabetes or hypertension. The Framingham Study showed that long-term prognosis after MI is not improved by lack of symptoms at the time of MI.<sup>29</sup> The absence of Q waves on the ECG, however, does not exclude the occurrence of a Q-wave MI in the past.<sup>43</sup> Those patients in whom the ECG reverts to normal have improved survival compared to those with consistent abnormalities, with or without Q waves. The presence of Q waves on a preoperative ECG in a high-risk patient, regardless of symptoms, should alert the anesthesiologist to the increased perioperative risk and the potential for active ischemia.

The 2014 ACC/AHA Clinical Practice Guideline recommends a preoperative resting 12-lead ECG only for patients with known CAD or other structural heart disease (except for low-risk surgical procedures) and consideration in asymptomatic patients with clinical risk factors (except for low-risk procedures).<sup>15</sup>

## **Noninvasive Cardiovascular Testing**

The exercise ECG stress test has been the traditional method for evaluating patients with suspected CAD. It represents the most cost-effective and least invasive method for detecting ischemia, with a sensitivity of 70% to 80% and a specificity of 60% to 75% for identifying CAD. A positive exercise stress test alerts the anesthesiologist that the patient is at risk for ischemia associated with increased heart rate, with the greatest risk in those who develop ischemia after only mild exercise. However, as discussed previously, the ability to exercise suggests that no further testing is necessary, and therefore exercise ECG stress testing is infrequently indicated.

Noninvasive pharmacologic stress testing before surgery can be used in high-risk patients who either are unable to exercise or have contraindications to exercise (e.g., claudication). These tests offer value in assessing risk in patients who have poor or indeterminate functional capacity (<4 METs), but should be performed only if their results will change management.<sup>15</sup> Testing options include the dobutamine stress echocardiogram (DSE), in which dobutamine is used to increase myocardial oxygen demand by increasing heart rate and blood pressure. The appearance of either new or more severe regional wall motion abnormalities by ECG with dobutamine represents areas at risk for myocardial ischemia and is considered a positive test. The advantage of a stress ECG is that it is a dynamic assessment of ventricular function. It is generally accepted that those at greatest risk demonstrate regional wall motion abnormalities at low heart rates.

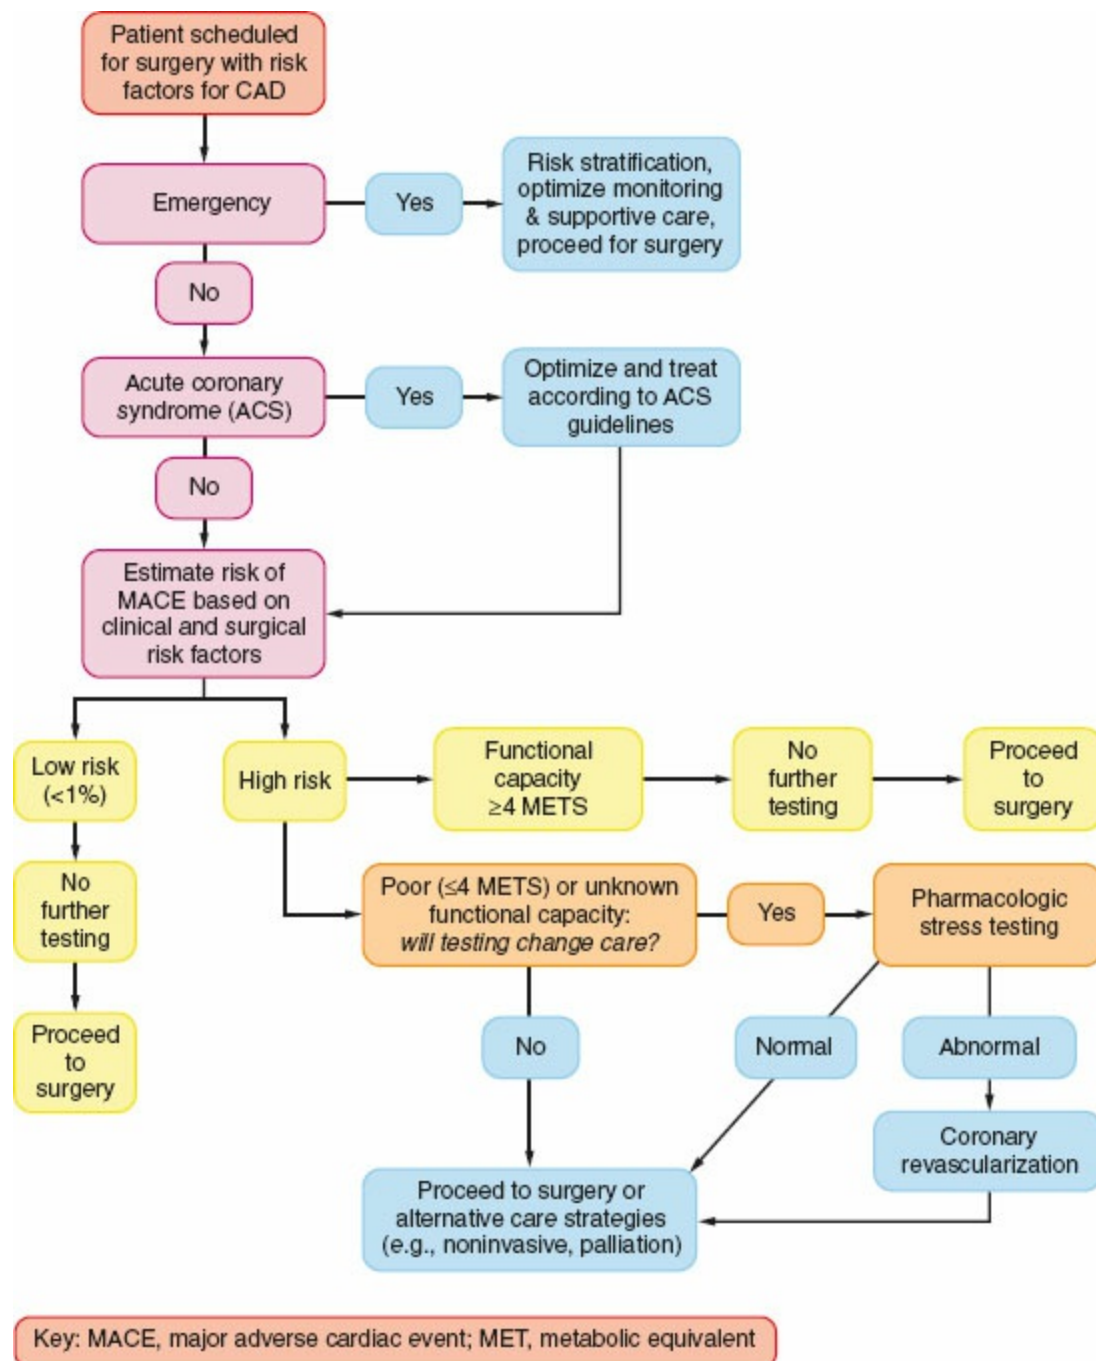

Another noninvasive stress test is dipyridamole/adenosine/regadenoson

myocardial perfusion imaging (MPI) with thallium-201 and/or technetium-99m and rubidium-82. Dipyridamole, adenosine, or regadenoson is administered as a coronary vasodilator to assess flow heterogeneity and the presence of a redistribution defect. The 2014 ACC/AHA Clinical Practice Guideline suggests that (1) a normal DSE or MPI supports a high negative predictive value for perioperative MI and/or cardiac death and (2) moderate to large areas of ischemia are associated with increased risk of perioperative MI and/or cardiac death. Findings of a fixed perfusion defect by MPI support a prior MI but offer limited predictive value, although this patient subset is at increased risk for long-term cardiac risk.<sup>15</sup>

The ambulatory ECG (e.g., Holter monitor) provides a means of continuously monitoring the ECG for significant ST segment changes. One study demonstrated that the presence of silent ischemia is a strong predictor of outcome, whereas its absence is associated with a favorable outcome in 99% of the patients studied.<sup>44</sup> Other investigators have demonstrated the value of ambulatory ECG monitoring, although the negative predictive values have not been as high.

Published meta-analyses of preoperative cardiac diagnostic tests have shown good predictive values for ambulatory ECG monitoring, dipyridamole thallium imaging, or DSE.<sup>45,46</sup> The studies demonstrated the superior value of DSE; however, there was significant overlap of the confidence intervals with other tests. The most important determinant with respect to the choice of preoperative testing is the testing expertise of the local institution.

Current recommendations are that patients with active cardiac conditions such as unstable angina, congestive heart failure, significant dysrhythmias, and severe valvular disease should undergo noninvasive stress testing before noncardiac surgery. For patients who require vascular surgery and have multiple clinical risk factors and poor functional capacity, it is reasonable to undergo noninvasive stress testing if it will change management.<sup>15</sup>

**Figure 23-2** Approach to perioperative cardiac assessment for patients with coronary artery disease (CAD). (Modified with permission from Fleisher LA, Fleischmann KE, Auerbach AD, et al. ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery. *Circulation*. 2014;130:e278–e333. <http://circ.ahajournals.org>.)

### Assessment of Ventricular and Valvular Function

Both echocardiography and radionuclide ventriculography can assess cardiac ejection fraction at rest and under stress. Echocardiography is less invasive and able to assess regional wall motion abnormalities, wall thickness, valvular function, and valve area. Pulse-wave Doppler can be used to determine the velocity time integral. Stroke volume can then be calculated by determining the cross-sectional area of the ventricle. Conflicting results exist with regard

to the predictive value of the ejection fraction using either echocardiographic or radionuclide measurements. It is reasonable for those with dyspnea of unknown origin and for those with current or prior heart failure with worsening dyspnea or other change in clinical status to have preoperative evaluations of left ventricular function.

Echocardiography has the added advantage of assessing valvular function, which may have important implications for either cardiac or noncardiac surgery. Aortic stenosis has been associated with a poor prognosis in noncardiac surgical patients, and knowledge of valvular lesions may modify perioperative hemodynamic goals and therapy. As noted previously, the 2014 AHA/ACC Guideline for the Management of Patients with Valvular Disease supports the importance of preoperative echocardiography testing for moderate or severe degrees of valvular stenosis or regurgitation with no echocardiography studies within 1 year, or worsening clinical status.<sup>26</sup>

### **Coronary Angiography**

Coronary angiography remains the best method for defining coronary anatomy and also assesses ventricular and valvular function. Hemodynamic indices can be determined, such as atrial and ventricular pressures, as well as pressure gradients across valves. Although a critical coronary stenosis delineates an area of risk for developing myocardial ischemia, the functional response of that ischemia cannot be assessed by angiography alone. A critical stenosis may or may not be the underlying cause for a perioperative MI that occurs. In the ambulatory population, many infarctions are the result of acute thrombosis of a noncritical stenosis. The 2014 ACC/AHA Clinical Practice Guidelines do not recommend routine preoperative coronary angiography prior to noncardiac surgery without specific clinical indications.<sup>15</sup> Patients with restricted physical activity in whom functional capacity is difficult to determine may benefit from sophisticated imaging techniques, such as cardiac computed tomography (CT).<sup>47</sup> The role of coronary CT angiography with calcium scoring requires further validation as a preoperative assessment for noncardiac surgery.

### **Perioperative Coronary Interventions**

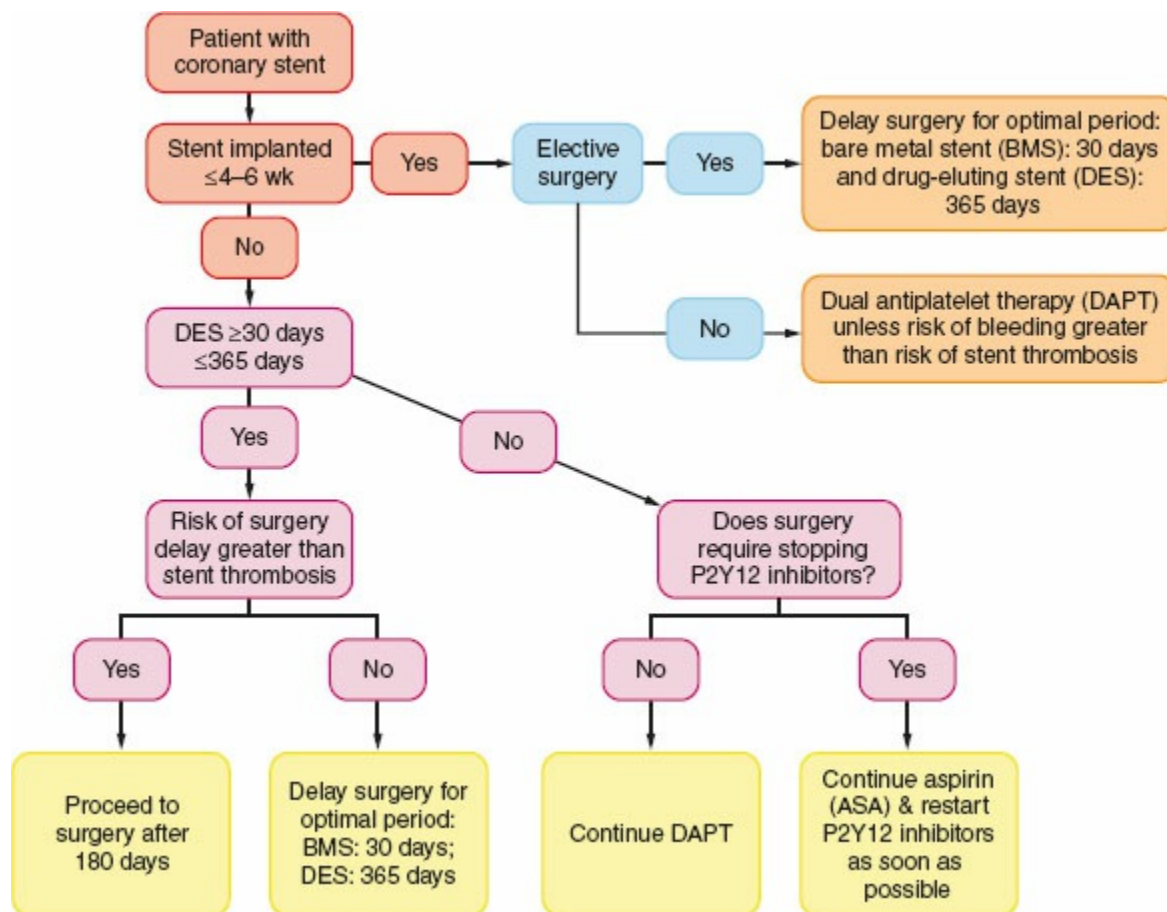

Guidelines to reduce the perioperative risk of noncardiac surgery have recently been reviewed. There are several large studies suggesting that for patients who survive CABG, the risk of subsequent noncardiac surgery is low.<sup>11,16</sup> Although there are little data to support the notion of coronary revascularization solely for the purpose of improving perioperative outcome, it is true that for some patients scheduled for high-risk surgery, long-term survival may be enhanced by revascularization. Two studies used the

Coronary Artery Surgery Study database and found that CABG significantly improved survival in those patients with both peripheral vascular disease and triple-vessel coronary disease, especially the group with depressed ventricular function.<sup>48</sup> After reviewing all available data, most clinicians believe the indication for CABG prior to noncardiac surgery remains the same as in other settings and is independent of the proposed noncardiac surgery.

The value of percutaneous transluminal coronary angioplasty is less well established, and current evidence does not support its use beyond established indications for nonoperative patients. In the recent ACC/AHA Clinical Practice Guideline, clinical factors that support percutaneous coronary interventions before noncardiac surgery included high-risk coronary anatomy (e.g., left main disease), unstable angina pectoris, MI, or life-threatening arrhythmias.<sup>15</sup>

### **Patients with Coronary Artery Stents**

Early surgery after coronary stent placement has been associated with adverse cardiac events. A significant incidence of perioperative death and hemorrhage in patients after stent placement has been reported. The 2014 ACC/AHA Clinical Practice Guideline supports the delay of elective noncardiac surgery for 14 days after coronary balloon angioplasty and 30 days after bare metal stent (BMS) placement. The optimal waiting period for elective noncardiac surgery after drug-eluting stents (DESs) is 12 months; however, elective noncardiac surgery may be considered after 6 months based on comparative benefits of surgery compared with risk of stent thrombosis and myocardial ischemia.<sup>15</sup> This difference is because the incidence of stent thrombosis for DESs has been found to be similar to that of BMSs in the early phase after placement but is less well defined over a longer period of time. Dual antiplatelet therapy, for example, aspirin and clopidogrel, is often used after stent placement. A thienopyridine (ticlopidine or clopidogrel) is generally continued with aspirin for 1 month after BMA placement and for 12 months after DES placement (Fig. 23-3). Perioperative management must weigh the risk of bleeding versus stent thrombosis. The decision must involve the anesthesiologist, surgeon, cardiologist, and intensivist. For those patients who have a high risk for stent thrombosis, many advocate that at least aspirin be continued in the perioperative period. Also, the anesthesiologist must weigh the risk of regional versus general anesthesia when these patients are taking antiplatelet therapy. Surgery in patients with recent stent placement should probably only be considered in centers where interventional cardiologists are continuously available.<sup>49,50</sup>

**Figure 23-3** Approach to perioperative cardiac assessment for patients with coronary artery stent. P2Y12, Platelet receptor inhibitor (e.g., clopidogrel). (Modified with permission from Fleisher LA, Fleischmann KE, Auerbach AD, et al. ACC/AHA Guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery. *Circulation*. 2014;130:e278–e333. <http://circ.ahajournals.org>.)

## Patients with Cardiovascular Implantable Electronic Devices

 With the increasing prevalence of patients treated with pacemakers and implantable defibrillators, preoperative evaluation must address the management of cardiovascular implantable electronic devices (CIEDs) during the perioperative period. The function of these devices can be impaired by electromagnetic interference during surgery. It is important to understand the type of device, its programming, and its underlying clinical need. The cardiologist often needs to be involved in programming the CIED before and after surgery. The Heart Rhythm Society and the ASA have published clinical practice guidelines for perioperative management of patients with implantable defibrillators, pacemakers, and arrhythmia monitors (see Appendix).<sup>51</sup>

## Pulmonary Disease

Postoperative pulmonary complications occur more frequently than cardiac

complications in patients having major noncardiac surgeries. Perioperative pulmonary complications include atelectasis, pneumonia, exacerbation of chronic obstructive pulmonary disease, pulmonary edema, and respiratory failure requiring mechanical ventilation.<sup>52</sup> Postoperative respiratory failure is a major cause of morbidity and mortality, contributing to increased length of hospital stay and substantial economic cost. The risk of mortality with the development of respiratory failure is substantial and higher than the risk after a perioperative MI. Epidemiologic analyses of large clinical databases have substantially increased the understanding of clinical risk factors.<sup>52,53</sup> Clinical guidelines from the American College of Physicians have been developed to assess the preoperative risk and recommend prevention strategies to limit the risk of respiratory failure.<sup>54</sup> Preoperative testing, such as pulmonary function testing and chest radiograph, is not recommended on a routine basis, as it appears to have limited benefit in predicting perioperative respiratory failure and complication rate. Although a preoperative chest radiograph can identify structural lung abnormalities, these are not frequently associated with significant changes in clinical management for the general population. In contrast, laboratory studies identifying a reduction in serum albumin levels and increased levels of blood urea nitrogen (BUN) appear to be associated with an increased risk of perioperative pulmonary morbidity.<sup>52</sup>

Epidemiologic studies significantly support the relationship of the anatomic location of the surgery and pulmonary risk.<sup>52</sup> With regard to the surgical site, open aortic, thoracic, and upper abdominal surgeries have been associated with the highest risk for postoperative pulmonary morbidity. However, cranial procedures also carry an increased risk, as do vascular and neck surgeries.<sup>52,55,56</sup> Decreases in postoperative vital capacity, functional residual capacity, as well as diaphragmatic dysfunction can contribute to hypoxemia and atelectasis.<sup>57</sup> Functional residual capacity may take up to 2 weeks to return to baseline. Diaphragmatic dysfunction occurs despite adequate analgesia and is theorized to be caused by phrenic nerve dysfunction.<sup>58</sup> Neurosurgery and neck surgery may be associated with perioperative aspiration pneumonia, likely due to an altered sensorium or cranial nerve dysfunction leading to aspiration.

The need for emergency surgery and the need for general anesthesia are also associated with increased risk. Not only can the surgery affect pulmonary function, but general anesthesia also results in mechanical changes, such as a decrease in the functional residual capacity and reduced diaphragmatic function, leading to ventilation/perfusion abnormalities and atelectasis. General anesthesia also induces negative changes at the microscopic level, causing inhibition of mucociliary clearance, increased alveolar–capillary permeability, inhibition of surfactant production, increased nitric oxide synthetase, and increased sensitivity of the pulmonary vasculature to

neurohumoral mediators. Subanesthetic levels of intravenous or volatile agents have the ability to blunt the ventilatory response to hypoxemia and hypercarbia as well. Duration of anesthesia is a well-established risk factor for postoperative pulmonary complications, with morbidity rates increasing after 2 to 3 hours.<sup>59</sup> However, when considering laparoscopic surgery, which is often longer in duration, the associated decrease in pulmonary complications compared with an open procedure usually outweighs the risk of increased anesthesia time.<sup>60</sup>

Brueckmann et al.<sup>61</sup> developed a simple scoring system using only preoperative variables to predict the risk of reintubation within the first 3 days after surgery, by examining the electronic records of over 33,000 adult patients who underwent inpatient surgery. The most common independent predictors for reintubation were: ASA Class 3 or greater, emergency surgery, high-risk surgical procedure (vascular, transplant, neurosurgery, thoracic, general, and burn surgery), history of congestive heart failure, and chronic pulmonary disease. A point value of 3, 3, 2, 2, and 1 were assigned to these predictors, respectively. They calculated the probability for reintubation as 0.12% with a score of 0, to 5.9% for scores of 7 to 11 (Table 23-10).

The preoperative evaluation is the time to identify pre-existing pulmonary disease and work with the patient and consultants to maximize the patient's health status (see following sections). It is also important to work with the surgeon to plan specific risk reduction strategies, such as epidural analgesia when appropriate, lung expansion methods, and deep venous thrombosis prophylaxis. Intraoperative measures to limit the risk of hospital-acquired pneumonia have been proposed, largely focused on reducing the risk of bacterial contamination of the lung during the perioperative period. For high-risk patient groups, studies support preoperative oral antiseptic decontamination before tracheal intubation as well as the role of specialized endotracheal tubes to decrease the risk of nosocomial pneumonia.<sup>62-64</sup>

**Table 23-10** Preoperative Risk Factors for Postoperative Reintubation

Predictors	Point Value
ASA score $\geq 3$	3
Emergency procedure	3
<sup>a</sup> High risk surgery	2
History of congestive heart failure	2
Chronic pulmonary disease	1

**Score for Prediction of Postoperative Reintubation**

0	1	2	3	4	5	6	7	8	9	10	11
---	---	---	---	---	---	---	---	---	---	----	----

0.1                      0.5                      1.5                      4.2                      11.2

Adapted from Brueckmann B, Villa-Urbe JL, Brian T, Bateman BT, et al. Development and validation of a score for prediction of postoperative respiratory complications. *Anesthesiology*. 2013;118:1276–1285.

## Tobacco Use

Smoking is an important risk factor, but one that usually is difficult to influence. Even among smokers who have not developed chronic lung disease, smoking is known to increase carboxyhemoglobin levels, decrease ciliary function, and increase sputum production, as well as cause stimulation of the cardiovascular system secondary to nicotine. Although cessation of smoking for 2 days can decrease carboxyhemoglobin levels, abolish the nicotine effects, and improve mucous clearance, prospective studies showed that smoking cessation for at least 4 to 8 weeks was necessary to reduce the rate of postoperative pulmonary complications.<sup>65,66</sup> Studies of nicotine transdermal patches used during the perioperative period have shown increased mortality and are best avoided.<sup>67</sup> Patients who smoke often show increased airway reactivity under general anesthesia; although without proven benefit, it may be useful to administer a bronchodilator, such as albuterol, preoperatively.

## Asthma

Asthma is one of the most common coexisting diseases that confront the anesthesiologist. During the patient interview, it is important to elicit information regarding inciting factors, severity, reversibility, and current status. Frequent use of bronchodilators, hospitalizations for asthma, and requirement for systemic steroids are all indicators of more severe disease. After an acute exacerbation of asthma, airway hyperreactivity may persist for several weeks.<sup>68</sup> In addition to bronchodilators, perioperative steroids are worth considering as prophylaxis for the severe asthmatic. The possibility of

adrenal insufficiency is also a concern in those patients who have received more than a “burst and taper” of steroids in the previous 6 months. This group of patients should be considered for “stress doses” of steroids perioperatively. Kabalin et al.<sup>69</sup> found there was a low complication rate for asthmatics treated with short-term steroids undergoing surgery. Significantly, they found no association with impaired wound healing or infections. For patients using inhaled steroids, they should be administered regularly, starting at least 48 hours prior to surgery for optimal effectiveness.

## Obstructive Sleep Apnea

OSA is a syndrome defined by periodic obstruction of the upper airway during sleep, leading to episodic oxygen desaturation and hypercarbia. This episodic desaturation, in turn, causes episodic arousal, leading to chronic sleep deprivation with daytime hypersomnolence and even behavioral changes in children. Depending on the frequency and severity of events, it may lead to other changes, such as chronic pulmonary hypertension and right heart failure. It is estimated to be present in 26% of US adults between 30 and 70 years of age, and the incidence is climbing in association with the obesity epidemic.<sup>70</sup> Because of their propensity for airway collapse and sleep deprivation, patients with OSA are especially susceptible to the respiratory depressant and airway obstructive effects of sedatives, opioids, and inhaled anesthetics both intraoperatively and postoperatively.

In 2014, the ASA published updated practice guidelines for the perioperative management of patients with OSA.<sup>71</sup> Preoperative identification of those patients at risk is critical to formulate a safe perioperative plan.

Physical characteristics commonly associated with an increased risk of sleep apnea are:

- Obesity—body mass index 35 kg/m<sup>2</sup> or more, or at least 95th percentile in pediatric patients
- Increased neck circumference (men—17 inches, women—16 inches)
- Severe tonsillar hypertrophy
- Nasal obstruction
- Anatomic abnormalities of the upper airway.

Specific questions should be directed toward the patient and family regarding the presence of the following symptoms and signs of OSA:

- Does the patient snore loudly enough to be heard through a door or snore frequently?
- Have you observed pauses in the patient’s breathing during sleep?
- Does the patient have frequent arousals from sleep or awakenings with a choking sensation?
- Does the patient experience frequent daytime somnolence and fatigue

or fall asleep easily in a nonstimulating environment?

- Does your child appear restless when sleeping or have difficulty with breathing?
- Does your child have night terrors, sleep in unusual positions, or have new-onset enuresis?
- Is your child difficult to arouse at normal awake hours?
- Is your child overly aggressive or does he or she have trouble concentrating?

If a patient has positive signs or symptoms in two or more of the above, then there is a high probability for OSA and the anesthesiologist in conjunction with the surgeon should determine if the patient needs referral for a sleep study. If a sleep study is not warranted or not possible, the patient should be managed as if he or she has OSA.

The risk of perioperative complications in patients with OSA increases with the severity of sleep apnea, the invasiveness of surgery, and the amount of postoperative opioids required.<sup>71</sup>

There is general consensus that preoperative initiation of nasal mask continuous positive airway pressure (CPAP) reduces perioperative risk, perhaps by decreasing the sleep deprivation and secondary hypersomnolence. Importantly, OSA is also associated with difficult airway management, making it even more important to examine previous anesthesia records and to perform a thorough airway examination. Emergency airway equipment should be readily available at the surgical center.

There are multiple management decisions to make in coordination with the surgeon with respect to the OSA patient:

- Determine whether there are noninvasive ways of performing the operation that would decrease the need for opioids postoperatively.
- Discuss whether it is feasible to perform surgery under neuraxial, regional, or local anesthesia, decreasing the total amount of anesthesia or opioids needed.
- Determine whether nonsteroidal anti-inflammatory agents are acceptable for postoperative analgesia.
- Discuss whether outpatient surgery is a safe option.
- Determine whether the patient will be able to use CPAP postoperatively.
- Determine whether postoperative admission to an intensive care unit or monitored unit is required for the patient who is a first-time user of CPAP.

The ASA practice guidelines for OSA recommend hospitalization after uvulopalatoplasty surgery and after tonsillectomy for OSA in children younger than 3 years. Postoperative hospitalization is also recommended for those OSA patients with other coexisting diseases.

## Endocrine Disease

### Diabetes Mellitus

Diabetes mellitus is the most common endocrinopathy, and according to the Centers for Disease Control and Prevention (CDC) Americans have an incidence of approximately 9% (almost 26% of those 65 years and older), with the highest rates in Native Americans, followed by Blacks, Hispanics, Asian Americans, then Whites (<http://www.cdc.gov/diabetes>). The incidence is expected to rise significantly for Americans born after 2000, largely because of the rise in obesity. Critical illness–induced hyperglycemia, defined as a blood glucose above 200 mg/dL in the absence of known diabetes, occurs most frequently in the elderly.<sup>72</sup> Diabetes mellitus has acute and chronic disease manifestations, making it more likely for diabetics to require surgery. The majority of diabetics develop secondary disease in one or more organ systems, which must be identified preoperatively so that an appropriate plan can be developed for perioperative management. Although long-term close control of glucose may limit some of the microvascular effects of diabetes (retinopathy, neuropathy, and nephropathy), macrovascular events such as myocardial ischemia, MI, or stroke may not be decreased. Diabetics have an increased risk of CAD, hypertension, congestive heart failure, and perioperative MI, with the incidence of silent ischemia increased due to associated autonomic neuropathy. The 2014 ACC/AHA Clinical Practice Guideline places diabetics, especially those receiving insulin, at an elevated risk.<sup>15</sup>

Diabetics are also more likely than the general population to have cerebral vascular, peripheral vascular, and renal vascular disease. Diabetes mellitus is the leading cause of renal failure requiring dialysis. Peripheral neuropathies and vascular disease make these patients more susceptible to positioning injuries both during and after surgery. Autonomic neuropathy may predispose the patient to hemodynamic instability during anesthesia and theoretically increase the risk of pulmonary aspiration because of the associated gastroparesis. These deficits should be documented prior to anesthesia and the anesthetic plan adjusted accordingly. Stiff joint syndrome due to glycosylation of proteins and abnormal collagen cross-linking may significantly affect the temporomandibular, atlanto-occipital, and cervical spine joints in patients with longstanding type 1 diabetes, resulting in difficulty with tracheal intubation. A thorough airway examination should be performed prior to anesthesia and a high index of suspicion maintained for a potentially difficult airway. Some suggest using the “prayer sign” as an evaluation tool; patients who are unable to completely oppose their hands (with no space between) should be suspected of also having changes in other joints potentially impacting airway manipulation.

Regimens for perioperative glycemic control vary enormously, not only between type 1 and type 2 diabetics but also within each group. Patients with type 1 diabetes have an absolute insulin deficiency usually due to destruction of pancreatic  $\beta$  cells. These patients must receive insulin to prevent diabetic ketoacidosis. Home glucose management most often relies on some combination of short, intermediate, and long-acting insulin regimens. Insulin pumps are increasingly common and are used to administer a continuous subcutaneous infusion of short-acting insulin, supplemented by boluses dictated by glucose levels, diet, and exercise. Type 2 diabetes accounts for the great majority of diabetics and is defined by variable degrees of insulin deficiency and resistance. Although most commonly associated with obesity, it may also be induced by corticosteroids or pregnancy. Ketoacidosis is uncommon in type 2 diabetics and the stress of severe infection or illness is more likely to provoke a nonketotic hyperosmolar state, which is characterized by severe dehydration, hyperglycemia, and hyperosmolarity. In type 2 diabetics, glucose control is most commonly achieved with diet, exercise, and oral hypoglycemic drugs. These agents primarily work by increasing endogenous insulin release, increasing insulin sensitivity, and/or decreasing hepatic gluconeogenesis. These drugs fall under the main categories of sulfonylureas, biguanides, thiazolidinediones, and meglitinides. If glycemic control is unsuccessful, then insulin is generally added to the regimen.

Ideally, both types 1 and 2 diabetic patients should be evaluated in the preoperative clinic as well as by the patient's endocrinologist 1 to 2 weeks before elective surgery. Questions should address the type, dose, and time of antidiabetic therapy as well as the frequency and manifestations of hypoglycemia and level at which symptoms occur.

In addition to a thorough history and physical examination, a judicious laboratory investigation should include determination of blood glucose, hemoglobin A1c, serum electrolytes, creatinine, and an ECG. If the patient's glycemic control is inadequate based on a hemoglobin A1c above the target range ( $<7.5\%$  for type 1 diabetics and  $<7\%$  for type 2 diabetics, as recommended by the American Diabetic Association), abnormal electrolytes, or ketonuria, then elective surgery should be delayed to allow optimization of preoperative glycemic control. Initiation of  $\beta$ -blockers prior to the day of surgery should be considered in diabetic patients with at least two other risk factors for an adverse cardiac event, as there is no evidence of worsened glucose intolerance or masking of hypoglycemic symptoms.<sup>15</sup>

### *Perioperative Glucose Management*

Anesthesia and surgery interrupt the regular meal and insulin administration schedules in patients with diabetes mellitus. Perioperative stress may increase

serum glucose concentrations secondary to the release of cortisol and catecholamines. The majority of available literature suggests that better glycemic control may limit morbidity (length of hospital/intensive care unit stay, infection rate, wound healing, outcomes after strokes/MIs) and mortality, particularly in cardiac surgery patients, carotid endarterectomy patients, and the critically ill.<sup>72-75</sup> Although a randomized trial found an increase in the incidence of death and perioperative stroke in cardiac surgery patients where an attempt was made to maintain the glucose between 80 and 100 mg/dL,<sup>76</sup> recent systematic reviews have found a reduction in morbidity and mortality associated with better glycemic control but recognize the increased risk of hypoglycemia.<sup>77</sup> More studies are needed to more closely define the target level for glucose control. There is general consensus that an attempt should be made to control the upper limit of glucose to less than 200 mg/dL, although some will argue that tighter control is warranted. Guidelines for ambulatory and hospitalized patients have been recently published.<sup>78,79</sup> The following recommendations can serve as a general guide:

#### *Guide for Perioperative Glucose Control*

- Plan with the surgeon to schedule the surgery as the first case of the day to prevent prolonged fasting.
- As a general rule, oral hypoglycemic agents are held on the day of surgery to avoid reactive hypoglycemia until oral intake is restarted.
- Insulin therapy should balance adequate glucose control with the avoidance of hypoglycemia. Insulin is usually continued through the evening before surgery.
- Schedule the patient to arrive in the early morning and check blood glucose on arrival.
- If patients develop symptoms or measurable hypoglycemia, they should be counseled to take a glucose tablet or clear juice.
- Type 1 diabetics should be continued on basal insulin administration even during preoperative fasting to prevent ketoacidosis. Administer half the usual morning dose of intermediate- or long-acting insulin after arrival to the surgery center, where a maintenance IV can be started. Hold the usual dose of rapid- or short-acting insulin.
- Use the patient's own sliding scale to administer short-acting insulin subcutaneously prior to the scheduled surgery and during short operations.
- Patients on insulin pumps may be managed by continuing the pump for short operations or changing over to an intravenous insulin infusion for longer or major operations.

This strategy, along with blood glucose determinations every 1 to 2 hours, may be all that is necessary for well-controlled diabetics undergoing short,

noninvasive outpatient operations. In addition, it is important to prevent postoperative nausea and vomiting and to encourage the early resumption of diet, allowing return to their previous insulin regimen. For type 1 or 2 diabetics undergoing longer or major surgery, insulin is generally administered in the form of an intravenous infusion of regular insulin. Discontinuing the patient's own insulin pump will avoid problems with insulin preparations and pump technology.

There are several methods of administering an insulin infusion, none of which has proved superior. Concurrent separate infusions of insulin and glucose are more easily adjusted and may provide better glycemic control than combined glucose/insulin/potassium infusions. To increase safety, the insulin infusion (which is on a separate pump) is added via a side port to the same line delivering the glucose infusion. A separate nonglucose isotonic solution should be used to replace deficits and intraoperative fluid losses. All protocols rely on the frequent determination of a plasma glucose level at least every 1 to 2 hours to allow titration of insulin.[80–82](#)

## **Thyroid and Parathyroid Diseases**

Thyroid and parathyroid diseases have clinical manifestations that are important to the preoperative evaluation. Although thyroid function tests are more sensitive, thyroid disease is usually adequately evaluated by clinical history, which should screen for signs and symptoms of hypothyroidism and hyperthyroidism. Hypothyroidism can lead to the development of hypothermia, hypoglycemia, hypoventilation, hyponatremia, and heart failure, as well as a susceptibility to anesthetics. Anesthesiologists should be alert to the possibility of the hypermetabolic state of thyroid storm in patients with hyperthyroidism. A large thyroid mass may distort the upper airway, producing inspiratory stridor or wheezing, especially evident in the supine position. In these cases, a chest x-ray should be obtained looking for evidence of tracheal deviation or narrowing. A CT scan of the upper airway and trachea will provide better detail of any airway compromise. Patients with hyperparathyroidism often have hypercalcemia, and a preoperative determination of a serum calcium level is warranted. Additional clinical manifestations of these conditions are shown in [Table 23-11](#).

## **Adrenal Disorders**

The classic clinical presentation of a patient with pheochromocytoma includes intermittent hypertension, headache, diaphoresis, and tachycardia. Patients with endocrine tumors have a higher incidence of multiple endocrine neoplasia syndrome and pheochromocytoma should be ruled out as the cause of unexplained hypertension. Over time, the mortality for surgical resection

of a pheochromocytoma has decreased because of improvements in perioperative therapy for patients with the syndrome. A more important issue is preoperative identification of patients with a possible pheochromocytoma before they are scheduled for other types of surgery.

*Adrenal–cortical suppression* is a potential disorder in patients presenting for surgery; one should have a high index of suspicion in those patients taking long-term corticosteroids. Cushing syndrome is the most obvious manifestation of long-term high-dose steroid treatment, including moon facies, striations of the skin, truncal obesity, hypertension, easy bruisability, and hypovolemia. Preoperative preparation for patients with adrenal suppression includes correction of any fluid and electrolyte abnormalities, as well as steroid supplementation.

Many anesthesiologists believe that patients taking corticosteroids for long periods within the last 6 months require perioperative steroid supplementation to cover the stresses of anesthesia and surgery, but not patients who have had only a short course of steroids more than 6 months prior. It is impossible to identify the specific duration of therapy or dose of steroids that produces clinically meaningful pituitary and adrenal suppression. Marked variability among patients exists, but one would expect more suppression in patients taking a higher dose for a longer duration. A conservative approach is to consider treatment in any patient who has received corticosteroid therapy for at least 1 month in the past 6 to 12 months and will be undergoing more than minor surgery. The dose and duration of supplemental steroid administration depend on an estimate of the stress of the surgical procedure in the perioperative period. The maximum dose of steroid given for coverage of the stress response is the patient's usual dosage the morning of surgery, followed by 100 mg of IV hydrocortisone before surgery and every 8 hours for the first day, followed by a taper. This dose is meant to approximate the maximum amount of steroid that the adrenal glands could produce during stress in a 24-hour period. Newer recommendations suggest giving 100 mg followed by 50 mg every 8 hours for the first day; for moderate procedures, it is recommended to decrease the hydrocortisone dose by 50%.<sup>83</sup> However, these various recommendations have been questioned and are not supported by studies.<sup>83</sup> The addition of supraphysiologic doses of steroids can increase the risk of acute side effects, such as hyperglycemia, hypertension, fluid retention, and an increased risk of infection. What experts do agree on is that patients should receive their usual daily glucocorticoid dose. Also, exogenous glucocorticoid administration should be considered in any patient who develops perioperative hypotension that is not responsive to standard resuscitative fluid administration or vasopressor therapy, and cannot be explained by other mechanisms, suggesting adrenal insufficiency.

**Table 23-11** Clinical Manifestations of Thyroid and Parathyroid Diseases

	Hyperthyroidism	Hypothyroidism	Hyperparathyroidism
General	Weight loss; heat intolerance; warm, moist skin	Cold intolerance	Weight loss, polydipsia
Cardiovascular	Tachycardia, atrial fibrillation, congestive heart failure	Bradycardia, congestive heart failure, cardiomegaly, pericardial or pleural effusion	Hypertension, heart block
Neurologic	Nervousness, tremor, hyperactive reflexes	Slow mental function, minimal reflexes	Weakness, lethargy, headache, insomnia, apathy, depression
Musculoskeletal	Muscle weakness, bone resorption	Large tongue, amyloidosis	Bone pains, arthritis, pathologic fractures
Gastrointestinal	Diarrhea	Delayed gastric emptying	Anorexia, nausea, vomiting, constipation, epigastric pain
Hematologic	Anemia, thrombocytopenia		
Renal		Impaired free water clearance	Polyuria, hematuria

Adapted from Roizen MF. Anesthesia for the patient with endocrine disease, part 1. *Curr Rev Clin Anesth*. 1987;6:43.

## Renal Disease

Renal disease has important implications for fluid and electrolyte management, as well as metabolism of drugs. The cause of renal failure has considerable impact on clinical management. Patients with primary renal disease are likely to be younger and have good cardiopulmonary reserve, whereas a significant percentage of older patients with renal failure secondary to diabetes mellitus or hypertension will also have diffuse atherosclerosis and heart disease. Chronic renal disease secondary to sickle cell anemia, systemic lupus erythematosus, or vasculitis implies multisystem involvement and dysfunction.<sup>84</sup> In those patients with renal failure, the timing of their most recent dialysis will determine whether they are hyper- or hypovolemic and hyper- or hypokalemic. It is important to assess the patient's electrolytes prior to surgery and to ensure they are euvolemic prior to induction of anesthesia. Some patients will require dialysis before surgery. Because renal failure is also associated with anemia and qualitatively deficient platelets, there should be a lower threshold for determining these laboratory results preoperatively.

## Liver Disease

Liver disease is associated with decreased plasma protein production, thereby affecting drug binding, volume of distribution, metabolism and clearance. Coagulopathy accompanies liver failure and the etiology can be multifactorial; it can result from malnutrition (poor absorption of nutrients as a consequence of cholestasis), impaired synthesis of coagulation factors, or thrombocytopenia. The history should identify specific risk factors for liver disease, such as previous blood transfusions, illicit drug use, or excessive alcohol intake. The anesthesiologist should inquire about bruising, bleeding,

or history of esophageal varices, the latter to potentially avoid esophageal instrumentation. Coagulation disorders may discourage the choice of regional anesthesia. The physical examination should screen for signs of underlying liver disease, such as jaundice, spider nevi, ascites, hepatosplenomegaly, or palmar erythema. Ascites, a more obvious physical finding of liver failure, may significantly affect the patient's respiratory mechanics and make it difficult to lie flat. In patients with chronic liver disease, perioperative risk increases with worsening severity of hepatic dysfunction as assessed by the Model for End-Stage Liver Disease (MELD) score. The MELD assigns the patient a score of 8 to 40 that is derived from a complex formula that incorporates three biochemical variables—the serum total bilirubin concentration, serum creatinine concentration, and international normalized ratio (INR). The MELD score has been prospectively validated as a prognostic marker of mortality in patients with cirrhosis, acute variceal bleeding, or acute alcoholic hepatitis.<sup>85</sup>

## **Other Diseases**

Arthritis is becoming more prevalent in our aging population, worsened by our sedentary lifestyle. Osteoarthritis may result in difficulty positioning the head to facilitate tracheal intubation or difficulty in positioning for regional anesthesia. These are likewise problems in patients with RA; however, of particular importance is the potential for atlantoaxial instability or superior migration of the odontoid causing spinal cord compression. Involvement of the cervical spine in RA patients typically parallels the extent of peripheral disease and may warrant preoperative radiologic screening.<sup>86</sup> Although not as common, RA of the temporomandibular joint may impede mouth opening for tracheal intubation. RA is a multisystem disease, potentially leading to derangements in other organ systems, causing restrictive lung disease, pleural effusions, pericarditis, and anemia.

Finally, the anesthesiologist should inquire about infectious diseases, including questions about foreign travel, that will dictate the need for increased protective measures for OR personnel and equipment.

## **Preoperative Laboratory Testing**

### **Defining Normal Values**

In attempting to determine the optimal choice of preoperative tests, it is important to understand the interpretation of the results. Ideally, tests would either confirm or exclude the presence of a disease; however, most tests only increase or decrease the probability of disease. In determining reference

ranges for diagnostic tests, values that fall outside the 95% confidence intervals for normal individuals are considered abnormal. Therefore, up to 5% of normal individuals can have “abnormal” test results. To determine its clinical relevance, a test must be interpreted within the context of the clinical situation. Performing tests in patients with no risk for having the pathophysiologic process of interest can yield a high number of false-positive results. For example, a low potassium value (3.0 mg/dL) in an otherwise healthy individual is most likely a normal result. Interpreting this test as abnormal, and initiating treatment, could lead to harm without any benefit.

### *Risks and Costs versus Benefits*

**8** The 2012 ASA Practice Advisory for Preanesthesia Evaluation<sup>1</sup> states that routine preoperative tests do not make an important contribution to preanesthetic evaluation of an asymptomatic patient. Selective preoperative tests should be ordered only after consideration of specific information obtained from the medical record, history and physical, and the type or invasiveness of the planned procedure and anesthesia.

Medical testing is associated with significant cost, both in real dollars and in potential harm. Routine preoperative testing has been estimated to cost billions of dollars annually in the United States. An “abnormal” test that is later determined to be a false result can lead to significant cost and real harm. For example, a positive exercise ECG stress test in a healthy 40-year-old woman may lead to coronary angiography. Coronary angiography is not a benign procedure and can lead to vascular injuries. On the basis of Bayesian analysis, a positive test result in this patient is most likely a false positive and the test was inappropriately used. Therefore, the woman and her physician would gain no additional information, thousands of dollars in medical costs would accrue, and she may sustain morbidity.

Several studies have evaluated the implications of reduced testing. Golub et al.<sup>87</sup> retrospectively reviewed the records of 325 patients who had undergone preadmission testing prior to ambulatory surgery. Of these, 272 (84%) had at least one abnormal screening test result, whereas only 28 surgeries were delayed or canceled. The authors estimated that only three patients potentially benefited from preadmission testing, including a new diagnosis of diabetes in one and nonspecific ECG changes in two, one of whom had known ischemic heart disease.

Narr et al.<sup>88</sup> demonstrated minimal benefits from routine testing and proposed that routine laboratory screening tests were not required in healthy patients. In a follow-up study, a cohort of patients who had no preoperative testing was reviewed and found to include no deaths or major perioperative morbidity.<sup>89</sup> The authors concluded that routine testing was not indicated in

this healthy cohort.

Even if testing better defines a disease state, the risks of any intervention based on the results may outweigh the benefit. Cardiovascular testing is a classic example. If a noninvasive test is positive, coronary angiography may be performed. A positive angiogram may then result in CABG prior to the planned noncardiac surgery. Although cardiovascular morbidity and mortality may be reduced in patients with significant CAD who have undergone coronary revascularization, the morbidity associated with both the testing and the revascularization procedure may be greater than any potential benefit. Roizen and Cohn<sup>90</sup> have suggested a protocol for screening tests based on both the preoperative evaluation and proposed procedure using a risk–benefit analysis. The following protocol for laboratory testing is modified from their recommendations and the 2012 ASA Practice Advisory for Preanesthetic Evaluation<sup>1</sup>:

## **Clinical Considerations for Laboratory Testing**

### *Blood Count*

- Extremes of age
- Liver or kidney disease
- Anticoagulant use
- Bleeding/hematologic disorder
- Malignancy
- Type and invasiveness of procedure

### *Coagulation Studies*

- Liver or kidney disease
- Bleeding disorder
- Anticoagulant use
- Chemotherapy

### *Serum Chemistries (glucose, electrolytes, renal and liver function)*

- Liver or renal disease, or perioperative risk of dysfunction
- Diabetes
- Diuretic, digoxin, or steroid use
- Central nervous system disease
- Endocrine disorders
- Elderly
- Malnutrition
- Type and invasiveness of procedure

### *Chest X-ray*

- Pulmonary disease or clinical manifestations
- Unstable cardiovascular disease
- Type and invasiveness of procedure

## *ECG*

Cardiovascular disease or clinical risk factors

Pulmonary disease

Type and invasiveness of procedure

## *Pregnancy Test*

Possible pregnancy

## *Complete Blood Count and Hemoglobin Concentration*

A preoperative hemoglobin or hematocrit value has been suggested as the only test necessary in many patients prior to elective surgery; however, even this minimal standard has been questioned. Baron et al.<sup>91</sup> reviewed the records of 1,863 pediatric patients scheduled for elective outpatient procedures. In only 1.1% of patients was the hematocrit abnormal, and in none of these patients was the procedure canceled or the anesthetic plan modified. However, a baseline hematocrit is still indicated in any procedure with a risk of significant blood loss.

Both the standard for the lowest acceptable perioperative hematocrit and the indication for a preoperative transfusion have changed during the past decade. The current recommendations of the National Blood Resource Education Committee are that a hemoglobin level of 7 g/dL is acceptable in patients without systemic disease. In patients with systemic disease, signs of inadequate systemic oxygen delivery (tachycardia, tachypnea) are an indication for transfusion.

## *Coagulation Studies*

Coagulation disorders can have a significant impact on the surgical procedure and perioperative management. In patients with hemophilia or von Willebrand disease, abnormal laboratory studies even in the absence of clinical abnormalities require preoperative preparation of the patient. Abnormal coagulation values may delay the surgery depending on the degree of abnormality and the procedure planned. For example, neurosurgery has little tolerance for values outside of the normal range due to the serious consequences if uncontrolled bleeding were to occur perioperatively. Surgery may be delayed for hours if fresh frozen plasma or platelets are needed to acutely correct a coagulopathy, or days if vitamin K is administered for correction.

## *Pregnancy Testing*

Routine pregnancy testing in women of childbearing potential is a subject of considerable debate. The rationale is that surgery may be delayed or specific agents avoided if it is necessary to proceed. Information regarding the last

menstrual period can help define the potential, but does not eliminate the possibility. A number of studies have evaluated the validity of history as a means of assessing pregnancy status in adolescents and yielded conflicting results. Current practice varies dramatically and may be a function of the population served.

### *Chest X-rays*

A preoperative chest x-ray can identify abnormalities that may lead to either delay or cancellation of the planned surgical procedure or modification of perioperative care. For example, identification of pneumonia, pulmonary edema, pulmonary nodules, or a mediastinal mass could all lead to modification of care. However, routine testing in the population without risk factors can lead to more harm than benefit. Roizen and Cohn<sup>90</sup> have demonstrated substantial harm from additional procedures based on an abnormal routine preoperative chest x-ray.

The American College of Physicians suggests that a chest x-ray is indicated in the presence of active chest disease or an intrathoracic procedure but not on the basis of advanced age alone.<sup>92</sup> In a meta-analysis, Archer et al.<sup>93</sup> reviewed the published reports from 1966 to 1992 in the English, French, and Spanish literature. On average, abnormalities were reported in 10% of routine preoperative chest x-rays, of which only 1.3% were unexpected. These findings resulted in modification in management in only 0.1% of patients, with unknown influence on outcome. The authors estimated a cost of \$23,000 for each finding that influenced management, concluding that routine chest x-rays without a clinical indication were not justified.

### *Pulmonary Function Tests*

Consensus guidelines do not support routine use of pulmonary function studies to predict perioperative respiratory complications. Pulmonary function tests can be divided into two categories: spirometry and arterial blood gas analysis. Spirometry can provide information on forced vital capacity (FVC), forced expiratory volume in 1 second (FEV<sub>1</sub>), ratio of FEV<sub>1</sub>/FVC, and average forced expiratory flow from 25% to 75% (FEF 25% to 75%). Although each of these measures has a sound physiologic basis, their practical assessment can vary greatly among healthy persons and the tests rarely provide additional information beyond that obtained from history. For those patients considered for pulmonary resection, evaluation using spirometry, diffusion capacity measurements, radionuclide lung perfusion scanning, and cardiopulmonary exercise testing may help to define those patients at high risk.<sup>94</sup>

With availability of the pulse oximeter, the use of preoperative arterial blood gas sampling has become less important. It may still be indicated in

those with poor pulmonary function, since determining the baseline CO<sub>2</sub> is useful in managing perioperative ventilator settings and resting hypercapnia is associated with increased perioperative risk. One method of assessing the probability of CO<sub>2</sub> retention is evaluation of the serum bicarbonate. A normal serum bicarbonate value will virtually exclude the diagnosis of chronic CO<sub>2</sub> retention.

## Summary of the Preoperative Evaluation

There are multiple factors that are associated with increased perioperative risk, as discussed within this chapter. Clinical judgment is necessary and requires addressing the following fundamental questions:

1. Are the risk factors modifiable?
2. Will delaying the procedure add to perioperative risk or patient morbidity?
3. What interventions during the preoperative period can be implemented to reduce risk?
4. Has the patient been provided enough information to make an informed decision?

An effective preoperative evaluation will address these concerns and recommend therapeutic interventions to limit risk. Finally, the anesthesiologist can play an important role in reducing inappropriate utilization of medical technology and in helping to coordinate the patient's care among the multiple physician specialties often required for patients with complex illnesses who require surgery.

## Preparation

9

### *Smoking Cessation*

The ASA is encouraging anesthesiologists to use the preoperative evaluation as a teachable moment to encourage patients to stop smoking, with educational resources for providers and patients available on the ASA website. Because patients will be unable to smoke in the hospital, such timing may help give them more incentive to quit. It should be explained to patients that they are at increased risk for pulmonary and cardiac complications as well as impaired wound healing and infection. The longer they are tobacco free before surgery the better, as their bodies will have more time for repair. Even only 12 hours of smoking cessation will reduce levels of nicotine and carbon monoxide, improving blood flow. The long-term benefits of quitting smoking include: addition of 6 to 8 years to their life, reduction in risk of lung cancer and heart disease, savings of at least \$1400 per year (not including health-

care costs), and reduced exposure of the family to secondhand smoke. Offer patients additional help to quit by referring them to 1-800-QUIT-NOW, a free, confidential counseling service (<http://www.asahq.org/resources/clinical-information/asa-stop-smoking-initiative>).

## *Continuing Current Medications/Treatment of Coexisting Diseases*

It is the responsibility of the anesthesiologist to instruct patients regarding which medications to take or not take preoperatively. Occasionally, new medications will be prescribed or doses increased, such as steroids for adrenal insufficiency. Prescribed and over-the-counter medications may affect the anesthetic; anesthesiologists must be knowledgeable about their actions. As a general rule, patients may take their prescription medications with water on the day of surgery. Exceptions exist, particularly for the management of diabetes.

### **$\beta$ -Blockers**

The role of  $\beta$ -blockers during the perioperative period has evolved over time, based on clinical studies evaluating both effectiveness and the potential for risk. Historically,  $\beta$ -blockers in this setting have been felt to reduce the incidence of mortality and nonfatal MIs after surgery. Current guidelines recommend that  $\beta$ -blockers be continued in those receiving  $\beta$ -blockers to treat angina pectoris, symptomatic arrhythmias, and hypertension. Recent clinical studies, however, have questioned the decision to initiate perioperative  $\beta$ -blockers and have suggested that the decision be based on clinical judgment in evaluating the patient's risk factors for cardiovascular complications together with the type of surgery. The POISE trial, a large, multicenter, randomized controlled trial, compared preoperative  $\beta$ -blocker therapy with placebo.<sup>95</sup> Patients receiving  $\beta$ -blocker therapy had a lower risk of perioperative MI, but were at significantly increased risk for mortality and stroke. As potential mechanisms for enhanced risk, perioperative hypotension and bradycardia were significantly increased in patients receiving  $\beta$ -blockers. A meta-analysis evaluating perioperative  $\beta$ -blockade in noncardiac surgery in 33 randomized controlled trials with 12,306 patients found no difference in overall mortality, but decreased risk of perioperative MI.<sup>96</sup> Similar to the POISE trial, the risk of nonfatal stroke was increased with  $\beta$ -blockade. Recognizing the previous referenced studies and others addressing the benefits and risks of perioperative  $\beta$ -blocker therapy, national guidelines from the ACC/AHA have been updated.<sup>97</sup> The guidelines support, as a class I recommendation, the perioperative continuation of  $\beta$ -blockers for patients receiving  $\beta$ -blocker for appropriate conditions. They support the role for  $\beta$ -

blocker therapy titrated to heart rate and blood pressure during vascular or intermediate-risk surgeries in patients with CAD, cardiac ischemia identified by preoperative testing, or more than one RCRI risk factor. Importantly, the ACC/AHA guidelines stress uncertainty for the role of  $\beta$ -blockade for vascular or intermediate-risk surgery in patients with only one risk factor without ischemic heart disease or in patients without risk factors who have not taken  $\beta$ -blocker therapy previously. On the basis of the POISE trial, there appears to be increased potential for perioperative risk associated with fixed, high-dose  $\beta$ -blocker therapy begun on the day of surgery. Initiation and titration of  $\beta$ -blockade prior to the day of surgery appears to offer a role in the reduction of risk for perioperative MI, but the optimal heart rate remains controversial.

## Statins

There is growing evidence in the literature to suggest that perioperative statin therapy is safe and beneficial in reducing morbidity and mortality in the perioperative period. Statins work via several mechanisms: lowering lipids, enhancing nitric oxide-mediated pathways, reducing expression of cytokines and adhesion molecules, and lowering C-reactive protein levels with associated vasodilatory, anti-inflammatory, and antithrombotic effects. The greatest benefit occurs in patients at higher risk for cardiovascular complications. There is good evidence that the perioperative withdrawal of statins increases morbidity; both the ACC/AHA and the European Society of Cardiology (ESC) have made a class I recommendation that patients who are on a statin preoperatively should be restarted on a statin postoperatively as soon as possible. Patients with noncoronary atherosclerosis should be treated with statin therapy for secondary prevention, independent of noncardiac surgery. The ESC also recommends that statins be started in high-risk surgery patients, optimally between 30 days and at least 1 week before surgery. Guidelines from the ACC/AHA state that statin use is reasonable for patients undergoing vascular surgery with or without clinical risk factors, and statins may be considered for patients with at least one clinical risk factor who are undergoing intermediate-risk procedures.<sup>98</sup>

## *Prevention of Perioperative Pulmonary Aspiration*

Many patients who present for anesthesia are at increased risk for aspiration. Research extrapolated from a study in monkeys led to the statement in 1974 that patients who had a 25 mL residual gastric volume with a pH lower than 2.5 were at risk. Using these guidelines in humans, some have estimated that 40% to 80% of patients scheduled for elective surgery may be at risk.<sup>99,100</sup> However, today, clinically significant pulmonary aspiration is very rare in

healthy patients undergoing general anesthesia, quoted as occurring in 1 in 3,000 to 1 in 6,000 anesthetics. This increases to 1 in 600 for emergency anesthesia. Data presented on aspiration from the Australian Anaesthetic Incident Monitoring Study<sup>101</sup> found 133 cases of aspiration in 5,000 incidents reported. They rated the top 10 risk factors as shown in [Table 23-12](#), although almost 25% of the patients had no risk factors. Errors in judgment, fault in airway management technique, and inadequate patient preparation were felt to be the most common factors contributing to the events.

### **ASA Fasting Guidelines**

The ASA published updated Practice Guidelines for Preoperative Fasting and Pharmacologic Intervention for the Prevention of Perioperative Aspiration in 2011.<sup>102</sup> The guidelines specifically address healthy patients of all ages scheduled for elective procedures in which general anesthesia, regional anesthesia, or sedation will be administered. The purpose of the guidelines is not only to minimize the risk of pulmonary aspiration but also to avoid case delays as well as prolonged fasting leading to dehydration, hypoglycemia, and patient dissatisfaction.

### **Recommendations for Clear Liquids: At Least 2 Hours**

The primary support for the task force recommendations comes from a meta-analysis of randomized controlled trials comparing fasting times for clear liquids of 2 to 4 hours versus more than 4 hours. Adult patients fasting for 2 to 4 hours had smaller gastric volumes and higher gastric pH values compared to those fasting more than 4 hours. The differences in gastric volumes were equivocal in children. Therefore, the task force recommendations are unchanged for healthy patients. Examples of clear liquids include, but are not limited to, water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee (no alcohol). The type of liquid was more important than the volume.

**Table 23-12** Top 10 Factors Predisposing to Aspiration

1	Emergency surgery
2	Inadequate anesthesia
3	Abdominal pathology
4	Obesity
5	Opioid medication
6	Neurologic deficit
7	Lithotomy
8	Difficult intubation/airway
9	Reflux
10	Hiatal hernia

Adapted from Kluger MT, Short TG. Aspiration during anaesthesia: A review of 133 cases from the Australian Anaesthetic Incident Monitoring Study (AIMS). *Anaesthesia*. 1999;54:19–26.

### **Recommendations for Breast Milk: At Least 4 Hours**

The fasting recommendations for breast milk are also unchanged, as the task force found only equivocal findings regarding gastric fluid volume and pH from observational studies in infants.<sup>102</sup>

### **Recommendations for Infant Formula, Nonhuman Milk, and Light Meal: At Least 6 Hours**

Again, among the observational and randomized control studies, the task force found no evidence to support any change in the previous recommendations for at least a 6-hour fast before elective procedures.<sup>102</sup> They noted that the amount and type of food must be considered, and recommended at least 8 hours before elective procedures for fried or fatty food that typically delays gastric emptying time.

For a summary of the fasting guidelines, see [Table 23-13](#).

### **Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration**

 Many different kinds of drugs have been used to decrease the volume and increase the pH of gastric fluid in an effort to reduce the risk of aspiration pneumonitis: Histamine-2 receptor antagonists, proton pump inhibitors (PPIs), antacids, antiemetics, and gastrokinetic agents. The ASA task force reviewed the literature and surveyed both experts and ASA members to arrive at their 2011 recommendations for pharmacologic agents. They found that the literature is insufficient to evaluate or support the effect of administering any of these classes of drugs on the perioperative incidence of emesis/reflux or pulmonary aspiration. Therefore, they could not recommend the routine preoperative use of such drugs for patients who have no apparent increased risk for pulmonary aspiration.<sup>102</sup> However, the drugs

were found to be effective for their intended use and are more cost-effective when prescribed for patients with risk factors for pulmonary aspiration.

**Table 23-13** Summary of Fasting Recommendations for All Ages to Reduce the Risk of Pulmonary Aspiration

Ingested Material	Minimum Fasting Period in hours
Clear liquids	2 h
Breast milk	4 h
Infant formula	6 h
Nonhuman milk	6 h
Light meal	6 h

This summary applies only to healthy patients who are undergoing elective procedures and is not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying. Examples of clear liquids are water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

Adapted from Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: Application to healthy patients undergoing elective procedures: An updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology*. 2011;114:495–511.

### *Histamine-2 (H-2) Receptor Antagonists*

Meta-analyses of randomized placebo-controlled trials support the efficacy of the H-2 receptor antagonists cimetidine, ranitidine, and famotidine in reducing gastric volume and acidity.<sup>102</sup> They block the ability of histamine to induce secretion of gastric fluid with a high hydrogen ion concentration. Multiple-dose regimens may be more effective in increasing gastric pH than a single dose before operation on the day of surgery.

### **Cimetidine**

Cimetidine is usually administered in 150- to 300-mg doses orally or parenterally. Administration of 300 mg of cimetidine orally 1 to 1.5 hours before surgery has been shown to increase the gastric fluid pH above 2.5 in 80% of patients.<sup>103,104</sup> Cimetidine can cross the placenta, but adverse fetal effects are unproved. The gastric effects of cimetidine last as long as 3 or 4 hours; thus, this drug is suitable for operations of that duration. Side effects of cimetidine include inhibition of the hepatic mixed-function oxidase enzyme system; therefore, it can prolong the half-life of many drugs, including diazepam, chlordiazepoxide, theophylline, propranolol, and lidocaine. The clinical significance of this after one or two preoperative doses of cimetidine is uncertain. Life-threatening cardiac dysrhythmias, hypotension, cardiac arrest, and central nervous system depression have been reported after cimetidine administration. These side effects may be especially likely to occur in critically ill patients after rapid intravenous administration. Cimetidine

does not affect gastric fluid already present.

## **Ranitidine**

Ranitidine is more potent, specific, and longer acting than cimetidine. The usual oral dose of 150 mg or 50 mg given parenterally will decrease gastric fluid pH within 1 hour. It is as effective in reducing the number of patients at risk for gastric aspiration as cimetidine and produces fewer cardiovascular or central nervous system side effects. The effects of ranitidine last up to 9 hours. Thus, it may be superior to cimetidine at the conclusion of lengthy procedures in reducing the risk of aspiration pneumonitis during emergence from anesthesia and extubation of the trachea.

## **Famotidine**

Famotidine is another H<sub>2</sub> receptor blocker that is given preoperatively to raise gastric fluid pH. The pharmacokinetics are similar to those of cimetidine and ranitidine, with the exception of having a longer serum elimination half-life than the other two drugs. Famotidine in a dose of 40 mg orally 1.5 to 3 hours preoperatively has been shown to be effective in increasing gastric pH.

## *Proton Pump Inhibitors*

PPIs suppress gastric acid secretion in a dose-dependent manner by binding to the proton pump of the parietal cell. Randomized controlled trials support their efficacy in reducing gastric volume and acidity.<sup>102,105</sup> For an adult patient, administering 40 mg of omeprazole intravenously 30 minutes before induction has been used. Oral doses of 40 mg to 80 mg must be given 2 to 4 hours before surgery to be effective. Effect on gastric pH may last as long as 24 hours.

## *Antacids*

Antacids are used to neutralize the acid in gastric contents. Randomized controlled trials demonstrate their effectiveness.<sup>102</sup> A single dose of antacid given 15 to 30 minutes before induction of anesthesia is almost 100% effective in increasing gastric fluid pH above 2.5. The nonparticulate antacid, 0.3 M sodium citrate, is commonly given before emergency operations. The nonparticulate antacids do not produce pulmonary damage themselves if aspiration should occur. Although colloid antacid suspensions may be more effective in increasing gastric fluid pH, aspiration of particulate antacids may cause significant and persistent pulmonary damage.

Withholding antacids because of concern about increasing gastric volume is not warranted, considering animal evidence documenting markedly increased mortality after aspiration of low volumes of acidic gastric fluid (0.3 mL/kg, pH 1) compared with aspiration of large volumes of buffered gastric

fluid (1 to 2 mL/kg, pH > 1.8).<sup>106</sup> Complete mixing of the antacid with all gastric contents may be questionable in the immobile patient, and the effect of antacids on food particles within the stomach is unknown.

### *Gastrokinetic Agents: Metoclopramide*

Metoclopramide is a dopamine antagonist that stimulates upper gastrointestinal motility, increases gastroesophageal sphincter tone, and relaxes the pylorus and duodenum to reduce gastric volume. A meta-analysis of randomized placebo-controlled trials supports the efficacy of metoclopramide to reduce gastric volume, but is equivocal regarding its effect on gastric acidity during the perioperative period.<sup>102</sup> It also has antiemetic properties. It may be administered orally or parenterally. A parenteral dose of 5 mg to 10 mg is usually given 30 minutes before induction. Administration intravenously over 3 to 5 minutes usually prevents the abdominal cramping that can occur from more rapid administration. An oral dose of 10 mg achieves onset within 30 to 60 minutes. The elimination half-life of metoclopramide is approximately 2 to 4 hours.

The clinical usefulness of the gastrokinetic agents is found in those patients who are likely to have large gastric fluid volumes, such as parturients, patients scheduled for emergency surgery, obese patients, trauma patients, and those with gastroparesis secondary to diabetes mellitus. However, it is not recommended for those patients diagnosed with bowel obstruction. The combination of metoclopramide with an H-2 receptor antagonist does not decrease the effect of either drug, and the effects may be additive.<sup>102</sup>

As reviewed earlier, the drugs used to decrease gastric fluid volume and acidity are effective and relatively free of side effects. The use of these agents is warranted in patients with decreased gastric emptying, reflux, and those presenting for emergency procedures. However, none of the drugs or combination of drugs is absolutely reliable in preventing the risk of aspiration in all patients all of the time. Therefore, their use does not eliminate the need for careful anesthetic techniques to protect the airway during induction, maintenance, and emergence from anesthesia.

## **Psychological Preparation/Premedication**

Anesthetic management for patients begins with preoperative psychological preparation and, if necessary, preoperative medication. The anesthesiologist should assess the patient's mental and physical condition during the preoperative visit. Because it is actually the beginning of the anesthetic, the decision to administer preoperative medication, and which one, should be based on the same considerations as the choice of anesthesia, including

considerations of the patient's medical problems, requirements of the surgery, and recovery goals. Satisfactory preparation lessens the patient's (and family's) anxiety and smooths the anesthetic induction. No consensus exists on the choice of preoperative medications and, historically, their use was dominated by tradition. However, the ever-increasing number of outpatient procedures has led to a significant decrease in preoperative sedation.

### *Psychological Preparation*

Psychological preparation of the patient involves a preoperative visit and interview with the patient and family members. The anesthesiologist should explain anticipated events and the proposed anesthetic management in an effort to reduce anxiety. Patients may perceive the day of surgery as the biggest, most threatening day in their lives; they do not wish to be treated impersonally in the OR. A growing number of patients receive their preanesthetic evaluations by others in preoperative evaluation clinics, such that their initial encounter with the anesthesiologist may be in the immediate preoperative period outside of the OR. Preoperative visits must be conducted efficiently, but they must also be informative and reassuring. Most of the anesthesiologist's time is spent with an unconscious or sedated patient; therefore, he or she must take time before the operation to earn the trust and confidence of that patient.

Studies show that, depending on the intensity of inquiry, 40% to 85% of patients are apprehensive before surgery. Most patients expect apprehension to be relieved before they arrive in the OR. An informative and comforting preoperative visit may replace many milligrams of a sedative medication. For example, the study by Egbert et al.<sup>107</sup> showed that more patients were adequately prepared for surgery after a preoperative interview than after 2 mg/kg of pentobarbital given intramuscularly 1 hour before surgery (Table 23-14). However, psychological preparation alone may not relieve all anxiety.

After the patient interview, the use of preoperative medication in selected patients serves to achieve sedation or amnesia as well as provide any needed analgesia. However, preoperative depressant drugs are not a substitute for a comforting and tactful preoperative visit.

### *Premedication*

The ideal drug or combination of drugs for preoperative pharmacologic preparation is as elusive as is the ideal anesthetic technique and is not based on comprehensive or definitive data. In selecting the appropriate drug and dose for preoperative medication, the patient's psychological condition, physical status, age, and prior response to depressant drugs must be

considered. Some patients should not receive depressant drugs before surgery. For example, those with little physiologic reserve, head injury, hypovolemia, or at the extremes of age may be harmed more than helped. Finally, the surgical procedure, expected duration, and postoperative discharge plan are important factors as well.

**Table 23-14** Comparison of Preoperative Visit to Pentobarbital Premedication (% of patients)

	Felt Drowsy	Felt Nervous	Adequate Preparation
Control group	18	58	35
Pentobarbital group	30	61	48
Preoperative visit	26	40	65
Preoperative visit and pentobarbital	38	38	71

IM, intramuscularly.

Data from Egbert LD, Battit GE, Turndorf H, et al. The value of the preoperative visit by the anesthetist. *JAMA*. 1963;185:553-555.

The goals to be achieved for each patient with preoperative medication should be tailored to the individual. Some goals, such as relief of anxiety, apply to almost every patient, whereas a goal to dry airway secretions may be reserved for the patient with a potentially difficult airway who may require fiberoptic tracheal intubation.

**10** The timing and route of administration of the preoperative medications are important. Every attempt should be made to time the administration so that the premedication achieves its full effect before the patient's arrival in the OR. As a general rule, oral tablets should be given to the patient 60 minutes before arrival in the OR. Intravenous agents, on the other hand, produce effects after a few circulation times. The drug(s), doses, route of administration, and effects should be recorded on the anesthetic record. A list of common preoperative medications is presented in [Table 23-15](#).

## Benzodiazepines

Benzodiazepines are among the most popular preoperative medications because they produce anxiolysis, amnesia, and sedation ([Table 23-16](#)). Because the site of action of benzodiazepines is located on the GABA receptor in the central nervous system, there is relatively little depression of the ventilatory or cardiovascular systems with premedicant doses. Benzodiazepines have a wide therapeutic index and a low incidence of toxicity. Other than central nervous system depression, these drugs lack the side effects common to opioids, such as nausea and vomiting. Two caveats to keep in mind: these drugs are not analgesic agents, and benzodiazepines may

not always produce a calming effect, but rarely can cause a paradoxical agitation, manifested as restlessness and delirium.

**Table 23-15** Common Preoperative Medications, Doses, and Administration Routes

Medication	Administration Route	Dose
Lorazepam	Oral, IV	0.5–4 mg
Midazolam	IV	1.0–2.5 mg doses
Fentanyl	IV	25–50 µg doses
Morphine	IV	1.0–2.5 mg doses
Meperidine	IV	10–25 mg doses
Cimetidine	Oral, IV	150–300 mg
Ranitidine	Oral	50–200 mg
Metoclopramide	IV	5–10 mg
Atropine	IV	0.2–0.4 mg
Glycopyrrolate	IV	0.1–0.2 mg

IV, Intravenous.

Modified from Stoelting RK, Miller RD, eds. *Basics of Anesthesia*. New York: Churchill Livingstone; 1984.

**Table 23-16** Comparison of Pharmacologic Variables of Benzodiazepines

	Diazepam	Lorazepam	Midazolam
Dose equivalent (mg)	10	1–2	3–5
Time to peak effect after oral dose (h)	1–1.5	2–4	0.5–1
Elimination half-time (h)	20–40	10–20	1–4
Clearance (mL/kg/min)	0.2–0.5	0.7–1.0	6.4–11.1
Volume of distribution (L/kg)	0.7–1.7	0.8–1.3	1.1–1.7

### Midazolam

Midazolam has predominantly replaced lorazepam and diazepam for preoperative medication and moderate sedation (Fig. 23-4). It is common to administer sedative doses intravenously just prior to transfer to the OR. The physicochemical properties of the drug allow for its water solubility and rapid metabolism. As with other benzodiazepines, midazolam produces anxiolysis, sedation, and amnesia. It is 2 to 3 times more potent than diazepam because of its increased affinity for the GABA receptor. The usual incremental dose is

1 mg to 2 mg titrated intravenously. There is no irritation or phlebitis with injection of midazolam, as opposed to diazepam. The incidence of side effects after administration is low, although depression of ventilation and sedation may be greater than expected, especially in elderly patients or when the drug is combined with other central nervous system depressants. The onset after intravenous administration typically occurs after 1 to 2 minutes. In addition to quicker onset, more rapid recovery occurs after midazolam compared with diazepam. This more rapid onset and recovery is the result of the lipid solubility of midazolam and its rapid redistribution to the peripheral tissues and metabolic biotransformation. For these reasons, midazolam should usually be given within 1 hour of induction. Midazolam is metabolized by hepatic microsomal enzymes to essentially inactive hydroxylated metabolites. H-2 receptor antagonists do not interfere with its metabolism. The elimination half-life of midazolam is approximately 1 to 4 hours and may be extended in the elderly. Tests show that mental function usually returns to normal within 4 hours of administration, and amnesia may only last 20 to 30 minutes.<sup>108</sup> These properties make midazolam ideal for shorter procedures.

### *Lorazepam and Diazepam*

Lorazepam is 5 to 10 times more potent than diazepam and can produce profound amnesia, anxiolysis, and sedation (Fig. 23-5).<sup>109</sup> Like diazepam, it has an extremely long half-life, but an even longer duration because of its affinity for the receptor.<sup>110</sup> Because of their duration, lorazepam and diazepam are not useful in instances in which rapid awakening is necessary, such as outpatient anesthesia. Their use may be more suited for those patients already taking chronic benzodiazepines for anxiety and who may need the anxiolysis prior to arrival in the preoperative area.

**Figure 23-4** Percentage of patients exhibiting anxiety from baseline to time after oral

midazolam. There was a positive association between dose and onset of anxiolysis ( $p = 0.01$ ); a larger proportion of children achieved satisfactory anxiolysis within 10 minutes at the higher doses. (Reprinted with permission from Coté CJ, Cohen IT, Suresh S, et al. A comparison of three doses of a commercially prepared oral midazolam syrup in children. *Anesth Analg*. 2002;94:37.)

Although lorazepam is insoluble in water and requires a solvent such as polyethylene glycol or propylene glycol, intravenous administration is not associated with pain on injection or phlebitis. In addition to the intravenous route, lorazepam is reliably absorbed orally. Bradshaw et al.<sup>111</sup> demonstrated clinical effects 30 to 60 minutes after oral administration of lorazepam. Peak plasma concentrations may not occur until 2 to 4 hours after oral administration. Therefore, oral lorazepam must be given well before surgery so that the drug has time to be effective. Lorazepam also may be given sublingually at a dose of 25 to 50  $\mu\text{g}/\text{kg}$ , not to exceed 4 mg.<sup>109,110</sup> With recommended doses, anterograde amnesia may be produced for as long as 4 to 6 hours without excessive sedation. Higher doses lead to prolonged and excessive sedation without more amnesia. There are no active metabolites of lorazepam and because its metabolism is not dependent on microsomal enzymes, there is less influence from age or liver disease. As with diazepam, little cardiorespiratory depression occurs with lorazepam.

## **Diphenhydramine**

Diphenhydramine is a histamine-1 receptor antagonist, which blocks the peripheral effects of histamine. It also has sedative, anticholinergic, and antiemetic activity. A dose of 50 mg will last 3 to 6 hours in an adult. Diphenhydramine is not often used for preoperative sedation, but it is often used in combination with histamine-2 blockers and steroids for prophylaxis in patients with latex allergy as well as for prophylaxis before chemotherapy and radiologic studies using contrast.

## **Opioids**

Morphine and meperidine were historically the most frequently used opioids for intramuscular preoperative medication during a time when the majority of patients were admitted the night before surgery. Currently, when analgesia is needed preoperatively, the administration of intravenous fentanyl, with its rapid onset and shorter duration, has become much more common. In a patient not experiencing pain, opioids may produce dysphoria. The opioids given in premedicant doses do not produce sedation or amnesia and are often combined with a benzodiazepine for these effects. Opioids are also useful to ameliorate the discomfort during regional anesthesia procedures or during the

insertion of invasive monitoring catheters or large intravenous lines. The analgesic properties and respiratory depressant effects of opioids usually go hand in hand. The decrease in the CO<sub>2</sub> drive at the medullary respiratory center may be prolonged. Furthermore, there is a decrease in the responsiveness to hypoxia at the carotid body after injection of even low doses of opioids.<sup>112</sup> The anesthesiologist may consider supplemental oxygen for the patient receiving opioid premedication. A common side effect of all opioids is nausea and vomiting, due to effects on both the chemoreceptor trigger zone and the vestibular system.

Fentanyl is a synthetic opioid agonist structurally similar to meperidine. It is approximately 100 times more potent than morphine in its analgesia. The lipid solubility of fentanyl is greater than that of morphine, which contributes to its rapid onset of action. Peak plasma concentrations occur within 6 to 7 minutes following intravenous administration and its elimination half-time is 3 to 6 hours. The drug's much shorter duration of action is attributed to redistribution to inactive tissues, such as the lungs, fat, and skeletal muscle. Metabolism occurs primarily by N-demethylation to norfentanyl, which is a less potent analgesic. In doses of 1 to 2 µg/kg intravenously, fentanyl may be used to provide preoperative analgesia. Fentanyl causes neither myocardial depression nor histamine release, but may be associated with ventilatory depression and profound bradycardia. Elderly and debilitated patients can have an increased sensitivity to its effects. Synergistic effects with benzodiazepines warrant close observation when this combination is given in the preoperative period.

**Figure 23-5** Percentage of patients in each group failing to recall specific events of the operative day. Medications were administered intramuscularly. OR, operating room; IV, intravenous. (Reprinted with permission from Fragen RJ, Caldwell N. Lorazepam premedication: Lack of recall and relief of anxiety. *Anesth Analg.* 1976;55:792.)

### Opioid-dependent Patients

Withdrawal symptoms produced by drug cessation preoperatively are an issue for the patient who is opioid dependent. There should be an attempt to maintain opioid use at the usual level by continuing methadone or substituting other appropriate agents for methadone. The anesthesiologist should be cautioned about using agonist–antagonist drugs in these patients for fear of producing withdrawal.

## Anticholinergics

Historically, anticholinergic drugs were widely used when inhalation anesthetics produced copious respiratory tract secretions and intraoperative bradycardia was a frequent danger. The advent of newer inhalation agents has markedly decreased the routine use of anticholinergic drugs for preoperative medication. Specific indications for an anticholinergic before surgery are (1) antisialagogue effect, (2) sedation and amnesia, and (3) vagolytic effect (Table 23-17). In the past, anticholinergics were also administered in an attempt to decrease gastric acid secretion, but research has shown them not to be effective for this purpose.<sup>102</sup>

### *Antisialagogue Effect*

Anticholinergics have been prescribed in a selective fashion when drying of the upper airway is desirable. For example, when awake fiberoptic tracheal intubation or bronchoscopic examination is planned, conditions will be more satisfactory for visualization when an anticholinergic drug has been administered.<sup>113</sup> Anticholinergics are also felt to increase the effectiveness of topical anesthesia in the airway by preventing a dilutional effect from secretions and facilitating contact of the local anesthetic with the mucosa. Surgeons may also request an antisialagogue for intraoral operations. Glycopyrrolate is the most potent antisialagogue, with less likelihood of increasing heart rate than atropine. Because glycopyrrolate is a quaternary amine, it does not easily cross the blood–brain barrier and does not produce sedation or amnesia as seen with scopolamine, a tertiary amine.

**Table 23-17** Comparison of Effects of Three Anticholinergic Drugs

	Atropine	Glycopyrrolate	Scopolamine
Increased heart rate	+++	++	+
Antisialagogue	+	++	+
Sedation	+	0	+++

0, no effect; +, small effect; ++, moderate effect; +++, large effect.  
Adapted from Stoelting RK. *Pharmacology and Physiology in Anesthetic Practice*. Philadelphia, PA: JB Lippincott; 1991.

## *Sedation and Amnesia*

Although midazolam has largely taken over as the preoperative sedative of choice, historically, scopolamine was often given intramuscularly in combination with an opioid. Scopolamine does not produce amnesia in all patients, and may not be as effective as lorazepam or diazepam in preventing recall. Scopolamine has an additive amnestic effect when combined with benzodiazepines. Frumin et al.<sup>114</sup> reported that the combination of diazepam and scopolamine produced amnesia more often than did diazepam alone. The additive amnestic effect may be useful for the unstable patient who does not tolerate general anesthesia; however, scopolamine is currently largely unavailable in the United States.

## *Vagolytic Action*

Vagolytic action of the anticholinergic drugs is produced through the blockade of acetylcholine at the sinoatrial node. Atropine given intravenously is more potent than glycopyrrolate in increasing heart rate. The vagolytic action of the anticholinergic drugs is useful in the prevention of reflex bradycardia that may result from traction on extraocular muscles or abdominal viscera, carotid sinus stimulation, or repeated doses of succinylcholine. As these bradycardic events occur intraoperatively, it is more effective to administer the drug during anesthesia.

## *Side Effects of Anticholinergic Drugs*

### **Central Nervous System Toxicity**

Scopolamine and atropine (tertiary amines) may cause central nervous system toxicity, the so-called central anticholinergic syndrome. This syndrome is most likely to occur after the administration of scopolamine, but can be seen after high doses of atropine and may include symptoms such as delirium, restlessness, confusion, and obtundation. Elderly patients and patients with pain appear to be particularly susceptible; the syndrome has been noted to be potentiated by inhalation anesthetics. The administration of 1 to 2 mg of physostigmine intravenously can successfully treat the syndrome.

### **Intraocular Pressure**

Mydriasis and cycloplegia from anticholinergic drugs may place patients with glaucoma at risk for increased intraocular pressure. Atropine and glycopyrrolate may be less likely to increase intraocular pressure than scopolamine. In patients with glaucoma, it is generally safe to continue most glaucoma medications up until the time of surgery or use atropine or glycopyrrolate when necessary.

### **Hyperthermia**

Sweat glands of the body are innervated by the sympathetic nervous system, but use cholinergic transmission. Therefore, administration of anticholinergic agents interferes with the sweating mechanism, which may cause body temperature to increase, especially when using active warming devices in the OR. The patient typically appears hot and dry. In children, the subsequent increase in temperature may exacerbate tachycardia.

## Antibiotic Prophylaxis

Surgical antibiotic prophylaxis has become an outcome measure on which hospital and anesthesia performance is measured. Reimbursement or even accreditation may depend on properly timed and dosed administration. Anesthesiologists frequently administer antibiotics to patients prior to surgery for contaminated and clean-contaminated procedures or for clean surgical procedures when infection would be catastrophic, such as for device implants. Other indications for the use of prophylactic antibiotics include the prevention of endocarditis and the prevention of infection in immunocompromised patients.

Cephalosporins are the most popular antibiotics because they cover common skin microbes. For intestinal surgery, however, anaerobic and Gram-negative coverage is needed. The National Surgical Infection Project recommends that antibiotics be administered within 1 hour prior to incision.<sup>115</sup> There are two exceptions to this policy: (1) vancomycin should be given 2 hours prior to incision and (2) when a tourniquet is used, the antibiotics should be administered prior to its inflation. Furthermore, if the surgical procedure is prolonged, it is recommended that the antibiotic be redosed when two half-lives have elapsed. For example, cefazolin has a half-life of 2 hours; therefore, it should be redosed if the surgical procedure extends past 4 hours. Research on morbidly obese patients has shown that the dose required to achieve adequate tissue levels is twice that for normal-weight patients.<sup>116</sup> Those allergic to penicillin, cephalosporins, and related compounds ( $\beta$ -lactam allergy) may receive either vancomycin or clindamycin.

## Summary of Patient Preparation

The anesthesiologist who takes the time to adequately prepare the patient medically and psychologically for anesthesia and surgery will find that his/her job of caring for the patient intraoperatively becomes easier, and is more likely to have both a positive clinical outcome and a satisfied patient.

Pemphigus

### KEY POINTS

- 1 The cytoskeleton of the muscle membrane in patients with muscular dystrophy is fragile. Succinylcholine and/or halogenated anesthetics can cause the massive release of intracellular contents resulting in hyperkalemic cardiac arrest.
- 2 Myotonic dystrophy produces cardiac conduction delay that can manifest as third-degree atrioventricular block.
- 3 Patients with myasthenia gravis are exquisitely sensitive to nondepolarizing muscle relaxants. Short-acting muscle relaxants and objective monitoring of neuromuscular function are indicated.
- 4 Many types of cancer, in addition to small-cell carcinoma of the lung, can produce myasthenic syndrome.
- 5 Patients with multiple sclerosis can have an exacerbation of their neurologic symptoms despite a well-managed anesthetic.
- 6 An unexpected increase in end-tidal carbon dioxide is the most sensitive sign of malignant hyperthermia.
- 7 Hypoglycemia and metabolic acidosis are constant risks to patients with glycogen storage diseases.
- 8 The deposition of mucopolysaccharides in the upper airway of patients with mucopolysaccharidoses often complicates airway management during anesthesia.
- 9 Repeated episodes of sickling in patients with sickle cell disease cause pulmonary hypertension that increases perioperative risks.
- 10 Rheumatoid arthritis is a multisystem disease that causes subclinical cardiac and pulmonary dysfunction.
- 11 Patients with rheumatoid arthritis can have significant degeneration of the cervical spine with few neurologic symptoms. Cervical manipulation during laryngoscopy and tracheal intubation requires special precautions.
- 12 Esophageal dysfunction in patients with scleroderma and dermatomyositis increases the risk of aspiration pneumonitis.
- 13 Patients with epidermolysis bullosa can have undiagnosed dilated cardiomyopathy.

### Musculoskeletal Diseases

## Muscular Dystrophy and Congenital Myopathy

Muscular dystrophies and congenital myopathies are a heterogeneous group of progressive genetic muscle disorders characterized by skeletal muscle weakness (Table 24-1). There is variation in the muscle groups affected, severity of weakness, and age of onset. Cardiac and smooth muscle of the gastrointestinal tract are also affected. The pathology is the result of insufficient or abnormal proteins, such as dystrophin and sarcoglycans that form the cytoskeleton of the muscle membrane (Fig. 24-1). Skeletal muscle in the extremities, torso, and head is affected as well as muscles of the respiratory system, cardiac muscle, and smooth muscle of the gastrointestinal tract. An accurate classification of muscular dystrophies is complicated by the recent realization that similar phenotypes may be the result of mutations in different proteins and that allelic disorders on the same protein can result in different diseases (Fig. 24-2).<sup>1</sup>

**Table 24-1** Types of Muscular Dystrophy and Congenital Myopathies

<b>Muscular Dystrophies</b>
Duchenne (DMD)
Becker (BMD)
Emery–Dreifuss
Limb-girdle (LGMD)
Facioscapulohumeral
Oculopharyngeal
Congenital muscular dystrophy
<b>Congenital Myopathies</b>
Nemaline myopathy
Central core disease
Minicore disease
Centronuclear myopathy

### Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is caused by the absence of dystrophin.

Dystrophin is a large protein that plays a major role in stabilization of the muscle membrane and signaling between the cytoskeleton and extracellular matrix. DMD is the most common inherited muscle disease of childhood and is inherited as an X-linked recessive trait. Patients suffer from progressive proximal muscle weakness and wasting that produces symptoms in early childhood resulting in loss of ambulation by 12 years of age. DMD patients have elevated creatine kinase (CK) levels early in life. As the patient ages and more muscle atrophies, the CK level begins to decrease.

Even with recent improvements in supportive care, cardiorespiratory complications cause most of the mortality that occurs before the fourth

decade of life. Typical ECG abnormalities include an R:S ratio greater than 1 in lead V1; deep Q waves in leads I, aVL, V5, and V6; right axis deviation; or a right bundle branch block. These ECG changes may precede other signs of cardiac dysfunction. Serial echocardiography reveals progressive left ventricular cavity expansion with impaired systolic and diastolic function. Contrast-enhanced MRI can identify early signs of myocardial damage and impending cardiac failure. Current recommendations call for cardiac evaluation every 2 years after diagnosis and each year after the age of 10 years. Early treatment with ACE inhibitors, diuretics, and  $\beta$ -adrenergic blockers may result in ventricular remodeling and functional improvement. Female carriers of DMD should be evaluated every 5 years, as they are prone to develop cardiomyopathy.<sup>2</sup>

Current treatment remains supportive and aimed at improving cardiorespiratory function. Noninvasive ventilation and cough assist techniques (manual and mechanical) can improve pulmonary function and reduce the risk of aspiration pneumonia. Gene therapies are under investigation.

### **Becker Muscular Dystrophy**

A reduction in normal amounts of dystrophin results in Becker muscular dystrophy (BMD). Patients with BMD have a similar, but milder disease course than patients with DMD. The age of onset of BMD is 12 years although some patients will not be symptomatic until later in life. Causes of mortality are similar to those for DMD, but death does not occur until the fifth to sixth decade. It is recommended that patients with BMD have cardiac evaluation every 5 years if they are asymptomatic. More frequent evaluation is indicated when symptoms of cardiac disease develop. Female carriers can also have cardiac abnormalities.

### **Emery–Dreifuss Muscular Dystrophy**

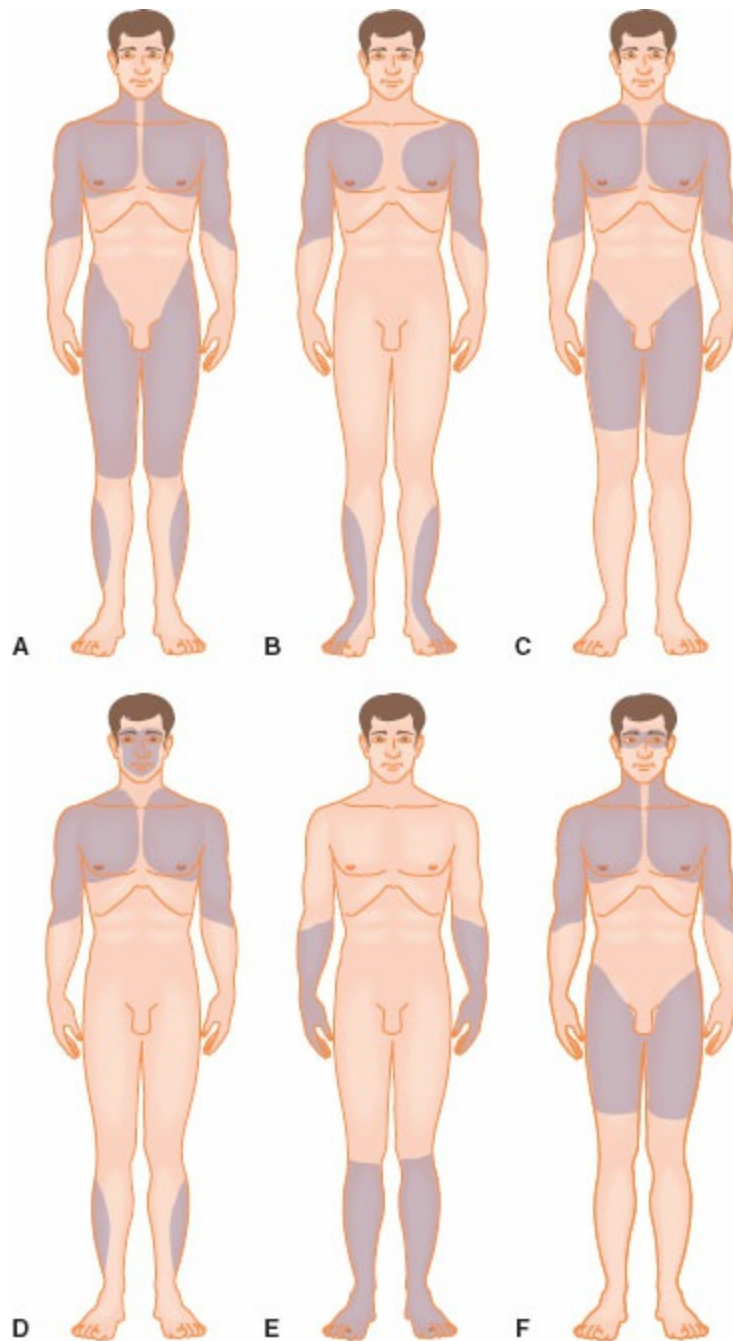

Emery–Dreifuss muscular dystrophy is caused by mutations in two proteins with different inheritance patterns. The X-linked form results from a mutation in the nuclear membrane protein emerin and the autosomal dominant form is the result of mutation in lamins A and C. Both forms typically present with contractures of the ankles, elbows, and neck. Progressive weakness of humeral and peroneal muscles and limb-girdle muscles develops. Cardiomyopathy and cardiac conduction abnormalities present by 30 years of age.<sup>3</sup>

**Figure 24-1** Muscle cell cytoskeleton. (Adapted from Duggan DJ, Gorospe JR, Fanin M, et al. Mutations in the sarcoglycan genes in patients with myopathy. *N Engl J Med.* 1997;336:618–624.)

### Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophy (LGMD) is a progressive dystrophy subclassified by inheritance pattern and causative gene mutations. The autosomal dominant groups tend to be less severe. CK levels can be normal, mildly elevated, or significantly elevated. LGMD patients suffer from shoulder and pelvic muscle weakness and can have significant cardiac involvement.

**Figure 24-2** Distribution of predominant muscle weakness in different types of muscular dystrophy. **A:** Duchenne-type and Becker type. **B:** Emery–Dreifuss. **C:** Limb-girdle. **D:** Facioscapulohumeral. **E:** Distal. **F:** Oculopharyngeal. (Adapted from Emery AE. The muscular dystrophies. *BMJ*. 1998;317:991–995.)

### **Facioscapulohumeral Muscular Dystrophy**

This autosomal dominant dystrophy presents with weakness in the facial and shoulder muscles that later extends to the foot and pelvic girdle muscles. Retinal vascular disease and hearing loss may occur. Cardiac conduction abnormalities can develop, but cardiac muscle involvement does not usually occur.

### **Oculopharyngeal Muscular Dystrophy**

Weakness in the extraocular, upper facial, neck, and proximal limb muscle characterizes oculopharyngeal muscular dystrophy. Ptosis and dysphagia are the usual presenting symptoms in the third decade of life and the reasons for seeking surgical therapy.

## **Congenital Muscular Dystrophy and Myopathy**

Congenital muscular dystrophy (CMD) is characterized by onset of hypotonia during infancy, developmental delay, feeding difficulties, and respiratory dysfunction. There are three groups of diseases: collagenopathies (Ulrich CMD, Bethlem myopathy); merosinopathies; and dystroglycanopathies (Fukuyama CMD, muscle-eye-drain disease, Walker–Warburg syndrome). The congenital myopathies, now recognized as a class of diseases different from CMD, include nemaline myopathy, central core and minicore disease, and centronuclear myopathy. Although respiratory muscle dysfunction can be severe, cardiac involvement is not as prominent as in DMD or BMD. Patients with congenital myopathies may be susceptible to malignant hyperthermia (MH).<sup>4,5</sup>

## **Management of Anesthesia**

The perioperative management of patients with muscular dystrophy is dependent of the particular disease and its progression. The complications of greatest concern are cardiac involvement and respiratory muscle weakness. Most recommendations for cardiac surveillance monitoring in the muscular dystrophies associated with heart failure or dysrhythmias call for echocardiograms and cardiac MRI. Preoperative review of these studies will assist in planning for anesthesia. Some patients with muscular dystrophy have very poor left ventricular function and will require advanced cardiac monitoring in the perioperative period.

Premedication can be administered for anxiolysis, unless there is a significant risk of respiratory dysfunction. Although muscular dystrophy was previously believed to be associated with an increased risk of MH, there is no evidence that the risk is greater than the general population. In contrast, patients with congenital myopathies such as central core disease or minicore disease should be considered to be at increased risk for MH.

Patients with muscular dystrophy, especially DMD, are at risk for rhabdomyolysis and severe hyperkalemia secondary to succinylcholine and possibly halogenated, inhaled anesthetics. The use of halogenated, inhaled anesthetics in patients with DMD is controversial.<sup>6</sup> A prudent approach would be to use halogenated, inhaled anesthetics only when necessary and for as brief a period of time as necessary. Succinylcholine should be avoided.

Patients with muscular dystrophy are sensitive to nondepolarizing muscle relaxants and neuromuscular function should be closely and objectively monitored. Dysfunction of gastrointestinal smooth muscle predisposes muscular dystrophy patients to impaired swallowing, delayed gastric emptying and increases the risk of aspiration pneumonia. Muscular dystrophy patients with preoperative muscle weakness may require postoperative mechanical ventilation.

## Myotonic Dystrophy

Myotonia is the delayed relaxation of skeletal muscle after voluntary contraction. Electromyography demonstrates repetitive muscle fiber discharges that fluctuate. These abnormalities are caused by dysfunction of ion channels in the muscle membrane. There are two types of myotonic dystrophy caused by mutations in two distinct gene loci: myotonic dystrophy type 1 (DM-1) and myotonic dystrophy type 2 (DM-2). The genetic alteration in DM-1 is an unstable trinucleotide expansion (CTG) on chromosome 19q. DM-2 is caused by a quadnucleotide expansion (CCTG) on chromosome 3q. Both mutations cause RNA toxicity.

**Table 24-2** Classification of Myotonic Dystrophy

<b><i>Muscular Dystrophy Type 1</i></b>
Congenital
Childhood-onset
Adult-onset
Late-onset
<b><i>Muscular Dystrophy Type 2</i></b>
Proximal myotonic dystrophy
Proximal myotonic myopathy
Proximal myotonic myopathy syndrome

### Myotonic Dystrophy Type 1

**Myotonic dystrophy type 1** (DM-1) is the more common form and is subdivided by age of onset (Table 24-2). DM-1 is a multisystem disease that affects the musculoskeletal system, heart, respiratory system, central nervous system (CNS), and endocrine system.<sup>7</sup> Muscle weakness begins distally and progresses proximally with eventual muscle wasting. Pulmonary function studies demonstrate a restrictive pattern, mild arterial hypoxemia, and diminished ventilatory responses to hypoxia and hypercapnia. Respiratory muscle weakness diminishes cough effectiveness and may lead to pneumonia. Aspiration of gastric contents may occur because of gastric atony and pharyngeal muscle dysfunction. Myotonia of the respiratory muscles can

cause intense dyspnea.

2 Cardiac manifestations include atrioventricular (AV) conduction delay, atrial tachydysrhythmias, diastolic dysfunction, mitral valve prolapse, and cardiomyopathy. Echocardiography may reveal subclinical evidence of left ventricular systolic and diastolic dysfunction.<sup>8</sup> Sudden death may be secondary to third-degree AV block or ventricular dysrhythmias.

Other clinical features of DM-1 include cataracts, premature balding, diabetes mellitus, thyroid dysfunction, adrenal insufficiency, and gonadal atrophy. Pregnancy may produce an exacerbation of myotonic dystrophy and congestive heart failure is more likely to occur during pregnancy. Cesarean section is often required because of uterine smooth muscle dysfunction. Infants of mothers with myotonic dystrophy may have hypotonia, feeding difficulty, and respiratory failure.

## **Myotonic Dystrophy Type 2**

Patients with myotonic dystrophy type 2 (DM-2) may have similar clinical features (e.g., cataracts) as patients with DM-1. The clinical course in patients with DM-2 is, however, milder than that of patients with DM-1. AV conduction delay occurs in DM-2 patients, but sudden death is less likely. When compared to patients with DM-1, DM-2 patients are less likely to have diabetes and disability from chronic myopathy occurs much later in life. DM-2 patients are more likely to have myalgia, muscle strength variation, hypertrophy of the calf muscles, exacerbations during pregnancy, and a normal life expectancy.

There is no specific treatment for patients with DM-1 or DM-2. Mexiletine or flecainide may be effective for relief of muscle stiffness. Implantation of a defibrillating pacemaker is indicated for DM patients at risk for third-degree AV block or ventricular dysrhythmias.

## **Management of Anesthesia**

Patients with DM-1 are more likely to have perioperative complications than patients with DM-2.<sup>9,10</sup> Considerations for anesthesia for patients with DM include the potential for cardiac and respiratory muscle disease and abnormal response to drugs used during anesthesia. Succinylcholine produces an exaggerated contracture and its use should be avoided. The myotonic response to succinylcholine can be so severe that ventilation and tracheal intubation are difficult. In theory neostigmine might provoke myotonia; however, patients with DM have received neostigmine without incident. The response to a peripheral nerve stimulator must be carefully evaluated because muscle stimulation may produce myotonia that could be misinterpreted as sustained tetanus when significant neuromuscular blockade still exists.

Sugammadex has been used for reversal of rocuronium in patients with DM.

No specific anesthetic technique has been shown to be superior for patients with DM. Most postoperative complications reported in patients with DM are respiratory. Patients should be advised that postoperative ventilatory support may be required. Selection of short-acting inhaled and intravenous drugs is preferred. Patients with DM may be more susceptible to the respiratory depressant effects of opioids and sedatives. Sevoflurane and propofol have been successfully used. The high incidence of cardiac abnormalities in patients with DM mandates close monitoring of cardiac rhythm and function. Regional anesthesia has been used for both children and adults with DM. Patients with DM-2 are likely to have myalgia, weakness, and muscle cramps after surgery.<sup>11</sup>

## **Skeletal Muscle Channelopathies**

Research in molecular biology and genetics has produced a reclassification of diseases with dissimilar clinical features (myotonia, periodic paralysis) but subcellular similarities. These diseases now constitute the group known as skeletal muscle channelopathies (Table 24-3). Disorders previously classified with myotonias but are now known to be channelopathies are myotonia congenita, sodium channel myotonia, and paramyotonia congenita. Diseases with periodic paralysis secondary to ion channel mutations are hyperkalemic periodic paralysis, hypokalemic periodic paralysis, thyrotoxic periodic paralysis, and Andersen–Tawil syndrome (ATS). The features that these disorders share are mutations in ion channels of the muscle membranes that affect muscle excitability or excitation-coupling.<sup>12</sup> The ion channels affected include chloride, sodium, calcium, and potassium channels.

### ***Hyperkalemic Periodic Paralysis***

Hyperkalemic periodic paralysis (hyperPP) is caused by a sodium ion channel mutation that causes prolonged muscle membrane depolarization and flaccid paralysis. Attacks can be provoked by potassium loading, rest after exercise, and cold (Table 24-4). Episodes of paralysis can last for minutes to hours. The respiratory muscles are generally spared. Fifty percent of patients with hyperPP also report episodes of myotonia.

**Table 24-3** Skeletal Muscle Channelopathies

Hyperkalemic periodic paralysis  
Hypokalemic periodic paralysis  
Sodium channel myotonia  
Thyrotoxic periodic paralysis  
Myotonia congenita  
Paramyotonia congenita  
Andersen–Tawil syndrome

**Table 24-4** Clinical Features of Familial Periodic Paralysis

**Hyperkalemic**  
Sodium channel defect  
Potassium >5.5 mEq/L during symptoms  
Precipitating factors  
    Rest after exercise  
    Potassium infusions  
    Metabolic acidosis  
    Hypothermia  
Skeletal muscle weakness may be localized to tongue and eyelids

**Hypokalemic**  
Calcium channel defect  
Potassium level <3 mEq/L during symptoms  
Precipitating factors  
    High glucose meals  
    Strenuous exercise  
    Glucose-insulin infusions  
    Stress  
    Hypothermia  
Chronic myopathy with aging

Measures that reduce serum potassium such as consumption of carbohydrate meals and administration of thiazide or carbonic anhydrase diuretics may prevent attacks. Severe attacks may require treatment with insulin and glucose.<sup>13</sup>

### **Hypokalemic Periodic Paralysis**

Hypokalemic periodic paralysis (hypoPP) is caused by mutations in calcium or sodium channels. Patients with hypoPP develop flaccid paralytic attacks after carbohydrate loading and rest after exercise. Diaphragmatic function is generally maintained during attacks. Chronic muscle weakness develops as the patient ages.

Thyrotoxic hypokalemic periodic paralysis occurs with hyperthyroidism in combination with hypokalemia. The paralysis resolves after treatment of the hyperthyroidism.

### **Andersen–Tawil Syndrome**

ATS is caused by a mutation in the potassium ion channel of skeletal muscle. This potassium ion channel is also abundant in ventricular myocytes. Patients with ATS develop periodic paralysis that may be associated with hypokalemia, normokalemia, or hyperkalemia. Ten percent of patients with ATS suffer a cardiac arrest.<sup>14</sup>

## Management of Anesthesia

The clinical features and ion channel mutations in patients with channelopathies are diverse and the reported anesthesia experience with patients with channelopathies is quite varied. Many of the adverse events in patients with channelopathies are triggered by changes in potassium. Preoperative electrolyte abnormalities should be corrected before surgery. An effort should be made to monitor serum potassium levels and to maintain normokalemia during the perioperative period for both hyperPP and hypoPP. Metabolic changes (acidosis, alkalosis) and medications that cause changes in potassium levels (diuretics, insulin) may cause weakness or paralysis. Succinylcholine should be avoided as it may cause potassium flux. Avoidance of glucose loading, normocapnia, and normothermia are indicated for patients with hypoPP. The ECG should be continuously monitored for evidence of potassium-related dysrhythmias. Patients with channelopathies may develop a chronic myopathy and can be sensitive to nondepolarizing muscle relaxants.<sup>15</sup>

There are reports of perioperative hypermetabolic crises in patients with hypoPP. Whether these are true episodes of MH is controversial. There are so many possible gene mutations that some patients may be susceptible to MH.

## Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disease with autoantibodies directed against acetylcholine receptors (AChRs) or other proteins in the postsynaptic membrane of the neuromuscular junction. Eighty-five percent of patients with MG have anti-AChR antibodies. Other patients with MG have autoantibodies against muscle-specific tyrosine kinase (MuSK) or lipoprotein-related protein 4 (LRP4). Five percent of MG patients have no detectable antibodies. It is likely that these seronegative MG patients have low autoantibody titers that cannot be measured with current techniques. Autoantibodies damage the muscle membrane by activation of complement, lysis of the postsynaptic membrane, and loss of synaptic folds.<sup>16</sup> The thymus may play a central role in the pathogenesis of MG as 90% of MG patients have a thymoma, thymic hyperplasia, or thymic atrophy.

The clinical hallmark of MG is skeletal muscle weakness that is aggravated by repetitive muscle use. There can be periods of exacerbation alternating

with remission. Any skeletal muscle can be affected, although there is a predilection for muscles innervated by cranial nerves. Initial symptoms include diplopia, dysarthria, or limb muscle weakness. Twenty to thirty percent of patients with MG will experience a myasthenic crisis during their life. A myasthenic crisis can be precipitated by poor control of MG, emotional stress, hyperthermia, or pulmonary infections. Myasthenic crisis is characterized by severe muscle weakness and respiratory failure. Cardiac manifestations of MG include focal myocarditis, atrial fibrillation, AV conduction delay, and left ventricular diastolic dysfunction. 3

Some pregnant patients have a remission during pregnancy whereas others (20% to 40%) have increased symptoms during pregnancy. Acute postpartum respiratory failure can occur. Fifteen to twenty percent of babies born to mothers with MG have transient myasthenia from passive transfer of AChR antibodies. Neonatal myasthenia begins 12 to 48 hours after birth and may persist for weeks. Babies with mothers with MuSK-MG have more severe neonatal myasthenia.

Disease classification is based on skeletal muscle groups affected as well as age of onset (Table 24-5). The Osserman staging system is based on the severity of the disease (Table 24-6).

No single test for myasthenia is diagnostic and the diagnosis of MG can be difficult, especially in the early stages of the disease. Diagnosis is based on symptomatology, serologic antibody testing, and electrodiagnostic testing.<sup>17</sup>

Treatment of MG includes cholinesterase inhibitors (pyridostigmine), corticosteroids, immunosuppressants, intravenous immunoglobulin (IVIG), and plasmapheresis. Cholinesterase inhibitors increase the concentration of acetylcholine (ACh) at the postsynaptic membrane. Consistent control with only pyridostigmine can be challenging. Underdosing will result in residual weakness and overdosing may produce a “cholinergic crisis” characterized by abdominal pain, salivation, bradycardia, and skeletal muscle weakness. Corticosteroids (prednisone) are nonspecific immunosuppressants used when pyridostigmine does not produce satisfactory control. Other immunomodulators that may be used include azathioprine, mycophenolate mofetil, rituximab, methotrexate, cyclosporine, and tacrolimus. The administration of IVIG and plasmapheresis can be used when rapid treatment is required. Thymectomy is recommended for patients with a thymoma and patients with early-onset MG.

**Table 24-5** Clinical Presentations of Myasthenia Gravis

Type	Etiology	Onset	Sex	Thymus	Course
Neonatal myasthenia	Passage of antibodies from myasthenic mothers across the placenta	Neonatal	Both sexes	Normal	Transient
Congenital myasthenia	Congenital end-plate pathology, genetic autosomal recessive pattern of inheritance	0–2 yr	Male > female	Normal	Nonfluctuating compatible with long survival
Juvenile myasthenia	Autoimmune disorder	2–20 yr	Female > male (4:1)	Hyperplasia	Slowly progressive, tendency to relapse and remission
Adult myasthenia	Autoimmune disorder	20–40 yr	Female > male thymoma	Hyperplasia > within 3–5 yr	Maximum severity
Elderly myasthenia	Autoimmune disorder	>40 yr	Male > female	Thymoma (benign or locally invasive)	Rapid progress, higher mortality

## Management of Anesthesia

The primary concern for anesthesia is the potential interaction between the disease, MG medications, and anesthetic drugs that may exacerbate muscle weakness. The uncontrolled MG patient is exquisitely sensitive to nondepolarizing muscle relaxants (Fig. 24-3). Small doses of nondepolarizing muscle relaxants can produce profound respiratory muscle weakness. An anesthetic technique that avoids the use of muscle relaxants would be preferred. Halogenated, inhaled anesthetics (isoflurane, sevoflurane, desflurane) that depress neuromuscular transmission may be adequate for tracheal intubation. If muscle relaxation is required, a small dose of a short-acting nondepolarizing muscle relaxant should be used. The successful use of rocuronium and reversal with sugammadex has been reported in patients with MG.<sup>18</sup> MG patients who are poorly controlled are resistant to succinylcholine; however, a dose of 1.5 to 2 mg/kg will be adequate for rapid tracheal intubation. Pyridostigmine may prolong the duration of action of succinylcholine. Close objective monitoring of neuromuscular function is necessary. Postoperative mechanical ventilation in an ICU should be done if there is any question about the ability of the patient to maintain adequate spontaneous ventilation.<sup>19</sup>

Exacerbations of MG should be anticipated during pregnancy. Epidural analgesia can be used during labor and delivery.<sup>20</sup> Amide local anesthetics may be better than ester local anesthetics as the metabolism of amides is not affected by cholinesterase activity.

**Table 24-6** Osserman Staging System for Myasthenia Gravis

Type	Description
I	Ocular weakness only
IIA	Generalized muscle weakness
IIB	Generalized moderate weakness and/or bulbar dysfunction
III	Acute, fulminant presentation and/or respiratory dysfunction
IV	Severe, generalized weakness

**Figure 24-3** Dose–response for vecuronium in normal patients and patients with myasthenia gravis. (Adapted from Eisenkraft JB, Book WJ, Papatostas AE. Sensitivity to vecuronium in myasthenia gravis: a dose-response study. *Can J Anaesth.* 1990;37:3012–3016.)

### Myasthenic Syndrome (Lambert–Eaton Syndrome)

The Lambert–Eaton syndrome (LEMS) is an autoimmune disease associated with cancer and is recognized as a paraneoplastic syndrome. Many tumors express onconeural antigens that resemble normal neural tissue components. Patients with LEMS have autoantibodies directed against presynaptic voltage-gated calcium ion channels. This results in a decreased release of acetylcholine and subsequent muscle weakness. Small-cell lung cancer is most frequently associated with LEMS and the weakness often precedes the discovery of the tumor. The typical LEMS patient is a male greater than 40 years of age with proximal muscle weakness (hip, shoulder) that affects gait and the ability to stand and climb stairs (Table 24-7). Autonomic dysfunction with dry mouth, constipation, erectile dysfunction, and reduced sweating often occurs. Paraneoplastic neurologic syndrome has also been reported with breast and ovarian cancer, lymphomas, testicular cancer, and neuroblastoma. The clinical diagnosis can be confirmed with

electrophysiologic testing (repetitive nerve stimulation) and serologic testing for the autoantibody.<sup>21</sup>

Treatment of the underlying neoplasm may improve the neurologic condition. The most effective drug for the treatment of the muscle weakness is 3,4-diaminopyridine. 3,4-Diaminopyridine prolongs the presynaptic action potential and increases the release of acetylcholine. Side effects of 3,4-diaminopyridine include perioral tingling, digital paresthesias, seizures, and supraventricular tachycardia. If treatment with 3,4-diaminopyridine is inadequate, prednisone, azathioprine, IVIG, or plasmapheresis may be used.<sup>22</sup>

## Management of Anesthesia

Patients with LEMS are sensitive to the effects of both depolarizing and nondepolarizing muscle relaxants. The most frequently reported perioperative complications are respiratory. The administration of 3,4-diaminopyridine should be continued until the time of surgery. Undiagnosed LEMS may be present in patients undergoing surgical procedures for cancer. This could be a cause of delayed recovery from muscle relaxants.<sup>23</sup>

## Guillain–Barré Syndrome (Polyradiculoneuritis)

Guillain–Barré syndrome (GBS) is the acute form of a group of disorders known as the inflammatory neuropathies. Other diseases in this group include acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor–sensory axonal neuropathy, Miller-Fisher syndrome, and chronic inflammatory demyelinating polyneuropathy (CIDP).

GBS is an autoimmune disease triggered by a viral or bacterial infection and is an example of molecular mimicry and cross-reactivity. The infectious agent produces a substance that causes an immune reaction. That substance resembles a neural component of the host and autoantibodies develop that attack the host. Patients with GBS develop antibodies to gangliosides in the peripheral nerves.<sup>24</sup>

Most patients with GBS have a history of a respiratory or gastrointestinal infection within 4 weeks of the onset of neurologic symptoms. Infections with *Campylobacter jejuni*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, Epstein–Barr virus, and cytomegalovirus are most frequently associated with GBS. There are sporadic reports of GBS or a GBS-like syndrome presenting after surgical procedures, trauma, or some vaccinations. GBS is characterized by onset of skeletal muscle weakness or paralysis of the legs. Paresthesias may precede the weakness. The paralysis progresses cephalad to include the muscles of the trunk and arms with maximal weakness developing 2 to 4

weeks after the onset. A plateau phase develops before recovery begins. The most serious problem is ventilatory insufficiency and 25% of patients with GBS will require mechanical ventilation. Autonomic nervous system dysfunction can produce wide fluctuations in heart rate and blood pressure. In a manner similar to autonomic hyperreflexia, physical stimulation can precipitate hypertension, tachycardia, and cardiac dysrhythmias.

Plasma exchange and IVIG have been shown to be effective for patients with GBS.<sup>25</sup> Although 85% of GBS patients achieve a good recovery, 3% to 5% develop a chronic recurrent neuropathy.

### Management of Anesthesia

Autonomic nervous system dysfunction may cause hypotension secondary to postural changes, blood loss, or positive pressure ventilation. Noxious stimuli such as laryngoscopy and tracheal intubation may produce exaggerated increases in heart rate and blood pressure.

Succinylcholine should be avoided because of the danger of hyperkalemia. This risk may persist after clinical recovery from GBS.<sup>26</sup> A short-acting nondepolarizing muscle with minimal cardiovascular effects (cisatracurium, rocuronium) would be a logical choice. The sensitivity to nondepolarizing muscle relaxants may vary from extreme sensitivity to resistance, depending on the phase of the disease.<sup>27</sup> It is likely that mechanical ventilation may be required in the immediate postoperative period. Patients with GBS who have pronounced sensory disturbances may benefit from neuraxial opioids. There are reports of GBS developing after neuraxial anesthesia.<sup>28</sup>

**TABLE 24-7** Comparison of Myasthenic Syndrome and Myasthenia Gravis

	Myasthenic Syndrome	Myasthenia Gravis
Manifestations	Proximal limb weakness (arms > legs) Strength improves with exercise Muscle pain common Reflexes absent or decreased	Extraocular, bulbar, and facial muscle weakness Fatigue with exercise Muscle pain uncommon Reflexes normal
Gender	Male > female	Female > male
Coexisting pathology	Small-cell carcinoma of lung	Thymoma
Response to muscle relaxants	Sensitive to succinylcholine and nondepolarizing muscle relaxants Poor response to anticholinesterases	Resistant to succinylcholine Sensitive to nondepolarizing muscle relaxants Poor response to anticholinesterases

## Central Nervous System Diseases

### Multiple Sclerosis

The features of multiple sclerosis (MS) are inflammation, demyelination, immune dysregulation, and failure of cell repair in the CNS. There is a

complex interaction between genetics and environmental factors that lead to demyelination of CNS cells and peripheral nerves. An antigen-presenting dendritic cell crosses the blood–brain barrier and converts some T cells into inflammatory cells. These T cells induce macrophages that produce cytokines and oxygen radicals that cause demyelination and axonal decay. Demyelination interferes with neural transmission and CNS dysfunction ensues. As the disease progresses there is loss of brain volume and gray matter.<sup>29</sup>

The symptoms of MS depend on the sites of demyelination. Brainstem involvement can produce nystagmus, diplopia, ataxia, autonomic dysfunction, and alterations in ventilation that lead to respiratory failure. Lesions of the spinal cord produce weakness and paresthesias. The legs are affected more than the arms. Bowel retention and urinary incontinence are frequent complaints. Many patients with MS develop central neuropathic pain, trigeminal neuralgia, spasticity, and tonic seizures. The course of MS is characterized by exacerbation of symptoms at unpredictable intervals over years. Patients are classified during the early stages of the disease as relapsing-remitting (85%) or primary progressive MS (15%). Many patients with relapsing-remitting MS develop neurodegeneration and are then categorized as secondary progressive MS.

Clinical criteria for the diagnosis of MS include onset between 10 and 50 years of age, signs and symptoms of CNS white matter disease, two or more attacks separated by a month or more, and involvement of two or more noncontiguous anatomic areas. Elevated levels of IgG and albumin in the cerebrospinal fluid are characteristic of MS. Magnetic resonance imaging (MRI) is a sensitive diagnostic tool for MS and provides direct evidence of demyelinated plaques in the CNS. Pregnancy is generally associated with reduced risk of exacerbations whereas the postpartum period is notable for an increased risk of relapse.

Treatment of MS is directed at modulating the immunologic and inflammatory responses that damage the CNS. Most of the immunomodulating drugs do increase the patient's risk of infection and malignancy. Interferon preparations and glatiramer are self-injectable drugs with good safety profiles. Mitoxantrone is a general immunosuppressant that has limited use because of cardiotoxicity and treatment-related leukemia. Natalizumab has limited use because of the development of progressive multifocal leukoencephalopathy (PML). There are three oral disease-modifying drugs currently used for the treatment of relapsing MS: fingolimod, teriflunomide, and dimethyl fumarate. Side effects of fingolimod include bradycardia, macular edema, hypertension, and liver dysfunction. Teriflunomide can cause lymphopenia, hepatotoxicity, hypertension, and peripheral neuropathy. Dimethyl fumarate causes flushing, nausea, abdominal

pain, and diarrhea. A number of monoclonal antibodies are under investigation for the treatment of MS.<sup>30</sup>

## Management of Anesthesia

The effect of surgery and anesthesia on the course of MS is controversial. Some reports have suggested that general or regional anesthesia can exacerbate MS. Most reports, however, have found no influence of anesthesia on the course of the disease. It is likely that other factors such as infection, hyperpyrexia, and emotional stress could contribute to a perioperative exacerbation. Preoperatively, the patient should be advised that surgery and anesthesia could produce a relapse despite a well-managed anesthetic. Most of the old controversies concerning regional and epidural/spinal anesthesia and MS have been resolved by several studies supporting the use of these modalities in patients with MS.<sup>31,32</sup> There is no evidence that exposure to inhaled anesthetics, including nitrous oxide, increases the risk of MS to anesthesia providers.

The chronic effects of the neurologic dysfunction caused by MS and potent therapeutic drugs can be manifest during the perioperative period as autonomic dysfunction, myopathy, cardiotoxicity, and sensitivity or resistance to muscle relaxants. Succinylcholine could produce an exaggerated release of potassium. Respiratory muscle weakness and poor respiratory control increase the likelihood of postoperative respiratory support.

## Epilepsy

A seizure is a common manifestation of many CNS diseases. A seizure is the result of an excessive discharge of large numbers of neurons depolarized in synchrony. Epilepsy (idiopathic seizures) begins in childhood. The onset of seizures in an adult may indicate focal brain disease (e.g., tumor). Onset of seizures after 60 years of age can be a result of cerebrovascular disease, head injury, tumor, infection, or metabolic abnormalities.

The most frequently encountered types of seizures are:

1. *Grand mal seizures* are characterized by generalized tonic-clonic activity. All respiratory effort ceases and arterial hypoxemia ensues. The tonic phase lasts 20 to 40 seconds and is followed by the clonic phase. In the postictal period, the patient is lethargic and confused.
2. *Focal cortical seizures* may be motor or sensory depending on the site of neuronal discharge. There is usually no loss of consciousness, although the focal seizure may induce a grand mal seizure.
3. *Absence seizures (petit mal)* are a sudden, brief loss of awareness (30 seconds). Additional features include staring, blinking, and rolling of

the eyes. These seizures typically occur in children and young adults.

4. *Akinetic seizures* are a sudden loss of consciousness and postural tone. These types of seizures usually occur in children and can cause severe head injury from the fall.
5. *Status epilepticus* is defined as two consecutive tonic–clonic seizures without regaining consciousness or seizure activity that is unabated for 30 minutes. Grand mal status epilepticus can last for 48 hours with four or five seizures per hour and the mortality can be 20%.<sup>33</sup> As the seizure progresses, skeletal muscle activity diminishes and seizure activity may only be evident on the EEG. Respiratory effects of status epilepticus include respiratory center inhibition, impaired ventilation from uncoordinated skeletal muscle activity, and bronchoconstriction.

There are many antiepileptic drugs (AEDs) ([Table 24-8](#)). Most AEDs affect ion transfer, increase inhibitory neurotransmitters (GABA), or decrease levels of excitatory neurotransmitters. AEDs can be divided into two general categories: Broad-spectrum AEDs such as valproate, lamotrigine, topiramate, levetiracetam, and zonisamide are useful for generalized seizures. Narrow-spectrum AEDs such as carbamazepine, phenytoin, gabapentin, tiagabine, oxcarbazepine, and pregabalin are more appropriate for focal seizures.<sup>34</sup> Vagal nerve stimulators are often implanted for the treatment of medically refractory epilepsy.

**Table 24-8** Antiepileptic Drugs Classified by Mechanism of Action

<b><i>Enhance GABAergic System</i></b>
Barbiturates
Valproic acid
Tiagabine
Benzodiazepines
Primidone
Vigabatrin
<b><i>Affect Cation Channels</i></b>
<b>Sodium channels</b>
Carbamazepine
Felbamate
Lamotrigine
Phenytoin
Topiramate
Oxcarbazepine
<b>Calcium channels</b>
Gabapentin
Pregabalin
Ethosuximide
<b>Potassium channels</b>
Retigabine
<b><i>Antagonists of Excitatory Amino Acids</i></b>
Lacosamide
Talampanel
Levetiracetam
<b><i>Unknown Mechanism of Action</i></b>
Acetazolamide
sultiame
<b><i>AEDs for Status Epilepticus</i></b>
Propofol
Lorazepam
Fosphenytoin
Diazepam
Midazolam

The treatment of patients with status epilepticus requires airway protection and appropriate ventilatory assistance. Drug therapy for status epilepticus often requires combinations of lorazepam, midazolam, phenytoin, fosphenytoin, phenobarbital, pentobarbital, and propofol. On rare occasions, general anesthesia may be required.

Recent research has identified many genetic variations in patients with epilepsy. It is hoped that this research will result in highly effective, individualized therapy for epilepsy in the future.

## **Management of Anesthesia**

Many anesthetics including halogenated inhaled anesthetics, nitrous oxide, etomidate, ketamine, and opioids have been reported to produce seizure activity. The clinical significance of these reports is unclear.<sup>35</sup> The degree of

preoperative seizure control may be more important than the anesthetic agents. Interruption of the patient's AED therapy should be minimized during the perioperative period.

Side effects of AEDs include leukopenia, anemia, hepatic dysfunction, pancreatitis, cardiotoxicity, hypothyroidism, and skin rash.<sup>36</sup> Vagal nerve stimulators can cause vocal cord paralysis, facial palsy, bradycardia/asystole, and airway obstruction.<sup>37</sup> AEDs can stimulate hepatic enzymes (cytochrome P450) that can lead to increased metabolism of other drugs.<sup>38</sup> In contrast, AEDs that are highly protein bound may increase blood concentrations of other drugs.

## **Alzheimer Disease**

Alzheimer disease (AD) is the major cause of dementia in the United States. The incidence of AD increases progressively after 65 years of age and may be as high as 30% in persons over 85 years of age. Ninety-five percent of AD cases are sporadic and 5% have a genetic basis. The pathogenesis of AD is complex but appears to start with amyloid- $\beta$  protein ( $A\beta$ ), possibly years before clinical manifestations develop.  $A\beta$  most likely begins a cascade of events culminating in deposition of amyloid plaques, neurofibrillary tangles, and neuronal apoptosis (amyloid cascade). These changes cause a loss of cholinergic activity and a loss of glutamatergic neurons.

AD is characterized by loss of cognition, poor decision making, language deterioration, gait disturbances, seizures, agitation, and psychosis. Imaging studies show hippocampal atrophy (MRI) and glucose hypometabolism (PET scan). Medications currently approved for the treatment of AD include three acetylcholinesterase inhibitors (donepezil, rivastigmine, galantamine) and one NMDA inhibitor (memantine).<sup>39</sup> Cholinesterase inhibitors improve the patient's ability to perform daily living activities and may improve cognition. Side effects of cholinesterase inhibitors include nausea, emesis, bradycardia, syncope, and fatigue. Antidepressants, anticonvulsants, and antipsychotics are used for neuropsychiatric symptoms. Therapies under investigation are directed at early interruption of the amyloid cascade.

## **Management of Anesthesia**

There is considerable concern that general anesthesia may cause postoperative cognitive dysfunction (POCD) and accelerate the processes that cause AD.<sup>40</sup> POCD is well known in elderly patients after surgery, but proof of cause has remained elusive.<sup>41</sup> Patients and their families should be advised that POCD may occur.

The selection of anesthetics will be influenced by the patient's physiologic

condition and the degree of neurologic impairment. The patient's preoperative drug list should be reviewed for the possibility of interactions with anesthetics. Patients are likely to be confused and uncooperative because of dementia. Sedative premedication should be used with caution, if at all, as mental confusion may worsen. If an anticholinergic is required, glycopyrrolate, which does not cross the blood–brain barrier, is preferred rather than atropine or scopolamine. Patients receiving cholinesterase inhibitors may have a prolonged response to succinylcholine.

## **Parkinson Disease**

Parkinson disease (PD) is a degenerative CNS disease caused by a loss of dopaminergic cells in the basal ganglia. The characteristic pathologic feature is the presence of Lewy bodies in the neurons of the substantia nigra. The etiology of PD is a complex interaction between a genetic predisposition and environmental factors such as pesticide exposure, agricultural occupation, rural living, prior head injury, and  $\beta$ -adrenergic blocker use.

The most characteristic features of PD are resting tremor, cog-wheel rigidity of the upper extremities, bradykinesia, shuffling gait, stooped posture, and facial immobility. These features are secondary to diminished inhibition of the extrapyramidal motor system as a result of dopamine deficiency. Other clinical manifestations include seborrhea, sialorrhea, constipation, orthostatic hypotension, bladder dysfunction, diaphragmatic spasm, oculogyric crises, dementia, and depression.<sup>42</sup>

Current therapies for PD are directed at amelioration of symptoms. Current treatment research is aimed at prevention of underlying neurodegeneration. Levodopa is the most effective treatment available for PD. Levodopa is used in combination with drugs such as carbidopa (peripheral decarboxylase inhibitor) and entacapone (catechol-*o*-methyltransferase inhibitor) that prevent the adverse peripheral effects of dopamine. Other drugs that may improve function in patients with PD are the monoamine oxidase-B inhibitors, selegiline, and rasagiline. Dopamine agonists such as bromocriptine, pramipexole, ropinirole, pergolide, and cabergoline may also be effective. Pergolide and cabergoline are ergot-derived drugs that can cause cardiac valvular fibrosis and insufficiency. Implantation of deep-brain stimulators (DBS) may be quite effective for patients with advanced PD. The therapeutic regimen for PD is complex and requires a skilled neurologist to individualize therapy.<sup>43</sup>

## **Management of Anesthesia**

The half-life of levodopa is short and interruption of therapy for more than 6

to 12 hours can result in severe skeletal muscle rigidity that interferes with ventilation. Consultation with the patient's neurologist and continuation of the patient's drug regimen may avert complications. Apomorphine is a dopamine agonist that can be administered subcutaneously or intravenously if oral levodopa cannot be given. Dopamine antagonists such as phenothiazines, droperidol, and metoclopramide should be avoided. Alfentanil and fentanyl may produce dystonic reactions when administered rapidly. The incidence of side effects from propofol is low. Although ketamine could produce an exaggerated sympathetic nervous system response with tachycardia and hypertension, it has been used without difficulty in patients with PD. There are no reports of adverse responses to isoflurane, sevoflurane, or desflurane. The likelihood of coexisting heart disease in elderly patients with PD will influence the selection of anesthetics and monitoring techniques.<sup>44</sup>

Anesthetics administered to patients who are receiving monoamine-B-oxidase inhibitors are generally uneventful. There are, however, reports of agitation, muscle rigidity, and hyperthermia in patients receiving selegiline and meperidine. Patients being treated with dopamine agonists may be at increased risk for neuroleptic malignant syndrome (NMS).

Autonomic dysfunction is common. The most consistent cardiovascular effect is orthostatic hypotension that may be aggravated by the vasodilatory effects of anti-Parkinson drugs and inhaled anesthetics. Excessive salivation and esophageal dysfunction are common and increase the risk of aspiration pneumonitis. Perioperative respiratory complications are common.<sup>45</sup> Upper airway obstruction may be a result of poor coordination of upper airway muscles secondary to neurotransmitter imbalance. Upper airway obstruction may respond favorably to anti-Parkinson drugs. Patients with PD are susceptible to postoperative confusion and hallucinations. These changes in mental function may not occur for 24 to 72 hours after surgery.

Anesthesia for PD patients undergoing implantation of DBS can be challenging. Awake techniques with sedation and local anesthesia are preferred so intraoperative testing of the stimulator can be performed. Agitated and uncooperative patients may require general anesthesia. Hypertension, seizures, and electrical interference with other devices can occur.<sup>46</sup>

## **Huntington Disease**

Huntington disease (HD) is an autosomal dominant inherited disease characterized by progressive neurodegeneration. HD is one of the trinucleotide repeat disorders. An increase in cytosine, adenine, and guanine (CAG) sequences on chromosome 4 is the genetic defect that produces a mutant huntingtin protein. Huntingtin is found in all human cells, but most

notably in brain cells. The role of huntingtin is not known, but it may prevent cell apoptosis. Neurons from patients with HD show abnormal inclusion bodies containing mutant huntingtin and polyglutamine. Associated with HD is atrophy of the caudate, putamen, and thalamus with cortical thinning. Recent evidence suggests that peripheral inflammatory mediators may gain access to the brain and trigger neurodegeneration. Identification of the huntingtin gene provides a reliable predictive test; however, the delayed nature of the clinical manifestations presents legal and ethical concerns about predictive testing.<sup>47</sup>

Onset of the clinical manifestations of HD typically begins between 35 and 40 years of age. Clinical features include choreiform movements, depression, and dementia. The disease continues to progress for several years and depression increases the possibility of suicide. Death occurs 17 to 20 years after diagnosis and is usually from malnutrition or aspiration pneumonitis. Hypothalamic atrophy can cause endocrine changes such as elevated cortisol levels, reduced testosterone levels, and diabetes. Hepatic dysfunction and skeletal muscle weakness are common.

There is no specific therapy for HD. Most therapy is palliative. Tetrabenazine is used for the treatment of chorea. Antiepileptics and antidepressants may be required for neuropsychiatric manifestations of HD.

## **Management of Anesthesia**

The medical literature is sparse with regard to the anesthetic management of patients with HD. Many of the manifestations of HD are typical of patients with neurodegenerative disorders. As the disease progresses, the pharyngeal muscles become dysfunctional and the risk of aspiration pneumonitis increases.<sup>48</sup> Delayed emergence and an increased likelihood of respiratory complications must be anticipated after surgery.

Although there are no specific contraindications to the use of intravenous or inhaled anesthetics, recovery from propofol may be faster than with other intravenous hypnotics. Short-acting muscle relaxants are preferable to long-acting muscle relaxants. Decreased plasma cholinesterase activity may prolong the response to succinylcholine. Spinal anesthesia has been successfully used in patients with HD.

## ***Amyotrophic Lateral Sclerosis***

Amyotrophic lateral sclerosis (ALS, Lou Gehrig disease) is a degenerative disease of motor neurons: upper motor neuron (UMN) and lower motor neuron (LMN). Although the cause of ALS has not been discovered, glutamate excitotoxicity and/or oxidative stress may be important components.

Degeneration of LMN and UMN may be dependent or independent processes. The end result is LMN degeneration and destruction of the neuromuscular junction. Progression of the disease is relentless—50% of patients die within 30 months of the onset of symptoms. Twenty percent may survive 5 to 10 years.

Signs and symptoms are influenced by the affected neurons. Initial symptoms are asymmetric limb weakness. Dysarthria and dysphagia are a result of bulbar atrophy. Pulmonary function testing demonstrates a decrease in vital capacity and maximal voluntary ventilation. Patients with ALS have autonomic dysfunction as evidenced by resting tachycardia, orthostatic hypotension, and elevated circulating levels of epinephrine and norepinephrine. Respiratory failure eventually develops and ventilatory support is required. The cause of death is respiratory failure or cardiovascular collapse.

Riluzole, a glutamate release inhibitor, is the only drug approved for the specific treatment of ALS. Improved survival, however, with riluzole is quite modest (3 to 6 months). Many other drugs may be employed to ameliorate the effects of ALS.<sup>49</sup> Treatment to avoid mechanical ventilation such as the use of diaphragmatic pacing is under investigation.

## **Management of Anesthesia**

Surgical interventions for palliative care (gastrostomy, central venous catheter insertion, tracheostomy) are frequently required. Short-acting anesthetics such as propofol, remifentanyl, sevoflurane, and desflurane are preferred. Neuromuscular transmission is abnormal and ALS patients may be very sensitive to nondepolarizing muscle relaxants. Succinylcholine should be avoided as it may provoke a massive release of potassium. The need for postoperative ventilatory support is likely.<sup>50</sup>

## **Creutzfeldt–Jakob Disease**

Creutzfeldt–Jakob disease (CJD) is one of a group of diseases termed the transmissible spongiform encephalopathies. Pathologically, these diseases are characterized by vacuolation of brain cells and neuronal death. CJD is an infection caused by a prion, a small protein devoid of nucleic acid. PrP<sup>c</sup> is a naturally occurring protein concentrated in neurons. A conformational change occurs in PrP<sup>c</sup> and changes it to the pathologic form PrP<sup>sc</sup>.<sup>51</sup> The structure of PrP<sup>sc</sup> renders the protein resistant to conventional decontamination methods. There are four types of CJD: familial (fCJD), sporadic (sCJD), iatrogenic (iCJD), and variant (vCJD). CJD is a very rare cause of dementia, but the discovery of transmission of a prion disease from cows to humans (mad cow

disease, 1996) catapulted CJD to international prominence. This form of CJD is the variant form (vCJD).

The clinical manifestations of sCJD are subacute dementia, myoclonus, and EEG changes. The EEG pattern is characteristic with diffuse slow activity and periodic complexes. Progressive loss of cognitive and neurologic function occurs. Patients with vCJD present with dysphoria, withdrawal, anxiety, and insomnia. Neurologic features develop 1 to 2 months after psychiatric changes commence. Transmission of vCJD is by ingestion of contaminated animal products. Iatrogenic transmission of iCJD has been linked to contaminated dural graft material, corneal transplants, contaminated surgical instruments, pooled human growth hormone, and blood. There is no specific treatment for CJD. Research has centered on therapies aimed at preventing prion transmission from the periphery to the CNS and neuronal regeneration.

## Management of Anesthesia

CJD is a transmissible disease and appropriate precautions should be observed when administering anesthesia. Patient tissues with a high likelihood of contamination include brain, spinal cord, cerebrospinal fluid, lymphoid tissue, and blood. Single-use anesthesia supplies, including face masks, breathing circuits, laryngoscopes, and tracheal tubes offer the highest degree of protection.<sup>52</sup>

Patients with degenerative neurologic diseases are prone to aspiration pneumonitis because they have impaired swallowing function and decreased laryngeal reflexes. Lower motor neuron dysfunction occurs in patients with CJD and succinylcholine should be avoided. The autonomic and peripheral nervous systems are adversely affected and abnormal cardiovascular responses to anesthesia and vasoactive drugs should be expected.

## Other Inherited Disorders

### *Malignant Hyperthermia*

MH is a pharmacogenetic disorder of skeletal muscle that, when triggered, results in a hypermetabolic process associated with significant morbidity and mortality. MH is commonly triggered by succinylcholine or halogenated, inhaled anesthetics. It has also been associated with extreme physiologic stress or heat exhaustion. Individuals susceptible to MH have a mutation of the ryanodine receptor that permits the uncontrolled release of calcium ( $\text{Ca}^{+2}$ ) from the sarcoplasmic reticulum (SR). This leads to sustained muscle contraction/rigidity, metabolic and respiratory acidosis, hypercarbia, tachycardia, hyperthermia, rhabdomyolysis, and

6

hemodynamic instability.<sup>53</sup> Other mechanisms of calcium control may also be defective in patients with MH (Fig. 24-4).<sup>54</sup> The incidence of MH in adults varies from 1:40,00 to 1:250,000, but may be as high as 1:15,000 in children. Although the knowledge of the pathophysiology and genetics of MH has increased, mortality may still be as high as 9.5%.<sup>55</sup>

### Management of the Acute Malignant Hyperthermia Episode

The earlier an episode of MH is identified and treated, the better the outcome. The first sign of an MH reaction is usually an increase in the end-tidal CO<sub>2</sub> (ETCO<sub>2</sub>) that does not respond to an appropriate increase in ventilation. Nonspecific signs of MH include tachycardia, tachypnea (spontaneous ventilation), and hypertension. Muscle rigidity, masseter spasm, and respiratory and metabolic acidosis develop subsequently. Hyperthermia may occur early or late in the episode. Other conditions that may mimic MH are sepsis, hyperthyroidism, and NMS. If the presumptive diagnosis is an MH episode, any halogenated, inhaled anesthetic should be discontinued and hyperventilation with 100% oxygen initiated. A scoring system has been developed to assist the clinician with the diagnosis of a true MH reaction (Table 24-9).<sup>56</sup> The surgical team should be informed and the procedure aborted or terminated as quickly as possible under intravenous anesthesia. Charcoal filters placed in the anesthesia breathing system will rapidly purge the system of any halogenated anesthetic. The most definitive treatment for MH is dantrolene, a hydantoin derivative that inhibits the pathologic release of Ca<sup>+2</sup>.<sup>57</sup> The initial intravenous dose of dantrolene is 2.5 mg/kg. Dantrolene should be repeated until the MH reaction has subsided. Some cases of acute MH may require 10 to 20 mg/kg of dantrolene. A newer formulation of dantrolene (Ryanodex, Eagle Pharmaceuticals, Woodcliff Lake, NJ) requires significantly less time for reconstitution than the older preparation.<sup>58</sup> Serial arterial blood gas measurements are helpful for tracking the response to therapy. Supportive measures include hyperventilation, treatment of acidosis and hyperkalemia, active cooling, and maintenance of an adequate urinary output (Table 24-10).<sup>59</sup>
