The relative volume of the central compartment in which drugs are first distributed remains unchanged in obese patients, but absolute body water content is decreased. Lean body and adipose tissue mass are increased, affecting lipophilic and polar drug distribution (Fig. 45-4). The VD in obese patients is affected by multiple factors including reduced total body water, increased total body fat, increased lean body mass, altered protein binding, increased blood volume, increased cardiac output, increased blood concentrations of free fatty acids, triglycerides, cholesterol, and  $\alpha_1$ -acid glycoprotein, lipophilicity of the drug, and organomegaly.<sup>7</sup> Increased redistribution of a drug prolongs its elimination half-life even when clearance is unchanged or increased. Hyperlipidemia and an increased concentration of  $\alpha_1$ -acid glycoprotein may affect protein binding, leading to a reduction in free drug concentration. Plasma albumin and total plasma protein concentrations and binding are not significantly changed by obesity, but when compared with normal-weight individuals, a relative increase in plasma protein binding may be evident. Splanchnic blood flow, blood volume, and cardiac output are all increased in obese patients. In contrast to the expected decrease in bioavailability of orally administered medications because of increased splanchnic blood flow, there is no significant difference in absorption and bioavailability when comparing obese and normal-weight subjects. Drugs that undergo phase I metabolism (oxidation, reduction, hydrolysis) are generally unaffected by changes induced by obesity, whereas phase II reactions (glucuronidation, sulfation) are enhanced.<sup>7</sup>

**Figure 45-4** Body composition in extremely obese and weight-reduced states compared with reference female values. ICW, intracellular water; ECW, extracellular water. (Adapted from Das SK, Roberts SB, Kehayias JJ, et al. Body composition methods in extreme obesity. *Am J Physiol Endocrinol Metab.* 2003;284:E1080.)

Histologic abnormalities of the liver are common in the obese, with concomitant deranged liver function tests, but drug clearance is not usually affected. Renal clearance of drugs is increased in obesity because of increased renal blood flow and glomerular filtration rate.<sup>55,62</sup> As a result of the increases in glomerular filtration rate and tubular secretion, drugs such as cimetidine and aminoglycoside antibiotics that depend on renal excretion may require increased dosing. Highly lipophilic substances such as barbiturates and benzodiazepines show significant increases in VD for obese individuals.<sup>7</sup> These drugs have a more selective distribution to fat stores and therefore a longer elimination half-life, but have comparable clearance values to normal individuals. Less lipophilic compounds have little or no change in VD with obesity. Exceptions to this rule include the highly lipophilic drugs digoxin, procainamide, and remifentanyl.<sup>63–65</sup> Drugs with weak or moderate lipophilicity may be dosed on the basis of LBW. Adding 20% to the estimated IBW dose of hydrophilic medications is sufficient to include the obese patient's extra lean mass. Nondepolarizing muscle relaxants can be dosed in this manner. A recent study evaluated recovery times after reversal of neuromuscular blockade with sugammadex in obese (BMI > 30 kg/m<sup>2</sup>) and nonobese (BMI < 30 kg/m<sup>2</sup>) patients.<sup>66</sup> In the study, recovery time did not correlate with BMI. The authors recommend sugammadex dosing be based on actual body weight in both obese and nonobese patients.

Increased blood volume in the obese patient decreases plasma concentrations of rapidly injected intravenous drugs. Fat, however, has poor blood flow, and doses calculated on actual body weight could lead to

excessive plasma concentrations. Calculating initial doses based on LBW with subsequent doses determined by pharmacologic response to the initial dose is a reasonable approach. Repeated injections may accumulate in fat, leading to a prolonged response because of subsequent release from this large depot. [Table 45-3](#) presents dosing of intravenous agents used in obese patients.<sup>67,68</sup>

### ***Other Perioperative Agents***

Patients' usual medications should be continued until the time of surgery, with the possible exception of certain antihypertensives, insulin, and oral hypoglycemics. Antibiotic prophylaxis is usually indicated because of an increased incidence of wound infections in the obese. A recent prospective, cross-sectional study of 896 patients undergoing RYGB determined that the rate of surgical site infection was less in patients receiving a continuous infusion of cefazolin (1.55%) throughout the procedure compared to patients receiving either bolus dose ampicillin/sulbactam (4.16%) or ertapenem (1.98%).<sup>69</sup> Anxiolysis and prophylaxis against both aspiration pneumonitis and deep vein thrombosis (DVT) should be addressed preoperatively. Oral benzodiazepines are reliable for anxiolysis and sedation. Intravenous midazolam can also be titrated in small doses for anxiolysis during the immediate preoperative period. Dexmedetomidine, because of its minimal respiratory depressant effects, should be considered. Pharmacologic intervention with H<sub>2</sub>-receptor antagonists, nonparticulate antacids, or proton pump inhibitors will reduce gastric volume, acidity, or both, thereby reducing the risk and severity of aspiration pneumonitis.

**Table 45-3** Intravenous Drug Dosing in Obesity<sup>66–68</sup>

Drug	Dosing	Practical Anesthesia Key Points
Thiopental	Induction: LBW (somewhat increased)	Increased initial dose due to increased blood volume, cardiac output, muscle mass Rapid distribution from plasma to periphery Increased absolute dose Prolonged duration of action due to high lipophilicity and increased VD Longer elimination half-life
Propofol	Induction: LBW (somewhat increased) Maintenance infusion: TBW	Short duration of action due to rapid redistribution Highly lipophilic Cardiac output is major determinant of peak plasma concentration Increased VD at steady state and increased clearance prevent increases in elimination half-life Total clearance and VD at steady state correlate with TBW during maintenance infusion Negative cardiovascular effects High affinity for fat and well-perfused organs High hepatic extraction and conjugation relate to TBW
Succinylcholine	TBW	Pseudocholinesterase activity increases linearly with increasing weight and large extracellular fluid compartment Dose of succinylcholine should be increased
Rocuronium	LBW	Dosing according to LBW to prevent delayed recovery due to increased VD Faster onset and longer duration when dosed according to TBW Pharmacokinetics and pharmacodynamics not altered in obese female patients
Vecuronium	LBW	Prolonged action when dosed according to TBW Dosing according to LBW to prevent delayed recovery due to increased VD and impaired hepatic clearance Obesity does not alter distribution or elimination of the drug
Atracurium	LBW	VD, absolute clearance, and elimination half-life unchanged by obesity Unchanged dose per unit body weight without prolongation of recovery because of organ function-independent elimination
Cis-atracurium	LBW	Pharmacokinetics similar to atracurium but prolonged duration of action when dosed according to TBW
Benzodiazepines		Highly lipophilic drugs with larger VD in obese patients result in longer duration of action Midazolam has potential for prolonged sedation because larger initial doses are required to achieve adequate serum concentrations
Fentanyl	LBW	Measured total body clearance has a nonlinear relationship to TBW and overestimates plasma concentration Fentanyl dosing based on a derived LBW or "pharmacokinetic mass" model correlates better with clearance than TBW dosing Dosing based on TBW overestimates dose requirements in the obese patient
Sufentanil	LBW	Highly lipid soluble Increased VD and prolonged elimination half-life, which correlates with degree of obesity Distributes extensively in excess body fat Similar pharmacokinetic parameters in obese and nonobese predict similar plasma concentrations Overestimation of plasma concentration occurs in the morbidly obese range (BMI >40 kg/m <sup>2</sup> )
Remifentanyl	LBW	Pharmacokinetics similar in obese and nonobese patients (i.e., more closely related to lean body mass than LBW) Systemic clearance and VD corrected per kilogram of TBW are significantly smaller in the obese patient; consider age and LBW for dosing
Dexmedetomidine	TBW	Highly selective $\alpha_2$ -adrenergic agonist Sedative-hypnotic, anesthetic-sparing analgesic, sympatholytic properties Lacks significant effects on respiration Ideal analgesic adjuvant in the morbidly obese patient As part of a balanced anesthetic, infusion rates of 0.2–0.7 $\mu\text{g}/\text{kg}/\text{hr}$ produce clinically effective sedation with decreased analgesic and anesthetic requirements
Neostigmine	TBW	Prompt early reversal but delayed full recovery during neostigmine-induced reversal of vecuronium dosed according to TBW
Sugammadex	TBW	A modified $\gamma$ -cyclodextrin compound that encapsulates rocuronium (and other steroid-based neuromuscular blockers to a lesser extent) May prove invaluable for more rapid and complete neuromuscular blockade reversal in obese patients

LBW, lean body weight; VD, volume of distribution; TBW, total body weight; BMI, body mass index.

## Preoperative Evaluation

A comprehensive preoperative evaluation of the obese surgical patient is

critical to identify and address possible multisystem comorbidities, and to allow the development of an individualized perioperative care plan.<sup>70–72</sup>

*Airway*—Preoperative airway assessment in obese patients is of paramount importance. Obesity played a significant role in US closed malpractice insurance claims related to airway management at induction.<sup>73</sup> Anatomic changes associated with obesity that contribute to a potentially difficult airway include limitation of movement of the atlantoaxial joint and cervical spine by upper thoracic and low cervical fat pads; excessive tissue folds in the mouth and pharynx; short, thick neck; thick submental fat pad; suprasternal, presternal, and posterior cervical fat; and large breasts in females. Excess pharyngeal tissue deposited in the lateral pharyngeal walls may not be noticed during routine airway examination. The history obtained from the patient and examination of previous records may help predict airway difficulties.

Obesity is an accepted risk factor for difficult mask ventilation and airway management. However, with adequate positioning and airway resources available, most obese patients can be adequately and safely managed. Overall, the magnitude of BMI does not significantly influence the difficulty of laryngoscopy.<sup>74</sup> Such difficulty in most studies correlates instead with increased age, male sex, temporomandibular joint pathology, Mallampati classes 3 and 4, OSA, and abnormal upper teeth.<sup>75–77</sup> The predictive role of OSA per se on difficult intubation has been recently disputed.<sup>78</sup> In a prospective study of bariatric patients by Neligan et al.<sup>78</sup> only a Mallampati **3** score of 3 or more and male gender, but not BMI, OSA, or the apnea–hypopnea index (AHI), predicted the risk of difficult intubation. The patient’s neck circumference has been identified as the single biggest predictor of problematic intubation in morbidly obese patients.<sup>76</sup> The probability of a problematic intubation is approximately 5% with a 40-cm (16-in) neck circumference compared with a 35% probability at 60-cm (24-in) neck circumference. In this study by Brodsky et al.<sup>76</sup> a larger neck circumference was associated with male gender, a higher Mallampati score, laryngoscopy grade 3 views, and OSA.

*Cardiopulmonary*—Attention should focus on issues peculiar to the obese patient including evaluation of the cardiopulmonary systems and the airway. Previous anesthetic experiences as detailed by the patient and previous anesthetic records are useful. Obese patients should be evaluated for systemic hypertension, pulmonary hypertension, signs of right and/or left ventricular failure, and ischemic heart disease. Signs of cardiac failure such as elevated jugular venous pressure, pathologic heart sounds, pulmonary crackles, hepatomegaly, and peripheral edema may all be difficult to detect because of excess adiposity. Pulmonary hypertension is fairly common in this patient population because of the chronic pulmonary impairment. The common

features of pulmonary hypertension are exertional dyspnea, fatigue, and syncope (which reflect an inability to increase cardiac output during activity). Tricuspid regurgitation on echocardiography is the most useful confirmatory test of pulmonary hypertension but should be combined with clinical evaluation. An ECG may demonstrate signs of right ventricular hypertrophy such as tall precordial R waves, right axis deviation, and right ventricular strain. The higher the pulmonary artery pressure the more sensitive the ECG. Chest radiographs may show evidence of underlying lung disease and prominent pulmonary arteries.<sup>79</sup> Further cardiac testing may be individually required.<sup>80</sup>

Evidence of OSA and OHS should be obtained preoperatively because they are frequently associated with difficult airway management and increased perioperative pulmonary complications. A history of hypertension or a neck circumference greater than 40 cm (16 in) correlates with an increased probability of OSA. OSA is a legitimate reason to delay surgery for a proper evaluation.<sup>33</sup> OSA patients should generally be treated as inpatients; however, outpatient surgery can be considered under certain circumstances, including mild OSA, use of local or regional anesthesia with minimal sedation, availability of a 23-hour observation postanesthesia care unit (PACU), and when patients can resume oral medication at the time of discharge. OSA patients using a CPAP device at home should be instructed to bring it with them to the hospital, as it may be needed postoperatively. The possibility of invasive monitoring, prolonged intubation, and postoperative mechanical ventilation should be discussed with obese patients. Arterial blood gas measurements help evaluate ventilation, as well as the need for perioperative oxygen administration and postoperative ventilation. Routine pulmonary function tests and liver function tests are not cost-effective in 4 asymptomatic obese patients.

*Metabolic*—Patients scheduled for repeat bariatric surgery should be screened preoperatively for long-term metabolic and nutritional abnormalities. The high prevalence of insulin resistance and diabetes in obese patients justifies the need of considering glycemia checks preoperatively, and correcting abnormalities if present. Preoperative evaluation should include assessment of therapies for glycemic control, last time and dose of preoperative administration, and usual glucose values for a specific patient. Electrolytes should be checked before surgery, particularly in patients with poor compliance to medications or acutely ill patients. Other nutritional deficiencies include vitamin B<sub>12</sub>, iron, calcium, and folate. Vitamin and nutritional deficiencies can lead to a collective form of postoperative polyneuropathy, known as acute postgastric reduction surgery (APGARS) neuropathy, a polynutritional multisystem disorder characterized by protracted postoperative vomiting, hyporeflexia, and muscular weakness.<sup>81</sup>

Differential diagnoses of this disorder include thiamine deficiency (Wernicke encephalopathy, beriberi), vitamin B<sub>12</sub> deficiency, and Guillain–Barré syndrome. Close attention to dosing and monitoring of neuromuscular blocking agents is recommended in cases of suspected or diagnosed APGARS neuropathy. Chronic vitamin K deficiency may lead to coagulation abnormalities, requiring administration of vitamin K analog or fresh-frozen plasma.

*Hematology*—Morbid obesity is a known risk factor for perioperative thromboembolic events, including both DVT and sudden death from acute pulmonary embolism.<sup>82</sup> Several thrombo-prophylaxis protocols exist or **5** are being developed,<sup>83</sup> but preoperative evaluation should confirm these plans. Guidelines from the American College of Chest Physicians recommend, in patients undergoing bariatric surgery, the combination of intermittent pneumatic compression devices with heparin (unfractionated or low molecular weight heparin), and warn that greater doses in obese patients may be needed than in nonobese ones.<sup>84</sup> Prolonged postoperative regimens (1 to 3 weeks) are being explored in bariatric patients.<sup>83</sup> Four important risk factors, namely venous stasis disease, BMI 60 or more, central obesity, and OHS and/or OSA, are significant in the development of postoperative DVT. If any of these factors are present, preoperative prophylactic placement of an inferior vena cava filter should be considered.<sup>82</sup> A combination of short duration of surgery, lower extremity pneumatic compression, and routine early ambulation may preclude mandatory heparin anticoagulation, except in patients with a history of previous DVT, a known hypercoagulable state, or a significant family history of DVT.<sup>85</sup>

## Intraoperative Considerations

### *Equipment and Monitoring*

Specially designed tables or two regularly sized operating room tables may be required for safe anesthesia and surgery in obese patients. Regular operating room tables have a maximum weight limit of approximately 200 kg, but operating room tables capable of holding up to 455 kg, with a greater width or side accessories to accommodate the extra girth, are available. Strapping obese patients to the operating room table in combination with a malleable beanbag helps keep them from falling off the operating room table.

Supine positioning causes ventilatory impairment and inferior vena cava and aortic compression in obese patients. FRC and oxygenation are decreased further with supine positioning (Fig. 45-1). Head-down positioning, often required during bariatric procedures, further worsens FRC and should be avoided if possible. Simply changing the obese patient from a sitting to supine

position can cause a significant increase in oxygen consumption and cardiac output. The head-up position provides the longest safe apnea period during induction of anesthesia.<sup>86</sup> The extra time gained may help preclude hypoxemia if tracheal intubation is delayed. Both intraoperative positive end-expiratory pressure (PEEP) and the head-up position significantly decrease the alveolar–arterial oxygen tension difference and increase total respiratory compliance to a similar degree, but the head-up position results in lower airway pressures. Both, however, decrease cardiac output significantly, which partially counteracts the beneficial effects on oxygenation. Prone positioning, rarely required in the obese patient, should be correctly performed with freedom of abdominal movement to prevent detrimental effects on lung compliance, ventilation, and arterial oxygenation. Lateral decubitus positioning allows for better diaphragmatic excursion and should be favored over prone positioning whenever the surgical procedure permits. Particular care should be paid to protecting pressure areas, because pressure sores, neural injuries, and rhabdomyolysis may occur. Brachial plexus and lower extremity nerve injuries are frequent. Carpal tunnel syndrome is the most common mononeuropathy after bariatric surgery.<sup>87</sup> Other reported neurologic complications include encephalopathy (Wernicke), optic neuropathy, and myelopathy associated with vitamin B<sub>12</sub> and copper deficiencies.<sup>88</sup>

Monitoring the surgical obese patient poses additional challenges. Careful selection of properly sized blood pressure cuff and its location are important. Blood pressure measurements can be falsely elevated if a cuff is too small. Cuffs with bladders that encircle a minimum of 75% of the upper arm circumference or, preferably, the entire arm, should be used. Forearm measurements with a standard cuff overestimate both systolic and diastolic blood pressures in obese patients.<sup>89</sup> Invasive arterial pressure monitoring may be indicated for the super morbidly obese patient, not only for those patients with cardiopulmonary disease but also for those patients in whom the noninvasive blood pressure cuff does not fit properly. Central venous catheterization, though not routinely needed, may be required for intravenous access in patients with inadequate peripheral access for perioperative fluid management.<sup>90</sup> Central venous catheters, pulmonary artery catheters, and/or transesophageal echocardiography can be used selectively in patients with significant cardiopulmonary disease or in patients undergoing extensive surgery.

### ***Airway Management***

Adequate preoxygenation is vital in obese patients because of rapid desaturation after loss of consciousness related to increased oxygen

consumption and decreased FRC. Although 100% oxygen increases the formation of atelectasis, it extends the nonhypoxic apnea period after induction of anesthesia. Recent recommendations encourage the addition of a head-up position during preoxygenation for prolonging the nonhypoxic apneic period in the obese patient.<sup>91-93</sup> The extra time gained may help preclude hypoxemia if tracheal intubation is delayed. The head-up position can be achieved with reverse Trendelenburg or semi-sitting positions<sup>86,94,95</sup> and may also help to prevent aspiration and facilitate visualization during laryngoscopy. Preoperative use of noninvasive positive pressure ventilation (NIPPV) or application of CPAP during induction will also delay peri-induction hypoxemia.<sup>96,97</sup> Passive apneic oxygenation adjuvant techniques have been proposed to delay apneic hypoxemia, via oxygen supplementation by nasal cannula or laryngeal mask airway (LMA).<sup>91</sup>

Obese patients are more likely than nonobese patients to present with difficult mask ventilation and tracheal intubation, especially if they have a short thick neck and OSA.<sup>73-75,98,99</sup> If a difficult intubation is anticipated, awake fiberoptic intubation using topical or regional anesthesia is a prudent approach to maintain spontaneous ventilation. During awake intubation, sedative-hypnotic medications should be minimized. Sedation with dexmedetomidine during awake intubation provides adequate anxiolysis and analgesia without respiratory depression.<sup>100</sup> Hypoxia and aspiration of gastric contents should be prevented at all costs during tracheal intubation. An experienced colleague who is present or immediately available during induction and airway management can be helpful with mask ventilation or attempts at intubation. A surgeon capable of accessing the airway surgically should be readily available. The “ramped” position elevating the obese patient’s upper body improves laryngoscopic view compared with the 8 standard “sniffing” position.<sup>101</sup> Towels or folded blankets under the shoulders and head can compensate for the exaggerated flexed position of posterior cervical fat (Fig. 45-5). The objective of this maneuver, known as “stacking,” is to position the patient so that the tip of the chin is at a higher level than the chest to facilitate laryngoscopy and tracheal intubation.

**Figure 45-5** Ramped position with “stacking” of towels and blankets.

Although direct laryngoscopy is used successfully in many obese patients with optimal positioning, the immediate availability of other intubating tools is highly recommended. These include videolaryngoscopes, intubating stylettes (e.g., Eschmann stylet, tube exchanger), LMAs, and fiberoptic bronchoscopes. Videolaryngoscopes have proven to be efficient tools for intubating obese patients, reducing the duration and number of intubation attempts, with a similar or better glottic view than standard direct laryngoscopy.<sup>99,102,103</sup> Multiple laryngoscopic attempts and repeated attempts at intubation are associated with increased airway and hemodynamic complications.<sup>104</sup> Closed malpractice claims data also support the recommendations to limit conventional tracheal intubation attempts to three before using other strategies.<sup>73</sup> LMAs can be useful for temporarily achieving airway patency in patients with difficult mask ventilation and tracheal intubation<sup>105</sup> or for placing a definitive endotracheal tube (intubating LMA).<sup>36,106</sup>

### **Induction and Maintenance**

Concerns of hypoxemia, gastric regurgitation, and aspiration during induction and tracheal intubation justify the common use of rapid sequence induction (RSI) strategies. Gastroesophageal reflux disease is relatively common in obese patients, and the incidence of regurgitation and severe pneumonitis in case of aspiration is increased in this population (as discussed earlier). Findings suggest that nonpremedicated nondiabetic fasting obese surgical patients with no significant gastroesophageal pathology are unlikely to have high volume, low pH gastric contents after routine preoperative fasting,<sup>50</sup> and that routine preoperative fasting guidelines (6 hours for solids, 2 hours for clear liquids) may be safe in obese patients.<sup>107</sup> In any case, the use of an RSI versus standard induction should be routinely and carefully evaluated in obese patients, and the final decision individualized based on the patient's risk of difficult mask ventilation, difficult tracheal intubation, hypoxemia, and gastric aspiration during induction.

No systematic comparison of anesthetic agents or techniques is available in obese patients. Larger doses of induction agents may be required because **9** blood volume, muscle mass, and cardiac output increase linearly with the degree of obesity. Any of the commonly available intravenous induction agents may be employed after taking into consideration problems peculiar to individual patients. An increased dose of succinylcholine is necessary because of an increase in pseudocholinesterase activity. Myalgia is not frequently seen following succinylcholine use in morbidly obese patients.<sup>108</sup> Succinylcholine is highly recommended for tracheal intubation especially in obese patients in which airway management is considered challenging or with high risk of peri-

induction hypoxemia or aspiration, due to its rapid onset and limited duration of action. Rocuronium can also be considered for tracheal intubation. However, its duration of action is more prolonged than succinylcholine.

Continuous infusion of a short-acting intravenous agent (e.g., propofol) or any of the inhalation agents—together or in combination—may be used to maintain anesthesia. Desflurane, sevoflurane, and isoflurane are minimally metabolized and therefore useful agents in the obese patient. Desflurane may provide adequate hemodynamic stability and slightly faster washout.<sup>109</sup> The use of nitrous oxide (N<sub>2</sub>O), despite its rapid elimination and analgesic properties, is limited by the high oxygen demand in this patient population. Short-acting opioid analgesics are preferred in obese patients to minimize postoperative respiratory depression. Remifentanyl and fentanyl, carefully titrated to clinical effect, are the most common choices.<sup>70</sup> Dexmedetomidine, an  $\alpha_2$ -agonist with sedative and analgesic properties, has no clinically significant adverse effects on respiration and is an attractive anesthetic adjunct in obese patients.<sup>110</sup> Furthermore, it reduces postoperative opioid analgesic requirements.<sup>110,111</sup>

Profound muscle relaxation is important during laparoscopic bariatric procedures both to facilitate ventilation and to maintain an adequate working space for visualization and safe manipulation of laparoscopic instruments. It also facilitates extraction of excised tissues. Collapse of the pneumoperitoneum and tightening of the patient's musculature around port sites are early indications of inadequate muscle relaxation.<sup>67</sup> Vecuronium, rocuronium, and cis-atracurium are useful nondepolarizing muscle blocking agents for maintenance of muscle relaxation. Pneumoperitoneum should not be increased above 15 mmHg since intra-abdominal pressures of 20 mmHg or greater can cause caval compression and decrease cardiac output.<sup>70</sup> Cephalad displacement of the diaphragm and carina from a pneumoperitoneum during laparoscopy can cause a firmly secured endotracheal tube to displace into a main stem bronchus.<sup>112</sup>

Anesthesia personnel may be asked to facilitate the proper placement of an intragastric balloon to help the surgeon size the gastric pouch, and also to facilitate performance of leak tests with saline or methylene blue through a nasogastric tube. Care should be taken to ensure a tight seal of the endotracheal tube cuff, otherwise aspiration of saline or methylene blue can occur. All endogastric tubes should be completely removed (not just merely pulled back into the esophagus) before gastric division to avoid unplanned stapling and transection of these devices.

## **Fluid Management**

Excess adipose tissue may mask peripheral perfusion, making fluid balance

difficult to assess. Blood loss is usually greater in the obese than in the nonobese patient for the same type of surgery, because technical difficulties accessing the surgical site necessitate larger incisions and more extensive dissection. Because intravenous fluid requirements are generally greater than predicted, fluid management is particularly challenging in the obese patient. Normovolemia should be the goal, to avoid increased hemodynamic instability, postoperative nausea and vomiting, and acute tubular necrosis (ATN) from hypovolemia. ATN occurs in approximately 2% of patients undergoing bariatric surgery. Associated risk factors include BMI greater than 50 kg/m<sup>2</sup>, prior history of renal disease, intraoperative hypotension, and prolonged surgical times.<sup>113</sup> Normovolemia also reduces the risk of hypervolemia resulting in decompensated congestive heart failure, peripheral tissue edema, and pulmonary complications. Rapid infusion of intravenous fluids should be avoided because pre-existing congestive cardiac failure is common in the obese patient. The use of IBW estimates and appropriate monitoring can help to avoid potential hyperhydration in morbidly obese patients.<sup>114</sup> Preliminary findings demonstrate that during laparoscopic bariatric surgery, urine output does not correlate with the rate of intraoperative fluid administration,<sup>115</sup> and the total volume of fluids infused does not seem to affect the incidence of postoperative rhabdomyolysis.<sup>116</sup>

### **Mechanical Ventilation**

Obesity makes titration of ventilatory settings challenging, since increasing weight does not imply a proportional growth of the lung. Obese patients are more likely to be exposed to higher tidal volumes because of miscalculation of PBW or IBW,<sup>117-119</sup> and also to higher airway pressures due to the decreased respiratory system compliance. Although similar ventilatory parameters in nonobese patients can be used, it may be challenging to maintain end-expiratory (plateau) pressures of no more than 30 cm H<sub>2</sub>O.<sup>6</sup> Greater inflation pressures may be tolerated in obese patients,<sup>120</sup> possibly because the extra adipose tissue partially attenuates lung overdistention.<sup>121</sup> In any case, 6 to 8 mL/kg PBW tidal volumes are often recommended for obese patients.<sup>92,122</sup> Larger tidal volumes offer no added advantages during ventilation of anesthetized morbidly obese patients.<sup>123</sup> Further increasing tidal volumes only increases the peak inspiratory airway pressure and plateau airway pressure without significantly improving arterial oxygen tension.<sup>124</sup> No specific ventilatory mode (volume vs. pressure control ventilation [PCV]) has been found significantly better for oxygenation and carbon dioxide clearance in obese patients, although pressure modes have in some studies correlated with increased oxygenation.<sup>91,125-127</sup>

PEEP is the only ventilatory parameter consistently shown to improve

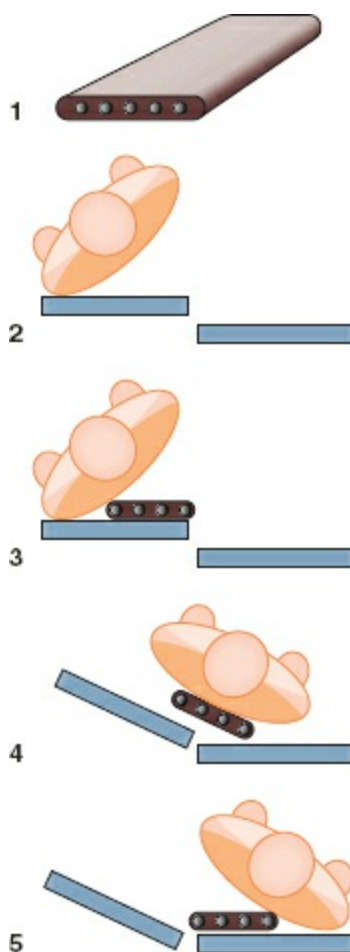

respiratory function in obese subjects, although the ideal PEEP value is still unknown.<sup>128–130</sup> Recruitment maneuvers in addition to the use of PEEP are the most effective ventilatory techniques to prevent postoperative atelectasis in obese patients and are increasingly recommended.<sup>122,127</sup> These techniques for alveolar recruitment are clearly beneficial in obese patients, compared to nonobese ones.<sup>91,131</sup> Different methods for performing recruitment maneuvers exist. A simple one proposed by Pelosi et al.<sup>123</sup> is a series of three short (6 seconds) inflations with PCV to administer a large tidal volume by reaching an inspiratory pressure of 40 to 55 cmH<sub>2</sub>O. Other recruitment techniques are summarized by Shah et al.<sup>91</sup> These higher-than-usual airway pressures may be needed to compensate for the decreased chest wall compliance, achieving an adequate transpulmonary pressure to avoid alveolar collapse. The combination of recruitment maneuvers and PEEP targets the opening and patency of small airway units, thereby improving ventilation–perfusion matching. This practice leads to less atelectasis and improved oxygenation,<sup>130,132</sup> shorter stay in the PACU, and decreased postoperative pulmonary complications<sup>132</sup> after laparoscopic bariatric surgery. Attention should be paid to avoid decreased venous return and cardiac output with PEEP or recruitment maneuvers, although they have been adequately tolerated in normovolemic morbidly obese patients.<sup>124</sup> Inspired oxygen fraction (FiO<sub>2</sub>) should be titrated to the minimum level that assures acceptable oxygenation levels, but avoids reabsorption atelectasis. Some experts recommend the FiO<sub>2</sub> to be kept lower than 0.8 in obese patients.<sup>123</sup>

## Emergence

**10** Prompt but safe extubation reduces the likelihood that the morbidly obese patient will become ventilator-dependent. This is especially important in patients with underlying cardiopulmonary disease. The patient should be extubated in the semirecumbent position and recovered in the sitting position, which has less adverse effect on respiration.<sup>123</sup> In some institutions, policies have been developed for the mandatory presence of two anesthesia providers at emergence and extubation of morbidly obese patients.<sup>133</sup> Supplemental oxygen should be administered after extubation. Some authors recommend an observation period of at least 5 minutes after extubation before transporting the patient away from the operating room.<sup>133</sup> The risk of hypoventilation in the immediate postoperative period, with the consequent hypercapnia with or without hypoxemia, is leading to the development of noninvasive monitoring techniques and the increasing use of CPAP.<sup>33</sup>

Lifting devices such as the HoverMatt (Patient Handling Technologies, Allentown, PA), the patient transfer device (PTD; Alimed, Dedham, MA), and gantry-style, mechanical sling lifting devices are useful for transporting

morbidly obese patients to and from the operating room table. The PTD can be combined with the Walter Henderson Maneuver (Fig. 45-6) to safely and gently transfer obese patients onto their postoperative beds.<sup>133</sup>

**Figure 45-6** Illustration of the Walter Henderson maneuver. **1.** Patient transfer device (PTD, i.e., roller); **2.** patient tilted to slip roller underneath; **3.** roller slipped under patient; **4.** table tilted to roll patient “downhill” onto bed; **5.** patient rolled onto bed. (Reprinted with permission from Ogunnaiké BO, Whitten CW. In response to Rosenblatt MA, Reich DL, Roth R, et al. [Letter]. *Anesth Analg.* 2004;98:1810.)

### **Monitored Anesthesia Care and Sedation**

Monitoring of the adequacy of ventilation and oxygenation is extremely important in obese patients. Obese patients present a higher risk of sedation-induced respiratory depression, so careful titration of benzodiazepines, opioids, and propofol is mandatory to avoid hypercapnia and/or hypoxemia. Hypoxemia may require unplanned tracheal intubation, so a thorough airway examination and preparation for unintended airway management is critical even in monitored anesthesia care (MAC) or sedation cases. The prevalence of closed malpractice claims related to adverse respiratory events during monitored anesthesia cases is increasing, compared to respiratory complications or airway management complications encountered during

general anesthesia.<sup>134</sup> In a closed claims analysis by Bhananker et al.,<sup>135</sup> obesity and suboptimal monitoring of pulse oximetry, end-tidal capnography, or both, were significant key factors in these adverse events during MAC.

## **Regional Anesthesia**

Neuraxial anesthetic techniques (spinal, epidural, combined spinal-epidural [CSE]) and peripheral nerve blocks are used alone or in combination with general anesthesia with increasing frequency as more obese patients are coming to the operating room. Several studies have demonstrated the efficacy of regional techniques in reducing opioid-related complications,<sup>136,137</sup> but there are other distinct advantages: (1) Minimal or reduced manipulation of the airway; (2) administration of fewer medications with cardiopulmonary depression; (3) reduced risk of postoperative nausea and vomiting; (4) better postoperative pain control; and (5) improved postoperative outcomes.<sup>138</sup> When epidural anesthesia is combined with general anesthesia, time to tracheal extubation may be reduced in patients receiving a combined technique compared to general anesthesia alone.<sup>139</sup> However, studies demonstrate that there is an increased risk of block failure in obese patients compared to those of normal weight.<sup>140</sup> Failure is often due to technical difficulties and limitations of regional anesthesia. In addition, these patients also experience an increased risk of complications.<sup>141</sup> With proper planning, these techniques may be used successfully and should be considered in the anesthetic plan for obese patients who are candidates for regional anesthesia. However, well-functioning intravenous access should be secured prior to block placement in case high spinal or local anesthetic systemic toxicity occurs following regional anesthesia.

## **Neuraxial Anesthesia**

*Physiologic changes associated with neuraxial anesthesia.* Neuraxial anesthesia can produce serious cardiopulmonary alterations in obese patients undergoing surgery. Because pulmonary mechanics, lung volumes, FRC, oxygenation, and ventilation are altered in these individuals, supine and Trendelenburg positioning during neuraxial anesthesia can lead to deterioration of lung volumes and further reductions in FRC. FRC may fall below closing capacity promoting small airway collapse, atelectasis, ventilation–perfusion mismatch, and hypoxia, especially during supine and Trendelenburg positioning (Fig. 45-1).<sup>142</sup> It is often helpful to measure the oxygen saturation in the sitting and supine positions to indicate the degree of pulmonary reserve prior to initiating neuraxial anesthesia. In addition to these pulmonary concerns, there are cardiovascular changes that warrant careful monitoring. The excess

weight of the abdominal wall can compress the vena cava, causing decreased cardiac preload, reflex tachycardia, and decreased cardiac output. In a large series of obese patients undergoing nonobstetric surgery who had received spinal anesthesia, more than one-third developed hypotension.<sup>143</sup> Three of the 1,000 patients in this series also experienced cardiac arrest. There are other reports of cardiac arrest after supine positioning in morbidly obese patients.<sup>144</sup> Changes to the supine position likely contributed to the circulatory changes resulting in these arrests.

Despite these important considerations, use of neuraxial techniques can offer important advantages when compared to general anesthesia alone. Parenteral opioid administration can be hazardous in these patients because of increased sensitivity to opioids, risk of hypoxemia, a high incidence of OSA, and increased incidence of adverse respiratory events following surgery. The American Society of Anesthesiologists has published guidelines for the care of patients with OSA and recommends that regional anesthetic techniques should be considered to reduce or eliminate the requirements for systemic opioids in patients with sleep apnea.<sup>33</sup>

*Positioning and placement.* Positioning is an important step in placement of a successful neuraxial anesthetic. Spinal or epidural placement in the sitting position will assist with identification of the midline. The patient's back should be parallel to the edge of the bed to prevent lateral needle deviation away from the midline. Lateral deviation of the midline will increase the depth to the epidural or spinal spaces and can result in block failure and an increased risk for intraoperative conversion to general anesthesia in less-than-ideal circumstances. Anatomic landmarks are often obscured in these patients. If spinal processes cannot be appreciated with deep palpation, a line can be drawn from the cervical vertebral spinal process to the uppermost portion of the gluteal cleft. This line approximates the midline of the patient over the vertebral column. Ultrasound imaging can also be helpful to identify spinal processes and has been shown to significantly reduce the number of needle passes and decrease the time for spinal block placement in morbidly obese patients undergoing orthopedic surgery.<sup>145</sup> Since the iliac crests may also be difficult to appreciate, the patient's skin folds can be used to aid in drawing a line perpendicular to the vertical line so that the intersection point can serve as a reasonable spinal or epidural needle insertion guide.

Neuraxial anesthetic placement can be particularly difficult, especially when bony landmarks are nonpalpable, there is limited back flexion,<sup>146</sup> and there are false losses of resistance due to fat deposition. It is often difficult to predict the depth to the epidural space, although it generally correlates with BMI.<sup>147</sup> A recent study suggests that prepuncture ultrasonography may be useful to facilitate epidural placement in obese parturients to predict the depth to the epidural space.<sup>148</sup> However, ultrasound has limitations in this

patient population because the image quality can be compromised due to fat overlying the epidural space and the distance to the epidural space may be inaccurate if the subcutaneous tissue is compressed. Future development of ultrasound technologies may incorporate the use of ultrasound-guided needle techniques to aid epidural placement in challenging patients.<sup>149</sup> In some cases, a long 25-gauge needle can be used for infiltration of local anesthetic, as well as to identify spinous processes. The patient is often helpful in determining whether needle placement is midline or lateral and directing the needle to the midline (e.g., Does it feel like I'm in the middle of your back?). A recent study demonstrated that obese women were less likely to identify the midline by pinprick compared to nonobese. However, both groups of women were correct 99% of the time in identifying whether a stimulus (fingertip or pinprick) was to the right or left of the midline.<sup>150</sup> In most cases, standard neuraxial needles (9 to 10 cm) are of sufficient length if placement is midline.<sup>151</sup> However, longer needles (16 cm) are sometimes needed in extremely obese parturients. These needles can cause serious injury so they should only be used after careful assessment of the midline when standard needles are inadequate.

*Spinal anesthesia.* Single injection spinal anesthesia is a popular neuraxial anesthetic technique but there are concerns about technical difficulties, exaggerated spread of local anesthetic, hypotension, and an inability to prolong the block, especially in the obese patient. Spinal anesthesia is reasonable if the airway examination is normal, there is no cardiopulmonary disease, and the surgery is expected to be less than 90 minutes. It is often easier to insert the spinal needle when a large gauge stiff epidural needle is used as a guide for the smaller flexible spinal needle.

Decreased cerebral spinal fluid (CSF) volumes have been confirmed in obese patients by magnetic resonance imaging<sup>152</sup> suggesting that the effective dose of spinal local anesthetic is reduced in obese patients compared to a nonobese patient. The decreased spinal fluid volume results from displacement of the CSF by soft tissue movement into the intervertebral foramen caused by an increase in abdominal pressure. This results in a direct positive correlation between the height of the block and the degree of obesity when patients receive the same volume and dose of spinal bupivacaine in the sitting position.<sup>153</sup> Others have demonstrated higher sensory levels of spinal anesthesia in obese patients<sup>154</sup> and the need for smaller volumes of bupivacaine in obese individuals to achieve similar sensory levels.<sup>155</sup> In addition to these factors, the large buttocks of obese patients may place the vertebral column in the Trendelenburg position, exaggerating the cephalad spread of spinal anesthesia. In order to avoid a high block when hyperbaric bupivacaine is used, a ramp can be placed under the patient's chest to elevate the cervical and thoracic spines to avoid the Trendelenburg position induced

by a large buttocks. Although there are other studies that report no clinical differences in the height of sensory block after hypobaric<sup>156</sup> and hyperbaric<sup>157</sup> spinal anesthesia in obese compared to nonobese parturients, spinal anesthesia should be performed with caution because of the consequences of extensive blockade, prolonged surgery, and the hazards of intraoperative induction of general anesthesia.

*Epidural anesthesia.* Epidural anesthesia offers several advantages over single-injection spinal anesthesia including titratable dosing of local anesthetics, ability to prolong the block, decreased risk of excessive motor block, more controllable hemodynamic changes, and utilization for postoperative analgesia. However, in laboring patients, a multicenter prospective observational study found that epidural anesthesia failed more often than spinal or CSE techniques.<sup>158</sup> Increased maternal BMI was significantly related to failure of neuraxial techniques. Hood and Dewan<sup>159</sup> also demonstrated an increased initial failure rate of epidural catheters in obese laboring patients—42% compared to 6% in the nonobese control group. In addition, Hodgkinson and Hussain<sup>160</sup> demonstrated that the height of an epidural block for a given volume of local anesthetic is proportional to BMI and maternal weight but not height. Incremental dosing of epidural-administered local anesthetics will reduce the risk of hypotension and high block.

Catheter dislodgment is another potential problem in obese patients. Because the ligamentum flavum has a mild grip on the epidural catheter, body repositioning allows the epidural catheter to be pulled into or out of the subcutaneous fat. Therefore, before securing the epidural catheter, a patient should move from an upright sitting position to a lateral position. Hamilton et al.<sup>161</sup> evaluated changes in epidural catheter distance to skin with patient position modifications (sitting flexed to upright, upright to lateral, flexed to lateral). These changes were significantly increased with BMI, and averaged a maximum of 0.67 cm to 1.04 cm in parturients with BMIs lower than 25 and greater than 30, respectively. A more than 4 cm change was observed in one obese patient.<sup>161</sup> After repositioning, the catheter is subsequently taped in place without adjusting the catheter. This maneuver is helpful in reducing the incidence of catheter dislodgement and block failure.

In cases of inadvertent dural puncture, catheters may be threaded into the subarachnoid space for continuous spinal analgesia. Continuous spinal anesthesia offers the benefits of a single-injection spinal (i.e., reliability, density); however, converting to spinal anesthesia does not appear to affect the rate of postdural puncture headache or epidural blood patch.<sup>162</sup> Each case must be handled individually and if a continuous spinal catheter is placed, care must be used to avoid accidental administration of an epidural dose of local anesthetic through the spinal catheter that will increase risk of a high

spinal, respiratory compromise, and loss of the airway patency. Higher levels of spinal anesthesia may result from reduced CSF volume<sup>152</sup> and large buttocks may increase cephalad spread. These catheters should be carefully marked so that they are not mistaken for an epidural catheter.

*Combined spinal-epidural (CSE).* CSE anesthesia is an alternative to conventional spinal or epidural anesthesia; however, there is concern that the technique is more complicated than either spinal or epidural alone, and the epidural catheter is “unproven” during the duration of spinal analgesia. Although CSE catheters fail at similar rates compared with conventional epidural catheters,<sup>163</sup> delayed recognition of a nonfunctional epidural catheter is a disadvantage of this technique, and is particularly problematic for prolonged surgical cases. This can increase the risk of intraoperative conversion to general anesthesia. However, even if the patient does not receive a “spinal dose” during CSE placement, the return of CSF in the spinal needle is confirmation of midline needle placement. This increases the likelihood of bilateral block, and improves sacral spread and onset of analgesia in laboring parturients.<sup>164</sup>

## **Peripheral Nerve Block**

The use of peripheral nerve blocks with and without general anesthesia is increasingly common for surgical procedures. In obese patients, these blocks can be technically challenging and have an increased failure rate compared to techniques performed in patients of normal weight.<sup>141,165</sup> Although experience of the anesthesiologist with these blocks may influence their success, a large prospective study evaluating peripheral nerve blocks determined that the risk of block failure increased proportionately with BMI.<sup>165</sup> Continuous supraclavicular, paravertebral, superficial cervical plexus, and epidural blocks had the highest failure rates. Supplemental general anesthesia was also needed to supplement these blocks more often in obese patients. Another study compared success rates of supraclavicular blocks in obese and nonobese patients, and reported a lower success rate in obese patients.<sup>166</sup> However, the rate of successful blocks in the obese patients remained high (94.3%). Case reports have also described the use of oblique subcostal transversus abdominis plane (TAP) catheters as an alternative to epidural analgesia after upper abdominal surgery.<sup>167,168</sup>

Dosing of local anesthetics during regional anesthesia can be challenging in the obese. For instance, if a patient receives too large of a dose, hypotension, systemic toxicity, or respiratory compromise related to diaphragmatic hemiparesis may occur. If the dose is too small, there is a risk of block failure. Although absorption of local anesthetics is dependent on the site of injection (i.e., greatest with intercostal blocks, followed by epidural

and spinal blocks), calculation of the maximum safe local anesthetic dose is important because this dose is often based on patient weight. However, basing the dose on the actual weight in this patient population will increase the risk for systemic toxicity. Therefore, local anesthetic dosing should be based on IBW rather than actual weight.

Although there are advantages of peripheral nerve blocks in these patients, placement is often difficult due to difficult positioning, obscure anatomic landmarks, and inadequate needle length. Since increased BMI is associated with increased number of attempts and risk of block failure,<sup>141</sup> the use of ultrasound in these patients may be a helpful tool to increase both block success<sup>169,170</sup> and safety. Unlike nerve stimulator or paresthesia techniques, ultrasound has the advantage of real-time identification of landmarks below the skin surface. Although real-time ultrasound has been shown to increase success rates,<sup>169–171</sup> decrease procedure time,<sup>172</sup> and decrease the minimum effective dose of local anesthetic solutions<sup>173</sup> in patients receiving peripheral nerve blocks who are of normal weight, reports of use of this technique in the obese are more limited. Because of greater soft tissue mass in the obese, the ultrasound must penetrate greater depths to visualize target structures.<sup>174</sup> Although low-frequency transducers increase depth of penetration, higher frequency transducers produce the best images.<sup>174</sup> Consequently, ultrasound images in the obese may be compromised, both due to an increased number of reflective surfaces as well as greater depth to the structures. Reports confirm increased success rates in the obese undergoing peripheral nerve blocks with ultrasound.<sup>169,170</sup> However, successful use of ultrasound for peripheral nerve blocks in patients of all sizes requires training and experience. The American Society of Regional Anesthesia and Pain Medicine and the European Society of Regional Anesthesia have recommended education and training guidelines for ultrasound-guided regional anesthesia.<sup>175</sup>

## Postoperative Considerations

### *Ventilatory Evaluation and Management*

There is an increased incidence of atelectasis in morbidly obese patients after general anesthesia, which persists into the postoperative period. Consequently, initiation of CPAP or bilevel positive airway pressure (BiPAP) has been advocated. Despite a theoretical risk, the use of NIPPV does not seem to increase the incidence of major anastomotic leakage after gastric bypass surgery. Postoperative CPAP may improve oxygenation, but does not facilitate CO<sub>2</sub> elimination.<sup>176</sup> Adequate analgesia, use of a properly fitted elastic binder for abdominal support, early ambulation, deep breathing

exercises, and incentive spirometry are all useful adjuncts to avoid postoperative hypoventilation and atelectasis. Pulse oximetry and arterial blood gases should be monitored when they are indicated.

## *Postoperative Analgesia*

Pain management is an important part of the postoperative care plan of obese patients. The goal of pain management in these individuals is not only to provide adequate analgesia but also to facilitate early mobilization and adequate respiratory function. Mobilization in these individuals is often difficult, yet critically important in the prevention of complications. Pressure ulcerations, pulmonary emboli, deep venous thrombosis, and pneumonia are some of the common complications that can be prevented by early mobilization. Plans for pain management should include: (1) Multimodal analgesics; (2) regional anesthesia/analgesia techniques; (3) early mobilization; (4) supplemental oxygen; and (5) elevation of the head of the bed. Besides delivery of a safe analgesic technique, adequate postoperative monitoring is required to ensure safety.

Obese patients with OSA have an increased likelihood of postoperative pulmonary complications.<sup>30</sup> Opioids increase the risk of central apnea in all patients, but those with OSA are at particular risk for opioid-induced apnea.<sup>33</sup> Because of the risk of hypoventilation and hypoxemia in obese patients with and without OSA, postoperative pain management should include opioid-sparing multimodal analgesic techniques, including regional anesthesia. These techniques are known to reduce the risk of opioid-related complications.<sup>136,137</sup> In patients with regional anesthesia contraindications, the use of **11** multimodal analgesics (e.g., local anesthetics, NSAIDs) will reduce opioid consumption and the risk of respiratory depression. The American Society of Anesthesiologists practice guidelines encourage the use of regional analgesic techniques instead of systemic opioids in the postoperative pain management of patients with OSA, and are summarized in [Table 45-4](#).

## *Monitoring*

Obese patients who have received either neuraxial or parenteral opioids require careful postoperative monitoring for respiratory depression. However, routine admission to intensive care or high acuity care units is unnecessary since admission to these units has not been shown to reduce the risk of **12** pulmonary complications or change perioperative outcome.<sup>177</sup> Patients with a history of OSA and being treated with CPAP should be encouraged to bring their own equipment to the hospital to reduce the risk of respiratory depression.<sup>178</sup> All patients receiving neuraxial opioids should be monitored for

adequacy of ventilation (respiratory rate, depth of respiration), oxygenation (pulse oximetry when appropriate), and level of consciousness.<sup>178</sup>

## Ambulatory Anesthesia

Identifying obese patients who are suitable candidates for ambulatory surgery depends upon early identification of patient comorbidities, invasiveness of the procedure, anesthetic technique, postoperative pain management, and skills of both the surgeon and anesthesiologist.<sup>179</sup> Although a number of studies have identified obesity as a risk factor for perioperative complications, a recent systematic review determined that BMI alone does not increase the risk for perioperative complications or unexpected admission after ambulatory surgery.<sup>180</sup> However, the authors caution that most super-obese patients (i.e., BMI  $\geq 50$  kg/m<sup>2</sup>) are not candidates for ambulatory surgery.

### **Table 45-4** Summary of Practice Guidelines for the Perioperative Management of Patients with Obstructive Sleep Apnea (OSA): A Report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea

Regional anesthetic techniques should be considered to reduce or eliminate the requirements for systemic opioids in patients with OSA. If neuraxial anesthesia is planned, the benefits and risks of using an opioid or opioid-local anesthetic mixture as compared to local anesthetic alone must be considered.

If patient-controlled systemic opioids are used, continuous background infusions should be avoided or used with extreme caution. Nonsteroidal anti-inflammatory agents and other modalities should be considered to reduce opioid requirements.

Supplemental oxygen should be administered continuously to all patients who are at increased perioperative risk from OSA until they are able to maintain their baseline oxygen saturation while breathing room air.

Hospitalized patients at increased risk of respiratory compromise from OSA should be monitored with continuous pulse oximetry after discharge from the recovery room.

Because many morbidly obese patients are diagnosed with sleep-disordered breathing, these patients may be considered for ambulatory procedures if their comorbid conditions are optimized and postoperative pain control is easily achieved with nonopioid techniques. The morbidly obese and those with OSA present unique and increasingly frequent challenges to ambulatory practices. Estimates suggest that 60% to 90% of all OSA patients have a BMI greater than or equal to 30 kg/m<sup>2</sup>.<sup>181</sup> However, many patients with OSA do not carry the formal diagnosis, yet are more likely to experience major anesthetic problems throughout the perioperative period. A recent prospective cohort study of ambulatory surgical patients with propensity for OSA revealed an increase in number of laryngoscopy attempts, difficult laryngoscopic grade view, and the use of fiberoptic intubation.<sup>182</sup> These patients may also have respiratory insufficiency soon after extubation, as well as increased risks for emergent re-intubation, respiratory failure, mechanical ventilation, aspiration pneumonia, atrial fibrillation, and acute respiratory

distress syndrome (ARDS).<sup>35,183,184</sup> These patients are also more likely to suffer from respiratory arrest with preoperative sedation or postoperative analgesia, because they are particularly sensitive to the respiratory depressant effects of even small dosages of sedatives or analgesics. Recent data suggest that patients who have a pre- or postoperative diagnosis of OSA are twice as likely to have respiratory complications compared to controls.<sup>185</sup> However, patients with a preoperative diagnosis of OSA who utilized CPAP were less likely to experience cardiovascular complications compared with patients who are diagnosed postoperatively.

Some recommend close postoperative monitoring of oxygen saturation in ambulatory OSA patients in an intensive care unit setting prior to discharge.<sup>186</sup> Use of local or regional anesthesia with minimal sedation and availability of a 23-hour observation PACU can facilitate such cases in the ambulatory setting. The possibility of invasive monitoring, prolonged tracheal intubation, and postoperative mechanical ventilation should also be discussed with obese patients. Although well-designed prospective trials are needed to assess the suitability of OSA patients for ambulatory surgery, patients receiving CPAP preoperatively should be advised to bring the CPAP device with them to the hospital and to use it for several days postoperatively.<sup>187</sup>

Recently, the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) database identified risk factors for morbidity and mortality with 72 hours after ambulatory surgery.<sup>188</sup> Although the incidence of morbidity and mortality was only 0.1% in nearly 250,000 cases, independent risk factors for perioperative morbidity included: high BMI, chronic obstructive pulmonary disease, hypertension, history of transient ischemic attack or stroke, previous cardiac surgery, and longer surgical times. In the cohort, unplanned postoperative intubation, pneumonia, and wound disruption were the most commonly identified comorbidities. Others have determined that increased BMI, ASA 3 or more, age above 80 years, and length of surgery above 1 hour all increased the risk for unplanned hospital admission. Because increased BMI is a contributor for increased perioperative risk, exclusion criteria should be developed for patients undergoing ambulatory surgery.

## **Critical Care and Resuscitation**

Caring for critically ill obese patients outside of the operating room poses the same challenges as during surgery, in terms of equipment, monitoring, and multiple comorbidities.<sup>120</sup> In addition, nutritional status of the critically ill obese patient is often paradoxical and difficult to address. Hyperglycemia from pre-existing or stress-induced diabetes is common and should be corrected because hyperglycemia is associated with a higher mortality rate.

Obese patients are more likely to become ventilator-dependent than nonobese patients. The risks of obesity and commonly associated comorbidities (e.g., diabetes)<sup>189</sup> for the development acute lung injury (ALI) and/or ARDS is still unclear. Although BMI has been associated with an increased risk of developing ALI/ARDS,<sup>119,190</sup> its effect on clinical outcomes is still being explored.<sup>119,191,192</sup>

The possible need for cardiopulmonary resuscitation should be entertained when caring for the morbidly obese critically ill patient, including both equipment and technical concerns. Chest compressions may not be effective and mechanical compression devices may be required. The maximum 400 J of energy on regular defibrillators is usually sufficient for morbidly obese patients because their chest wall is usually not much thicker, but the higher transthoracic impedance from the fat may require a greater number of attempts. Airway management by conventional means may be very difficult. Tracheostomy, percutaneous cricothyrotomy, transtracheal jet ventilation, and retrograde wire intubation are time-consuming and technically difficult procedures in such emergency situations and should be reserved as final options and be performed by experienced practitioners.<sup>193</sup> Direct visualization of anatomic hallmarks during emergent cricothyroidotomy can also be extremely challenging in the obese patient. A novel technique has recently been proposed, in which palpation of the cricothyroid membrane can facilitate placement of an Eschmann stylette preloaded with a tracheal tube and inserted using a Seldinger-like technique.<sup>194</sup>

## Morbidity and Mortality

Postoperative morbidity is increased in obese patients, but increased mortality is controversial.<sup>192,195,196</sup> The most common postoperative complications are respiratory (atelectasis, pneumonia), vascular (thrombophlebitis, DVT), and wound complications (infection, dehiscence). In addition, rhabdomyolysis is more common in morbidly obese patients undergoing laparoscopic procedures when compared with open procedures, especially with prolonged procedures. The incidence of perioperative adverse events is strongly associated with pre-existing disease more so than BMI alone.<sup>197</sup> For example, a patient with previously diagnosed metabolic syndrome has significantly greater risk of perioperative morbidity and mortality than an obese patient with no metabolic syndrome features.<sup>198,199</sup> Obese patients present a higher risk of perioperative pulmonary complications, especially if preoperative respiratory conditions (e.g., OSA) are present.<sup>30,70</sup> Obesity increases the risk of surgical site infections.<sup>200,201</sup> Some known contributing factors are hyperglycemia or diabetes,<sup>201</sup> longer duration of surgical procedures,<sup>201</sup> hypoperfusion or low tissue oxygen

tension,<sup>202,203</sup> and low tissue antibiotic concentration. Morbid obesity significantly increases the risk of postoperative thromboembolic events.<sup>82</sup> Sequential compression devices (SCDs), routine early ambulation, and careful perioperative anticoagulation decrease the risk of thromboembolism.<sup>85</sup> Because of the higher risk of postoperative complications than in nonobese patients, outpatient surgery in this population should be individualized,<sup>70,204</sup> although it is becoming more accepted and safe in selected patients and procedures.<sup>70,205</sup>

## KEY POINTS

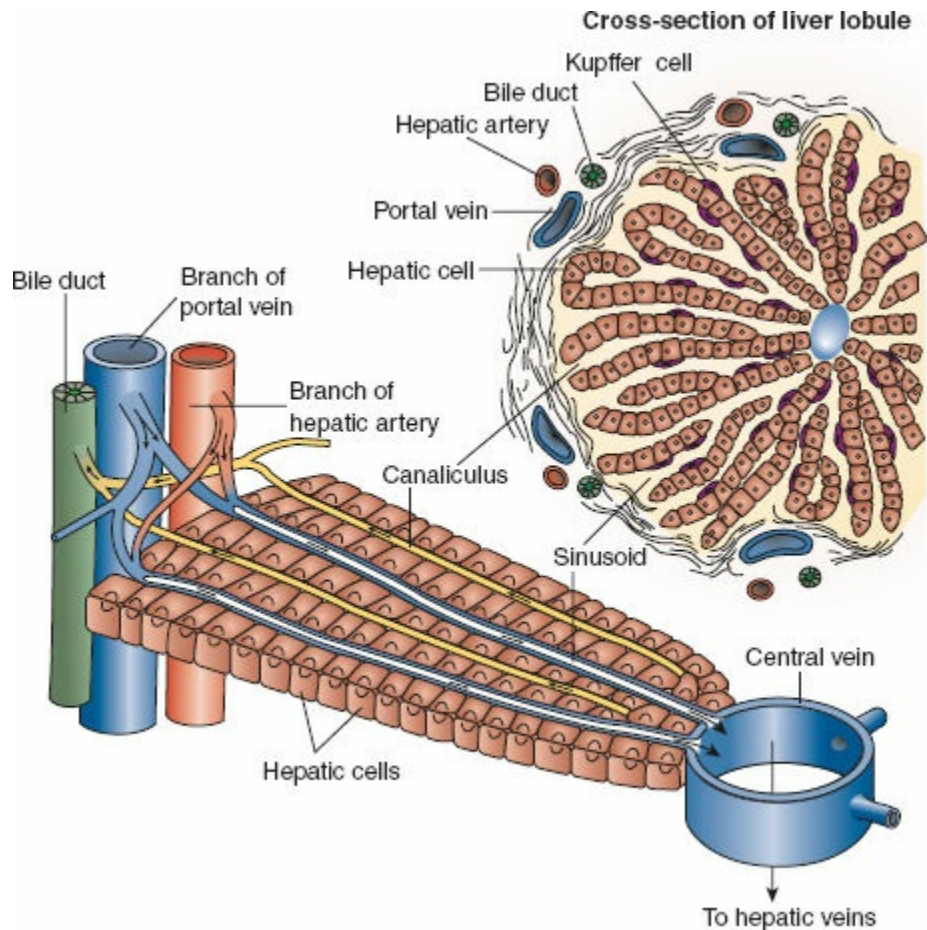

- 1 The liver is the largest internal organ, accounting for 2% of the total body mass of adults. It receives 25% of the cardiac output via a dual afferent blood supply. The portal vein supplies 75% of the hepatic blood flow, whereas the hepatic artery supplies the remainder. Because of the higher oxygen content in the hepatic artery, each vessel provides roughly 50% of the hepatic oxygen supply.
- 2 The liver plays a pre-eminent role in the intermediary metabolism of nutrients (glucose, nitrogen, and lipids) and the detoxification of chemicals, including lipophilic medications. Liver dysfunction affects the metabolism of nutrients and xenobiotics, and negatively impacts nearly every other organ system.
- 3 Portal hypertension, the end result of hepatic injury and fibrotic changes, results in portosystemic shunts that bypass the liver's metabolic and detoxification capabilities. When nitrogenous waste and other substances normally cleared by the liver enter the central circulation, hepatic encephalopathy ensues.
- 4 Additional complications of portal hypertension include variceal hemorrhage, ascites, and hepatorenal syndrome. Cardiac sequelae include hyperdynamic circulation due to decreased systemic vascular resistance, which results in an increase in cardiac output.
- 5 Perioperative complications encountered by cirrhotic patients include liver failure, postoperative bleeding, infection, and renal failure. Patients with a model for end-stage liver disease (MELD) score of less than 11 have a low postoperative mortality and represent an acceptable surgical risk. End-stage liver disease patients with a risk of postoperative liver failure should have elective abdominal surgery at institutions with a liver transplant program. In patients with a MELD score of 20 or higher, the high mortality risk contraindicates elective procedures until after liver transplantation.
- 6 Medical management undertaken to optimize cirrhotic patients undergoing surgery should be directed toward treating active infection, minimizing vasoactive infusions, optimizing central blood volume and renal status, minimizing ascites, and improving encephalopathy and coagulopathy.
- 7 The perioperative risk of patients with end-stage liver disease depends

more on the operative site and the degree of liver impairment than the anesthetic technique.

## Hepatic Function in Health

The liver is the largest internal organ and is the body's metabolic headquarters. It weighs 1.5 kg or about 2% of the total body weight in an adult. The functional unit of the liver is the lobule, a structure roughly  $1 \times 2$  mm that consists of plates of hepatocytes located in a radial distribution about a central vein. The afferent blood supply from the portal vein and hepatic arteriole enters at the periphery of the lobule. Bile, formed in the hepatocytes, flows into canaliculi located between the plates of hepatocytes and drains into bile ducts located at the periphery of the lobule next to portal venules and hepatic arterioles. The large pores in the endothelium lining, the sinusoids, allow plasma and its proteins to move readily into the tissue spaces surrounding hepatocytes, an area known as the spaces of Disse. This fluid drains into the lymphatic system. The liver generates about half of the body's lymph (Fig. 46-1).

The liver receives approximately 25% of the cardiac output via a dual **1** supply. The portal venules conduct blood from the portal vein, which drains the gastrointestinal tract. The portal vein supplies 75% of the liver inflow, or about 1 L/min. The hepatic arterioles supply the remaining 25% of the hepatic blood flow. Due to the higher oxygen content of arterial blood, each vessel contributes about 50% of the hepatic oxygen supply.

**Figure 46-1** A magnified cross-section of a liver lobule (**right**) with its component cells and structures is juxtaposed to a 90-degree rotated view of a portion of this cross-section (**left**) showing the mixing of hepatic portal and arterial blood in the hepatic sinusoids. The sinusoids empty into the central vein, which sends blood to the hepatic vein and from there into the vena cava. (Adapted with permission from Porth CM. Disorders of hepatobiliary and exocrine pancreas function. *Essentials of Pathophysiology: Concepts of Altered Physical States*. 4th ed. Philadelphia, PA: Wolters Kluwer; 2015:726.)

The liver's high blood flow is due to low vascular resistance in the portal vein. The average portal vein pressure is 8 to 10 mmHg, which exceeds hepatic venous pressure by 4 to 5 mmHg. However, when injured hepatocytes are replaced by fibrous tissue, blood flow is impeded and portal hypertension ensues. A hepatic venous pressure gradient (HVPG) greater than 5 mmHg is abnormal and defines portal hypertension.<sup>1</sup> Sympathetic innervation from T3 to T11 controls resistance in the hepatic venules. Changes in compliance in the hepatic venous system contribute to the regulation of cardiac output and blood volume. In the presence of reduced portal venous flow, the hepatic artery can increase flow by as much as 100% to maintain hepatic oxygen delivery. The reciprocal relationship between flow in the two afferent vessels is termed the "hepatic arterial buffer response."<sup>2</sup>

The microcirculation of the liver lobule is divided into three zones that receive varying oxygen content.<sup>3</sup> Zone 1 receives oxygen-rich blood from the

adjacent portal vein and hepatic artery. As blood moves through the sinusoid it passes from the intermediate zone 2 into zone 3, which surrounds the central vein. Blood entering zone 3 is oxygen poor. Pericentral hepatocytes have a greater quantity of cytochrome P450 enzymes and are the site of anaerobic metabolism. Hypoxia and reactive metabolic intermediates from biotransformation affect zone 3 more prominently than other zones.

Due to its ability to distend, the liver is capable of storing up to 1 L of blood. The liver serves as a reservoir capable of accepting blood, or releasing blood at times of low blood volume. The liver also stores vitamins, particularly vitamins B<sub>12</sub> (1-year supply), D (3-month supply), and A (10-month supply). Excess body iron is transported via apoferritin to the liver for storage as ferritin, which is released when circulating iron levels are low. Thus, the liver apoferritin system serves as a blood iron buffer.

Reticuloendothelial cells called Kupffer cells line the venous sinusoids. These macrophages phagocytize bacteria that enter the sinusoids from the intestines. Less than 1% of bacteria that enter the liver pass through the systemic circulation.

The liver is involved in energy production and storage of nutrients absorbed from the intestines. The liver aids in blood glucose regulation through its glucose buffer function. This is accomplished by storing glucose as glycogen, converting other carbohydrates (principally fructose and galactose) to glucose, and synthesizing glucose from amino acids and triglyceride (gluconeogenesis).<sup>4</sup> In patients with altered liver function, blood glucose concentration can rise several fold higher than the postprandial levels found in patients with normal hepatic function.

The liver synthesizes fat, cholesterol, phospholipids, and lipoproteins. It also efficiently metabolizes fat, converting fatty acids to acetyl coenzyme A (CoA), an excellent source of energy, which can be diverted to the citric acid cycle to liberate energy for the liver. The liver generates more acetyl-CoA than it consumes. The excess is packaged as acetoacetic acid for use elsewhere in the body. The majority of cholesterol synthesized in the liver is converted to bile salts and secreted in the bile. The remainder is distributed to the rest of the body where it is used to form cellular membranes and other vital structures. Fat synthesis from protein and carbohydrates occurs almost exclusively in the liver, and the liver is responsible for most fat metabolism.

The liver also plays a key role in protein metabolism. The liver synthesizes all of the plasma proteins with the exception of  $\gamma$ -globulins, which are formed in plasma cells. The liver is capable of forming 15 to 50 g of protein per day, an amount sufficient to replace the body's entire supply of protein in several weeks. Albumin is the major protein synthesized by the liver and is the primary determinant of plasma oncotic pressure. The liver also synthesizes the nonessential amino acids from keto acids, which are also synthesized in

the liver.

The liver is capable of deamination of amino acids, which is required for energy production or the conversion of amino acids to carbohydrates or fats. Deamination produces ammonia, which is toxic. Intestinal bacteria are an additional source of ammonia. The liver removes ammonia through the formation of urea.

All of the blood clotting factors, with the exception of factors III (tissue thromboplastin), IV (calcium), and VIII (von Willebrand factor), are synthesized in the liver. Vitamin K is required for the synthesis of prothrombin (factor II) and factors VII, IX, and X.

Hepatocytes produce roughly 500 mL of bile daily. Between meals, the high pressure in the sphincter of Oddi diverts bile to the gallbladder for storage. The gallbladder holds 35 to 50 mL of bile in concentrated form. The presence of fat in the duodenum causes release of the hormone cholecystokinin from duodenal mucosa, which reaches the gallbladder via circulation and stimulates gallbladder contraction. Bile contains bile salts, bilirubin, and cholesterol. Bile salts act as a detergent, solubilizing fat into micelles, which are absorbed. Bile salts return to the liver via the portal vein, completing the enterohepatic circulation. Bile salts are needed for fat absorption, and cholestasis can result in steatorrhea and vitamin K deficiency.

The liver has the unique ability to restore itself after injury or partial hepatectomy. As much as two-thirds of the liver can be removed with regeneration of the remaining liver in a matter of weeks.<sup>5</sup> Hepatocyte growth factor, produced by mesenchymal cells in the liver, and other growth factors, such as epidermal growth factor (EGF), cytokines, tumor necrosis factor (TNF), and interleukin-6, are involved in stimulating regeneration. Growth factor- $\beta$ , a known inhibitor of hepatocyte proliferation, is involved in halting the regenerative process, which appears to be related to the ratio of liver-to-body weight.<sup>5,6</sup> Inflammation, such as with a viral infection of the liver, impairs regeneration.

## Assessment of Hepatic Function

A number of laboratory tests are available to assess the liver. Collectively termed *liver function tests* (LFTs), many, including aspartate aminotransferase (AST) and alanine aminotransferase (ALT), do not assess function but rather cellular injury. Increased serum levels of these enzymes, AST (formerly serum glutamic oxaloacetic transaminase; SGOT) and ALT (formerly serum glutamic pyruvic transaminase; SGPT), occur in many types of hepatic disease. Because AST is also found in nonhepatic tissues (including the heart, skeletal muscle, kidney, and brain), elevations are not specific for hepatic disease. ALT is primarily localized to the liver.

Fatty liver and chronic infections are associated with mild (several fold) elevations of AST and ALT. Acute hepatitis produces larger increases, but the highest concentrations, which can exceed 50 times normal, are seen with acute hepatic necrosis. Absolute levels of these enzymes are not always helpful, as declining values may indicate recovery or conversely a lack of surviving hepatocytes. The AST/ALT ratio may be helpful in differentiating alcoholic liver disease, in which the ratio is typically greater than 2, from viral hepatitis, which is associated with a ratio lower than 1.

Indices of bile flow obstruction include serum levels of alkaline phosphatase (AP), 5'-nucleotidase (5'-NT),  $\gamma$ -glutamyl transferase (GGT), and bilirubin. AP isoenzymes are found in multiple organs including the liver, bone, kidney, intestines, placenta, and leukocytes. Normally, most circulating AP originates from liver and bone. Hepatic AP is concentrated in the microvilli of bile canaliculi and the sinusoidal surface of hepatocytes. Elevations of serum AP disproportionate to changes in AST and ALT occur with obstructions to bile flow. However, AP elevations may originate from other tissues, including the placenta during pregnancy. Although 5'-NT is also found in many tissues, elevations are highly specific for hepatobiliary obstruction. Elevations of 5'-NT may reflect the detergent action of bile salts on plasma membranes, a requirement for its release. Because 5'-NT is specific for liver diseases, it is useful to determine whether elevated AP is of hepatic origin. Serum GGT is the most sensitive laboratory indicator of biliary tract disease but it is less specific than 5'-NT and has largely been replaced by 5'-NT.

Bilirubin originates primarily from the breakdown of hemoglobin released from senescent red blood cells. Serum bilirubin levels are determined by the van den Bergh reaction, which separates bilirubin into two fractions: A lipid-soluble, indirect-reacting form (unconjugated bilirubin) and a water-soluble, direct-reacting form (conjugated bilirubin). Elevated levels of unconjugated bilirubin indicate an excess production of bilirubin (hemolysis) or a decrease in the uptake and conjugation of bilirubin by hepatocytes. Conjugated bilirubin is elevated by impaired intrahepatic excretion or extrahepatic obstruction. Even with complete biliary tract obstruction, the bilirubin rarely exceeds 35 mg/dL because of renal excretion of conjugated bilirubin.

Tests of hepatic synthetic function focus on the measurement of serum albumin and coagulation testing. Although the liver is the primary site of albumin synthesis, excessive protein losses (enteropathy, burns, nephrotic syndrome) can also result in low albumin levels. Because of its 3-week half-life, serum albumin is not a reliable indicator of acute liver disease. In contrast, the prothrombin time (PT) and international normalized ratio (INR) are sensitive indicators of hepatic disease because of the short half-life of factor VII. The PT depends upon sufficient intake of vitamin K, which in turn

depends upon adequate biliary secretion of bile salts. In patients with biliary obstruction, the PT can be prolonged despite preserved hepatic function. Other conditions that can affect the PT in the absence of liver disease include congenital coagulation factor deficiencies, consumptive coagulopathies such as disseminated intravascular coagulation (DIC), and warfarin therapy.

A number of other tests exist to assess hepatic function, though their use in the United States is limited primarily to research applications. Indocyanine green (ICG) elimination estimates hepatic blood flow and hepatocellular function due to the high extraction ratio of ICG (>70%). The MEGX test measures the conversion of lidocaine to monoethylglycinexylidide (MEGX) via hepatic demethylation. Other metabolic tests include antipyrine clearance, aminopyrine breath test, caffeine breath test, galactose elimination capacity, and urea synthesis.

Ancillary tests to confirm specific diagnoses include serologic tests for the various hepatitis viruses, autoantibodies (for the diagnosis of primary biliary cirrhosis [PBC]), ceruloplasmin (Wilson disease), ferritin (hemochromatosis),  $\alpha_1$ -antitrypsin ( $\alpha_1$ -antitrypsin deficiency), and  $\alpha$ -fetoprotein (hepatocellular carcinoma [HCC]). Serum ammonia is useful for following patients with hepatic encephalopathy (HE).

## Hepatobiliary Imaging

Selection of the appropriate imaging technique depends on the differential diagnosis and whether a concurrent therapeutic intervention is planned. Plain radiography has a limited role in the evaluation of liver disease. Abdominal x-rays can be useful to detect calcified or gas-containing lesions. Examples include calcified gallstones, chronic calcific pancreatitis, gas-containing liver abscesses, portal venous gas, and emphysematous cholecystitis.

Ultrasonography is the primary screening test for hepatic parenchymal disease and extrahepatic biliary disease. It is the method of choice for detecting gallstones, the presence of ascites, and portal or hepatic vein thrombosis. Its major limitations are its dependence on the operator's skill and its inability to penetrate bone or air, including bowel gas.

Radioisotope scanning has largely been replaced by computed tomography (CT) scanning. However, it is still in use in patients with suspected acute cholecystitis. Radioisotopes visualized in the gallbladder rule out obstruction of the cystic duct, whereas visualization of the biliary tree and common bile duct without the gallbladder indicates cystic duct obstruction and the presence of cholecystitis.

CT scanning supplements ultrasonography, providing information on the liver texture, gallbladder disease, bile duct dilatation, and mass lesions of the liver and pancreas. CT provides more resolution than ultrasonography and is

less operator-dependent. Lesions can be biopsied under CT guidance. The disadvantages of CT include radiation exposure and cost.

Magnetic resonance imaging (MRI) is increasingly used for the evaluation of hepatobiliary disease. MRI is superior to CT for the assessment of malignant focal liver lesions and diffuse liver disease.<sup>7</sup> MRI is also useful for the evaluation of biliary disease.<sup>8</sup> MRI also offers the advantages of avoidance of radiation and contrast nephropathy. The primary disadvantage is the need for breath-hold sequences, which can require sedation or anesthesia in young and/or uncooperative patients.

Percutaneous transhepatic cholangiography (THC) is the percutaneous injection of contrast into the bile ducts under fluoroscopic guidance. It can be used to determine the site and cause of biliary obstruction and to evaluate whether cholangiocarcinoma is surgically resectable. It can also be used for balloon dilatation of biliary strictures and/or placement of an internal stent or external drain. Endoscopic retrograde cholangiopancreatography (ERCP) uses endoscopy to visualize the ampulla of Vater and selectively inject contrast material into the pancreatic and common bile ducts. ERCP has the advantage over THC of not requiring a dilated biliary tree to achieve a high probability of success. ERCP permits sphincterotomy and stone extraction, biopsy, brushings, balloon dilatation, and stent insertion.

## Liver Biopsy

Liver biopsy continues to have a role in the evaluation of patients with liver disease. It is the method of choice to determine whether liver damage is due to necrosis, inflammation, steatosis, or fibrosis. The presence of coagulopathy or thrombocytopenia may contraindicate percutaneous liver biopsy, although transjugular liver biopsy is often performed under these conditions.

## Hepatic and Hepatobiliary Diseases

Liver disease may be the result of a variety of causes, which include developmental or genetic defects, metabolic abnormalities, autoimmune diseases, infectious diseases, neoplasm, alcohol, environmental toxins, and drug toxicity. A preliminary report from the National Vital Statistics System for the year 2013 lists liver disease as the 12th leading cause of death in the United States, being responsible for over 36,000 deaths in that year.<sup>9</sup> A minimum estimated 33.4 million people in the United States have chronic liver disease (CLD) and another 20 million have biliary disease, together affecting slightly more than a third of the adult population.<sup>10-12</sup>

Liver disease can be divided into two main groups on the basis of the primary anatomy affected. Processes may be considered primarily

hepatocellular (parenchymal) or biliary. Progressive biliary disease may eventually lead to fibrotic changes and cirrhosis, but it is characteristic of the biliary diseases that cholestasis precedes hepatocellular dysfunction. In hepatocellular diseases evidence of cholestasis and synthetic dysfunction appear synchronously (Table 46-1). The fact that hepatocellular function is preserved until late in the course of cholestatic disease disadvantages patients with cholestatic liver disease awaiting liver transplantation.

Liver disease may also be described as acute or chronic. The most common causes for acute liver disease are drug toxicity and infection. Acute illnesses may resolve spontaneously, segue into chronic disease, or result in acute liver failure (ALF). Although the primary cause of ALF in the United States was once infectious (presumed acute hepatitis A and B), acetaminophen toxicity is currently the leading cause of this condition. Other causes of acute liver dysfunction include alcoholic hepatitis, nonacetaminophen drug toxicity, and pregnancy-related hepatic diseases. The most common causes for CLD are chronic viral hepatitis, alcoholic liver disease, and nonalcoholic fatty liver disease (NAFLD). Although the prevalence rates of chronic viral hepatitis and alcoholic liver disease have been relatively stable over the past 10 years, the prevalence of NAFLD has grown significantly and appears to be linked to the current epidemic of obesity.<sup>13</sup> The most important consequences of CLD are portal hypertension, cirrhosis, and malignancy.

**Table 46-1** Blood Tests and the Differential Diagnosis of Hepatic Dysfunction

	Bilirubin Overload (Hemolysis)	Parenchymal Dysfunction	Cholestasis
Aminotransferases	Normal	Increased (may be normal or decreased in advanced stages)	Normal (may be increased in advanced stages)
Alkaline phosphatase	Normal	Normal	Increased
Bilirubin	Increased Unconjugated	Increased Conjugated	Increased Conjugated
Serum proteins	Normal	Decreased	Normal (may be decreased in advanced stages)
Prothrombin time	Normal	Decreased (may be normal in early stages)	Normal (may be prolonged in advanced stages)
Blood urea nitrogen	Normal	Normal (may be decreased in advanced stages)	Normal
Sulfobromophthalein/ indocyanine green	Normal	Retention	Normal or retention

From Gelman S. Anesthesia and the liver. In: Barash P, Cullen B, Stoelting R, eds. *Clinical Anesthesia*. 3rd ed. Philadelphia, PA: Lippincott-Raven; 1997:1011.

### Acute Liver Failure

ALF (previously termed fulminant hepatic failure) is defined as the appearance of encephalopathy together with coagulopathy, usually an INR 1.5 or more, in a patient who has no previous history of liver disease and who has had an illness of shorter than 26 weeks' duration. Although further

distinctions in duration of disease, such as hyperacute and subacute, were once used, they are no longer considered useful for prognosis and have been abandoned. ALF is a rare entity with an incidence of about 2,000 cases per year in the United States. Drug-related toxicity accounts for over half of the cases of ALF in the United States. Of these drug-related cases, over 80% are the result of acetaminophen ingestion. In descending order the next most common causes are idiopathic, acute viral hepatitis, autoimmune, and ischemic.<sup>14</sup> The natural history of adult ALF in the United States is one of spontaneous recovery in approximately 45% of patients, liver transplantation in 25%, and death without transplantation in 30%.<sup>15</sup> Etiology has a significant bearing on outcome, with the most favorable prognosis for patients with acetaminophen overdose, ischemic injury, and hepatitis A and poor prognoses for those with nonacetaminophen drug-induced liver injury (DILI), acute hepatitis B, Wilson disease, and autoimmune hepatitis.<sup>16</sup>

Patients with no previous history of liver disease who present with signs or symptoms and laboratory evidence of a significant hepatitis should have an INR measured and undergo a careful mental status examination. An INR of 1.5 or more and any evidence of encephalopathy should lead to admission to the hospital for ALF. History should include questions about potential infectious or toxic exposures and a detailed history of recent medications or ingestions. Questions should include details about herbal and nutritional supplements, because these have been associated with ALF as well. Except for the finding of encephalopathy, physical examination may be unrevealing. In particular, evidence of CLD should not be present, as the patient should not have had adequate time to develop the stigmata of portal hypertension and cirrhosis. Acute decompensation of CLD or “acute on chronic” liver disease is a separate condition with different etiologies, therapy, and prognostic indicators.

Standard initial laboratory tests are indicated in [Table 46-2](#).<sup>16</sup> Further laboratory and investigative studies are directed by the history, for example, radiologic imaging or ultrasound for suspected hepatic vein thrombosis. Although etiologies of ALF are heterogeneous, there are manifestations that are common to all patients who have massive hepatic necrosis, regardless of its provenance. The most serious, and often the proximate cause of death, is acute cerebral edema and intracranial hypertension. Effects on other organ systems include coagulopathy, circulatory dysfunction and hypotension, acute kidney injury, and metabolic derangements. Encephalopathy is a necessary finding to diagnose ALF. Encephalopathy is graded on a I to IV scale and is described in [Table 46-3](#). The presence of cerebral edema is directly related to the depth of encephalopathy. The incidence of cerebral edema is almost negligible in stage I to stage II coma, but increases to 25% to 35% with stage III and 75% with stage IV.<sup>17</sup> As with the encephalopathy of cirrhosis, the underlying mechanism is not completely understood but hyperammonemia

plays a significant role. Ammonia, which is toxic, is generally metabolized via the urea cycle in the liver. The brain has no cells capable of utilizing the urea cycle and thus must resort to detoxifying ammonia by synthesizing glutamine from ammonia and glutamate within astrocytes. Glutamine is osmotically active and results in osmotic astrocyte edema. Other contributors to the observed cerebral edema may include a systemic inflammatory response<sup>18,19</sup> and the loss of cerebral autoregulation, which leads to cerebral hyperemia.<sup>20</sup> Potential targets for therapy include osmotic and mechanical reduction of cerebral edema, elimination of ammonia, manipulation of cerebral blood flow and metabolism, and reduction of the inflammatory response.

**Table 46-2** Initial Laboratory Analysis of Suspected Acute Liver Failure

Prothrombin time/INR
Chemistries
Sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphate glucose
AST, ALT, alkaline phosphatase, GGT, total bilirubin, albumin creatinine, blood urea nitrogen
Arterial blood gas
Arterial lactate
Complete blood count
Blood type and screen
Acetaminophen level
Toxicology screen
Viral hepatitis serologies
Anti-HAV IgM, HBSAg, anti-HBc IgM, anti-HEV, <sup>a</sup> anti-HCV <sup>b</sup>
Ceruloplasmin level <sup>c</sup>
Pregnancy test (females)
Ammonia (arterial if possible)
Autoimmune markers
ANA, ASMA, immunoglobulin levels
HIV status <sup>d</sup>
Amylase and lipase

<sup>a</sup>If clinically indicated.

<sup>b</sup>Done to recognize potential underlying infection.

<sup>c</sup>Done only if Wilson disease is a consideration (e.g., in patients less than 40 yrs without another obvious explanation for ALF); in this case uric acid level and bilirubin to alkaline phosphatase ratio may be helpful as well.

<sup>d</sup>Implications for potential liver transplantation.

INR, international normalized ratio; AST, aspartate aminotransferase; ALT, alanine aminotransferase; GGT, gamma-glutamyl transferase; HAV, hepatitis A virus; IgM, immunoglobulin M; HBSAg, hepatitis B surface antigen; HEV, hepatitis E virus; HCV, hepatitis C virus; ANA, antinuclear antibody; ASMA, anti-smooth muscle antibody.

**Table 46-3** Grades of Encephalopathy

- I. Changes in behavior with minimal change in level of consciousness
- II. Gross disorientation, drowsiness, possibly asterixis, inappropriate behavior
- III. Marked confusion, incoherent speech, sleeping most of the time but arousable to vocal stimuli
- IV. Comatose, unresponsive to pain, decorticate or decerebrate posturing

Note: Some patients will overlap grades; clinical judgment is required. Adapted from Conn HO, Leevy CM, Vlahcevic ZR, et al. Comparison of lactulose and neomycin in the treatment of chronic portal-systemic encephalopathy: a double blind controlled trial. *Gastroenterology*. 1977;72:573.

General measures to reduce cerebral edema include maintaining the patient in a 30-degree head-up position and making sure the head is in neutral position so as not to impede venous return. Once a patient is intubated, muscle relaxants should be considered to minimize rises in intracranial pressure (ICP) from coughing, bucking, and shivering. Mannitol can be used to induce an osmotic diuresis, but may have limited utility in the patient with compromised renal function. Another option may be hypertonic saline, ideally targeting a serum sodium of 145 to 155 mEq/L.<sup>21</sup>

Although hyperventilation may acutely reduce the cerebral hyperemia associated with ALF, the response is short-lived. There is no evidence that chronic hyperventilation affords any decrease in episodes of intracranial hypertension or any survival benefit.<sup>22</sup> Current recommendations are to maintain normocarbia and to reserve hyperventilation for response to acute rises in ICP. Barbiturates can be used to decrease cerebral metabolism; however, their use may be limited by hypotension.

Ammonia can be eliminated by the administration of lactulose or nonabsorbable antibiotics such as rifaximin or neomycin; however, there is no evidence to support their use in the setting of ALF. Furthermore, neomycin is specifically contraindicated because of the risk of nephrotoxicity.

Corticosteroids have not been shown to be effective in ALF, but there may be a place for prophylactic antibiotics to prevent sepsis and minimize the inflammatory mediator burden. The US Acute Liver Failure Study Group has recommended empiric administration of antibiotics in the following settings: (a) when surveillance cultures reveal significant isolates; (b) progression to stage III or stage IV coma; (c) refractory hypotension; or (d) when the patient exhibits elements of the systemic inflammatory response syndrome, that is, temperature greater than 38°C or lower than 36°C, heart rate more than 90 bpm, white blood cell count more than 12,000 or less than 4,000.<sup>23</sup> Other potential modalities to decrease the inflammatory response include modest hypothermia to a target temperature of 32°C to 34°C and indomethacin.<sup>24</sup>

How to monitor the presence and progression of cerebral edema and

intracranial hypertension is controversial. Serial head CTs are often obtained for patients who progress to stage III or stage IV coma, but they are not reliable for diagnosing or quantitating intracranial hypertension due to a lack of sensitivity. CT can, however, provide information on structural abnormalities such as intracranial hemorrhage.<sup>25</sup> Although many centers will place an ICP monitor to guide therapy in patients with stage III to stage IV coma, there are no randomized controlled studies to support this practice. Furthermore, ICP monitor placement is not a benign procedure, frequently entailing aggressive correction of coagulopathy and transport to and from the OR for a critically ill, fragile patient. Nonetheless, many believe that ICP monitors are invaluable for guiding acute therapy and for helping to determine who may no longer be a viable candidate for transplantation. In addition to measuring ICP, these monitors allow calculation of cerebral perfusion pressure (CPP = MAP – ICP), which should be kept between 50 and 80 mmHg. In one case series, a sustained CPP lower than 40 mmHg for greater than 2 hours was associated with a poor neurologic outcome.<sup>26</sup> An effective protocol for managing intracranial hypertension in patients with stage III or stage IV encephalopathy has been described (Table 46-4) and resulted in a 95% response to treatment of episodes of ICP greater than 20 mmHg. Furthermore, in this prospective series, ICP was monitored in all patients, and no patients died of isolated cerebral edema. The authors used a protocol that included activated recombinant factor VII (rFVIIa) to correct coagulopathy prior to ICP placement. Significant bleeding complications from ICP monitoring were not encountered.<sup>27</sup>

**Table 46-4** ICP Management Protocol

<p>Initiate in rapid stepwise fashion for ICP &gt;20 mmHg for &gt;5 min          Keep CPP &gt;60 mmHg with norepinephrine or phenylephrine infusion          Mannitol 1 g/kg IV bolus, may repeat if serum osmolality &lt;320 mOsm/kg          Hyperventilation to target PCO<sub>2</sub> 30–35 mmHg          Hypothermia using cooling blanket to core temperature of 33°–34°C          Initiate neuromuscular blockade if needed with cis-atracurium 0.2 mg/kg IV bolus, 3 µg/kg/min infusion—adjust to 2/4 on train of four          Pentobarbital 5 mg/kg bolus, repeated 3–5 mg/kg boluses as necessary—titrate to ICP effect          3% saline: Calculate dose to achieve serum sodium in 145–155 mEq/L range</p>

Deciding which patient should receive a transplant, which may recover spontaneously, and which are unlikely to benefit from transplantation is one

of the most difficult decisions encountered during the management of patients with liver disease. Unfortunately there is no ideal guideline for making these decisions. The two most widely used prognostic models are the Clichy or Paul Brousse Hospital criteria and the King's College Hospital criteria. The Clichy criteria recommend transplantation for patients in stage III or stage IV coma on the basis of age and factor V levels. The transplantation threshold is 20% factor V activity for patients under 30 years or 30% factor V activity for patients above 30 years.<sup>28</sup> There is no distinction made for the etiology of ALF, which is felt to be a weakness of these criteria. The King's College Hospital (Table 46-5) criteria accounted for better spontaneous outcomes of patients who had ALF on the basis of acetaminophen toxicity and divided their criteria accordingly. Although the positive predictive value of King's College Hospital criteria has been shown to be clinically acceptable in ALF patients, the negative predictive value drops below 50% in nonacetaminophen patients.<sup>29</sup> Thus, patients who fail to fulfill these criteria include a number of patients who will die without being properly considered for transplantation. Modifications to the King's College Hospital criteria to improve performance and other prognostic scoring models for specific etiologies have been proposed, such as consideration of serum lactate levels<sup>30</sup> or the addition of an apoptosis marker.<sup>31</sup> However, these marginally improved specificity at the expense of sensitivity. It has been suggested that the Sequential Organ Failure Assessment (SOFA) or Acute Physiology and Chronic Health Evaluation II (APACHE II) scores may provide significantly more specificity with a minimal decrement in sensitivity compared to the King's College criteria and that the discriminative value of these indices deserve further investigation.<sup>32</sup>

**Table 46-5** King's College Selection Criteria for Liver Transplantation According to the Etiology of Acute Liver Failure

Etiology	Selection Criteria for Transplantation
Acetaminophen	Arterial pH <7.30 despite normal intravascular filling pressures (irrespective of grade of encephalopathy) OR Prothrombin time >100 s + serum creatinine >300 μmol/L in patients in grade III or IV encephalopathy
Nonacetaminophen	Prothrombin time >100 s (irrespective of grade of encephalopathy) OR Any three of the following (irrespective of grade of encephalopathy): Non-A, non-B hepatitis (cryptogenic), halothane hepatitis, or other drug toxicity Age <10 yrs or >40 yrs Jaundice to encephalopathy interval >7 d Prothrombin time >50 s Serum bilirubin >300 μmol/L

Coagulopathy is also a necessary finding for the diagnosis of ALF; however, clinically significant spontaneous bleeding is uncommon. Traditional standard of care recommends correction of thrombocytopenia to 50,000/mm<sup>3</sup> or more and INR to 1.5 or less for the bleeding patient or the patient about to undergo an invasive procedure.<sup>16,23</sup> However, it has become clear that conventional coagulation studies such as INR and platelet count are poor predictors of bleeding complications of invasive procedures in liver disease.<sup>33–35</sup> Small studies suggest that whole blood viscoelastic studies are more accurate predictors of bleeding in both high- and low-risk invasive procedures<sup>36,37</sup>; however, they have not yet been fully validated for this purpose. Specific treatment thresholds for the nonbleeding patient are difficult to define, but it is suggested that prophylactic therapy not be undertaken except for severe abnormalities, for example, platelet count 10,000/mm<sup>3</sup> or less, INR greater than 7, and fibrinogen less than 100 mg/dL.<sup>16</sup> Occasionally, the use of rFVIIa or prothrombin complex concentrate is used to correct a resistant INR abnormality or to avoid fluid overload. It should be kept in mind that these agents carry a thrombotic risk and are contraindicated when the etiology of ALF is associated with hypercoagulability, such as pregnancy or Budd–Chiari syndrome.

Hypotension in ALF may be the result of several days of gastrointestinal losses, poor intake, or myocardial dysfunction, but likely includes a component of decreased arterial tone as liver necrosis progresses. The

hypotensive ALF patient should undergo volume status and cardiac function assessment prior to consideration of inotropes or vasopressors. Vasopressors may be used either to treat systemic hypotension or to maintain an adequate CPP. On the basis of recommendations for septic patients, either norepinephrine or dopamine may be used. The use of arginine vasopressin (AVP) or its analogues cannot be recommended as there is evidence that their use is associated with increases in ICP.<sup>38</sup>

## **Acute Hepatitis**

The most common causes of acute viral hepatitis are, collectively, the five identified viral hepatitis: A (HAV), B (HBV), C (HCV), D (HDV or delta-virus), and E (HEV). HAV and HBV have been well characterized and vaccines have been developed to prevent their transmission. As a result of widespread vaccination, the incidence of new cases of HAV and HBV has decreased steadily worldwide. Unfortunately, the same cannot be said for HCV, for which there is no currently available vaccine. The number of reported new cases of HCV is decreasing but this is likely the result of better screening of transfused blood products and the adoption of universal precautions. HDV is a single-strand RNA genome that requires the helper function of HBV for virion assembly and so must occur either as a coinfection or as a superinfection with HBV. HEV is a small RNA virus that has been responsible for several epidemics of hepatitis, primarily in underdeveloped countries with poor sanitation.

The diagnosis of acute hepatitis is made on the basis of classic signs and symptoms, together with laboratory studies to assess liver damage and serologic assays. Symptoms can be nonspecific, such as fatigue, poor appetite, nausea, vomiting, and abdominal pain, and many infections are subclinical. Signs may include jaundice, or a serum-sickness-type presentation with fever, arthralgia or arthritis, and rash that results from circulating hepatitis antigen-antibody complexes. Incubation periods can be several weeks to even months and patients may undergo surgery without awareness of illness. For this reason viral hepatitis should be part of the differential diagnosis when there is any evidence of postoperative liver injury.

HAV is a picornavirus that is spread primarily by the fecal-oral route or via contaminated food or water. HAV has a wide range of manifestation from asymptomatic disease (particularly in children) to ALF. ALF is rare (<1%) and is more likely than other causes to result in spontaneous recovery (69%) in patients without underlying liver disease. There is no chronic disease state associated with HAV.

HBV is a DNA virus that is spread via parenteral, cutaneous, or mucosal exposure to infected blood or body fluids. HBV surface antigen (HBsAg) is the

hallmark of active HBV infection and usually appears during the incubation period, 1 to 10 weeks after exposure. ALF caused by acute HBV infection occurs in less than 1% of cases, but has only a 20% rate of spontaneous recovery. Maintenance of seropositivity for HBsAg for more than 6 months after recovery suggests chronic infection and occurs in 2% to 5% of infected adults.

HDV infection occurs in conjunction with HBV infection and is estimated to be present in 5% of patients with chronic HBV. Two types of HDV infection are described: coinfection with acute HBV and superinfection on top of chronic HBV. Both types cause severe infection and may cause ALF.

HCV, once referred to as non-A, non-B hepatitis until its identification in 1989, is transmitted primarily parenterally. Because the identification of HCV, the ability to serologically screen blood products for its presence has all but eliminated it as a source of posttransfusion hepatitis. Causes of transmission are often not identifiable, but the most commonly known risk factor is parenteral drug use. HCV has a high rate of progression to chronic disease (50% to 85%) and a risk of developing cirrhosis ranging from 5% to 25% over 25 to 30 years.<sup>32</sup> HCV is currently the leading cause for liver transplantation in the United States, which is performed for cirrhosis and/or associated HCC. The therapy of chronic HCV infection has recently been revolutionized by the use of combination direct-acting antiviral agents that have achieved reported cure rates of 84% to 100% depending on patient population, drug combination, and viral genotype.<sup>39–42</sup>

## **Alcoholic Hepatitis**

Alcoholic hepatitis is the syndrome marked by the development of jaundice and liver dysfunction in the setting of heavy alcohol use. Encephalopathy may be present in severe alcoholic hepatitis and, if so, portends a poorer prognosis. Laboratory studies show moderate serum aminotransferase elevations (<300 IU/mL), with AST being elevated more than ALT. The AST:ALT ratio is more than 2 in about 70% of patients with alcoholic hepatitis.<sup>43</sup> Elevations of serum creatinine are particularly ominous as they may indicate impending hepatorenal syndrome (HRS).

A history of excessive alcohol use is supportive of the diagnosis of alcoholic hepatitis, but up to 20% of these patients may have a coexisting cause of liver disease.<sup>44</sup> Although liver biopsy is not required to make the diagnosis of alcoholic hepatitis, it is important to investigate other potential causes of acute liver disease.

The key component of therapy for alcoholic hepatitis is abstinence. For those patients with severe alcoholic hepatitis, medical therapy should also be considered. This consists of nutritional therapy that takes into account not

only protein-calorie nutrition but vitamin and mineral deficiencies as well.

### **Drug-induced Liver Injury**

Often considered as an afterthought when a patient presents with new abnormalities in liver-related laboratory studies, DILI is a significant cause of morbidity and mortality. Although the process of diagnosing DILI is not well defined and it is largely a diagnosis of exclusion, DILI should always be considered when formulating the differential diagnosis of patients presenting with liver abnormalities. Moreover, DILI is a serious problem for the pharmaceutical industry, as it is the most common reason for regulatory actions such as failure of approval, removal from market, or restrictions on indications for use. Nonacetaminophen drug-induced idiosyncratic liver injury accounts for 11% to 13% of cases of ALF and, with a 20% rate of survival with supportive care, has a poorer than average rate of spontaneous recovery.<sup>14,45</sup>

A recent report from the international DILI Expert Working Group has defined laboratory criteria for diagnosing DILI (Table 46-6). DILI can further be characterized as hepatocellular, cholestatic, or mixed, on the basis of the relative abnormalities of laboratory values. This is done by calculating the  $R$  value, such that  $R = (\text{ALT}/\text{ULN})/(\text{ALP}/\text{ULN})$ , where ALT is the alanine aminotransferase, ALP is the alkaline phosphatase, and ULN is the upper limit of normal value. The higher the  $R$  value, the more abnormal the ALT in comparison to the ALP. Thus  $R$  values 5 or more are used to define a hepatocellular pattern of damage.  $R$  values 2 or less define a cholestatic pattern, and  $R$  values between 2 and 5 define a mixed pattern. A prognostic rule of thumb is eponymously named “Hy law” after Hyman J. Zimmerman, a leader in DILI research. It was his observation that jaundice (defined as bilirubin  $>2$  ULN) in patients with hepatocellular DILI carried a poor prognosis, with a mortality of more than 10%. This observation has been confirmed and recognized for many years by the FDA as a tool for identifying which drugs may be expected to cause significant hepatotoxicity.<sup>46</sup>

**Table 46-6** Clinical Chemistry Criteria for Drug-Induced Liver Injury (DILI)

Any one of the following:

ALT at least fivefold elevation above the ULN

ALP at least twofold elevation above the ULN (particularly with accompanying elevations in concentrations of 5'-nucleotidase or  $\gamma$ -glutamyl transpeptidase in the absence of known bone pathology driving the rise in ALP level)

ALT at least threefold elevation in concentration plus simultaneous elevation of bilirubin concentration exceeding twice the ULN

Level of evidence: 2b (exploratory/retrospective cohort studies)

ALT, alanine aminotransferase; ALP, alkaline phosphatase; ULN, upper limit of normal.

Adapted with permission from Aithal GP, Watkins PB, Andrade RJ, et al. Case definition and phenotype standardization in drug-induced liver injury. *Clin Pharmacol Ther.* 2011;89:806.

The liver is commonly involved in drug toxicity because of its central role in drug metabolism. Drugs may either be directly hepatotoxic or propagate toxic metabolites, most often as products of phase I drug metabolism and the cytochrome P450.<sup>47</sup> Cell injury follows via cell stress, mitochondrial injury, or immune-mediated injury. Cell stress may result from glutathione depletion or the binding of reactive metabolites to intracellular enzymes, proteins, or lipids. Mitochondrial injury may result from the uncoupling of mitochondrial respiration with the depletion of ATP and accumulation of reactive oxygen species (ROS). Immune-mediated injury may result from the binding of reactive metabolites to cell structures, creating antigenic entities that can invoke the formation of antibodies against the cell structures themselves.

In anesthesiology perhaps the best known potentially hepatotoxic drug is halothane. Halothane was introduced to patient care in 1956 and, because of its clinical advantages of lack of flammability, potency, and patient tolerance of administration, rapidly enjoyed widespread use. However, reports of postoperative liver injury began to appear shortly thereafter and, by 1963, over 300 cases of “halothane hepatitis” had been reported.<sup>48</sup> The National Academy of Sciences produced a retrospective epidemiologic study on the use of halothane from these reports. The National Halothane Study reviewed cases of fatal hepatic necrosis occurring within 6 weeks of the administration of a general anesthetic, from among 34 centers in the United States. Of the 856,000 anesthetics reviewed, about 255,000 involved halothane, and 82 cases of fatal hepatic necrosis were identified. Sixty-three of these cases could be ascribed to an identifiable clinical factor, leaving 19 with otherwise unexplained hepatic necrosis. Fourteen of the nineteen had received a halothane anesthetic, but did not have consistent histologic findings. Uncertainty over the direct association between halothane and the cases of fatal hepatic necrosis, together with the calculated incidence of 1 in 35,000 anesthetics even if such association did exist, led to the conclusion that

halothane overall had a good safety record. The possible association with repeated exposure to halothane did not go unrecognized, and there was an editorial recommendation that halothane be avoided in patients with a history of unexplained fever and jaundice following a general anesthetic.<sup>49</sup>

It is generally agreed that halothane hepatitis is composed of two different manifestations. A relatively mild, self-limited form is characterized by elevations in liver-related laboratory studies without evidence of liver failure. This may occur in up to 20% of patients after halothane exposure.<sup>50</sup> A proposed mechanism for this hepatocellular damage is the combination of halothane degradation products and hypoxia caused by imbalance in the hepatic oxygen supply–demand relationship.<sup>51</sup> There is strong evidence that the severe, fulminant form of halothane hepatitis is an immune-mediated process. The association with repeated halothane exposure and the appearance of rash and eosinophilia support this hypothesis. Furthermore, circulating IgG antibodies against liver proteins, modified by the reactive trifluoroacetyl (TFA) metabolite of halothane, have been identified in the sera of patients with clinical halothane hepatitis.<sup>52</sup> Although other halogenated inhalational anesthetics that produce TFA metabolites such as enflurane, isoflurane, and desflurane have been associated with acute hepatic failure, the incidences of hepatitis attributed to them have been very small. Because halothane is by far the most extensively metabolized of these agents (20% halothane metabolized vs. 2% enflurane, 0.2% isoflurane, and 0.01% desflurane) the production of TFA metabolites would seem to correlate with the incidence of associated hepatitis. Indeed, an animal study examining the extent of hepatic tissue trifluoroacylation after exposure to halogenated anesthetics showed that halothane produced significantly more tissue acylation than enflurane, isoflurane, or desflurane.<sup>53</sup>

### ***Pregnancy-related Liver Diseases***

Abnormalities in liver studies occur in 3% to 5% of pregnancies. Although many causes reflect underlying hepatic or biliary disease, the most common causes are one of the five acute, pregnancy-related conditions: Hyperemesis gravidarum; intrahepatic cholestasis of pregnancy; preeclampsia; preeclampsia complicated by hemolysis, low platelet count, and elevated liver enzymes (HELLP syndrome); and acute fatty liver of pregnancy (AFLP; [Table 46-7](#)). Hyperemesis gravidarum is a feature of the first trimester of pregnancy and is characterized by vomiting of sufficient severity to warrant intravenous (IV) hydration. Risk factors include hyperthyroidism, molar pregnancy, and multiple pregnancies.<sup>54</sup> Liver enzymes may be elevated in 50% of patients, with up to 20-fold elevation, but little if any elevation of bilirubin.<sup>55,56</sup> It is important to distinguish hyperemesis from acute viral hepatitis or from drug

toxicity with appropriate laboratory values and a careful medication history. Therapy is primarily supportive and the condition usually resolves by the second trimester.

Intrahepatic cholestasis of pregnancy usually presents in the second to third trimester of pregnancy. The proposed etiology is interference with bile acid transport across the canalicular membrane, resulting in elevated serum bile acid elevation and pruritus. In addition to modest increases in bilirubin (usually  $<5$  mg/dL) aminotransferases may also be elevated up to 20-fold and serum bile acids may be elevated up to 100-fold.<sup>56</sup> As with hyperemesis gravidarum, treatment is primarily supportive, aimed at relieving pruritus. Unlike hyperemesis, intrahepatic cholestasis of pregnancy may be associated with chronic placental insufficiency, premature labor, and sudden fetal death. Therefore, pregnancies complicated by intrahepatic cholestasis of pregnancy are considered fetal high-risk pregnancies.

The three remaining uniquely pregnancy-related conditions all present in the third trimester. Preeclampsia is diagnosed by the triad of hypertension, edema, and proteinuria. Elevation of aminotransferases is indicative of severe preeclampsia. The appearance of microangiopathic hemolytic anemia (MAHA), elevated liver enzymes, and low platelet count in the preeclamptic patient comprises the HELLP syndrome and occurs in 20% of severely preeclamptic patients. MAHA is the result of vascular endothelial injury with subsequent fibrin deposition and platelet consumption. This also leads to areas of hepatic infarction and subsequent hemorrhage, which may coalesce into large hematomas and lead to capsular rupture and intraperitoneal bleeding. Laboratory studies show elevated aminotransferases, up to 10- to 20-fold, and modest increases in bilirubin. A peripheral smear will show the characteristic schistocytes and burr cells of MAHA. Platelet count may be used to distinguish between mild, moderate, and severe HELLP, with platelet counts of 100,000 to 150,000/mm<sup>3</sup>, 50,000 to 100,000/mm<sup>3</sup>, and less than 50,000/mm<sup>3</sup>, respectively.

**Table 46-7** Distinguishing Features of Intrahepatic Cholestasis of Pregnancy (ICP), the HELLP Syndrome, and Fatty Liver of Pregnancy (AFLP)

	ICP	HELLP	AFLP
Pregnancies	0.1% (United States)	0.2–0.6%	0.005–0.01%
Onset	25–32 wks	3rd trimester or postpartum	3rd trimester or postpartum
Family history	Often	No	Occasionally
Presence of preeclampsia	No	Yes	50%
Typical clinical features	Pruritus, mild jaundice, elevated bile acids, decreased vitamin K	Hemolysis, thrombocytopenia (<50,000 often)	Liver failure with coagulopathy, encephalopathy hypoglycemia, DIC
Aminotransferases	Mild to 10- to 20-fold elevation	Mild to 10- to 20-fold elevation	300–500 typical but variable elevation
Bilirubin	<5 mg/dL	<5 mg/dL unless massive necrosis	Often <5 mg/dL, higher if severe
Hepatic imaging	Normal	Hepatic infarcts, hematomas, rupture	Fatty infiltration
Histology	Normal–mild cholestasis, no necrosis	Patchy/extensive necrosis and hemorrhage	Microvesicular fat in zone 3
Maternal mortality	0%	1–25%	7–18%
Fetal/perinatal mortality	0.4–1.4%	11%	9–23%
Recurrence in subsequent pregnancies	45–70%	4–19%	$\alpha$ -Subunit, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) defect—yes No fatty acid oxidation defect—rare

DIC, disseminated intravascular coagulation.

Adapted with permission from Hay JE. Liver disease in pregnancy. *Hepatology*. 2008;47:1067.

Abdominal CT imaging is the preferred study to detect major hepatic complications of infarct, hematoma, or rupture. Contained hepatic hemorrhage can be managed conservatively with correction of volume deficit and coagulopathy. Capsular rupture or rapid extension of a hematoma is life-threatening and demands more aggressive treatment for control of bleeding, usually emergency laparotomy. Rarely, there may be an indication for transplantation for the patient in whom bleeding cannot be controlled. Delivery is definitive therapy for HELLP syndrome. Therapy remains the same regardless of timing of presentation and most patients will rapidly resolve abnormalities after delivery.

AFLP is the result of rapid microvesicular fatty infiltration of the liver resulting in acute portal hypertension and encephalopathy. Although the exact mechanism of AFLP is unknown, there is an association between it and abnormalities in the enzymes involved in  $\beta$ -oxidation of fatty acids. Symptoms are similar to severe preeclampsia and HELLP syndrome; however, the AFLP patient may additionally have laboratory and clinical findings more unique to liver failure, such as hypoglycemia, elevated ammonia, asterixis, and encephalopathy.

Arrangements for rapid delivery should follow diagnosis of AFLP, as recovery can only follow delivery. Recovery may be prolonged in patients who are severely ill upon presentation, and there is a role for transplantation in the patient who continues to deteriorate into ALF after delivery.

## Cirrhosis and Portal Hypertension

**3**  Cirrhosis is the end product of the long course of CLD, during which there have been either steady or recurrent episodes of parenchymal inflammation and necrosis with resultant disruption of normal hepatic architecture. Areas of fibrosis and regenerative nodules replace the normal arrangement of hepatic lobules. Blood flow through the liver is disrupted as well, with the formation of shunts between afferent (portal venous and hepatic arterial) and efferent (hepatic venous) vessels.<sup>57</sup> Increased resistance to blood flow through the liver leads to portal hypertension. When portal hypertension becomes severe (generally defined as an HVPg of >10 to 12 mmHg), CLD becomes a systemic illness, affecting other organ systems as well.<sup>58</sup>

### Hemostasis

Hemostasis is a dynamic process that is the product of interaction between coagulation, platelets, and fibrinolysis, resulting in the formation and revision of clot. Liver disease affects all three of these components, both quantitatively and qualitatively.

The liver is the site of synthesis for all procoagulant and anticoagulant factors, with the exception of tissue thromboplastin (III), calcium (IV), and von Willebrand factor (VIII). It is also the site for clearance of activated factors.

Cirrhotic patients are customarily considered to have a bleeding diathesis on the basis of abnormalities in conventional tests of coagulation such as PT and partial thromboplastin time (PTT). However, such tests reflect the activity of only a portion of the procoagulant factors and do not consider the concomitant decrease in anticoagulant factors, which are not customarily measured. It is the balance of procoagulant and anticoagulant forces, not the isolated measurement of either portion of the coagulation system, that indicates the effective generation of thrombin.<sup>59,60</sup> Not surprisingly, PT and PTT abnormalities correlate poorly with bleeding complications following invasive procedures, such as liver biopsy.<sup>61–63</sup> In fact there is evidence that, should one account for differences in the anticoagulant levels between normal and cirrhotic patients by adding thrombomodulin (an activator of the anticoagulant protein C) to the PT assay, normal and cirrhotic patients generate the same amounts of thrombin.<sup>64</sup> Thus, one may conclude that the decreased levels of protein C in cirrhotic patients balance the decreased levels of procoagulants, leaving thrombin generation in vivo unaltered.

Even more counterintuitive is the increasing evidence that cirrhotic patients not only have normal thrombin generation but may actually also

have a procoagulant imbalance on the basis of reduced levels of anticoagulants protein C and antithrombin III, together with an increase in FVIII and von Willebrand factor.<sup>59,60,65</sup> Clinically, this is supported by studies reporting not only the lack of protection of liver disease against the formation of venous thromboembolism (VTE)<sup>66,67</sup> but also an increased risk of VTE formation associated with the presence of cirrhotic and noncirrhotic liver disease.<sup>68</sup>

The cholestatic diseases (e.g., PBC, sclerosing cholangitis) may eventually progress to cirrhosis, but until that happens the coagulopathy of these diseases has a different nature from that of hepatocellular dysfunction. The coagulopathy of biliary disease is characterized by functional deficiencies in the vitamin K–dependent procoagulants II, VII, IX, and X and anticoagulants protein C and protein S. Vitamin K is a fat-soluble cofactor necessary for the final step in the production of these factors: Carboxylation of the precursor produced by the liver. Bile salts are necessary for absorption of vitamin K, and impaired bile secretion in cholestasis results in vitamin K deficiency. Parenteral vitamin K can correct this deficiency and return coagulation to normal as long as the liver is still capable of manufacturing adequate amounts of factor precursors. It cannot, however, correct the coagulopathy of hepatocellular dysfunction.

Dysfibrinogenemia has been described in acute, chronic, and neoplastic liver disease and is the most common qualitative defect of coagulation factors, occurring in 70% to 80% of cirrhotics.<sup>69</sup> Its presence does not appear to be related to the severity of hepatic dysfunction, but instead to be associated with hepatic tissue regeneration. Excess sialic acid residues on the fibrinogen interfere with the enzymatic activity of thrombin and cause abnormal polymerization of fibrin monomers. Thus, although serum fibrinogen levels may be adequate, function is not accurately reflected.

Platelets provide primary hemostasis by interaction with the vessel wall at the site of injury and forming a physical plug. Thrombocytopenia is a well-known feature of cirrhosis. Estimates of incidence range from 30% to 64% of chronic cirrhotics, but platelet counts below 30,000/mm<sup>3</sup> are rare.<sup>70</sup> Because the liver is the primary site of thrombopoietin production, decreased levels of thrombopoietin contribute. Other factors include immunologic mechanisms, direct bone-marrow suppression, and consumptive processes such as DIC. However, the primary cause is splenic sequestration in the setting of portal hypertension. Up to 90% of the platelet population may be sequestered in the spleen. Elevated levels of von Willebrand factor are felt to compensate for decreased platelet counts, augmenting the platelet–endothelial cell interaction on vessel walls.

A second function of platelets is to promote thrombin generation. Activated platelets provide negatively charged phospholipids on their

surfaces, which act as receptors for the assembly of coagulation factors and thus promote coagulation. A series of assays measuring thrombin generation concluded that platelet counts below a threshold of  $100,000/\text{mm}^3$  negatively correlated with thrombin production. It was further estimated that the minimum platelet count necessary to support near-normal thrombin generation was  $56,000/\text{mm}^3$ .<sup>64</sup> This information provides further support to the use of platelet transfusion in the bleeding patient with platelet counts in and below that range. Platelet transfusions are not indicated in the absence of bleeding.

The fibrinolytic system limits and revises clot formation. The initial step is activation of plasmin from plasminogen by enzymes such as tissue plasminogen activator (tPA). Plasmin consumes fibrin, producing fibrin degradation products such as D-dimer. The fibrinolytic system in cirrhotic patients has many abnormalities which may account for accelerated fibrinolysis, which has a reported incidence of 30% to 46% in patients with end-stage liver disease.<sup>71,72</sup> The liver is the site of tPA clearance, and elevated tPA levels have been noted in patients with cirrhosis.<sup>73</sup> Furthermore, the liver is the site of synthesis for plasmin inhibitors, such as plasmin activator inhibitor-1 (PAI-1) and thrombin-activatable fibrinolysis inhibitor (TAFI). However, as with the process of coagulation, what matters is the balance of these factors that promote and inhibit fibrinolysis and where their net forces lie. Commonly used studies for assessing the presence and severity of accelerated fibrinolysis include the euglobulin clot lysis time (ECLT) and thromboelastography (TEG). A clot lysis index in TEG has been defined as the ratio of the clot amplitude at 60 minutes post achievement of maximum amplitude (A60) to the clot maximum amplitude (MA). A ratio of less than 0.85 indicates the presence of accelerated fibrinolysis and suggests the need for an antifibrinolytic agent such as epsilon aminocaproic acid or tranexamic acid in the presence of otherwise unexplained bleeding.

DIC is primarily a thrombotic diathesis, followed by widespread secondary fibrinolysis. As factors are consumed, DIC becomes a bleeding diathesis of factor and platelet deficiencies. Whether or not DIC is a feature of stable CLD is controversial. Because cirrhosis shares common laboratory abnormalities with DIC, standard laboratory values cannot distinguish between consumption and decreased synthesis and so have little utility. More recent approaches to answer this question have utilized assays for substances that would be expected to be elevated as the result of excessive thrombin production, the sine qua non of DIC. These include the cleaved by-products of coagulation factor activation such as prothrombin fragment F1 + 2, fibrinopeptide A, and thrombin-antithrombin (TAT) complexes. Elevation of these would suggest that low levels of procoagulation factors are the result of consumption rather than underproduction.

It is generally agreed on the basis of examination of these special assays that overt DIC is probably not a feature of stable CLD.<sup>74</sup> However, an entity called “accelerated intravascular coagulation and fibrinolysis (AICF)” has been described. This may be considered a low-grade consumptive process that occurs in less than 30% of cirrhotics, primarily in those with severe, decompensated disease.<sup>75</sup> Although it may not have immediate clinical consequence, patients who exhibit this phenomenon are considered at increased risk to progress to DIC in the presence of a known stimulus, such as sepsis or spontaneous bacterial peritonitis (SBP).

### *Cardiac Manifestations*

The cirrhotic patient typically has a hyperdynamic circulation, 4 characterized by a high cardiac output, low arterial blood pressure, and low systemic vascular resistance. On examination the patient is warm and appears well perfused despite systolic arterial pressures in the 80s and 90s. Although pulmonary arterial pressures may be mildly elevated, the pulmonary vascular resistance (PVR) is usually within the normal range. Consideration of the formula for calculating PVR (mean pulmonary artery pressure, mPAP, minus pulmonary capillary wedge divided by cardiac output) reveals the explanation: The cardiac output is elevated proportionally to the transpulmonary gradient (the numerator in the equation). Although these patients have an elevated intravascular volume this is not usually reflected in an elevated wedge pressure. This is due to sequestration of this volume into the massively dilated and collateralized splanchnic vascular bed. Thus, the effective circulating volume is reduced, which has consequences on other organ systems as well.

At the heart of these circulatory changes is portal hypertension. Portal hypertension causes local production of vasodilators such as natriuretic peptides, vasoactive intestinal peptide, endotoxin, glucagon, and especially nitric oxide.<sup>76</sup> Elevated production of nitric oxide has been observed to precede the formation of the hyperdynamic circulation in cirrhosis, and inhibition of nitric oxide formation has been shown to increase arterial pressure in cirrhotic patients. Furthermore, there is reduced circulatory responsiveness to sympathetic stimulation primarily due to overproduction of vasodilators.<sup>77</sup>

In addition to hyperdynamic circulation, the cirrhotic patient may have a combination of other cardiac functional abnormalities that are not immediately apparent in the baseline state. These abnormalities comprise four key components of a condition termed “cirrhotic cardiomyopathy.” They include (1) the aforementioned increase in cardiac output and decrease in peripheral vascular resistance, (2) systolic and diastolic dysfunction, (3)

cardiac resistance to  $\beta$ -adrenergic stimulation, and (4) electrophysiologic abnormalities.

Historically, cirrhosis has not been associated with cardiomyopathy because the hyperdynamic circulation was presumed to reflect cardiac vigor and the few patients who had overt dilated cardiomyopathy were thought to be manifesting alcoholic cardiomyopathy. However, elevated cardiac output is only a consequence of the profound decrease in afterload resulting from the dilated peripheral circulation. Systolic incompetence is revealed by physiologic or pharmacologic stress and is manifested by an inability to increase cardiac output in response to exercise and an inability to increase ejection fraction despite an increase in end-diastolic volume. Furthermore, the severity of cardiac dysfunction seems to be directly correlated with the severity of liver disease.<sup>78</sup>

Diastolic dysfunction has been described in cirrhotic patients as well, on the basis of diagnostic echocardiographic findings of abnormalities in transmitral flow during diastole. This consists of decrement or reversal of the E/A wave ratio and prolongation of E wave deceleration time, reflecting ventricular resistance to diastolic filling. Also supportive of the presence of diastolic dysfunction is the finding of septal and left ventricular hypertrophy on echo examination. Diastolic dysfunction renders cirrhotic patients very sensitive to changes in cardiac filling making them vulnerable to both heart failure and prerenal insufficiency.

Autonomic dysfunction is another characteristic of the altered cirrhotic cardiovascular system. Chronotropic and hemodynamic incompetence in response to various challenges such as sustained handgrip, ice water hand submersion, Valsalva maneuver, and tilt table testing has demonstrated autonomic neuropathy in 43% of cirrhotic patients. Although apparently unrelated to autonomic dysfunction, prolonged Q-Tc interval is also observed in cirrhotic patients with an incidence ranging from 30% in Child's A to 60% in Child's C patients (see later).<sup>79</sup> This should be kept in mind when treating these patients with drugs known to prolong Q-T interval.

Coronary artery disease (CAD) in cirrhotic patients has become an area of interest particularly as the application of liver transplantation has expanded to include older patients with comorbidities. Risk factors for coronary artery disease in cirrhotic patients are similar to those of other patient populations: hypertension, dyslipidemia, age, gender, and obesity. However, Nonalcoholic Steatohepatitis (NASH) has been recognized as an increasingly important cause for transplantation and carries with it both the cardiac disease risks of its attendant maladies, obesity and diabetes, and a chronic inflammatory state. The optimal test for identifying cirrhotic patients with significant CAD is unclear. Because many of these patients cannot exercise, pharmacologic stress testing is most commonly employed. Unfortunately, studies

investigating the predictive value of noninvasive functional testing, particularly dobutamine stress echocardiography, have generally shown poor sensitivity and variable quality of negative predictive value (75% to 89%).<sup>80</sup> Thus, among liver transplantation candidates, consideration should be given to proceeding with coronary angiography if the patient is judged to have a high likelihood of CAD.<sup>81</sup> For less complex surgeries, however, this may not be warranted.

## **Renal Dysfunction**

The hallmarks of renal dysfunction in cirrhosis are the seemingly inappropriate avid retention of sodium and free water, together with renal hypoperfusion and consequent decreased glomerular filtration. The extreme manifestation of this is the HRS, a prerenal functional abnormality that is the renal response to the circulatory abnormalities of advanced cirrhosis. Renal function is an important risk factor for mortality, a fact that is emphasized by its presence as one of only three variables used in calculating the MELD score, the primary predictor of 3-month mortality for patients on the liver transplantation waiting list.

Although the most dramatic and unique renal manifestation of CLD is the HRS, cirrhotic patients are also at high risk for more prosaic causes of renal dysfunction, such as parenchymal renal disease, sepsis, nephrotoxicity, and hypovolemia. It is important to remember that HRS is a diagnosis of exclusion and that other possible potentially treatable causes must be ruled out because therapies will differ.

Despite the fact that the cirrhotic patient's liver disease predominates, one should be mindful of any comorbidities that exist. Glomerulonephritis and diabetic nephropathy are not infrequent findings. NAFLD, the most common nonviral cause for adult CLD, is associated with type II diabetes. Immune complex nephropathies such as IgA nephropathy and membranous proliferative glomerulonephropathy are associated with chronic hepatitis C infection.<sup>82</sup> In addition, some underlying causes of liver failure are directly associated with renal dysfunction. These include such diseases as amyloidosis, systemic lupus erythematosus, autoimmune hepatitis, polycystic liver disease, and Alagille syndrome.

The cirrhotic circulatory system is characterized by marked sympathetic stimulation, and activation of the renin–angiotensin–aldosterone and vasopressin systems in response to the loss of effective circulating volume to the massively dilated splanchnic vasculature of portal hypertension. These systems combine to save salt and water and reduce renal perfusion. Elevated levels of renal prostaglandins help to maintain renal perfusion. Thus, cirrhotic patients are very sensitive to the prostaglandin inhibition of nonsteroidal anti-

inflammatory medications. Aminoglycosides, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers are other drug groups associated with nephrotoxicity in cirrhotic patients. Despite the expectation that contrast administration would be nephrotoxic, there is no evidence to support that concern.<sup>83</sup>

Cirrhotic patients are at risk for hypovolemia from a number of causes, including gastrointestinal bleeding, diuretic use, and diarrhea resulting from lactulose or rifaximin administration. Unfortunately, it can be difficult to assess intravascular volume status in patients who are total-body volume overloaded, whose measured central filling pressures may reflect transmitted elevated intra-abdominal pressures because of ascites, and whose measured serum creatinine levels are poor estimates of GFR due to decreased muscle mass.<sup>84,85</sup> Nonetheless, pursuit of a diagnosis by discontinuing diuretics and providing volume expansion with albumin can help differentiate hypovolemia from the other prerenal etiology of interest, HRS. Failure to improve creatinine in response to such measures is strongly suggestive of HRS as the underlying cause.

HRS is the end-stage renal manifestation of the systemic circulatory derangement of cirrhosis. It is considered a functional derangement, primarily on the basis of successful transplantation of kidneys from HRS patients.<sup>86</sup> Although it is often invoked in the differential diagnosis of acute renal dysfunction in cirrhotic patients, it accounts for only about 23% of the cases of acute kidney injury in hospitalized cirrhotic patients.<sup>87</sup> Nonetheless, in cirrhotic patients with ascites, the incidence of HRS is 18% at 1 year and 39% at 5 years.<sup>88</sup>

The generally agreed-upon criteria for diagnosing HRS are those proposed by the International Ascites Club.<sup>89,90</sup> Two manifestations of HRS are recognized, called type I and type II. Although they were once considered variants of the same disorder, it has become increasingly clear that they must be treated as two different entities.

Type I HRS is characterized by rapidly progressive renal failure, typically represented by at least a doubling of serum creatinine over the course of 2 weeks in close proximity to a precipitating cause such as SBP, sepsis, gastrointestinal bleeding, or surgical stress. Patients with type I HRS have a median survival of 2 to 4 weeks without therapy.<sup>88,91</sup> Type I HRS is associated with failure of other organ systems, including adrenal insufficiency. Most notably, however, when type I HRS responds to medical therapy that response is usually sustained, even after withdrawal of therapy.<sup>92</sup>

Type II HRS is more indolent and may be considered the expected consequence of continuous and progressive activity of the circulatory homeostatic triad of the sympathetic renin–angiotensin–aldosterone and vasopressin systems in an attempt to compensate for the progressive loss of

effective circulating blood volume to the increasingly dilated splanchnic vasculature. The most compelling clinical problem in these patients is refractory ascites. Patients with type II HRS have a median survival of about 6 months.<sup>93</sup>

Although profound renal vasoconstriction is the proximate cause of HRS, therapy aimed at directly increasing renal perfusion by the use of prostaglandins, dopamine agonists, or endothelin antagonists has not proved successful. More effective has been therapy targeting the underlying pathology that leads to the renal vasoconstrictive response, that is, reduction of portal hypertension and/or splanchnic vasodilation.

Vasoconstrictors such as AVP or its analogues, somatostatin or its analogues, and  $\alpha$ -agonists such as norepinephrine and midodrine, combined with volume expansion, have shown efficacy in reversing type I HRS (typically defined as a reduction in creatinine to 1.5 mg/dL).<sup>94</sup> AVP and its analogues are particularly attractive, because they interact with V1 receptors, which mediate vasoconstriction and are particularly well represented in the splanchnic circulation. Choices among these therapies are to some extent dictated by drug availability because, for example, terlipressin is not available in the United States. Terlipressin is perhaps the most studied vasopressor for HRS and is effective in 40% to 60% of type I patients.<sup>94,95</sup> Predictive factors of successful treatment include a starting creatinine lower than 5 mg/dL and a sustained rise in MAP from baseline throughout the 1- to 2-week course of treatment.<sup>96</sup> More importantly, when therapy is withdrawn, recurrence is uncommon and occurs in lower than 15% of patients.<sup>95</sup> Although response to vasopressor plus volume expansion has been observed in type II HRS, recurrence after withdrawal of therapy is the rule.

Placement of a transjugular intrahepatic portal shunt (TIPS) lowers portal pressures and would be expected to decompress the splanchnic circulation, returning volume directly to the central circulation. Although pilot studies have shown TIPS capable of reversing both types of HRS, it has limited application primarily because of the exclusionary criteria used in these studies; for example, Child–Pugh score above 12, active infection, and serum bilirubin above 5 mg/dL, as well as risk of de novo development or worsening of HE.<sup>97</sup> Furthermore, even when initially successful there is a high rate of shunt stenosis and migration.

Liver transplantation is the definitive therapy for HRS. For patients with HRS who are transplant candidates, renal replacement therapy is the typical bridge to transplantation. In countries where terlipressin is available, terlipressin plus albumin volume expansion is also an option. In fact there is evidence that treatment of HRS I with terlipressin and albumin while awaiting liver transplantation may improve posttransplant outcome. Although renal recovery is anticipated, 35% of patients with pretransplant HRS will continue

to require support in the immediate postoperative period, compared to 5% of patients without pretransplant HRS.<sup>98</sup> Gradual improvement in GFR occurs over the following 1 to 2 months, reaching 30 to 40 mL/min. There is some sense that, if allowed to continue, HRS that requires renal replacement therapy may not be reversible. In the First International Liver Transplantation Society Expert Panel Consensus on Renal Insufficiency in Liver Transplantation, it was recommended that patients who had received dialysis at least twice weekly for more than 6 weeks prior to transplantation be considered for combined liver–kidney transplantation.<sup>99</sup>

## **Pulmonary Complications**

Pulmonary complications have long been associated with portal hypertension with or without intrinsic hepatic disease. Estimates of as high as 50% to 70% of patients with CLD complain of shortness of breath.<sup>100</sup> There are many commonplace mechanisms underlying pulmonary abnormalities observed in patients with liver disease. The differential diagnoses include ventilation–perfusion abnormalities associated with underlying obstructive airways disease, fluid retention, pleural effusion, and decreased lung capacities secondary to large volume ascites.  $\alpha_1$ -Antitrypsin disease is a metabolic syndrome that has both lung and liver manifestations, as may cystic fibrosis. In addition, there are two types of vascular abnormalities unique to the setting of portal hypertension, which have significant morbidity and mortality. These abnormalities have been termed hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPHTN). Their severity may even overshadow the underlying liver disease, so much so that their presence and severity influences candidacy for liver transplantation.

HPS consists of the triad of liver dysfunction, otherwise unexplained hypoxemia, and intrapulmonary vascular dilation (IPVD) that may be present in up to 20% of patients who present for liver transplantation. The diagnostic criteria for HPS are as follows<sup>101</sup>:

- Oxygenation defect: Partial pressure of oxygen below 80 mmHg or alveolar–arterial oxygen gradient of at least 15 mmHg while breathing ambient air
- Pulmonary vascular dilatation: Positive findings on contrast-enhanced echocardiography or abnormal uptake in the brain (>6%) with radioactive lung-perfusion scanning
- Liver disease: Portal hypertension (most common) with or without cirrhosis

Staging of HPS is given in [Table 46-8](#).

IPVDs are of two types. Type I lesions are more common and are manifested as precapillary dilations at the alveolar level. Type II lesions are

larger dilations that are more centrally located in the lungs and behave as anatomic shunts. Demonstration of IPVD may be made by agitated saline contrast-enhanced echocardiography or by technetium-labeled microaggregated albumin (TcMAA). In the absence of HPS, microbubbles and albumin microaggregates injected into the venous circulation are trapped by the pulmonary capillary bed. The delayed (>3 cardiac cycles) appearance of microbubbles in the left atrium or increased (>5%) extrapulmonary uptake of TcMAA suggests direct arteriovenous communication in the lungs and the presence of IPVDs. Type I IPVDs are functional, rather than true anatomic shunts. IPVDs result in a massive increase in pulmonary capillary diameter, from 8 to 15  $\mu\text{m}$  to 50 to 500  $\mu\text{m}$ . This, together with the usually hyperdynamic circulation of the cirrhotic patient, allows insufficient time for oxygen diffusion through the entire stream of capillary blood. This results in a central stream of poorly oxygenated blood that is functionally shunted. This lesion is easily correctable with the administration of oxygen, because increased  $\text{FiO}_2$  increases oxygen diffusion through the dilated capillary. In fact, failure of 100% oxygen to correct the  $\text{PaO}_2$  to greater than 150 mmHg is suggestive of the presence of true anatomic or type II shunt.<sup>102</sup> Also of interest is the unique positional oxygenation change that occurs with this syndrome, called orthodeoxia. Because IPVDs predominate in the bases of the lungs, standing worsens hypoxemia and the supine position improves oxygenation as blood is redistributed from the bases to the apices.

**Table 46-8** Staging of the Hepatopulmonary Syndrome

Stage	Alveolar–Arterial Oxygen Gradient (mmHg)	Partial Pressure of Oxygen (mmHg)
Mild	$\geq 15$	$\geq 80$
Moderate	$\geq 15$	$\geq 60 < 80$
Severe	$\geq 15$	$\geq 50 < 60$
Very severe	$\geq 15$	$< 50$ ( $< 300$ while the patient is breathing 100% oxygen)

The alveolar–arterial gradient is determined as follows:

$$\text{PAO}_2 - \text{PaO}_2 = (\text{FiO}_2 - P_{\text{atm}} - \text{PH}_2\text{O}) - [\text{PaCO}_2/\text{R}] - \text{PaO}_2$$

where  $\text{PAO}_2$  denotes partial pressure of alveolar oxygen,  $\text{PaO}_2$  partial pressure of arterial oxygen,  $\text{FiO}_2$  fraction of inspired oxygen,  $P_{\text{atm}}$  atmospheric pressure,  $\text{PH}_2\text{O}$  partial pressure of water vapor at body temperature, and  $\text{PaCO}_2$  partial pressure of arterial carbon dioxide, and R the respiratory quotient.

Data from Rodriguez-Roisin R, Krowka MJ. Hepatopulmonary syndrome: a liver-induced lung vascular disorder. *N Engl J Med*. 2008;358:2378.

The natural history of HPS is usually one of progressive hypoxemia. The pathogenesis of HPS is poorly understood, hampering the development of effective therapy. Suspected contributing factors include nitric oxide, splanchnic endotoxemia, decreased clearance of inflammatory mediators, and

angiogenesis. Genetic factors are thought to contribute also. Post-liver-transplantation correction of hypoxemia is almost universal, although it may take up to a year to do so.<sup>103,104</sup> Mortality without transplantation is greater than in a matched cohort, with a median survival of 24 months and a 5-year survival of 23% versus a median survival of 87 months and a 5-year survival of 63% in transplant candidates without HPS.<sup>105</sup> A PaO<sub>2</sub> no more than 50 mmHg or a TcMAA-quantitated shunt fraction 20% or more are predictors of increased mortality regardless of whether the patient receives a transplant. However, in the largest single-center series of liver transplantation for HPS the overall 5-year survival was 76%, an outcome comparable to transplantation in non-HPS patients.<sup>103,105,106</sup> Taken together, these findings suggest that timely transplantation in patients with HPS results in good outcomes. The transplant community has recognized this by granting MELD exception points to patients with HPS and room air PaO<sub>2</sub> less than 60 mmHg.<sup>107</sup>

PPHTN is defined as pulmonary hypertension that exists in a patient who has portal hypertension with no other known cause. The specific diagnostic criteria put forth by the European Respiratory Society Task Force on Hepatopulmonary Diseases<sup>108</sup> follow:

1. Clinical evidence of portal hypertension with or without hepatic disease.
2. mPAP of 25 mmHg at rest or 30 mmHg during exercise.
3. Mean pulmonary artery occlusion pressure (mPAOP) less than 15 mmHg.
4. PVR more than 240 dynes/sec/cm<sup>5</sup> or 3 Wood units.

There is support for replacing the requirement that the mPAOP be less than 15 mmHg with one that requires the transpulmonary gradient (TPG = mPAP – mPAOP) to be more than 12 mmHg. Patients with pulmonary hypertension may be fluid overloaded as well, and such a measurement would help distinguish the contribution of volume status to an elevated mPAP. A TPG more than 12 mmHg would be consistent with increased PVR, suggesting a component of pulmonary hypertension in the increased mPAP. The requirement for calculation of the PVR is a reflection of the fact that many cirrhotic patients have mildly elevated mPAP simply on the basis of an elevated cardiac output. Calculated PVR in these hyperdynamic patients is often normal. Severity of PPHTN is graded by mPAP, with mild, moderate, and severe PPHTN defined as less than 35 mmHg, 35 to 50 mmHg, and more than 50 mmHg, respectively.

The occurrence of PPHTN is 2% in a population of patients with known portal hypertension,<sup>109</sup> as compared to 0.13% in an unselected population.<sup>110</sup> Among liver transplant candidates the prevalence is 4% to 6%.<sup>111,112</sup> The occurrence of PPHTN is unrelated to the severity of the underlying liver

disease or portal hypertension, with one epidemiologic study documenting a distribution of 51% Child's class A, 38% Child's class B, and 11% Child's class C patients among a population of patients sent to a referral center with the diagnosis of PPHTN.<sup>113</sup> Female patients as well as patients with underlying autoimmune hepatitis are at increased risk for PPHTN, and patients with chronic hepatitis C are at decreased risk.<sup>111,113</sup>

Although a theory commonly put forth for the pathophysiology of PPHTN invokes a vascular proliferative reaction to the shear stress of a chronically elevated cardiac output, the increased incidence in women and in autoimmune hepatitis suggests hormonal and immunologic processes may also contribute. Furthermore, as with other types of pulmonary hypertension, increased levels of endothelin are also thought to play a role. Clinical improvement in PPHTN patients with the endothelin antagonist, bosentan, has been documented albeit in a small study.<sup>114</sup>

Similar to HPS patients, symptoms of PPHTN are nonspecific, commonly consisting of dyspnea, generalized weakness, and decreased exercise tolerance. Although HPS and PPHTN may coexist, such an occurrence is uncommon and PPHTN patients may have only a modest decrease in PaO<sub>2</sub> if at all. The single best screening study for PPHTN is the 2D transthoracic echocardiography (TTE). TTE allows estimation of RV systolic pressure (RVSP) by the velocity of the tricuspid regurgitant jet. TTE screening has a sensitivity of 97% and a specificity of 77% in diagnosing moderate to severe PPHTN in patients undergoing pretransplantation workup.<sup>115</sup> However, right-sided cardiac catheterization is necessary, both to confirm elevated pressures and to measure PVR.

Therapy includes conventional measures such as diuresis, as well as some specific vasodilator therapy. Calcium channel blockers, often used in other patients with pulmonary hypertension, are contraindicated in this population because they promote mesenteric vasodilation and worsen portal hypertension. Other drugs used include prostanoids, phosphodiesterase inhibitors, and endothelin antagonists. Reported success with these modalities is on the basis of case reports or case series, and no one therapy has emerged as definitive. Nonetheless, one goal of therapy is to make the patient transplant-eligible by reducing mPAP and PVR into an acceptable range.

Epoprostenol (Pgl) has been shown to reduce pulmonary pressures in PPHTN and has been documented to have a survival benefit in pulmonary hypertension.<sup>116</sup> Epoprostenol also has an antiplatelet effect and promotes vascular remodeling. However, it must be administered as a continuous infusion via central access with little tolerance for interruption of the infusion. It has also been associated with splenomegaly and worsening thrombocytopenia, sufficient to limit its use.<sup>117</sup> The phosphodiesterase inhibitor sildenafil has also shown ability to reduce pulmonary pressures at 3

months, but without a sustained response at 12 months.<sup>118</sup> Nonetheless, it may be useful in combination therapy or it may provide a window for transplantation. Bosentan is the best studied of the endothelin antagonists. Although there are concerns for hepatic toxicity, published case reports and case series have not documented significant increases in liver enzymes with its use.<sup>119</sup>

The role of liver transplantation in the treatment of PPHTN is not well defined because outcomes of transplantation are not predictable. Some patients have resolution of PPHTN with transplant, some may have no or incomplete resolution and continue to require medical therapy, and some may experience worsening of their PPHTN. Nonetheless, it is an option for a select group of patients whose pulmonary hemodynamics and cardiac function suggest they will tolerate the procedure. Evaluation of the patient for potential transplantation must include a right-heart catheterization to measure mPAP and calculate PVR. Patients with mPAP less than 35 mmHg can be expected to tolerate transplant and do well postoperatively. Those with mPAP 35 mmHg or more and elevated PVR may be considered if they respond to therapy sufficiently to reduce their mPAP below 35 mmHg and PVR below 400 dynes/sec/cm<sup>5</sup>.<sup>120,121</sup>

### *Hepatic Encephalopathy*

HE is a serious, albeit reversible, neuropsychiatric complication that is a feature of both CLD and acute liver disease. The manifestations range from subtle, subclinical abnormalities that can only be discerned by formal psychometric tests (minimal HE) to clearly evident neurologic and behavioral derangements that are easily diagnosed at the bedside (overt HE). Although HE can appear as the result of portal–systemic shunting without intrinsic liver disease, the onset of HE is generally associated with advanced hepatocellular disease. Moreover, even minimal HE can affect the patient’s ability to maintain employment, drive a car, perform quotidian activities, and interact with family. The fact that HE is frequently reversible emphasizes the importance of identifying and treating this condition.

The diagnosis of overt HE encompasses two sets of criteria: Neuropsychologic and neuromotor. Neuropsychologic assessment focuses on level of consciousness, attention and ability to follow commands, and effect. This is most often graded on a 0 to 4 scale using the West Haven criteria (Table 46-9).<sup>122</sup> Physical examination may elicit asterixis or other evidence of hyperreflexiveness such as clonus or Babinski sign. Other focal findings can include nystagmus or decerebrate posturing. However, focal neurologic findings should prompt appropriate imaging to rule out structural neurologic lesions, because these patients are at risk for intracranial bleeding and are not

immune to other neurologic pathologies such as ischemic brain disease, abscess, and tumor.

It is generally agreed that HE is the result of the failure of the liver to adequately metabolize certain substances that when accumulated are neurotoxic, rather than failure to synthesize substances critical to normal neurotransmission. The proposed World Congress definitions support this by recognizing a type of HE that is associated with normal hepatocellular function but shunting of blood around the liver (type B). Historically, HE has been attributed to hyperammonemia resulting from inadequate hepatic metabolism of ammonia. Although ammonia continues to be considered an important contributor, severity of HE does not necessarily correlate with ammonia levels. This may be explained by recent investigations which have provided evidence for a multitude of other factors and mechanisms contributing to HE, including other gut-derived neurotoxins,  $\gamma$ -aminobutyric acid (GABA) and other endogenous GABA receptor agonists, oxidative stress, inflammatory mediators, hyponatremia, and abnormal serotonin and histamine neurotransmission.<sup>123,124</sup> Nonetheless, ammonia and its effect on astrocytes play a central role in the pathogenesis of HE. Ammonia is a by-product of nitrogen-containing compounds that is toxic and must be removed from the body. The liver is the primary site of ammonia metabolism and excretion via the urea cycle, but the brain, skeletal muscle, and possibly kidneys contribute as well. Unfortunately, neither the brain nor the skeletal muscle is capable of utilizing the urea cycle and instead use glutamine synthetase to synthesize glutamine from ammonia and glutamate. Astrocytes are major constituents of the blood–brain barrier and are the primary location for glutamine synthetase in the brain. Because these are the cells capable of metabolizing ammonia, as ammonia levels rise intracellular levels of glutamine rise in concert. There are two consequences to this: (1) Glutamine, which is osmotically active, pulls water intracellularly, causing astrocyte swelling and cerebral edema; and (2) glutamate, which is an important excitatory neurotransmitter, is first released and then consumed in producing glutamine. Experimental in vitro evidence has demonstrated a glutamate release from astrocytes in response to elevated levels of ammonia.<sup>125</sup> It is thought that this release may be related to the neuroexcitatory signs such as agitation and seizures observed in acute HE (type A). On the other hand, a neuroinhibitory state is characteristic of the HE associated with cirrhosis (type C) and may reflect chronic adaptive changes that include downregulation of glutamate receptors, inactivation of astrocyte glutamate transporters, and an increase in GABAergic tone (Table 46-10).<sup>125</sup> GABA is a major inhibitory neurotransmitter whose receptor complex can be activated by benzodiazepines and inhibited by flumazenil. Subsequent studies of plasma and CSF from HE patients were reported to demonstrate increased

benzodiazepine-like substances. Improvement in mental status following flumazenil administration was observed in HE patients who had not received benzodiazepines, leading to the proposal that the production of endogenous benzodiazepine-like substances contributed to HE.<sup>126,127</sup> Unfortunately, the benefits of flumazenil appear to be limited by its short duration of action and lack of demonstrable survival or recovery advantage.<sup>128,129</sup>

**Table 46-9** West Haven Criteria for Semiquantitative Grading of Mental State

Grade 1	Trivial lack of awareness Euphoria or anxiety Shortened attention span Impaired performance of addition
Grade 2	Lethargy or apathy Minimal disorientation for time or place Subtle personality change Inappropriate behavior Impaired performance of subtraction
Grade 3	Somnolence to semistupor, but responsive to verbal stimuli Confusion Gross disorientation
Grade 4	Coma (unresponsive to verbal or noxious stimuli)

Sepsis is a well-known precipitating factor for HE. Inflammatory mediators such as TNF- $\alpha$ , and cytokines IL-1 and IL-6 cause cytotoxic compromise of the blood–brain barrier, leading to or worsening cerebral edema. Astrocyte swelling is a trigger for production of ROS and RNOS, which can mediate local cell membrane damage and cause further blood–brain barrier permeability.<sup>130</sup>

The initial step in evaluating the patient with liver disease who presents with encephalopathy is to rule out causes other than HE. The differential diagnosis includes other metabolic encephalopathies such as uremia, sepsis, glucose and electrolyte abnormalities, and endocrinopathies. Structural and vascular CNS lesions or CNS infections should also be considered. Because cirrhotic patients are exquisitely sensitive to sedative medications and have impaired hepatic (and often renal) metabolism, careful search for possible drug-related encephalopathy should be undertaken. Once other potential causes have been eliminated, the next step should be a systematic search for an underlying cause or precipitating factor (Table 46-11). Once identified, treatment or elimination should commence as soon as possible and may be sufficient for clinical improvement.

If addressing the underlying cause does not produce improvement, the

next step is to employ therapy designed to either reduce the production of or increase the excretion of ammonia. Historically, the nonabsorbable disaccharide lactulose has been the mainstay of therapy and remains the first-line drug for treating HE.<sup>131</sup> Although the basis for its benefit is unclear there are two proposed mechanisms for its salutary effect. First, anaerobic bacteria in the colon ferment lactulose to produce weak acids and acidify the colon. This acid milieu converts ammonia into ammonium, which is poorly absorbed. Secondly, it is proposed that this acid milieu is also cathartic, and that catharsis augments reduced absorption.

**Table 46-10** Proposed Nomenclature of Hepatic Encephalopathy

HE Type	Nomenclature	Subcategory	Subdivisions
A	Encephalopathy associated with acute liver failure		
B	Encephalopathy associated with portal–systemic bypass and no intrinsic hepatocellular disease		
C	Encephalopathy associated with cirrhosis and portal hypertension/or portal–systemic shunts	Episodic HE	Precipitated Spontaneous <sup>a</sup> Recurrent
		Persistent HE	Mild Severe
		Minimal HE	Treatment-dependent

For definitions, see text.

<sup>a</sup>Without recognized precipitating factors.

Although simple reduction in protein intake seems an intuitive solution, in fact protein restriction may be harmful for cirrhotic patients who tend to have little nutritional reserve due to poor intake and who have likely lost nutritional ground with every hospitalization. Practice guidelines for the treatment of HE patients recommend a normal protein intake (1 to 1.5 g/kg/day), preferably in the form of plant-based rather than animal protein because of its higher calorie to nitrogen ratio.<sup>131</sup>

Zinc is a cofactor in the urea cycle and may be a dietary deficiency in cirrhotic patients. Although it is unclear which patients might benefit, practice guidelines recommend consideration of chronic zinc supplementation to HE patients.

**Table 46-11** Precipitating Factors in Hepatic Encephalopathy

Constipation
Dehydration
Gastrointestinal bleeding
Bowel obstruction or ileus
Infection—esp. spontaneous bacterial peritonitis, sepsis
Excessive dietary protein
Hypokalemia
Hypoglycemia
Hypothyroidism
Hypoxia
Metabolic alkalosis
Anemia
Azotemia/uremia
Hepatic malignancy
Transjugular intrahepatic portal shunt, surgical shunt
Vascular occlusion

## Ascites

Ascites is the most common complication of cirrhosis leading to hospitalization.<sup>132</sup> The occurrence of ascites marks a threshold in the nature of the underlying liver disease and is associated with a 50% mortality rate within 3 years.<sup>133</sup> Thus, the current recommendation is that patients who present with ascites and who are potential candidates for liver transplantation should be referred for liver transplantation evaluation. Not all ascites is hepatic in nature; about 15% has a nonhepatic etiology. Nonhepatic causes include malignancy, cardiac failure, renal disease, pancreatitis, and tuberculosis. Perhaps the most expeditious study to define the nature of new-onset ascites is a paracentesis. In particular, the serum–ascites albumin gradient (SAAG) is extremely useful for delineating portal hypertensive ascites from other causes. It is calculated as the difference between simultaneously measured serum and ascites albumin levels. An SAAG 1.1 mg/dL or more indicates portal hypertension with 97% accuracy.<sup>134</sup> Standard initial therapy for portal hypertensive ascites is salt restriction (2 g/day) and diuretics. Hyponatremia is common among cirrhotic patients with ascites and generally does not warrant fluid restriction unless the serum sodium level is below 120 to 125 mEq/L.<sup>132</sup> Rapid correction of hyponatremia is undesirable because cirrhotic patients are particularly at risk for central pontine myelinolysis, a potentially devastating neurologic complication. Observations in liver transplant recipients suggest limiting correction to 16 mEq/L or less over an 8-day period.<sup>135</sup>

Refractory ascites, defined as ascites that is immutable to sodium restriction, maximum doses of diuretics, and paracentesis, heralds another change in the nature of the underlying cirrhosis. It is the hallmark complication of type II HRS and indicates increased disease severity. Once

patients become refractory to maximum standard medical therapy, the 6-month mortality is 21%.<sup>136</sup> Therapeutic options for patients are limited and include serial paracentesis, liver transplantation, TIPS placement, and peritoneovenous shunt. Although current practice is to replace albumin when ascitic fluid is drained, this practice is not well supported by randomized prospective trials. The reasons for using albumin replacement include preventing paracentesis-induced circulatory dysfunction, minimizing electrolyte disturbances, minimizing the nutritional impact of albumin loss, and preventing renal impairment. Current recommendations are that patients with drainage volumes less than 5 L do not need albumin replacement, and for larger volume paracentesis 6 to 8 g albumin/L may be considered.<sup>132</sup> TIPS placement can generally be expected to improve quality of life by obviating the need for serial paracentesis, but this must be balanced against an increase in encephalopathy and the high incidence of shunt malfunction.<sup>137,138</sup> Peritoneovenous shunting is an older intervention that has generally fallen into disuse because of associated complications and lack of survival benefit. However, for patients who cannot easily travel for serial paracentesis and who are not candidates for TIPS or transplantation, this may be the only option.

Infections of ascitic fluid are sufficiently common that the American Association for the Study of Liver Diseases recommends paracentesis for all hospitalized patients with ascites. SBP is diagnosed when the PMN count in ascitic fluid is 250 cells/mm<sup>3</sup> or more in the absence of any other identifiable intra-abdominal source. Bacterial translocation from the bowel is the most common source of SBP, although nosocomial infection from bacteremia associated with invasive procedures occurs as well. Because cell counts are available more quickly than culture results, the decision to treat is made empirically on that basis. Patients should immediately be treated with a broad-spectrum antibiotic. Sepsis may develop rapidly in these patients and SBP is a recognized precipitating factor for type I HRS. Because of this, timely administration of antibiotics in this fragile population is so important that empiric antibiotics are warranted even for patients who do not meet the diagnostic ascitic fluid PMN cell count but who exhibit signs and symptoms suggesting infection such as fever, abdominal pain, evidence of worsening hepatic or renal function, and otherwise unexplained worsening encephalopathy.<sup>132</sup>

## Varices

Varices, particularly esophageal varices, are one of the end results of portal hypertension. In cirrhosis, increases in portal pressure result from distorted hepatic architecture left in the wake of inflammatory insults. Fibrosis and

regenerative nodules cause impedance to splanchnic flow through the liver and lead to formation of portosystemic collaterals, particularly with the gastric and esophageal venous systems. Progression of portal hypertension leads to increased local production of nitric oxide and, eventually, massive splanchnic vasodilation. Thus, portal hypertension becomes a problem not only of impedance to flow but also of a massive increase in flow to the liver. Rupture of the high-pressure collaterals that are formed is a highly lethal and feared complication of portal hypertension.

Portal hypertension is diagnosed by measurement of the wedged hepatic venous pressure (WHVP). Although this is not a direct measure of portal pressure WHVP has been demonstrated to correlate well with it.<sup>139</sup> This is done by advancement of a catheter into a hepatic vein to wedge position. To correct for the contribution of increased intra-abdominal pressure from ascites, a free hepatic venous pressure or an inferior vena caval pressure should be subtracted from the measured WHVP to give the HVPG. A normal HVPG is 3 to 5 mmHg. Patients with esophageal varices can be expected to have HVPGs of at least 10 to 12 mmHg.<sup>140,141</sup>

Esophagogastroduodenoscopy is the gold-standard procedure for diagnosing varices. Presence of varices correlates with the severity of the underlying liver disease, with incidence increasing from 40% in Child's A patients to 85% in Child's C patients.<sup>142</sup>

Nonselective  $\beta$ -blockers reduce portal pressure by two mechanisms: A decrease in cardiac output ( $\beta_1$ ) and splanchnic vasoconstriction ( $\beta_2$ ). There is no evidence that they prevent formation of varices; however, they are effective as primary prophylaxis for variceal bleeding. For those patients who cannot tolerate  $\beta$ -blockers or in whom they are contraindicated, another option for primary prophylaxis of variceal bleeding is endoscopic ligation. TIPS is associated with a higher incidence of encephalopathy and higher mortality and is not indicated for primary prophylaxis.<sup>142</sup>

Acute variceal bleed should be managed with a combination of volume resuscitation, correction of severe coagulopathy, pharmacologic manipulation of portal pressure, and endoscopic variceal ligation. Although the temptation to vigorously volume resuscitate and completely correct all coagulation abnormalities can be overwhelming in this setting, it should be resisted. Because bleeding is, to some extent, a pressure-related phenomenon, aggressive volume replacement may lead to resistant or recurrent bleeding.<sup>143,144</sup> The goal instead should be adequate resuscitation to maintain a hemoglobin level of 8 mg/dL and consideration of blood product transfusion to improve significant abnormalities in platelet count and INR.<sup>142</sup> Elective intubation for airway protection is often warranted in these patients as well. Medications to reduce portal pressure include vasopressin and its analogues and somatostatin and its analogues. Although  $\beta$ -blockers can reduce portal

pressures, their effect on systemic pressures makes them undesirable in this setting. Early endoscopic variceal ligation in combination with pharmacotherapy is the preferred treatment for acute variceal bleed.

Resistant or early recurrent variceal bleeding occurs in about 10% to 20% of patients. A measured HVPG above 20 mmHg is a risk factor for failure of standard therapy, predicting greater length of ICU stay as well as greater transfusion requirements.<sup>145</sup> Balloon tamponade can be effective in this setting, but is associated with significant and potentially lethal complications such as esophageal rupture or necrosis and perforation, migration of the balloon components, and aspiration. If employed, it is recommended as a bridge to more definitive therapy such as surgical shunt or TIPS.<sup>142</sup>

## Chronic Cholestatic Disease

Biliary obstruction increases pressures in the bile ducts, leading to reflux of bile into the liver sinusoids where it may also communicate with the vascular system. Serum levels of bilirubin, bile salts, and AP (which is synthesized by the biliary epithelium) rise. If bacteria are present in bile, the patient is at risk for infectious complications such as ascending cholangitis, hepatic abscess, and sepsis as well. Cholestasis and hyperbilirubinemia are associated with an increased incidence of acute kidney injury. This may be mediated by endotoxemia, as the result of both sepsis and loss of bile salts to the vascular space. Bile salts are normally secreted into the intestine where they prevent bacterial overgrowth and bind endotoxin, thereby preventing its absorption into the portal circulation. Loss of intestinal bile salts because of biliary obstruction may cause portal and systemic endotoxemia, leading to kidney injury. Kidney injury may additionally be exacerbated by the induced diuresis, as well as impairment of myocardial contractility, resulting from elevated serum levels of bile salts.<sup>146,147</sup> It has also been noted that patients who come to transplant for the chronic cholestatic diseases, PBC and primary sclerosing cholangitis (PSC), have evidence of preserved or hypercoagulability on the basis of increased incidence of portal venous thrombosis, elevated levels of TAT complexes, and thromboelastographic indices consistent with hypercoagulability.<sup>148,149</sup>

Chronic cholestatic disease in the adult population is primarily the result of immunologic mechanisms resulting in PBC or PSC. These diseases are frequently associated with other autoimmune pathology.

PBC is a disease characterized by the progressive destruction of small intrahepatic bile ducts, together with portal inflammation that eventually leads to cirrhosis. The laboratory hallmark of PBC is the antimitochondrial antibody, which is present in 95% of patients. Liver biopsy confirms diagnosis, as well as providing histologic disease staging. The typical disease

course is one of steady progressive loss of small bile ducts together with increasing fibrosis, leading to cirrhosis over the course of 10 to 20 years. Ursodeoxycholic acid, which may have immunomodulatory effects, is the only drug demonstrated to retard progression of the disease and offer survival benefit. Liver transplantation is the most definitive therapy, but is associated with a recurrence rate of 10% to 35%.<sup>150</sup>

PSC is a progressive inflammatory disease of the medium and large intra- and extrahepatic bile ducts. The diagnostic studies of choice are ERCP and magnetic resonance cholangiopancreatography (MRCP), which reveal the characteristic beaded pattern of the biliary tree caused by multiple stenotic lesions. PSC has an extremely high association with inflammatory bowel disease (IBD), primarily ulcerative colitis but occasionally Crohn disease. It is also associated with other autoimmune diseases, such as insulin-dependent diabetes and psoriasis. Other contributors to the morbidity of PSC are recurrent bacterial cholangitis, cholangiocarcinoma, and, particularly in those patients with coexisting IBD, colon carcinoma. Over the average 15-year disease course of PSC, 15% to 30% of patients are likely to develop cholangiocarcinoma, which carries a very poor prognosis and may cause ineligibility for transplant.<sup>151</sup> Liver transplantation is the most definitive therapy for PSC, but is associated with disease recurrence.

## Chronic Hepatocellular Disease

CLD is a major public health burden in the United States, with an increase in prevalence from 11.78% in the period 1988 to 1994 to 14.78% in the period 2005 to 2008. Chronic viral hepatitis, particularly hepatitis C, has historically been the most common cause of CLD, but recent data show that NAFLD has overtaken chronic hepatitis for this distinction. In the period 2005 to 2008, the prevalence of the most common causes of CLD was hepatitis B 0.3%, hepatitis C 1.7%, alcoholic liver disease 2.0%, and NAFLD 11.0%.<sup>13</sup> In 2013, NAFLD overtook alcoholic liver disease to become the second leading etiology for new registration on the liver transplantation waitlist.<sup>152</sup> Although chronic hepatitis C is still the leading cause of liver transplantation and is implicated in the increase in cases of HCC, the rise in prevalence of NAFLD together with the recognition that it can progress to cirrhosis and is a risk factor for HCC suggests that it is poised to become the next hepatic scourge.

## Hepatocellular Carcinoma

Worldwide, HCC is the third leading cause of cancer-related death. Within the United States, it is the fifth most common cancer in men and the seventh in women.<sup>153</sup> Risk factors include chronic viral hepatitis infection,

hemochromatosis, and cirrhosis of any provenance. The prevalence of underlying cirrhosis in patients with HCC is 80% to 90%. Even if the HCC patient does not have cirrhosis, there is almost always an underlying chronic hepatitis/chronic necroinflammatory state that seems to be key ingredient for HCC. Among patients with chronic viral hepatitis, the presence of cirrhosis or evidence of active inflammation (characterized by elevations in serum ALT) leads to increased HCC occurrence compared to patients without cirrhosis or those with persistently normal to near-normal ALT.<sup>154</sup> The American Association for the Study of Liver Diseases recommends surveillance of at-risk patients. Ideally this should be in the form of liver ultrasonography every 6 months, with the use of  $\alpha$ -fetoprotein only if ultrasound is not available.<sup>155</sup>  $\alpha$ -Fetoprotein lacks adequate sensitivity and specificity to be an effective screening tool, but may be valuable in diagnosis because a level above 200 ng/mL in a cirrhotic patient with a hepatic mass has a high positive predictive value for HCC.<sup>155</sup> Diagnosis of HCC can often be made with noninvasive studies, with biopsy reserved for lesions with atypical or discordant imaging.

Surgical resection is the optimal treatment for HCC for those patients who have sufficient hepatic reserve. Unfortunately many patients with HCC have cirrhosis and are unable to tolerate resection. In the United States, fewer than 5% of patients are candidates for resection.<sup>153</sup> Liver transplantation can be an option for those patients who are not resection candidates but whose disease can be expected to have transplant outcomes similar to that of other indications for transplant. The Milan criteria (one tumor <5 cm or three tumors all <3 cm) define those patients, and those patients who meet the criteria and are transplanted have 5-year survival rates of 65% to 78% compared to 5-year survival of 68% to 87% for nontumor indications.<sup>156</sup>

Patients who are neither surgical candidates nor transplant candidates may be managed by radiofrequency ablation or chemoembolization of their tumors. In addition, some centers use these therapies to maintain transplant eligibility for patients on the waiting list.

## Nonalcoholic Fatty Liver Disease

NAFLD describes a range of conditions characterized by excessive fat deposition in the liver. NAFLD ranges in severity from simple fat deposition (steatosis) to fat deposition together with inflammation and hepatocellular necrosis (steatohepatitis or NASH). Primary NAFLD is associated with insulin resistance and its attendant manifestations, which are components of the metabolic syndrome: Obesity, central adiposity, type II diabetes, arterial hypertension, and hypertriglyceridemia. In fact it is often referred to as the hepatic manifestation of the metabolic syndrome. The prevalence of NAFLD increases with age, is greater in males, and differs by ethnicity. In the United

States, the prevalence of NAFLD is 45% in Hispanics, 33% in Caucasians, and 24% in African-Americans,<sup>157</sup> with an estimated overall prevalence of 30%. Unsurprisingly, NAFLD is the most common cause of elevated liver enzymes in adults.<sup>158</sup> NAFLD may coexist with other hepatic pathologies and exacerbates damage when it appears together with chronic hepatitis C, hemochromatosis, or alcoholic liver disease.<sup>159</sup> Within the disease spectrum of NAFLD, only NASH is associated with the serious consequences of HCC and cirrhosis. The gold standard for distinguishing NASH from other NAFLD is liver biopsy with the key features of macrovesicular steatosis, lobular inflammation, hepatocyte ballooning, and often perisinusoidal fibrosis. The prevalence of NASH in the United States is estimated to be 3% to 5%.<sup>158</sup> There is evidence, although from small studies and with different end points, that lifestyle modifications that improve insulin sensitivity such as weight loss and exercise can reduce intrahepatic lipid content in NASH.<sup>160</sup> Medications that may augment weight loss, such as orlistat and rimonabant, have been shown to result in histologic improvement in NASH when associated with actual weight loss. For those patients who are unable to lose weight by more conservative means, bariatric surgery has been shown to result in dramatic histologic and chemical improvement, with decreased steatosis/inflammation on biopsy and decreases in serum aminotransferases. In a meta-analysis of morbidly obese patients who underwent bariatric surgery, the pooled patient incidence of biopsy-proven NASH was 53.87%. Of these patients, 81.3% showed improvement or resolution of steatohepatitis on follow-up biopsy, with 69.5% showing complete resolution.<sup>161</sup>

## Preoperative Management

### *Hepatic Evaluation*

The evaluation of hepatic function begins with a thorough history, starting with an inquiry into risk factors and the presence of symptoms attributable to CLD. Prior episodes of jaundice, particularly in relationship to surgical procedures and anesthesia, should be thoroughly investigated. Alcohol consumption, use of recreational or illicit drugs, medications (including herbal products), presence of tattoos, sexual promiscuity, consumption of raw seafood, and a history of travel to areas in which hepatitis is endemic should be sought. Symptoms of fatigue, anorexia, weight loss, nausea, vomiting, easy bruising, pruritus, dark-colored urine, biliary colic, abdominal distention, and gastrointestinal bleeding warrant further investigation for the presence of liver disease.

Physical examination findings suggestive of active liver disease include icterus, palmar erythema, spider angiomas, gynecomastia,

hepatosplenomegaly, ascites, testicular atrophy, petechiae, ecchymoses, and asterixis.

In the absence of findings suggestive of liver disease, routine laboratory tests to assess hepatocellular integrity and hepatic synthetic function are not warranted. Routine laboratory testing may yield false-positive results, and true-positive results are infrequent in asymptomatic patients. Among over 19,000 Air Force trainees, 0.5% had liver-enzyme elevations; however, the cause was found in only 12 of the 99 with elevations.<sup>162</sup> In a study of over 7,600 surgical patients who underwent routine preoperative screening, liver-enzyme tests were abnormal in roughly 1 of 700 (0.1%) asymptomatic patients. Of the 11 patients with elevations, 3 (1 in 2,500 or 0.04%) developed jaundice.<sup>163</sup>

Because the normal range for laboratory tests is defined as the mean plus or minus two standard deviations, 5% of normal patients can be expected to fall outside the normal range, with 2.5% following above the upper limit of normal. As a result, minor elevations of liver-enzyme results—those less than twice the normal range—may be of no clinical importance.<sup>164</sup> The recommended approach is to avoid testing liver enzymes in asymptomatic patients. Nonetheless, in the presence of abnormal results (in an asymptomatic patient) the safest approach is to repeat the results; in the absence of elevations greater than twice the upper limits of normal it is reasonable to proceed with surgery.

In patients with more substantial elevations of liver enzymes, causes include alcohol abuse, medications, chronic hepatitis B and C, NASH, autoimmune hepatitis, hemochromatosis, Wilson disease, and  $\alpha_1$ -antitrypsin deficiency. Nonhepatic causes include celiac sprue and muscle diseases. Medications include selected antibiotics, antiepileptic drugs, lipid-lowering agents, nonsteroidal anti-inflammatory agents, and sulfonylureas. Herbal medications and drugs of abuse are also associated with liver-enzyme abnormalities.<sup>164</sup>

### *Perioperative Risk Associated with Liver Disease*

In patients with known liver disease, the etiology of hepatic dysfunction should be determined. Based on retrospective, small case series from the 1960s and 1970s, acute hepatitis confers a prohibitive risk for elective surgery. In a series of 36 patients with undiagnosed hepatitis who underwent laparotomy (for suspected biliary obstruction or hepatic malignancy) nearly one-third died. All patients with acute hepatitis, due to either virus or alcohol, died. The majority of patients suffered complications that included bacterial peritonitis, wound dehiscence, and hepatic failure.<sup>165</sup>

With improved diagnostic testing, which includes serologic testing for

hepatitis C, ultrasound testing for gallstones, and improved imaging techniques for hepatic cancer, it is far more likely today that accurate diagnoses can be made preoperatively. As a result laparotomies are unlikely in patients with unsuspected hepatitis. In the absence of accumulating evidence, consensus opinion is that elective surgery should be postponed in patients with acute hepatitis.<sup>166,167</sup>

In patients with CLD it is not feasible to postpone surgery until recovery. A number of studies have investigated the risk of surgery in patients with cirrhosis.<sup>168–171</sup> Each of the studies identified various components of the Child–Turcotte–Pugh score, as well as the composite score, as important prognostic factors for perioperative mortality.

Child and Turcotte first described their classification system in 1964. They identified five factors—albumin, bilirubin, ascites, encephalopathy, and nutritional status—as important prognostic factors for patients with cirrhosis. Each of the factors was categorized according to three levels of severity and combined to generate a composite score leading to an assignment of one of three classes of severity (class A, B, or C, with C representing the most severe hepatic dysfunction). In 1972 Pugh modified the score, replacing nutritional status with PT ([Table 46-12](#)). The score was originally designed for patients undergoing portosystemic shunt procedures, but has subsequently been applied to patients with cirrhosis undergoing other surgeries. In studies conducted over multiple decades, the modified Child score performed similarly in predicting postoperative mortality: 10% in Child A, 17% to 30% in Child B, and 60% to 80% in Child C.<sup>170–172</sup> The 3-month mortality for hospitalized patients not undergoing surgery was 4% for Child A, 14% for Child B, and 51% for Child C.<sup>171</sup>

The MELD score was originally designed to predict mortality for patients undergoing transjugular intrahepatic portocaval shunt (TIPS) procedures.<sup>173</sup> Subsequently it was identified as an improvement to the Child score for the allocation of organs for liver transplant candidates due to its replacement of the subjective elements of the Child score (ascites, encephalopathy) with more objective ones, INR and creatinine. The MELD score is a useful predictor of 90-day wait list mortality in liver transplant candidates.<sup>174</sup> The MELD score weighs the continuous variables linearly or logarithmically instead of assigning arbitrary categories, as is the case with the Child score: MELD score =  $9.57 \times \log_e(\text{creatinine mg/dL}) + 3.78 \times \log_e(\text{bilirubin mg/dL}) + 11.2 \times \log_e(\text{INR}) + 6.43$ .

**Table 46-12** Modified Child–Pugh Score

	Points <sup>a</sup>		
Presentation	1	2	3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time			
Seconds prolonged	<4	4–6	>6
International normalized ratio	<1.7	1.7–2.3	>2.3
Bilirubin (mg/dL) <sup>b</sup>	<2	2–3	>3
Ascites	Absent	Slight–moderate	Tense
Encephalopathy	None	Grade I–II	Grade III–IV

<sup>a</sup>Class A = 5 to 6 points; B = 7 to 9 points; C = 10 to 15 points.

<sup>b</sup>Cholestatic diseases (e.g., primary biliary cirrhosis) produce bilirubin elevations that are disproportionate to the hepatic dysfunction. Thus, the following adjustments should be made: Assign 1 point for a bilirubin level of 4 mg/dL; 2 points for bilirubin concentrations between 4 and 10 mg/dL; and 3 points for bilirubin >10 mg/dL.

**5** The MELD score appears to predict perioperative mortality of cirrhotic patients. In a single-center study of 140 surgical procedures, the *c*-statistic for the MELD score's ability to predict 30-day mortality was 0.72. A *c*-statistic of 0.5 indicates predictive ability similar to chance (a 50:50 likelihood of predicting the outcome), whereas a *c*-statistic of 0.7 and higher is considered useful. In the cohort of patients undergoing abdominal surgery, the *c*-statistic improved to 0.80. In this study a MELD score between 25 and 30 was associated with a 30-day mortality of 50% after abdominal surgery.<sup>175</sup> Each point in the MELD score up to a score of 20 equated to an additional 1% mortality; each MELD point over 20 equated to an additional 2% mortality. A larger study of 772 cirrhotics found similar results. In this study, 75% of the patients underwent abdominal surgery. A MELD score of 25 was associated with 30-day mortality of 50%. Other than the MELD score, the other important predictors of perioperative mortality in cirrhotics were age (age >70 equated to 3 MELD points) and coexisting disease (ASA physical status > IV equated to 5 MELD points).<sup>176</sup> The perioperative complications encountered by cirrhotic patients include liver failure, postoperative bleeding, infection, and renal failure. These authors concluded that patients with a MELD score of less than 11 have a low postoperative mortality and represent an acceptable surgical risk. However, based on the list of complications, the authors recommend that these patients should preferably have surgery at institutions with a liver transplant center. In patients with a MELD score of 20 or higher, the high mortality risk contraindicates elective procedures until after liver transplantation.<sup>176</sup>

**6** Medical management undertaken to optimize cirrhotic patients undergoing surgery should be directed toward treating active infection, optimizing central blood volume and renal status while minimizing ascites,

and improving encephalopathy and coagulopathy. However, there is little evidence to support specific goal-directed targets for preoperative care. The perioperative risk depends more on the operative site and the degree of liver impairment than the anesthetic technique. Upper abdominal surgery (cholecystectomy), when compared to hysterectomy, was associated with liver-enzyme abnormalities, whereas the anesthetic technique (halothane, enflurane, or fentanyl) was not.<sup>177</sup> In a retrospective study of 733 cirrhotic patients mortality was associated with a number of factors in addition to the Child score: male gender, the presence of ascites, cryptogenic cirrhosis (vs. other etiologies), elevated creatinine, preoperative infection, higher ASA physical status, and surgery on the respiratory system.<sup>178</sup> The presence of each additional factor conferred additional risk. For instance, 1-year mortality in patients with six risk factors was over 80%; mortality with two risk factors was approximately 30%.

In addition to optimizing medical management, efforts should be made to minimize surgical risk through the consideration of less invasive surgery. Gallstones are twice as common in cirrhotic patients as in patients without cirrhosis.<sup>168</sup> Laparoscopic surgery appears safe in patients with Child–Pugh A and B cirrhosis. In uncontrolled retrospective studies the advantages included low mortality and shorter hospital stay.<sup>179,180</sup> However, Child’s C patients may benefit from percutaneous drainage of the gallbladder rather than a laparoscopic approach.<sup>180</sup> In a series of over 4,200 laparoscopic cholecystectomies from Taiwan, the group with cirrhosis ( $n = 226$ ) had a mortality of approximately 1:100, whereas mortality was 1:2,000 for those without cirrhosis.<sup>181</sup> Meta-analyses of randomized trials in cirrhotic patients showed the laparoscopic approach was associated with less blood loss, shorter operative time, and shorter hospitalization compared to an open approach.<sup>182,183</sup> Preoperative decompression of portal hypertension by TIPS may improve outcomes in patients with severe portal hypertension.<sup>184</sup> However, TIPS is associated with increases in pulmonary artery pressure and can worsen encephalopathy.<sup>97,185</sup>

## Intraoperative Management

### *Monitoring and Vascular Access*

In addition to routine noninvasive monitors, the need for arterial pressure monitoring should be considered for patients with end-stage liver disease. The decision is based on the presence of preoperative systemic hypotension due to vasodilation, anticipated blood loss, the need for intraoperative laboratory studies, coexisting disease, and age. Arterial cannulation should be considered in patients undergoing liver resection. The usefulness of CVP monitoring to

predict fluid responsiveness has been questioned.<sup>186</sup> Some experts have abandoned CVP monitoring in the setting of liver resection.<sup>187–189</sup> In our practice we do not place a CVP catheter exclusively for monitoring. Pulmonary artery catheterization is used for patients with known or suspected pulmonary artery hypertension and for patients with a low cardiac ejection fraction. Transesophageal echocardiography (TEE) is a sensitive monitor for the assessment of preload, contractility, ejection fraction, regional wall motion abnormalities, and emboli. In a small series of patients with esophageal varices, TEE universally aided in diagnosis and was not associated with bleeding complications, although transgastric views were avoided to minimize esophageal manipulation.<sup>190</sup> Other authors have confirmed the safety of TEE in this population.<sup>191,192</sup> Viscoelastic coagulation testing using TEG or thromboelastometry, if available, may be a useful guide for coagulation management.<sup>59</sup> Viscoelastic tests reflect the overall effects of altered levels of endogenous pro- and anticoagulant factors, which may be in balance if both are reduced proportionally. Recently the clinical significance of an abnormal PT as a predictor of bleeding risk has been questioned because this test reflects only procoagulant factor levels rather than the rebalanced hemostatic system, which may be capable of normal thrombin generation.<sup>60</sup>

## *Selection of Anesthetic Technique*

### **Neuraxial versus General Anesthesia**

The effect of neuraxial anesthesia on hepatic blood flow appears related to alterations of systemic blood pressure.<sup>193,194</sup> More recent studies support the conclusion that hepatic blood flow is reduced by epidural anesthesia and, interestingly, further reduced by an infusion of norepinephrine.<sup>195</sup> However, other studies suggest that vasopressors (ephedrine and dopamine) restore hepatic blood flow.<sup>196,197</sup> Other data conflict with this, suggesting that dopamine does not improve splanchnic blood flow.<sup>198</sup> Despite this confusing picture high (T-5) neuraxial blocks appear to reduce hepatic blood flow, and this effect may not be reversed when block-related hypotension is corrected with catecholamines. Thus, avoidance of high neuraxial block and hypotension seems prudent in patients with advanced liver disease.

Standard contraindications to neuraxial blockade should be considered and weighed against the procedure's benefits on a case-by-case basis. Many patients with advanced hepatic disease may not warrant consideration for neuraxial techniques due to coagulopathy and/or thrombocytopenia. Nerve blockade may be appropriate even when neuraxial blockade is contraindicated. The transversus abdominal plane (TAP) block has been used successfully for abdominal surgery, including hepatobiliary procedures.<sup>199,200</sup>

However, the efficacy has been questioned and complications, including abdominal wall hematoma, have been reported.

## **Volatile Anesthetics**

Volatile anesthetics decrease hepatic blood flow, albeit to a variable degree.

Halothane is more likely than other inhaled anesthetics to cause cardiovascular depression and results in the greatest reduction of hepatic blood flow. Newer volatile agents, including isoflurane and sevoflurane, have less significant effects on hepatic blood flow.<sup>201</sup> At anesthetic concentrations of 1 MAC these agents produce very little reduction in hepatic blood flow. However, desflurane appears to more substantially decrease hepatic blood flow at 1 MAC, causing a 30% reduction at this anesthetic depth.<sup>202</sup> Animal studies suggest desflurane preserves total hepatic blood flow.<sup>203</sup> At higher anesthetic concentrations isoflurane results in a dose-dependent reduction in hepatic blood flow beyond that seen at 1 MAC. This dose-dependent reduction in hepatic blood flow does not occur with sevoflurane. In animal studies both sevoflurane and isoflurane maintain the hepatic arterial buffer response, which increases hepatic arterial blood flow in the presence of reductions of portal blood flow.<sup>204,205</sup>

In addition to variable effects on hepatic blood flow, concern exists regarding the production of reactive intermediates during the metabolism of volatile anesthetics. Halothane hepatitis, described earlier in this chapter, is largely responsible for these concerns. However, there is little evidence to suggest that other volatile anesthetics are responsible for hepatic complications. With the exception of sevoflurane, volatile anesthetics undergo metabolism that yields reactive TFA intermediates. These bind to hepatic proteins and produce an immunologic reaction. However, the incidence of liver injury correlates with the extent to which inhaled anesthetics undergo oxidative metabolism. Although 20% of halothane and 2.5% of enflurane are metabolized to TFA intermediates, the corresponding percentages for isoflurane and desflurane are 0.2% and 0.02%, respectively.<sup>53</sup>

Although there is a lack of evidence supporting a role for current volatile anesthetics in causing hepatic injury, several reports describe instances when repeated exposure to halogenated anesthetics is associated with hepatic dysfunction. Because there is no pathognomonic liver pathology, the diagnosis is based on the exclusion of other causes and a history of recent exposure. The potential for toxic metabolites seems related to the degree of *in vivo* biotransformation of the various halogenated anesthetics.<sup>206</sup> Nonetheless, desflurane, which undergoes the least biotransformation, has been implicated in a case of hepatotoxicity in a patient who may have been sensitized by previous halothane exposure.<sup>207</sup>

Sevoflurane undergoes more extensive metabolism than isoflurane or desflurane, rapidly producing detectable plasma concentrations of fluoride and hexafluoroisopropanol (HFIP), which are conjugated by the liver and excreted by the kidney. In distinction to the other agents, sevoflurane does not produce reactive TFA metabolites or fluoroacetylated liver proteins. This fact led to the suggestion that patients sensitized to other volatile anesthetics could be safely anesthetized with sevoflurane.<sup>208</sup> Indeed, despite the more extensive metabolism, there is no evidence that sevoflurane's metabolites, including compound A (produced in a reaction with carbon dioxide absorbents), produce hepatic injury.<sup>209</sup> In rodents there is evidence that sevoflurane protects against hepatic ischemia–reperfusion injury while isoflurane does not.<sup>210</sup> However, there is a single case report of ALF occurring 2 days after sevoflurane exposure for heart surgery.<sup>211</sup> Although the cause in this case is not certain, this report suggests that patients who are sensitized to one volatile anesthetic (i.e., evidence of hepatic injury following prior exposure) should not subsequently receive any other fluorinated anesthetic.

## **Nitrous Oxide**

Nitrous oxide administration has not been shown to cause hepatocellular injury in the absence of hepatic hypoxemia.<sup>212</sup> In patients with mild alcoholic hepatitis, a nitrous oxide/narcotic technique was compared to nitrous oxide/enflurane and tetracaine spinal techniques for peripheral surgery. None of the techniques were associated with biochemical worsening.<sup>213</sup> Due to sympathomimetic effects, nitrous oxide can lead to decreased hepatic blood flow, and inhibition of methionine synthase can occur after even brief exposures. However, the clinical significance of these effects is unclear, although prolonged or repeated exposure could induce a vitamin B<sub>12</sub> deficiency.<sup>214</sup>

## **Intravenous Anesthetics**

IV anesthetics, such as propofol, etomidate, and midazolam, do not appear to alter hepatic function when given for a short duration during minor procedures. The effects of IV anesthetics after prolonged infusions and in patients with advanced liver disease are not well studied. A rare syndrome of lactic acidosis, lipemia, rhabdomyolysis, hyperkalemia, myocardial failure, and death has been reported after prolonged infusions of propofol. The initial reports were in children.<sup>215</sup> Liver dysfunction resulting in altered lipid metabolism may predispose to the propofol infusion syndrome, as may genetic defects.<sup>216</sup> Patients on prolonged propofol infusions should be monitored for worsening lactic acidosis and escalating vasopressor requirements. In the event of such findings, propofol should be discontinued.

There is no evidence that opioids have an effect on hepatic function that is independent of hepatic blood flow. All opioids increase sphincter of Oddi pressure. Some authors have suggested that morphine causes spasm in the sphincter of Oddi, but a review failed to show a differential effect, concluding that morphine may be preferred over meperidine for the treatment of patients with acute pancreatitis due to less risk of seizures.<sup>217</sup>

### **Pharmacokinetic and Pharmacodynamic Alterations**

The decreased functional mass of hepatocytes and reduced hepatic blood flow due to portocaval shunts lead to reduced metabolism of drugs that rely on hepatic metabolism for clearance.

Factors that affect hepatic clearance include blood flow to the liver, the fraction of the drug unbound to plasma proteins, and intrinsic clearance. Drugs with low extraction ratios, less than 0.3, have restrictive hepatic clearance. Clearance of drugs in this class is affected by protein binding, the induction or inhibition of hepatic enzymes, age, and hepatic pathology, but clearance is not significantly affected by hepatic blood flow. Drugs with a high extraction ratio (greater than 0.7) undergo extensive first-pass metabolism, which alters their bioavailability after oral administration. Regardless of the route of administration, drugs with high extraction ratios are significantly affected by alteration in hepatic blood flow, which can occur with hemodynamic changes or hepatic inflow clamping during liver resection. High extraction ratio drugs tend to have short elimination half-lives (e.g., propranolol  $t_{1/2} = 3.9$  hours).

Benzodiazepines are an example of a drug with a low extraction ratio. As is commonly the case for drugs with low extraction ratios, the elimination half-life can be prolonged (diazepam  $t_{1/2} = 43$  hours). Studies have shown conflicting effects of cirrhosis on the metabolism of midazolam, possibly due to changes in protein binding.<sup>218,219</sup> As hepatic protein synthesis declines with advancing liver disease, the drug fraction bound to protein decreases. Because only the unbound drug is available for metabolism by hepatic enzymes, the elimination may be unaffected despite a reduction in intrinsic hepatic clearance.<sup>220</sup> Bilirubin and bile acids can increase the unbound drug fraction by displacing drugs from protein binding sites. An increase in the free fraction of a drug leads to enhanced effects. The volume of distribution can increase with an increase in the unbound drug. However, the volume of distribution of thiopental, another drug with a low extraction ratio, is not altered in cirrhotic patients.<sup>221</sup> This illustrates the complex interactions that affect pharmacokinetics in patients with end-stage liver disease. However, the altered pharmacodynamic effects that occur in patients with encephalopathy frequently lead to an increased sensitivity to sedatives and analgesics.

Opioid metabolism is reduced in patients with liver disease. Dosing intervals should be increased to avoid drug accumulation. Prolonged elimination is more prominent with morphine and meperidine than the shorter-duration synthetic opioids, although contradictory data exist that suggest pharmacokinetics is not significantly altered by liver disease. The clearance of the meperidine metabolite normeperidine is reduced in liver disease, which can lead to neurotoxicity.<sup>222</sup> The elimination of a single IV opioid bolus is less affected than a continuous infusion due to redistribution to storage sites. Remifentanyl, rapidly hydrolyzed by blood and tissue esterases, is an exception among the opioids as its elimination is independent of both hepatic function and the duration of infusion. The pharmacodynamic effects of opioids are altered by liver disease, which argues for a dose reduction in patients with advanced disease because of the ability to precipitate or worsen encephalopathy.

Most induction agents, including ketamine, etomidate, propofol, and thiopental, are highly lipophilic and have high extraction ratios.<sup>223</sup> Although elimination should be prolonged in the presence of liver disease, clearance in cirrhotics is similar to normal patients. However, the pharmacodynamic effects are more pronounced, and in some cases, as with dexmedetomidine and the benzodiazepines, the duration of action can be prolonged.<sup>224</sup>

The intermediate-duration neuromuscular blocking agents metabolized by the liver, vecuronium and rocuronium, exhibit a prolonged duration of action in patients with liver disease.<sup>225,226</sup> Pancuronium's action is also prolonged. Despite this, a resistance to the initial dose of neuromuscular blocker typically occurs due to elevated  $\gamma$ -globulin concentrations and an increase in the volume of distribution (due to edema and/or ascites). Atracurium and cis-atracurium undergo organ-independent elimination. Their durations of action are not affected by liver disease. However, their metabolite, laudanosine, is eliminated by the liver but neurotoxicity has not been reported.<sup>227</sup> Succinylcholine metabolism is altered due to reduced plasma cholinesterase activity in cirrhotic patients; however, the clinical impact is rarely significant.

## **Vasopressors**

In contrast to the increased response to sedatives, patients with liver disease exhibit a reduced response to endogenous vasoconstrictors, including angiotensin II, AVP, and norepinephrine.<sup>228</sup>

Hyporesponsiveness to catecholamines may be modulated by the release of nitric oxide, prostacyclin, and other endothelial-derived factors in response to humoral and mechanical stimuli.<sup>229</sup>

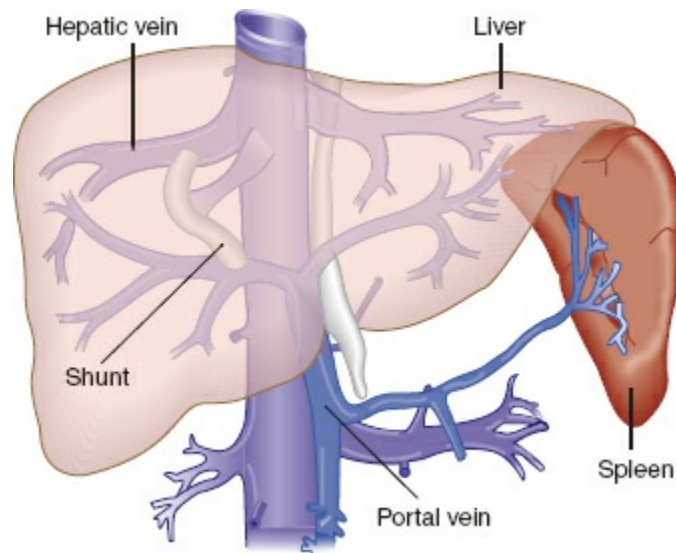

## ***Volume Resuscitation***

The selection of fluid and blood products for volume resuscitation is, in general, similar in patients with and without liver disease. However, in end-stage liver disease serum albumin function is quantitatively and qualitatively decreased.<sup>230</sup> Albumin has three major indications in the treatment of cirrhotic patients.<sup>231</sup> The first is after large volume (4 to 5 L) paracentesis.<sup>232</sup> The second is in the presence of SBP to prevent renal impairment, specifically in patients with bilirubin greater than 4 mg/dL or creatinine higher than 1 mg/dL.<sup>232</sup> The third situation is in the presence of type I HRS, where its use is beneficial in conjunction with splanchnic vasoconstrictors. In a randomized trial of terlipressin with and without concomitant albumin, a higher proportion (77%) of the group that received albumin showed a complete response (defined as a creatinine <1.5 mg/dL) compared to the terlipressin-only group (25%).<sup>233</sup>

## ***Transjugular Intrahepatic Portosystemic Shunt Procedure***

TIPS creates a connection between the portal and systemic circulations using a minimally invasive technique (Fig. 46-2). The indications are to decompress portal hypertension in the setting of esophageal varices and/or intractable ascites.

Sedation is commonly used to facilitate placement, though some proceduralists prefer general anesthesia, as it limits patient movement, controls diaphragmatic excursion, and reduces the risk of aspiration. In patients with recent variceal bleeding, volume resuscitation may be necessary. Due to coagulopathy, patients may require clotting factors and/or platelets before the procedure.<sup>234</sup> Complications include pneumothorax or vascular injury during access to the jugular vein. Dysrhythmias can occur during catheter insertion due to stimulation of the endocardium. Providers should be prepared for the possibility of hemorrhage, which can occur in the presence of extrahepatic artery or portal vein puncture.<sup>235</sup>

**Figure 46-2** Transjugular intrahepatic portosystemic shunt procedure. A stent (or stents) is passed through the internal jugular vein over a wire into the hepatic vein. The wire and stent or stents are then advanced into the portal vein, after which blood can pass through the portal vein into the hepatic vein and bypass and decompress dilated esophageal veins.

## Hepatic Resection

In the late 1800s, the first gastrectomies and cholecystectomies were performed in Europe, but surgery on the liver was regarded as dangerous, if not impossible.<sup>236</sup> In 1908, Pringle described the technique of digital compression of the hepatic hilar vessels to control bleeding, which was a significant advance. Lortat-Jacob is credited with the first right hepatectomy in 1952. Another advance occurred in 1957 when segmental liver anatomy was described by Couinaud and others (Fig. 46-3).<sup>237</sup>

Despite these advances, hepatic surgery was associated with operative mortality rates of 20% or more as recently as the 1980s. Hemorrhage was a **1** significant cause of morbidity and mortality. Persistence, along with further advances in surgery, anesthesia, and intensive care led to a reduction of mortality. Today hepatic resections are performed with mortality rates of 5% or less. Partial hepatectomy in normal, noncirrhotic livers is associated with mortality rates of 1% to 2%.<sup>238</sup> The percentage of patients requiring major hepatectomy (resection of three or more liver segments) for primary or secondary cancer appears to be decreasing; however, the perioperative mortality of major hepatectomy appears unchanged over time.<sup>239</sup> Further improvements in outcome are most likely to come from efforts to preserve parenchyma and prevent abdominal infection.

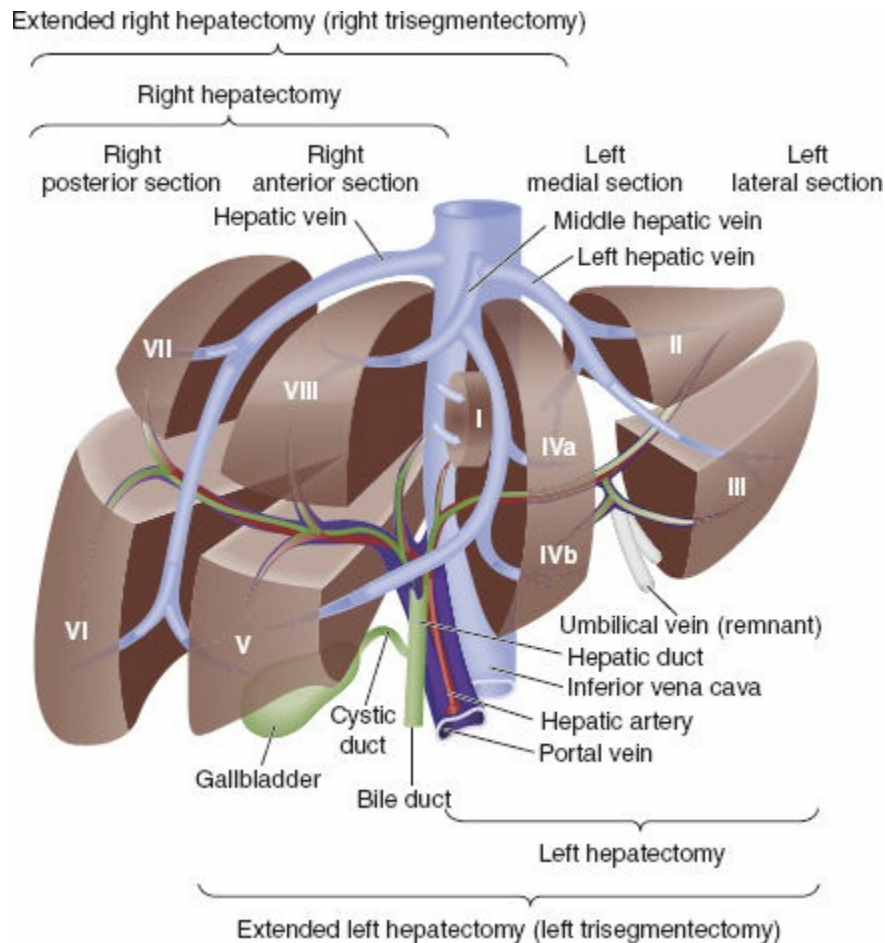

Improved surgical technique with avoidance of the thoracoabdominal approach, which was associated with high morbidity, contributes to improved outcomes. Smooth fracture of liver parenchyma accompanied by bipolar

coagulation made parenchymal transection possible. New transection techniques using ultrasonic dissectors, high-pressure water jets, and/or harmonic scalpels may be helpful, but they have not been proven to be superior to conventional clamp crush techniques.<sup>240–242</sup> Preoperative imaging techniques delineate variations in portal, arterial, and bile duct anatomy. Transfusion is necessary in less than 20% of patients.<sup>243,244</sup>

Yet, bleeding remains a major complication, and the hepatic veins are a significant source of blood loss. Techniques to maintain CVP at normal or even low (<5 cm H<sub>2</sub>O) levels has been suggested as a technique to limit blood loss.<sup>245</sup> Whether a low CVP is deleterious to renal function is uncertain. In a single-center, uncontrolled series of nearly 500 hepatic resection patients who were managed with low CVP, no cases of renal failure were attributed to the technique.<sup>246</sup> Others have suggested that peripheral venous pressure is an acceptable surrogate for CVP during hepatic resection and liver transplantation.<sup>247,248</sup>

A number of authors question the necessity of a low CVP technique given that blood loss is less significant in the current era.<sup>187–189,240</sup> Others question whether CVP is a reliable monitor of fluid responsiveness.<sup>186</sup> Lastly, two single-center series of living liver donors came to the same conclusion that CVP is not a predictor of blood loss during hepatic resection.<sup>249,250</sup> A recent meta-analysis concluded that optimal methods to lower CVP are uncertain, and that low CVP does not reduce morbidity.<sup>251</sup>

Vasopressors have a direct effect on splanchnic vessels, which reduces splanchnic pressure and decreases blood loss.<sup>252</sup> Portal triad clamping (of the afferent vessels) and total vascular occlusion (of the afferent vessels plus the supra- and infrahepatic vena cava) are both effective in decreasing blood loss during hepatic resection. Portal triad clamping is better tolerated and as effective as total vascular occlusions.<sup>253</sup> Portal triad clamping is well tolerated hemodynamically and has little effect on liver function if intermittent.<sup>254,255</sup> Ischemic preconditioning (10-minute inflow occlusion, followed by a 10-minute reperfusion period) followed by continuous inflow clamping for up to 75 minutes was equally effective to intermittent inflow clamping (15-minute periods followed by 5-minute reperfusion) with regard to protection against postoperative liver injury in noncirrhotic patients undergoing hepatic resection. Ischemic preconditioning plus continuous clamping resulted in less blood loss than intermittent clamping.<sup>256</sup>

**Figure 46-3** Schematic depiction of Couinaud segmental liver anatomy and the normal portal venous structures.

Air embolism, a known complication of hepatic resection, can be predicted on the basis of the need for a large hepatectomy (such as a right lobectomy) or when the tumor is near the vena cava or involves portal vessels. Low CVP may increase the risk of venous air embolism, though this has not been substantiated.<sup>257</sup>

Even in patients with normal preoperative coagulation profiles, the INR and platelet count can be abnormal after liver resection. The severity of the derangement correlates with the extent of the resection, peaks postoperative day 1 to 2, and takes up to 5 or more days to resolve.<sup>258,259</sup> This has implications in regards to postoperative continuous epidural analgesia. Some authors advise against preoperative epidural catheter placement, whereas others recommend correcting coagulation abnormalities prior to catheter removal.<sup>260</sup> Others, using viscoelastic testing, report brief hypercoagulability after liver resection despite prolonged PTs.<sup>261</sup> Nonetheless, alternatives that avoid epidural catheter placement have been sought. These include intrathecal opioid combined with IV analgesics, and local anesthesia infusion systems.<sup>262</sup>

Surgical techniques for hepatic resection continue to evolve, though indications for newer procedures are not always clearly defined. Examples include minimally invasive liver surgery, thermal ablation of hepatic tumors,

and portal vein embolization to induce hypertrophy of the remnant liver. Despite this, complications are common after hemihepatectomy (52% of 144 patients); these include pleural effusions, biliary leakage, wound dehiscence, ascites and, intra-abdominal abscess.<sup>263</sup> In this series a higher preoperative MELD score was associated with the development of complications.

## Postoperative Liver Dysfunction

Postoperative liver dysfunction is considered in the presence of asymptomatic elevation of hepatic transaminases, jaundice, and/or symptoms suggestive of liver failure, such as encephalopathy. Mild elevations of liver enzymes can occur after surgery, particularly upper abdominal procedures. Elevations that are less than two times the upper limit of normal are frequently transient and do not require investigation. More severe elevations suggest hepatocellular injury, which can result from a number of causes including hypoxemia, viral or bacterial insult, trauma, and chemical toxicity.

Asymptomatic, mild elevations of hepatic enzymes are not unusual within hours after surgery, but they do not usually persist for more than 2 days. Such elevations were more common after halothane than enflurane (incidence of 50% vs. 20%, respectively) but are uncommon in patients without hepatic dysfunction following currently used inhaled anesthetics.<sup>264-268</sup>

Jaundice, or more severe elevations of hepatic enzymes, requires investigation. Hepatic hypoxemia can result from a number of causes ([Table 46-13](#)) including cardiopulmonary etiologies (pneumonia, atelectasis, heart failure), hypoperfusion (secondary to shock), anemia, or fever. Surgery itself decreases hepatic blood flow.<sup>269</sup> Reabsorption of surgical or traumatic hematomas and transfusion of red blood cells are major causes of postoperative jaundice. Ten percent of transfused red cells hemolyze within 24 hours of transfusion. The bilirubin load per unit transfused is 250 mg. The liver may take time to clear the bilirubin load that results from significant hemolysis.

**Table 46-13** Causes of Postoperative Liver Dysfunction

<b>Hepatocellular</b>
Drugs
Anesthetics
Ischemia
Shock, hypotension, iatrogenic injury
Viral hepatitis
<b>Cholestasis</b>
Benign postoperative cholestasis
Sepsis
Bile duct injury
Drugs
Antibiotics, antiemetics
Choledocholithiasis or pancreatitis
Cholecystitis
Gilbert syndrome

Unconjugated hyperbilirubinemia suggests hemolysis or an inherited disorder such as Gilbert syndrome, or the less common Crigler–Najjar syndrome. In both syndromes the absence or marked decrease of bilirubin glucuronyltransferase produces an unconjugated hyperbilirubinemia. Surgical and anesthetic problems are uncommon in patients with Gilbert and Crigler–Najjar syndromes. Hemoglobinopathies (e.g., sickle cell disease), erythrocyte metabolism defects (e.g., glucose-6-phosphate dehydrogenase deficiency), transfusion reactions, and prosthetic heart valves can also cause hemolysis.

If over 50% of bilirubin is conjugated cholestasis, hepatocellular dysfunction is likely. Hypoxemia, toxic reactions, unsuspected pre-existing liver disease, trauma, and congenital disorders should be considered (Table 46-14). Dubin–Johnson and Rotor syndromes are congenital disorders associated with a defect in bilirubin excretion, which causes a conjugated bilirubinemia. Surgery can worsen these syndromes.

The nature and site of the surgical procedure is an important risk factor for postoperative liver failure.<sup>167</sup> Abdominal surgery appears to reduce hepatic blood flow significantly. Abdominal traction can elevate prostaglandin levels, which may be responsible.<sup>270</sup> Not surprisingly, hepatic resection is a risk factor for postoperative liver failure. The indication for resection in many patients is HCC, which is associated with chronic hepatitis or cirrhosis.<sup>167</sup> The functional reserve of the remnant hepatic parenchyma is difficult to estimate in the cirrhotic liver. In a series of 747 hepatic resections, patients with obstructive jaundice due to malignancy had a higher postoperative mortality (21%) than those with cirrhosis (8.7%), whereas patients with a normal liver had a postresection mortality of 1%.<sup>271</sup> In a series of 373 patients undergoing surgery for obstructive jaundice, those with malignancy or markedly elevated bilirubin had a 1-month mortality higher than 20%.<sup>272</sup> When renal failure accompanies hyperbilirubinemia, the mortality exceeds 50%.<sup>273</sup> Low intestinal levels of bile salts appear to

promote the absorption of endotoxin from the gastrointestinal tract, whereas vasoconstrictive inflammatory mediators can precipitate renal hypoperfusion.<sup>274</sup>

**Table 46-14** Causes of Hyperbilirubinemia

<b>Unconjugated (indirect)</b>
Excessive bilirubin production (hemolysis)
Immaturity of enzyme systems
Physiologic jaundice of newborn
Jaundice of prematurity
Inherited defects
Gilbert syndrome
Crigler–Najjar syndrome
Drug effects
<b>Conjugated (direct)</b>
Hepatocellular disease (hepatitis, cirrhosis, drugs)
Intrahepatic cholestasis (drugs, pregnancy)
Benign postoperative jaundice, sepsis
Congenital conjugated hyperbilirubinemia
Dubin–Johnson syndrome
Rotor syndrome
Obstructive jaundice
Extrahepatic (calculus, stricture, neoplasm)
Intrahepatic (sclerosing cholangitis, neoplasm, primary biliary cirrhosis)

Adapted from Friedman L, Martin P, Munoz S. Liver function tests and the objective evaluation of the patient with liver disease. In: Zakim D, Boyer T, eds. *Hepatology: A Textbook of Liver Disease*. 3rd ed. Philadelphia, PA: WB Saunders; 1996:791.

Cardiac surgery in patients with cirrhosis is not well tolerated. Cardiopulmonary bypass exacerbates pre-existing hepatic disease by unknown mechanisms. The overall perioperative mortality in patients with cirrhosis was 31%, and 80% in patients with Child’s class B cirrhosis.<sup>275</sup> Another series of cardiac patients reported 1-year mortality of 20%, 55%, and 84% in Child’s class A, B, and C patients, respectively.<sup>276</sup> For comparison, the mortality in patients without cirrhosis is approximately 2%.<sup>277</sup> These authors concluded that cardiac surgery that involves cardiopulmonary bypass can be performed in cirrhotic patients with Child’s class A cirrhosis and in selected patients with class B.

## Conclusions

In patients with new-onset liver disease, elective surgery should be postponed until the course of the disease is known. In patients with pre-existing liver disease, the severity of the disease should be characterized in order to assess risk. Elective high-risk procedures (abdominal and cardiac surgery) in patients with Child’s C cirrhosis should be deferred until after liver transplantation. Child’s A and B patients should be medically optimized prior to surgery.

Although no anesthetic technique is universally preferred, the presence of coagulopathy may contraindicate neuraxial regional techniques. The chosen technique should be designed to maintain splanchnic, hepatic, and renal perfusion. When surgery is unavoidable in patients with advanced liver disease, transfer to a liver transplant center should be considered in order to facilitate pretransplant evaluation and listing.

## Endocrine Response to Surgical Stress

### KEY POINTS

- 1 The major risk of anesthesia in the poorly controlled thyrotoxic patient is thyroid storm, which must be aggressively treated with  $\beta$ -blockers, iodide, and antithyroid drugs.
- 2 Asymptomatic or mild hypothyroidism does not appear to significantly increase anesthetic risk and is not a contraindication to surgery. Moderate to severe hypothyroidism should be corrected before surgery to prevent multisystem complications.
- 3 Patients who have received corticosteroids for more than 1 week in the past year may have adrenal suppression and should receive supplemental steroids in the perioperative period.
- 4 Preoperative preparation of the pheochromocytoma patient with  $\alpha$ -blockers decreases intraoperative hemodynamic instability.
- 5 Pheochromocytoma manipulation is associated with severe hypertension that should be treated aggressively with nitroprusside, phentolamine, or other rapidly acting vasodilators.
- 6 The major perioperative risks to the diabetic patient come from coexisting disease, especially coronary artery disease. Coexisting disease must be aggressively sought and optimized.
- 7 Very tight control of perioperative blood glucose levels appears to increase the risk of hypoglycemic complications without clearly reducing the risk of hyperglycemic complications.
- 8 Endotracheal intubation may be unpredictably difficult in patients with acromegaly.

## Thyroid Gland

The thyroid gland secretes thyroid hormones, thyroxine (T<sub>4</sub>) and 3,3',5-triiodothyronine (T<sub>3</sub>), which are the major regulators of cellular metabolic activity. Thyroid hormones exert a variety of actions by regulating the synthesis and activity of various proteins. They are necessary for proper cardiac, pulmonary, and neurologic function during both health and illness.

### *Thyroid Metabolism and Function*

The production of thyroid hormone is initiated by the active uptake and concentration of iodide in the thyroid gland (Fig. 47-1). Dietary iodine is reduced to iodide in the gastrointestinal (GI) tract. Circulating iodide is taken up by the thyroid gland, where it is then bound to tyrosine residues to form

various iodotyrosines. After organification, monoiodotyrosine or diiodotyrosine is coupled enzymatically by thyroid peroxidase to form either T<sub>3</sub> or T<sub>4</sub>. These hormones are attached to the thyroglobulin protein and stored as colloid in the gland. The release of T<sub>3</sub> and T<sub>4</sub> from the gland is accomplished through proteolysis from the thyroglobulin and diffusion into the circulation. Thyrotropin (thyroid-stimulating hormone [TSH]) is produced in the anterior pituitary gland, and its secretion is regulated by thyrotropin-releasing hormone produced in the hypothalamus. TSH is responsible for maintaining the uptake of iodide and proteolytic release of thyroid hormone. Excess iodide inhibits the synthesis and secretion of thyroid hormone. Circulating thyroid hormone inhibits thyrotropin-releasing hormone and TSH secretion in a negative-feedback loop. The thyroid gland is solely responsible for the daily secretion of T<sub>4</sub> (80 to 100 µg/day). The half-life of T<sub>4</sub> in the circulation is about 7 days.

Approximately 80% of T<sub>3</sub> is produced by the extrathyroidal deiodination of T<sub>4</sub> and 20% is produced by direct thyroid secretion. The half-life of T<sub>3</sub> is 24 to 30 hours. Most of the effects of thyroid hormones are mediated by the more potent and less protein-bound T<sub>3</sub>. The degree to which these hormones are protein bound in the circulation is the major factor influencing their activity and degradation. T<sub>4</sub> is metabolized by monodeiodination to either T<sub>3</sub> or reverse T<sub>3</sub> (rT<sub>3</sub>). T<sub>3</sub> is biologically active, whereas rT<sub>3</sub> is inactive. The major fraction of circulating hormone is bound to thyroxine-binding globulin (TBG), with a smaller fraction bound to albumin and transthyretin. Less than 0.1% is present as free, unbound hormone. Changes in serum-binding protein concentrations have a major effect on total T<sub>3</sub> and T<sub>4</sub> serum concentrations. The plasma normally contains 5 to 12 µg/dL of T<sub>4</sub> and 60 to 180 ng/dL of T<sub>3</sub>. Many drugs can affect thyroid function, including amiodarone and dopamine.<sup>1</sup>

**Figure 47-1** Thyroid hormone biosynthesis consists of four stages: (1) organification, (2) binding, (3) coupling, and (4) release. TSH, thyroid-stimulating hormone;  $T_3$ , triiodothyronine;  $T_4$ , thyroxine.

Although the thyroid hormone is important to many aspects of growth and function, the anesthesiologist is most often concerned with the cardiovascular manifestations of thyroid disease.<sup>2</sup> Thyroid hormones affect tissue responses to sympathetic stimuli and increase the intrinsic contractile state of cardiac muscle.

$\beta$ -Adrenergic receptors are increased in number, and cardiac  $\alpha$ -adrenergic receptors are decreased by thyroid hormone.<sup>3</sup>

## Tests of Thyroid Function

### Serum Thyroxine

The serum  $T_4$  assay is a standard test for evaluation of thyroid gland function (Table 47-1). The total  $T_4$  is elevated in approximately 90% of patients with hyperthyroidism, and it is low in 85% of those who are hypothyroid. The concentration of  $T_4$  is measured by radioimmunoassay (RIA). The serum  $T_4$  concentration is influenced by thyroid hormone protein-binding capacity. An

increase or decrease in TBG levels or in protein binding may therefore alter the total T<sub>4</sub> but not the concentration of the free T<sub>4</sub>. Because of the effect of TBG on circulating total T<sub>4</sub>, the T<sub>4</sub> levels should never be used alone to evaluate thyroid disease. Elevations in the TBG concentration are the most common cause of hyperthyroxinemia in euthyroid patients. Increases in TBG due to acute liver disease, pregnancy, or drugs (oral contraceptives, exogenous estrogens, clofibrate, opioids) may be the causative factor. Because a total T<sub>4</sub> can be misleadingly high in euthyroidism or normal in hypothyroidism, some measure of free thyroid hormone activity (free T<sub>4</sub>) must also be used.

### Serum Triiodothyronine

The serum T<sub>3</sub> is also measured by RIA. Serum T<sub>3</sub> levels are often determined to detect disease in patients with clinical evidence of hyperthyroidism in the absence of elevations of T<sub>4</sub>. T<sub>3</sub> may be the only thyroid hormone produced in excess. T<sub>3</sub> concentrations may be depressed by factors that impair the peripheral conversion of T<sub>4</sub> to T<sub>3</sub> (sick euthyroid syndrome). In 50% of hypothyroid patients, the serum T<sub>3</sub> concentration is low; in the remaining 50%, it is normal.

### Tests for Assessing Thyroid Hormone Binding

Because conventional assays measure total hormone levels, which can be affected by protein binding without affecting free hormone levels, it is necessary to correct for thyroid-binding proteins to correctly interpret total thyroxine levels. Most commonly, a direct measurement of unbound T<sub>3</sub> and T<sub>4</sub> can be performed by free immunoassays. The T<sub>3</sub> uptake test measures the ability of the patient's serum to bind exogenously introduced T<sub>3</sub> and reflects the amount of TBG and the extent of T<sub>3</sub> saturation on TBG. The T<sub>3</sub> uptake is inversely related to the degree of unsaturation of TBG. Indirect measurement of free hormone levels can be calculated by multiplying the total hormone level by the thyroid hormone binding ratio, which can be calculated from the T<sub>3</sub>-resin uptake. This product is the free T<sub>3</sub> or T<sub>4</sub> index.

**Table 47-1** Tests of Thyroid Gland Function

	T <sub>4</sub>	T <sub>3</sub>	THBR	TSH
Hyperthyroidism	Elevated	Elevated	Elevated	Normal or low
Primary hypothyroidism	Low	Low or normal	Low	Elevated
Secondary hypothyroidism	Low	Low	Low	Low
Sick euthyroidism (decreased peripheral conversion of T <sub>4</sub> to T <sub>3</sub> )	Normal	Low	Normal	Normal
Pregnancy	Elevated	Normal	Low	Normal

T<sub>4</sub>, total serum thyroxine; T<sub>3</sub>, serum triiodothyronine; THBR, thyroid hormone binding rate; TSH, thyroid-stimulating hormone.

## Thyroid-stimulating Hormone

The RIA for thyroid-stimulating hormone is sensitive and specific enough to become the first test in evaluating suspected thyroid dysfunction. It is often higher than 20  $\mu\text{IU/mL}$  in primary hypothyroidism (normal 0.4 to 4.5  $\mu\text{IU/mL}$ ). Hyperthyroidism can be suspected from depressed TSH levels. A condition characterized by elevated TSH and normal  $T_4$  may represent subclinical hypothyroidism. A low TSH level in a clinically hypothyroid patient indicates disease at the pituitary or hypothalamic level. The goal of thyroid replacement therapy is to normalize TSH levels.<sup>3</sup> Starvation, fever, stress, corticosteroids, and  $T_3$  or  $T_4$  can all depress TSH levels.

## Radioactive Iodine Uptake

The thyroid gland has the ability to concentrate large amounts of inorganic iodide. The oral administration of radioactive iodine ( $^{131}\text{I}$ ) can be used to indicate thyroid gland activity. Thyroid uptake is elevated in hyperthyroidism unless the hyperthyroidism is caused by thyroiditis, in which case the uptake is low or absent. Because of overlap in values, it is difficult to distinguish euthyroid from hypothyroid people. Radioactive iodine uptake may be increased by a variety of factors, including dietary iodine deficiency, renal failure, and congestive heart failure. Because uptake is under TSH control, elevated free  $T_4$  levels and corticosteroids decrease radioactive iodide uptake. Functioning (“hot”) thyroid tissue is rarely malignant. Nonfunctioning (“cold”) tissue may be malignant or benign.

## Hyperthyroidism

Hyperthyroidism results from the exposure of tissues to excessive amounts of thyroid hormone (Table 47-2). The most common cause is the multinodular diffuse goiter of Graves disease. This typically occurs between the ages of 20 and 40 years and is predominant in women. Most patients with this condition demonstrate a syndrome characterized by diffuse glandular enlargement, ophthalmopathy, dermopathy, and clubbing of the fingers. A thyroid-stimulating autoantibody may be present. Thyroid adenoma is the second most common cause. Another cause of increased thyroid hormone synthesis is thyroiditis. Subacute thyroiditis frequently follows a respiratory illness and is characterized by a viral-like illness with a firm, painful gland. This type of thyroiditis is frequently treated with anti-inflammatory agents alone. Rarely, subacute thyroiditis may occur in a patient with a normal-sized painless gland. Hashimoto thyroiditis is a chronic autoimmune disease that usually produces hypothyroidism but may occasionally produce hyperthyroidism. Hyperthyroidism may also be associated with pregnancy,  $^{131}\text{I}$  therapy, thyroid

carcinoma, trophoblastic tumors, or TSH-secreting pituitary adenomas. Iatrogenic hyperthyroidism may follow thyroid hormone replacement or may occur after iodide exposure (angiographic contrast media) in patients with chronically low iodide intake (Jod-Basedow phenomenon). The antiarrhythmic agent amiodarone is iodine rich and is another cause of iodine-induced thyrotoxicosis.<sup>4</sup>

The major manifestations of hyperthyroidism are weight loss, diarrhea, skeletal muscle weakness and stiffness, warm and moist skin, heat intolerance, and nervousness. Cardiovascular manifestations include increased left ventricular contractility and ejection fraction, tachycardia, elevated systolic blood pressure, and decreased diastolic blood pressure. Hypercalcemia, thrombocytopenia, and a mild anemia may be present. Elderly patients may present with heart failure, atrial fibrillation, or other cardiac dysrhythmias. They may also present with apathetic hyperthyroidism characterized by depression and withdrawal, without the usual systemic signs or symptoms.

**Table 47-2** Causes of Hyperthyroidism

Intrinsic thyroid disease
• Hyperfunctioning thyroid adenoma
• Toxic multinodular goiter
Abnormal TSH stimulator
• Graves disease
• Trophoblastic tumor
Disorders of hormone storage or release
• Thyroiditis
Excess production of thyroid-stimulating hormone
• Pituitary thyrotropin (rare)
Extrathyroidal source of hormone
• Struma ovarii
• Functioning follicular carcinoma
Exogenous thyroid
• Iatrogenic
• Iodine induced

TSH, thyroid-stimulating hormone.

## Treatment and Anesthetic Considerations

 The most important goal in managing the hyperthyroid patient is to make the patient euthyroid before any surgery, if possible. The drugs propylthiouracil and methimazole are thiourea derivatives that inhibit organification of iodide and the synthesis of thyroid hormone.<sup>5</sup> Propylthiouracil also decreases the peripheral conversion of T<sub>4</sub> to T<sub>3</sub>. Normal thyroid glands usually contain a store of hormone that is large enough to maintain a euthyroid state for several months, even if synthesis is abolished. Therefore, hyperthyroid patients are unlikely to be regulated to a euthyroid state with antithyroid drugs alone in less than 6 to 8 weeks. Toxic reactions

from these drugs are uncommon but include skin rash, nausea, fever, agranulocytosis, hepatitis, and arthralgias.

Inorganic iodide inhibits iodide organification and thyroid hormone release—the Wolff–Chaikoff effect. Iodide is also effective in reducing the size and vascularity of the hyperplastic gland and has a role in the preparation of the patient for emergency thyroid surgery. Antithyroid drugs should be started before iodide treatment because of the possibility of worsening the thyrotoxicosis.

$\beta$ -Adrenergic antagonists are effective in attenuating the manifestations of excessive sympathetic activity and should be used in all hyperthyroid patients unless contraindicated.  $\beta$ -Adrenergic blockade alone does not inhibit hormone synthesis, but specifically propranolol does impair the peripheral conversion of T<sub>4</sub> to T<sub>3</sub> over 1 to 2 weeks. Propranolol given over 12 to 24 hours decreases tachycardia, heat intolerance, anxiety, and tremor. Any  $\beta$ -blocker may be used, and long-acting agents are more convenient. The combination of propranolol (in doses titrated to effect) plus potassium iodide (2 to 5 drops every 8 hours) is frequently used before surgery to ameliorate cardiovascular symptoms and reduce circulating concentrations of T<sub>4</sub> and T<sub>3</sub>. Preoperative preparation usually requires 7 to 14 days.

Heart failure secondary to poorly controlled paroxysmal atrial fibrillation may improve with slowing of the ventricular rate, but abnormalities of left ventricular function secondary to hyperthyroidism may not be corrected with the use of  $\beta$ -antagonists. If a hyperthyroid patient with clinically apparent disease requires emergency surgery,  $\beta$ -adrenergic blockade should be administered to achieve a heart rate below 90 beats per minute.  $\beta$ -Blockers do not prevent thyroid storm. Glucocorticoids such as dexamethasone (8 to 12 mg/day) are used in the management of severe thyrotoxicosis because they reduce thyroid hormone secretion and the peripheral conversion of T<sub>4</sub> to T<sub>3</sub>.

Radioactive iodine therapy is an effective treatment for some patients with thyrotoxicosis.<sup>6</sup> However, it should not be administered to patients who are pregnant because it crosses the placenta and may destroy the fetal thyroid. A side effect of radioiodine therapy is hypothyroidism; 10% to 60% of cases occur in the first year of therapy and an additional 2% occur per year thereafter.

A variety of anesthetic techniques and drugs have been used for hyperthyroid patients undergoing surgery. All antithyroid medications are continued through the morning of surgery. The goal of intraoperative management in the hyperthyroid patient is to achieve a depth of anesthesia that prevents an exaggerated sympathetic response to surgical stimulation while avoiding the administration of medication that stimulates the sympathetic nervous system. Pancuronium should be avoided. It is best to avoid using ketamine for induction, even when a patient is clinically

euthyroid. Hypotension that occurs during surgery is best treated with direct-acting vasopressors rather than a medication that provokes the release of catecholamines. The incidence of myasthenia gravis is increased in hyperthyroid patients; thus, the initial dose of muscle relaxant should be reduced and a twitch monitor should be used to titrate subsequent doses. Regional anesthesia is an excellent alternative when appropriate; however, epinephrine-containing solutions should be avoided.

**Table 47-3** Management of Thyroid Storm

Administer IV fluids
Administer sodium iodide, 250 mg PO or IV q6h
Administer propylthiouracil, 200–400 mg PO or via NGT q6h
Administer hydrocortisone, 50–100 mg IV q6h
Administer propranolol, 10–40 mg PO q4–6h, or esmolol infusion to treat hyperadrenergic signs
Cooling blankets and acetaminophen and meperidine (25–50 mg) IV q4–6h may be used to prevent shivering
Use digoxin for heart failure especially in the presence of atrial fibrillation with rapid ventricular response

NGT, nasogastric tube.

Thyroid storm is a life-threatening exacerbation of hyperthyroidism **1** that most commonly develops in the undiagnosed or untreated hyperthyroid patient because of the stress of surgery or nonthyroid illness.<sup>7</sup> Operating on an acutely hyperthyroid gland may provoke thyroid storm, although this is probably not due to mechanical release of hormone.<sup>8</sup> Its manifestations include hyperthermia, tachycardia, dysrhythmias, myocardial ischemia, congestive heart failure, agitation, and confusion. It must be distinguished from, or considered with, pheochromocytoma, malignant hyperthermia, and light anesthesia. Although free T<sub>4</sub> levels are often markedly elevated, no laboratory test is diagnostic. Treatment involves large doses of propylthiouracil and supportive measures to control fever and restore intravascular volume (Table 47-3). Invasive hemodynamic monitoring is especially useful in guiding the treatment of patients with significant left ventricular dysfunction (Table 47-3). Again, it is essential to remove or treat the precipitating event.

### Anesthesia for Thyroid Surgery

Thyroidectomy as an alternative to prolonged medical therapy is used less frequently now than in the past. Indications include failed medical therapy, underlying cancer, and symptomatic goiter. It is usually performed under general endotracheal anesthesia, although the use of the laryngeal mask airway is increasing.<sup>9</sup> Use of a laryngeal mask airway allows real-time visualization of vocal cord function because the patient is allowed to breathe

spontaneously. Limited thyroidectomy may also be performed under bilateral superficial cervical plexus block. The anesthesiologist must be prepared to manage an unexpected difficult intubation because the incidence of difficult intubation during goiter surgery is 5% to 8%.<sup>10</sup> Thyroid cancer increases the risk of difficult intubation, but the size of the goiter is not predictive. Large goiters, especially if associated with evidence of significant airway obstruction or tracheal deviation, may warrant securing the airway while the patient is awake. Large substernal goiters can behave as anterior mediastinal masses and cause intrathoracic airway obstruction after induction of general anesthesia. Computed tomography (CT) or magnetic resonance imaging (MRI) should be reviewed. Minimally invasive procedures such as robot-assisted transaxillary<sup>11</sup> and transoral thyroidectomies are beginning to occur. Nasal intubations are required for the transoral approach. The complications after thyroidectomy include recurrent laryngeal nerve (RLN) damage, tracheal compression secondary to hematoma or tracheomalacia, and hypoparathyroidism. Pneumothorax may occur during resection of substernal goiters. Hypoparathyroidism secondary to the inadvertent surgical removal of parathyroid glands is most frequently seen after total thyroidectomy. The symptoms of hypocalcemia develop within 24 to 96 hours after surgery (see [Chapter 14](#)).<sup>12</sup> Laryngeal stridor progressing to laryngospasm may be one of the first indications of hypocalcemic tetany. Intravenous (IV) administration of calcium chloride or calcium gluconate is warranted in this situation. Magnesium levels should also be monitored and corrected if low. Bilateral injury is an extremely rare injury and necessitates reintubation. Unilateral nerve injury is more common and is often transient.<sup>13</sup> Unilateral damage to the RLN is characterized by hoarseness and a paralyzed vocal cord, whereas bilateral injury causes aphonia (see [Chapter 28](#)). It is wise to evaluate vocal cord function before and after surgery by laryngoscopy or by asking the patient to phonate by saying the sound for “E.” Routine postoperative visualization of the vocal cords is not warranted. Some surgeons elect to monitor RLN function intraoperatively. A nerve stimulator may be used by the surgeon to stimulate suspicious structures and contraction of the laryngeal muscles noted. Alternatively, the NIM (Nerve Integrity Monitor; Medtronic Xomed) endotracheal tube can be used. This endotracheal tube has two pairs of electrodes embedded in the shaft of the endotracheal tube just above the cuff. When properly positioned, the electrodes will be in contact with the vocal cords and an electromyographic signal can be monitored. Muscle relaxants and topical laryngeal anesthesia must be avoided to obtain appropriate signals during surgery. Succinylcholine or a small dose of rocuronium can be used to facilitate intubation. Care must be taken that the NIM tube is still positioned properly after the head and neck position have been optimized for surgery.<sup>14</sup> Postoperative extubation of the trachea should

be performed under optimal conditions. Intraoperative laryngeal nerve injury or collapse of the tracheal rings from previous weakening may mandate emergency reintubation.

## Hypothyroidism

Hypothyroidism is a relatively common disease (0.3% to 5% of the adult population) that results from inadequate circulating levels of T<sub>4</sub>, T<sub>3</sub>, or both.<sup>15</sup> The development of hypothyroidism is often slow and progressive, making the clinical diagnosis difficult, especially in more subtle cases. Hypofunctioning of the thyroid gland has many causes (Table 47-4). Primary failure of the thyroid gland refers to decreased production of thyroid hormone, despite adequate TSH production, and accounts for 95% of all cases of thyroid dysfunction. The remainder of the cases are caused by either hypothalamic or pituitary disease (secondary hypothyroidism) and are associated with other pituitary deficiencies.

**Table 47-4** Causes of Hypothyroidism

Primary hypothyroidism
• Autoimmune
• Irradiation to the neck
• Previous <sup>131</sup> I therapy
• Surgical removal
• Thyroiditis (Hashimoto disease)
• Severe iodine depletion
• Medications (iodines, propylthiouracil, methimazole)
• Hereditary defects in biosynthesis
• Congenital defects in gland development
Secondary or tertiary hypothyroidism
• Pituitary
• Hypothalamic

Adapted from Petersdorf RG, ed. *Harrison's Principles of Internal Medicine*. 10th ed. New York, NY: McGraw-Hill; 1983.

A lack of thyroid hormone produces a variety of signs and symptoms. These early findings are often nonspecific and difficult to recognize. A history of radioiodine therapy, external neck irradiation, or the presence of a goiter is helpful in diagnosis. There is a generalized reduction in metabolic activity resulting in lethargy, slow mental functioning, cold intolerance, and slow movements. The cardiovascular manifestations of hypothyroidism reflect the importance of thyroid hormone for myocardial contractility and catecholamine function. These patients exhibit bradycardia, decreased cardiac output, and increased peripheral resistance.<sup>16</sup> The accumulation of a cholesterol-rich pericardial fluid produces low voltage on the electrocardiogram (ECG). Heart failure only rarely occurs in the absence of coexisting heart disease. Angina pectoris itself is unusual in hypothyroidism

but can appear when thyroid hormone treatment is initiated. Ventilatory responsiveness to hypoxia and hypercapnia is depressed in hypothyroid patients. This depression is potentiated by sedatives, opioids, and general anesthesia. Postoperative ventilatory failure requiring prolonged ventilation is rarely seen in hypothyroid patients in the absence of coexisting lung disease, obesity, or myxedema coma. Other abnormalities found in hypothyroidism include anemia, coagulopathy, hypothermia, sleep apnea, and impaired renal free water clearance with hyponatremia. Decreased GI motility can compound the effect of postoperative ileus. In longstanding or severe disease, the stress response may be blunted and adrenal depression may occur.

### Treatment and Anesthetic Considerations

Treatment of symptomatic hypothyroidism is with hormone replacement therapy.<sup>17</sup> Controversy remains regarding the preoperative anesthetic management of the hypothyroid patient. Although it seems logical, given the multisystem effects of thyroid hormone, to recommend that all hypothyroid surgical candidates be restored to a euthyroid state before surgery, such a recommendation is, in general, based on individual case reports. There have been few controlled studies to support the position that most hypothyroid patients are unusually sensitive to anesthetic drugs, have prolonged recovery times, or have a higher incidence of cardiovascular instability or collapse.

No increase in serious complications in patients with mild or moderate hypothyroidism undergoing general anesthesia has been noted.<sup>18</sup> One study noted a higher incidence of intraoperative hypotension and postoperative GI and neuropsychiatric complications in mild and moderately hypothyroid patients undergoing noncardiac surgery, but still noted there were no compelling clinical reasons to postpone surgery in these patients.<sup>19</sup> Surgery in severely hypothyroid patients should be postponed when possible until these patients are at least partially treated.

#### Table 47-5 Management of Myxedema

Tracheal intubation and controlled ventilation as needed  
Levothyroxine, 200–300 µg IV over 5–10 min initially, and  
100 µg IV q24h  
Hydrocortisone, 100 mg IV, then 25 mg IV q6h  
Fluid and electrolyte therapy as indicated by serum electrolytes  
Cover to conserve body heat; no warming blankets

IV, intravenous(ly).

The management of hypothyroid patients with symptomatic coronary artery disease has been a subject of particular controversy.<sup>20</sup> The need for

thyroid hormone replacement therapy must be weighed against the risk of precipitating myocardial ischemia. Several studies and a literature review found no differences in the frequency of intraoperative or postoperative complications when mild or moderately hypothyroid patients underwent cardiac surgery. In symptomatic patients or unstable patients with cardiac ischemia, thyroid replacement should probably be delayed until after coronary revascularization.

There appears to be little reason to postpone surgery in patients who have mild or moderate hypothyroidism. However, thyroid replacement therapy is indicated for patients with severe hypothyroidism or myxedema coma and for pregnant patients who are hypothyroid. Untreated hypothyroidism in pregnant patients is associated with an increased incidence of spontaneous abortion and mental and physical abnormalities in the offspring.

A number of anesthetic medications have been used without difficulty in hypothyroid patients. Although ketamine has been proposed as the ideal induction agents, all IV induction agents have been used in the hypothyroid patient. The maintenance of anesthesia may be safely achieved with either IV or inhaled anesthetics. There appears to be little, if any, decrease in the minimum alveolar concentration for volatile agents. Regional anesthesia is a good choice in the hypothyroid patient, provided the intravascular volume is well maintained. Monitoring is directed toward the early recognition of hypotension, congestive heart failure, or hypothermia. Scrupulous attention should be paid to maintaining normal body temperature.

Myxedema coma represents a severe form of hypothyroidism characterized by stupor or coma, hypoventilation, hypothermia, hypotension, and hyponatremia. This is a medical emergency with a high mortality rate (25% to 50%) and, as such, requires aggressive therapy (Table 47-5). Only lifesaving surgery should proceed in the face of myxedema coma. IV thyroid replacement is initiated as soon as the clinical diagnosis is made. An IV loading dose of T<sub>4</sub> (sodium levothyroxine, 200 to 300 µg) is given initially and followed by a maintenance dose of T<sub>4</sub>, 50 to 200 µg/day intravenously.<sup>21</sup> Alternatively, T<sub>3</sub> may be used because it has a more rapid onset. Improvements in heart rate, blood pressure, and body temperature may occur within 24 hours. However, replacement therapy with either form of thyroid hormone may precipitate myocardial ischemia. There is also an increased likelihood of acute primary adrenal insufficiency in these patients, and they should receive stress doses of hydrocortisone. Steroid replacement continues until normal adrenal function can be confirmed.

## Parathyroid Glands

### Calcium Physiology

The normal adult body contains approximately 1 to 2 kg of calcium ( $\text{Ca}^{2+}$ ), of which 99% is in the skeleton.<sup>22</sup> Plasma calcium is present in three forms: (a) a protein-bound fraction (50%), (b) an ionized fraction (45%), and (c) a diffusible but nonionized fraction (5%) that is complexed with phosphate, bicarbonate, and citrate (see [Chapter 14](#)). This division is interesting because it is the ionized fraction that is physiologically active and homeostatically regulated. The normal total serum calcium concentration is 8.8 to 10.4 mg/dL. Albumin binds approximately 90% of the protein-bound fraction of calcium, and total serum  $\text{Ca}^{2+}$  consequently depends on albumin levels. In general, an increase or decrease in albumin of 1 g/dL is associated with a parallel change in total serum  $\text{Ca}^{2+}$  of 0.8 mg/dL. The serum ionized  $\text{Ca}^{2+}$  concentration is affected by temperature and blood pH through alterations in  $\text{Ca}^{2+}$  protein binding to albumin. Acidosis decreases protein binding (increases ionized  $\text{Ca}^{2+}$ ), and alkalosis increases protein binding (decreases ionized  $\text{Ca}^{2+}$ ). The concentration of free  $\text{Ca}^{2+}$  ion is of critical importance in regulating skeletal muscle contraction, coagulation, neurotransmitter release, endocrine secretion, and a variety of other cellular functions. As a consequence, the maintenance of serum  $\text{Ca}^{2+}$  concentration is subject to tight hormonal control by parathyroid hormone (PTH) and vitamin D (Fig. 47-2).

PTH acts to maintain the extracellular fluid  $\text{Ca}^{2+}$  concentration through direct effects on bone resorption and renal  $\text{Ca}^{2+}$  resorption at the distal tubule and indirectly through its effects on the synthesis of 1,25-dihydroxyvitamin D. The renal effects of PTH include phosphaturia and bicarbonaturia, in addition to enhanced  $\text{Ca}^{2+}$  and magnesium resorption. Most evidence suggests that rapid changes in blood  $\text{Ca}^{2+}$  levels are primarily the result of hormonal effects on bone and, to a lesser extent, on renal  $\text{Ca}^{2+}$  clearance, whereas maintenance of overall  $\text{Ca}^{2+}$  balance depends more on the indirect effects of the hormone on intestinal calcium absorption.

PTH secretion is primarily regulated by the serum ionized  $\text{Ca}^{2+}$  concentration. This negative-feedback mechanism is exquisitely sensitive in maintaining calcium levels in a normal range. Release of PTH is also influenced by phosphate, magnesium, and catecholamine levels. Acute hypomagnesemia directly stimulates PTH release, whereas chronic magnesium depletion appears to inhibit proper functioning of the parathyroid gland. The plasma phosphate concentration has an indirect influence on PTH secretion by causing reciprocal changes in the serum ionized  $\text{Ca}^{2+}$  concentration.

Vitamin D is absorbed from the GI tract and can be produced enzymatically by ultraviolet irradiation of the skin. Vitamin D (cholecalciferol) is made from cholesterol metabolites and is inactive. Calciferol is hydroxylated in the liver to 25-hydroxycholecalciferol (25-OHD)

and in the kidney is further hydroxylated to 1,25-dihydroxycholecalciferol [1,25(OH)<sub>2</sub>D] or 24,25-dihydroxycholecalciferol [24,25(OH)<sub>2</sub>D]. 25-OHD is the major circulating form of vitamin D. The synthesis of this form is not regulated by a hormone or by Ca<sup>2+</sup> or phosphate levels. 1,25(OH)<sub>2</sub>D and 24,25(OH)<sub>2</sub>D are the major active metabolites of vitamin D, and their production is reciprocally regulated at the kidney. Hypocalcemia and hypophosphatemia cause an increased production of 1,25(OH)<sub>2</sub>D and a decreased production of 24,25(OH)<sub>2</sub>D. 1,25(OH)<sub>2</sub>D stimulates bone, kidney, and intestinal absorption of calcium and phosphate. Vitamin D deficiency can lead to decreased intestinal absorption of Ca<sup>2+</sup> and secondary hyperparathyroidism.

### **Hyperparathyroidism**

Primary hyperparathyroidism is most commonly due to a benign parathyroid adenoma (90% of cases) or hyperplasia (9%) and very rarely to a parathyroid carcinoma.<sup>23</sup> Primary hyperparathyroidism may also exist as part of a multiple endocrine neoplastic (MEN) syndrome. Hyperplasia usually involves all four glands. Although most patients with primary hyperparathyroidism are hypercalcemic, most are asymptomatic at the time of diagnosis. When symptoms occur, they usually result from the hypercalcemia that accompanies the disease. Primary hyperparathyroidism occurring during pregnancy is associated with a high maternal and fetal morbidity rate (50%). The placenta allows the fetus to concentrate calcium, promoting fetal hypercalcemia and leading to hypoparathyroidism in the newborn. Pregnant women with primary hyperparathyroidism should generally be treated with surgery.

**Figure 47-2** Parathyroid hormone (PTH) and vitamin D metabolism and action. 25-OH, 25-hydroxycholecalciferol; 1,25-(OH)<sub>2</sub>, 1,25-dihydroxycholecalciferol. (Reprinted with permission from McClatchey KD. *Clinical Laboratory Medicine*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002.)

Hypercalcemia is responsible for a broad spectrum of signs and symptoms. Nephrolithiasis is the most common manifestation, occurring in 60% to 70% of patients. Polyuria and polydipsia are also common complaints. An increase in bone turnover may lead to generalized demineralization and subperiosteal bone resorption; however, only a small group of patients (10% to 15%) have clinically significant bone disease. Patients may experience generalized skeletal muscle weakness and fatigability, epigastric discomfort, peptic ulceration, or constipation. Psychiatric manifestations include depression, memory loss, confusion, or psychosis. Between 20% and 50% of patients are hypertensive, but this usually resolves with successful treatment of the disease. Cardiac function is enhanced in the early stages of hypercalcemia. Calcium flux into the cells is reflected in the plateau phase of the action potential (phase 2). As extracellular calcium increases, the inward flux is more rapid, and phase 2 is shortened (see [Chapter 12](#)). The corresponding ECG change is a shorter QT interval. Cardiac contractility may increase until a level between 15 and 20 mg/dL is reached. At this point, there is a

prolongation of the PR segment and QRS complex that can result in heart block or bundle-branch block. Bradycardia also occurs.

An elevated serum  $\text{Ca}^{2+}$  concentration is a valuable diagnostic indicator of primary hyperparathyroidism. The serum phosphate concentration is nonspecific, with many patients having normal or near-normal levels. The reported incidence of hyperchloremic acidosis varies widely in primary hyperparathyroidism, but most patients usually have a serum chloride concentration in excess of 102 mEq/L. Rarely does a patient with hypercalcemia secondary to ectopic PTH production (malignancy) present with hyperchloremic acidosis. The definitive diagnosis of primary hyperparathyroidism is made by RIA demonstration of an elevation in PTH levels in the presence of hypercalcemia. An elevated nephrogenous cyclic adenosine monophosphate is noted in over 90% of patients with primary hyperparathyroidism.

Hypercalcemia may also result from the ectopic production of PTH or PTH-like substances from lung, genitourinary, breast, GI, or lymphoproliferative malignancies. Tumors may also produce hypercalcemia through direct bone resorption or the production of osteoclast-activating factor. In the absence of a clinically obvious neoplasm, there may be difficulty in differentiating between PTH-producing malignancies and primary hyperparathyroidism. PTH fragments from malignant tissue differ from native PTH, so precise laboratory identification may aid in distinguishing between ectopic PTH production and primary hyperparathyroidism.

Secondary hyperparathyroidism represents an increase in parathyroid function as a result of conditions that produce hypocalcemia or hyperphosphatemia. Chronic renal disease is a common cause of hyperphosphatemia (due to decreased phosphate excretion) and decreased vitamin D metabolism. The hypocalcemia that results leads to an increased production of PTH. GI disorders accompanied by malabsorption may also lead to a secondary increase in parathyroid activity. Tertiary hyperparathyroidism refers to the development of hypercalcemia in a patient who has had prolonged secondary hyperparathyroidism that has caused adenomatous changes in the parathyroid gland and unregulated PTH.

## **Treatment and Anesthetic Considerations**

Surgery is the treatment of choice for the patient with symptomatic disease. However, there is considerable controversy surrounding the choice of treatment in the asymptomatic patient. It is not clear whether mild primary hyperparathyroidism decreases longevity. Surgery is often chosen over medical therapy because it offers definitive treatment and is generally safe.

Preoperative preparation focuses on the correction of intravascular volume

and electrolyte irregularities. It is particularly important to evaluate the patient with chronic hypercalcemia for abnormalities of the renal, cardiac, or central nervous systems. Emergency treatment of hypercalcemia is undertaken before surgery when the serum  $\text{Ca}^{2+}$  concentration exceeds 15 mg/dL (7.5 mEq/L). Lowering of the serum  $\text{Ca}^{2+}$  concentration is initially accomplished by expanding the intravascular volume and establishing a sodium diuresis. This is achieved with the IV administration of normal saline and furosemide. Rehydration alone is capable of lowering the serum  $\text{Ca}^{2+}$  level by at least 2 mg/dL. Hydration dilutes the serum  $\text{Ca}^{2+}$ , and sodium diuresis promotes  $\text{Ca}^{2+}$  excretion through an inhibition of sodium and  $\text{Ca}^{2+}$  resorption in the proximal tubule. Hypokalemia and hypomagnesemia may result.

Another element in the treatment of hypercalcemia is the correction of hypophosphatemia. Hypophosphatemia increases GI absorption of  $\text{Ca}^{2+}$ , stimulates the breakdown of bone, and impairs the uptake of  $\text{Ca}^{2+}$  by bone. Low serum phosphate levels impair cardiac contractility and may contribute to congestive heart failure. Hypophosphatemia also causes skeletal muscle weakness, hemolysis, and platelet dysfunction.

Other medications that have a role in lowering the serum  $\text{Ca}^{2+}$  include bisphosphonates, mithramycin, calcitonin, and glucocorticoids. Bisphosphonates are pyrophosphate analogs that inhibit osteoclast action. They are the drugs of choice for severe hypercalcemia. Toxic effects include fever and hypophosphatemia. Mithramycin, a cytotoxic agent, inhibits PTH-induced osteoclast activity and can lower the serum  $\text{Ca}^{2+}$  levels by at least 2 mg/dL in 24 to 48 hours. Toxic effects include azotemia, hepatotoxicity, and thrombocytopenia. Calcitonin is useful in transiently lowering the serum  $\text{Ca}^{2+}$  level 2 to 4 mg/dL through direct inhibition of osteoclastic bone resorption. The advantages of calcitonin are the mild side effects (urticaria, nausea) and the rapid onset of activity. Calcitonin resistance usually develops within 24 to 48 hours. Glucocorticoids are effective in lowering the serum  $\text{Ca}^{2+}$  concentration in several conditions (sarcoidosis, some malignancies, hyperthyroidism, vitamin D intoxication) through their actions on osteoclast bone resorption, GI absorption of calcium, and the urinary excretion of calcium. Glucocorticoids are usually of no benefit in the treatment of primary hypercalcemia. Finally, hemodialysis or peritoneal dialysis can be used to lower the serum  $\text{Ca}^{2+}$  level when alternative regimens are ineffective or contraindicated.

There is no evidence that a specific anesthetic drug or technique has advantages over another. A thorough knowledge of the clinical manifestations attributable to hypercalcemia is of the greatest value in choosing an anesthetic technique. Special monitoring is usually not required. Because of the unpredictable response to neuromuscular-blocking drugs in the

hypercalcemic patient, a conservative approach to muscle paralysis makes sense. There is an increased requirement for vecuronium, and probably all nondepolarizing muscle relaxants, during onset of neuromuscular blockade.<sup>24</sup> Careful positioning of the osteopenic patient is necessary to avoid pathologic bone fractures.

## **Anesthesia for Parathyroid Surgery**

General anesthesia is most commonly used for parathyroid surgery. Minimally invasive parathyroidectomy is superior to conventional bilateral cervical exploration in patients with sporadic primary hyperparathyroidism<sup>25</sup> and can usually be performed under bilateral cervical plexus block.<sup>26</sup> Some centers use an intraoperative rapid PTH assay to help determine when a hyperfunctioning gland has been removed. A freely back-flowing IV catheter is needed for frequent sampling. There is *in vitro*, but no clinical,<sup>27</sup> evidence that propofol can interfere with the assay, so many surgeons prefer that propofol not be used within 15 minutes of an assay. Postoperative complications include RLN injury, bleeding, and transient or complete hypoparathyroidism. Unilateral RLN is characterized by hoarseness and usually requires no intervention. Bilateral RLN injury is a rare complication, producing aphonia and requiring immediate tracheal intubation.

After successful parathyroidectomy, a decrease in the serum  $\text{Ca}^{2+}$  level should be observed within 24 hours. Patients with significant preoperative bone disease may have hypocalcemia after removal of the PTH-secreting glands. This “hungry bone” syndrome comes as a result of the rapid remineralization of bone. Thus, serum  $\text{Ca}^{2+}$ , magnesium, and phosphorus levels should be closely monitored until stable. The serum  $\text{Ca}^{2+}$  nadir usually occurs within 3 to 7 days.

## **Hypoparathyroidism**

An underproduction of PTH or resistance of the end-organ tissues to PTH results in hypocalcemia ( $<8$  mg/dL).<sup>28</sup> The normal physiologic response to hypocalcemia is an increase in PTH secretion and  $1,25(\text{OH})_2\text{D}$  synthesis, with an increase in  $\text{Ca}^{2+}$  mobilization from bone, GI absorption, and renal tubule reclamation. The most common cause of acquired PTH deficiency is unintentional removal of the parathyroid glands during thyroid or parathyroid surgery. Other causes of acquired hypoparathyroidism include  $^{131}\text{I}$  therapy for thyroid disease, neck trauma, granulomatous disease, or an infiltrating process (malignancy or amyloidosis). Severe hypomagnesemia ( $<0.8$  mEq/L) from any cause can produce hypocalcemia by suppressing PTH secretion and interfering with PTH action. Renal insufficiency leads to phosphorus retention

and impaired 1,25(OH)<sub>2</sub>D synthesis, which results in hypocalcemia. These patients are commonly treated with vitamin D, which increases intestinal calcium absorption and suppresses secondary increases in PTH secretion. Hypocalcemia due to pancreatitis and burns results from the suppression of PTH and from the sequestration of calcium.

## Clinical Features and Treatment

The clinical features of hypoparathyroidism are a manifestation of hypocalcemia. Neuronal irritability and skeletal muscle spasms, tetany, or seizures reflect a reduced threshold of excitation. Latent tetany may be demonstrated by eliciting the Chvostek or Trousseau sign. A Chvostek sign is a contracture of the facial muscle produced by tapping the facial nerve as it passes through the parotid gland. A Trousseau sign is a contraction of the fingers and wrist after application of a blood pressure cuff inflated above the systolic blood pressure for approximately 3 minutes. Other common complaints of hypocalcemia include fatigue, depression, paresthesias, and skeletal muscle cramps. The acute onset of hypocalcemia after thyroid or parathyroid surgery may manifest as stridor and apnea. Cardiovascular manifestations of hypocalcemia include congestive heart failure, hypotension, and a relative insensitivity to the effects of  $\beta$ -adrenergic agonists (see [Chapter 12](#)). Delayed ventricular repolarization results in a prolonged QT interval on the ECG. Although prolongation of the QT interval may be a reliable sign of hypocalcemia in an individual patient, the ECG is relatively insensitive for the detection of hypocalcemia.

The treatment of hypoparathyroidism consists of electrolyte replacement. The objective is to have the patient's clinical symptoms under control before anesthesia and surgery. Hypocalcemia caused by magnesium depletion is treated by correcting the magnesium deficit. Serum phosphate excess is corrected by the removal of phosphate from the diet and the oral administration of phosphate-binding resins (aluminum hydroxide). The urinary excretion of phosphate can be increased with a saline volume infusion.  $\text{Ca}^{2+}$  deficiencies are corrected with  $\text{Ca}^{2+}$  supplements or vitamin D analogs. Patients with severe symptomatic hypocalcemia are treated with IV calcium gluconate (10 to 20 mL of 10% solution) given over several minutes and followed by a continuous infusion (1 to 2 mg/kg/hr) of elemental  $\text{Ca}^{2+}$ . The correction of serum  $\text{Ca}^{2+}$  levels should be monitored by measuring serum  $\text{Ca}^{2+}$  concentrations and following clinical symptoms. When oral or IV calcium is inadequate to maintain a normal serum-ionized calcium level, vitamin D is added to the regimen.

## Adrenal Cortex

The adrenal cortex functions to synthesize and secrete three types of hormones. Endogenous and dietary cholesterol is used in the adrenal biosynthesis of glucocorticoids (cortisol), mineralocorticoids (aldosterone and 11-deoxycorticosterone), and androgens (dehydroepiandrosterone). Cortisol and aldosterone are the two essential hormones, whereas adrenal androgens are of relatively minor physiologic significance in adults. The major biologic effects of adrenal cortical hyperfunction or hypofunction occur as a result of cortisol or aldosterone excess or deficiency. Abnormal function of the adrenal cortex may render a patient unable to respond appropriately during a period of surgical stress or critical illness.

### **Glucocorticoid Physiology**

Cortisol (hydrocortisone) is the most potent endogenous glucocorticoid and is produced by the inner portions of the adrenal cortex. Cortisol is produced under the control of adrenocorticotrophic hormone (ACTH; corticotropin), a polypeptide synthesized and released by the anterior pituitary gland. Glucocorticoids exert their biologic effects by diffusing into the cytoplasm of target cells and combining with specific high-affinity receptor proteins.

The daily production of endogenous cortisol is approximately 20 mg. The maximal output is 150 to 300 mg. Most of the circulating hormone is bound to the  $\alpha$ -globulin cortisol-binding globulin. It is the relatively small amount of free hormone that exerts the biologic effects. Endogenous glucocorticoids are inactivated primarily by the liver and are excreted in the urine as 17-hydroxycorticosteroids. Cortisol is also filtered at the glomerulus and may be excreted unchanged in the urine. Although the rate of cortisol secretion is decreased by approximately 30% in the elderly patient, plasma cortisol levels remain in a normal range because of a corresponding decrease in hepatic and renal clearance.

Cortisol secretion is directly controlled by ACTH, which in turn is regulated by the corticotropin-releasing factor from the hypothalamus. ACTH is synthesized in the pituitary gland from a precursor molecule that also produces  $\beta$ -lipotropin and  $\beta$ -endorphin. The secretion of ACTH and corticotropin-releasing factor is governed chiefly by glucocorticoids, the sleep-wake cycle, and stress. Cortisol is the most potent regulator of ACTH secretion, acting by a negative-feedback mechanism to maintain cortisol levels in a physiologic range. ACTH release follows a diurnal pattern, with maximal activity occurring soon after awakening. This diurnal pattern of activity occurs in normal subjects and in those with adrenal insufficiency. Psychological or physical stress (trauma, surgery, intense exercise) also promotes ACTH release, regardless of the level of circulating cortisol or the time of day.

Cortisol has multiple effects on intermediate carbohydrate, protein, and fatty acid metabolism, as well as maintenance and regulation of immune and circulatory function. Glucocorticoids enhance gluconeogenesis, elevate blood glucose, and promote hepatic glycogen synthesis. The catabolic effect of glucocorticoids is partially blocked by insulin. The net effect on protein metabolism is enhanced degradation of muscle tissue and negative nitrogen balance. In supraphysiologic amounts, glucocorticoids suppress growth hormone secretion and impair somatic growth. The anti-inflammatory actions of cortisol relate to its effect in stabilizing lysosomes and promoting capillary integrity. Cortisol also antagonizes leukocyte migration inhibition factor, thus reducing white cell adherence to vascular endothelium and diminishing leukocyte response to local inflammation. Phagocytic activity does not decrease, although the killing potential of macrophages and monocytes is diminished. Other diverse actions include the facilitation of free water clearance, maintenance of blood pressure, a weak mineralocorticoid effect, promotion of appetite, stimulation of hematopoiesis, and induction of liver enzymes.

### *Mineralocorticoid Physiology*

Aldosterone is the most potent mineralocorticoid produced by the adrenal gland. This hormone binds to receptors in sweat glands, the alimentary tract, and the distal convoluted tubule of the kidney. Aldosterone is a major regulator of extracellular volume and potassium homeostasis through the resorption of sodium and the secretion of potassium by these tissues. The major regulators of aldosterone release are the renin–angiotensin system and serum potassium levels (Fig. 47-3). The juxtaglomerular apparatus that surrounds the renal afferent arterioles produces renin in response to decreased perfusion pressures and sympathetic stimulation. Renin splits the hepatic precursor angiotensinogen to form the decapeptide angiotensin I, which is then altered enzymatically by converting enzyme (primarily in the lung) to form the octapeptide angiotensin II. Angiotensin II is the most potent vasopressor produced in the body. It directly stimulates the adrenal cortex to produce aldosterone. The renin–angiotensin system is the body's most important protector of volume status. Other stimuli that increase the production of aldosterone include hyperkalemia and, to a limited degree, hyponatremia, prostaglandin E, and ACTH.

**Figure 47-3** Interrelationship of the volume and potassium feedback loops on aldosterone secretion. (Adapted from Petersdorf RG, ed. *Harrison's Principles of Internal Medicine*. 10th ed. New York, NY: McGraw-Hill; 1983.)

### Glucocorticoid Excess (Cushing Syndrome)

Cushing syndrome, caused by either overproduction of cortisol by the adrenal cortex or exogenous glucocorticoid therapy, is a syndrome characterized by truncal obesity, hypertension, hyperglycemia, increased intravascular fluid volume, hypokalemia, fatigability, abdominal striae, osteoporosis, and muscle weakness. Most cases of Cushing syndrome that occur spontaneously are due to bilateral adrenal hyperplasia secondary to ACTH produced by an anterior pituitary microadenoma or nonendocrine tumor (e.g., of the lung, kidney, or pancreas) (see [Chapter 37](#)). The primary overproduction of cortisol and other adrenal steroids is caused by an adrenal neoplasm in approximately 20% to 25% of patients with Cushing syndrome. These tumors are usually unilateral and approximately half are malignant. When Cushing syndrome occurs in patients older than 60 years of age, the most likely cause is an adrenal carcinoma or ectopic ACTH produced from a nonendocrine tumor. Finally, an increasingly common cause of Cushing syndrome is the prolonged administration of exogenous glucocorticoids to treat a variety of illnesses.

The signs and symptoms of Cushing syndrome follow from the known actions of glucocorticoids. Truncal obesity and thin extremities reflect increased muscle wasting and a redistribution of fat in facial, cervical, and truncal areas. Impaired calcium absorption and a decrease in bone formation may result in osteopenia. Sixty percent of patients have hyperglycemia, but overt diabetes mellitus (DM) occurs in less than 20%. Hypertension and fluid retention are seen in most patients. Profound emotional changes, ranging from emotional lability to frank psychosis, may be present. An increased susceptibility to infection reflects the immunosuppressive effects of corticosteroids. Hypokalemic alkalosis without distinctive physical findings is

common when adrenal hyperplasia is caused by ectopic ACTH production from a nonendocrine tumor.

The laboratory diagnosis of hyperadrenocorticism is based on a variable elevation in plasma and urinary cortisol levels, urinary 17-hydroxycorticosteroids, and plasma ACTH. Once the diagnosis is established, simultaneous measurement of plasma ACTH and cortisol levels can determine whether the Cushing syndrome is due to primary pituitary or adrenal disease.<sup>29</sup>

Alternatively, a dexamethasone suppression test can be used. Patients with pituitary adenomas frequently show depression in cortisol and 17-hydroxycorticosteroid levels when a high dose of dexamethasone is administered because the tumor retains some negative-feedback control, and adrenal tumors do not.

## **Anesthetic Management**

General considerations for the preoperative preparation of the patient include treating hypertension, diabetes, and normalizing intravascular fluid volume and electrolyte concentrations. Diuresis with the aldosterone antagonist spironolactone helps mobilize fluid and normalize potassium concentration. Careful positioning of the osteopenic patient is important to avoid fractures. Intraoperative monitoring is planned after evaluation of the patient's cardiac reserve and consideration of the site and extent of the proposed surgery. When either unilateral or bilateral adrenalectomy is planned, glucocorticoid replacement therapy is initiated at a dose equal to full replacement of adrenal output during periods of extreme stress (see Steroid Replacement during the Perioperative Period). The total dosage is reduced by approximately 50% per day until a daily maintenance dose of steroids is achieved (20 to 30 mg/day). Hydrocortisone given in doses of this magnitude exerts significant mineralocorticoid activity, and additional exogenous mineralocorticoid is usually not necessary during the perioperative period. After bilateral adrenalectomy, most patients require 0.05 to 0.1 mg/day of fludrocortisone (9- $\alpha$ -fluorohydrocortisone) starting around day 5 to provide mineralocorticoid activity. Slightly higher doses may be needed if prednisone is used for glucocorticoid maintenance because it has little intrinsic mineralocorticoid activity. The fludrocortisone dose is reduced if congestive heart failure, hypokalemia, or hypertension develops. For the patient with a solitary adrenal adenoma, unilateral adrenalectomy may be followed by normalization of function in the contralateral gland over time. Treatment plans should therefore be individualized and adjustments in dosage may be necessary. The production of glucocorticoids or ACTH by a neoplasm may not be eliminated if the tumor is unresectable. These patients often need continuous medical

therapy with steroid inhibitors such as metyrapone to control their symptoms.

There are no specific recommendations regarding the use of a particular anesthetic technique or medication in patients with hyperadrenocorticism. When significant skeletal muscle weakness is present, a conservative approach to the use of muscle relaxants is warranted. Etomidate has been used for temporizing medical treatment of severe Cushing syndrome because of its inhibition of steroid synthesis.

### ***Mineralocorticoid Excess***

Hypersecretion of the major adrenal mineralocorticoid aldosterone increases the renal tubular exchange of sodium for potassium and hydrogen ions. This leads to hypertension, hypokalemic alkalosis, skeletal muscle weakness, and fatigue. Possibly as many as 1% of unselected hypertensive patients have primary hyperaldosteronism. The increase in renal sodium reabsorption and extracellular volume expansion is partly responsible for the high incidence of diastolic hypertension in these patients. Patients with primary hyperaldosteronism (Conn syndrome) characteristically do not have edema. Secondary aldosteronism results from an elevation in renin production. The diagnosis of primary or secondary hyperaldosteronism should be entertained in the nonedematous hypertensive patient with persistent hypokalemia who is not receiving potassium-wasting diuretics. Hyposecretion of renin that fails to increase appropriately during volume depletion or salt restriction is an important finding in primary aldosteronism. The measurement of plasma renin levels is useful in distinguishing primary from secondary hyperaldosteronism. It is of limited value in differentiating patients with primary aldosteronism from those with other causes of hypertension because renin activity is also suppressed in approximately 25% of patients with essential hypertension.

### **Anesthetic Considerations**

Preoperative preparation for the patient with primary aldosteronism is directed toward restoring the intravascular volume and the electrolyte concentrations to normal. Hypertension and hypokalemia may be controlled by restricting sodium intake and administration of the aldosterone antagonist spironolactone. This diuretic works slowly to produce an increase in potassium levels, with dosages in the range of 25 to 100 mg every 8 hours. Total-body potassium deficits are difficult to estimate and may be in excess of 300 mEq. Whenever possible, potassium should be replaced slowly to allow equilibration between intracellular and extracellular potassium stores. The usual complications of chronic hypertension need to be assessed.

## Adrenal Insufficiency (Addison Disease)

The undersecretion of adrenal steroid hormones may develop as the result of a primary inability of the adrenal gland to elaborate sufficient quantities of hormone or as the result of a deficiency in the production of ACTH.

Clinically, primary adrenal insufficiency is usually not apparent until at least 90% of the adrenal cortex has been destroyed. The predominant cause of primary adrenal insufficiency used to be tuberculosis; however, today, the most frequent cause of Addison disease is idiopathic adrenal insufficiency secondary to autoimmune destruction of the gland. Autoimmune destruction of the adrenal cortex causes both a glucocorticoid and a mineralocorticoid deficiency. A variety of other conditions presumed to have an autoimmune pathogenesis may also occur concomitantly with idiopathic Addison disease. Hashimoto thyroiditis in association with autoimmune adrenal insufficiency is termed Schmidt syndrome. Other possible causes of adrenal gland destruction include certain bacterial, fungal, and advanced human immunodeficiency virus infections; metastatic cancer; sepsis; and hemorrhage. Secondary adrenal insufficiency occurs when the anterior pituitary fails to secrete sufficient quantities of ACTH. Pituitary failure may result from tumor, infection, surgical ablation, or radiation therapy. Pituitary surgery may cause transient adrenal insufficiency requiring supplemental glucocorticoids.<sup>30</sup>

Patients receiving chronic corticosteroid therapy will not generally have frank adrenal insufficiency, but may have hypothalamic–pituitary–adrenal (HPA) suppression and may develop acute adrenal insufficiency during the stress of the perioperative period. Relative adrenal insufficiency is a common finding in critically ill surgical patients with hypotension requiring vasopressors.<sup>31</sup> Therefore, a patient with signs of chronic glucocorticoid excess can have findings of acute adrenal insufficiency.

### Clinical Presentation

The cardinal symptoms of idiopathic Addison disease include chronic fatigue, muscle weakness, anorexia, weight loss, nausea, vomiting, and diarrhea. Hypotension is almost always encountered in the disease process. Female patients may exhibit decreased axillary and pubic hair growth because of the loss of adrenal androgen secretion. An acute crisis can present as abdominal pain, severe vomiting and diarrhea, hypotension, decreased consciousness, and shock. Diffuse hyperpigmentation occurs in most patients with primary adrenal insufficiency and is secondary to the compensatory increase in ACTH and  $\beta$ -lipotropin. These hormones stimulate an increase in melanocyte production. Mineralocorticoid deficiency is characteristically present in primary adrenal disease; as a result, there is a reduction in urine sodium conservation. Hyperkalemia may be a cause of life-threatening cardiac

dysrhythmias. Adrenal insufficiency secondary to pituitary disease is not associated with cutaneous hyperpigmentation or mineralocorticoid deficiency. Salt and water balance is usually maintained unless severe fluid and electrolyte losses overwhelm the subnormal aldosterone secretory capacity. Organic lesions of pituitary origin require a diligent search for coexisting hormone deficiencies. Acute adrenal insufficiency from inadequate replacement of steroids on chronic steroid therapy is rare and can present as refractory, distributive shock. In critically ill patients, adrenal insufficiency may not present with classic symptoms. The clinical picture may resemble that of sepsis without a source of infection.<sup>32</sup> A high degree of suspicion must be maintained if the patient has cardiovascular instability without a defined cause.<sup>33,34</sup>

## Diagnosis

The patient's pituitary–adrenal responsiveness should be determined when the diagnosis of primary or secondary adrenal insufficiency is first suspected. Biochemical evidence of impaired adrenal or pituitary secretory reserve unequivocally confirms the diagnosis. Patients who are clinically stable may undergo testing before treatment is initiated. Those believed to have acute adrenal insufficiency should receive immediate therapy.

Plasma cortisol levels are measured before and 30 and 60 minutes after the IV administration of 250 µg of synthetic ACTH. There are multiple determinants for adequate adrenal reserve; usually the plasma cortisol rises at least 500 nmol/L 60 minutes after the injection of the synthetic ACTH.<sup>35</sup> Patients with adrenal insufficiency usually demonstrate little or no adrenal response.

## Treatment and Anesthetic Considerations

Normal adults secrete about 20 mg of cortisol (hydrocortisone) and 0.1 mg of aldosterone per day. Glucocorticoid therapy is usually given twice daily in sufficient dosage to meet physiologic requirements. A typical regimen in the unstressed patient may consist of prednisone, 5 mg in the morning and 2.5 mg in the evening, or hydrocortisone, 20 mg in the morning and 10 mg in the evening. The daily glucocorticoid dosage is typically 50% higher than basal adrenal output to cover the patient for mild stress. Replacement dosages are adjusted in response to the patient's clinical symptoms or the occurrence of intercurrent illnesses. Mineralocorticoid replacement is also administered on a daily basis; most patients require 0.05 to 0.1 mg/day of fludrocortisone. The mineralocorticoid dose may be reduced if severe hypokalemia, hypertension, or congestive heart failure develops, or it may be increased if postural hypotension is demonstrated.

**Table 47-6** Management of Acute Adrenal Insufficiency

Hydrocortisone, 100 mg IV bolus, followed by hydrocortisone, 100 mg q6h for 24 h  
Fluid and electrolyte replacement as indicated by vital signs, serum electrolytes, and serum glucose

Secondary adrenal insufficiency often occurs in the presence of multiple hormone deficiencies. A decrease in ACTH production results in the decreased secretion of cortisol and adrenal androgens, but aldosterone control by more dominant mechanisms remains intact. A liberal salt diet is encouraged. Glucocorticoid substitution follows the same guidelines previously outlined for primary adrenal insufficiency.

Immediate therapy of acute adrenal insufficiency is mandatory, regardless of the etiology, and consists of electrolyte resuscitation and steroid replacement (Table 47-6). Initial therapy begins with the rapid IV administration of an isotonic crystalloid solution. A dose of 100 mg of hydrocortisone is administered as an IV bolus over several minutes. Steroid replacement is continued during the first 24 hours with 100 mg of IV hydrocortisone given every 8 hours. If the patient is stable, the steroid dose is reduced starting on the second day. After adequate fluid resuscitation, if the patient continues to be hemodynamically unstable, inotropic support may be necessary. Invasive monitoring is extremely valuable as a guide to both diagnosis and therapy.

### **Steroid Replacement during the Perioperative Period**

Perioperatively, patients with adrenal insufficiency and those with HPA suppression from chronic steroid use require additional corticosteroids to mimic the increased output of the normal adrenal gland during stress. The normal adrenal gland can secrete up to 100 mg/m<sup>2</sup> of cortisol per day or more during the perioperative period.<sup>36</sup> The pituitary–adrenal axis is usually considered to be intact if a plasma cortisol level higher than 19 µg/dL is measured during acute stress, but there is no precise threshold. The degree of adrenal responsiveness has been correlated with the duration of surgery and the extent of surgical trauma. The mean maximal plasma cortisol level measured during major surgery (colectomy, hip osteotomy) was 47 µg/dL. Minor surgical procedures (herniorrhaphy) resulted in mean maximal plasma cortisol levels of 28 µg/dL. Adrenal activity may also be affected by the anesthetic technique used. Regional anesthesia is effective in postponing the elevation in cortisol levels during surgery of the lower abdomen and extremities.<sup>37</sup> Deep general anesthesia may also suppress the elevation of stress hormones such as ACTH and cortisol during the surgical procedure.

Although symptoms indicative of clinically significant adrenal insufficiency

have been reported during the perioperative period, these clinical findings have rarely been documented in direct association with glucocorticoid deficiency.<sup>38</sup> There is evidence in adrenally suppressed primates that subphysiologic steroid replacement causes perioperative hemodynamic instability and increased mortality.

**Table 47-7** Management Options for Steroid Replacement in the Perioperative Period

Hydrocortisone, 25 mg IV, at the time of induction followed by hydrocortisone infusion, 100 mg over 24 h  
Hydrocortisone, 100 mg IV, before, during, and after surgery

Identifying which patients require steroid supplementation can be difficult. Though recommended by some, provocative testing with ACTH stimulation is too costly to justify compared with the risk of brief steroid supplementation. HPA suppression can occur after five daily doses of prednisone of at least 20 mg. Recovery of HPA function occurs gradually and can take up to 9 to 12 months. HPA suppression can occur with topical, regional, and inhaled steroids. Alternate-day therapy decreases the risk of HPA suppression.

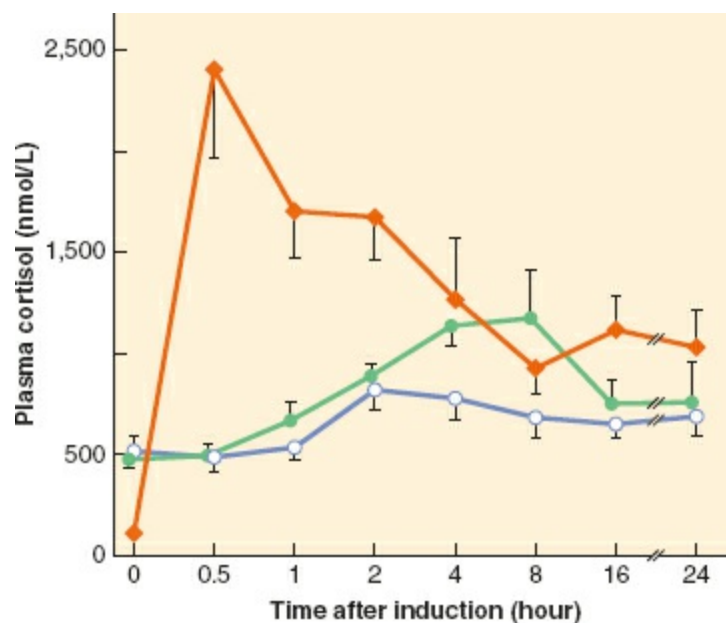

The clinical problem is how much steroid to give. There is no proven optimal regimen for perioperative steroid replacement (Table 47-7). A low-dose cortisol replacement program using an IV infusion of 25 mg of cortisol before the induction of anesthesia, followed by a continuous infusion of cortisol (100 mg) in the next 24 hours, has been advocated (Fig. 47-4).<sup>39</sup> This low-dose cortisol replacement program was used in patients with proven adrenal insufficiency and resulted in plasma cortisol levels as high as those seen in healthy control subjects subjected to a similar operative stress. One study with a limited number of patients found no problems with cardiovascular instability if patients received their usual dose of steroids.<sup>40</sup> An extensive review concluded that the best evidence was that patients should receive their usual daily dose but no supplementation.<sup>41</sup> Although the low-dose approach appears logical, many clinicians are unwilling to adopt this regimen until further trials have been undertaken in patients receiving physiologic steroid replacement. A popular regimen calls for the administration of 200 to 300 mg of hydrocortisone per 70 kg body weight in divided doses on the day of surgery. The lower dose is adjusted upward for longer and more extensive surgical procedures. Patients who are using steroids at the time of surgery receive their usual dose on the morning of surgery and are supplemented at a level that is at least equivalent to the usual daily replacement. Glucocorticoid coverage is rapidly tapered to the patient's normal maintenance dosage during the postoperative period. Although no conclusive evidence supports an increased incidence of infection or abnormal wound healing when supraphysiologic doses of supplemental steroids are used

acutely, the goal of therapy is to use the minimal drug dosage necessary to adequately protect the patient.

### Exogenous Glucocorticoid Therapy

The therapeutic use of supraphysiologic doses of glucocorticoids has expanded, and the anesthesiologist should be familiar with the various preparations (Table 47-8). Dexamethasone, methylprednisolone, and prednisone have less mineralocorticoid effect than cortisone or hydrocortisone. Prednisone and methylprednisolone are precursors that must be metabolized by the liver before anti-inflammatory activity can occur and should be used cautiously in the presence of liver disease.

**Figure 47-4** Plasma cortisol concentrations (mean  $\pm$  SEM) were measured in three groups of patients undergoing elective surgery. Group I control patients,  $n = 8$  (closed circles), had never received corticosteroids. Group II patients,  $n = 8$  (open circles), received preoperative corticosteroids with a normal response to preoperative adrenocorticotrophic hormone (ACTH; corticotropin) stimulation testing. These patients and control patients received no corticosteroid substitution during the perioperative period. Group III,  $n = 6$  (closed diamonds), consisted of patients receiving long-term corticosteroid therapy with an abnormal response to ACTH stimulation testing during the perioperative period. These patients (group III) received intravenous (IV) cortisol, 25 mg, after the induction of anesthesia plus a continuous IV infusion of cortisol, 100 mg, during the next 24 hours. Plasma cortisol levels in group III were significantly lower than in the other two groups before the induction of anesthesia. After IV administration of cortisol to group III patients, plasma concentrations were significantly higher than in groups I and II for the next 2 hours ( $p < 0.01$ ). Thereafter, the mean plasma concentrations were similar for all groups. There were no clinical signs of circulatory insufficiency in any group. (Reprinted with permission from Symreng T, Karlberg BE,

Kagedol B, et al. Physiological cortisol substitution of long-term steroid-treated patients undergoing major surgery. *Br J Anaesth.* 1981;53:949.)

## Mineralocorticoid Insufficiency

Isolated mineralocorticoid insufficiency has been reported as a congenital biosynthetic defect, after unilateral adrenalectomy for removal of an aldosterone-secreting adenoma, during protracted heparin therapy, and in patients with a deficiency in renin production. This syndrome is commonly seen in patients with mild renal failure and longstanding DM. A feature common to all patients with hypoaldosteronism is a failure to increase aldosterone production in response to salt restriction or volume contraction.

Most patients present with hypotension, hyperkalemia that may be life-threatening, and a metabolic acidosis that is out of proportion to the degree of coexisting renal impairment. Patients with low renin secretion, hypoaldosteronism, and renal dysfunction respond to ACTH stimulation. Nonsteroidal anti-inflammatory drugs, which inhibit prostaglandin synthesis, may further inhibit renin release and exacerbate the condition. Patients with isolated hypoaldosteronism are given fludrocortisone orally in a dose of 0.05 to 0.1 mg/day. Patients with low renin secretion usually require higher doses to correct the electrolyte abnormalities. Caution should be observed in patients with hypertension or congestive heart failure. An alternative approach in these patients is the administration of furosemide alone or in combination with mineralocorticoid.

## Adrenal Medulla

The adrenal medulla is derived embryologically from neuroectodermal  3 cells. As a specialized part of the sympathetic nervous system, the adrenal medulla synthesizes and secretes the catecholamines epinephrine (80%) and norepinephrine (20%). Preganglionic fibers of the sympathetic nervous system bypass the paravertebral ganglia and pass directly from the spinal cord to the adrenal medulla. The adrenal medulla is analogous to a postganglionic neuron, although the catecholamines secreted by the medulla function as hormones, and not as neurotransmitters.

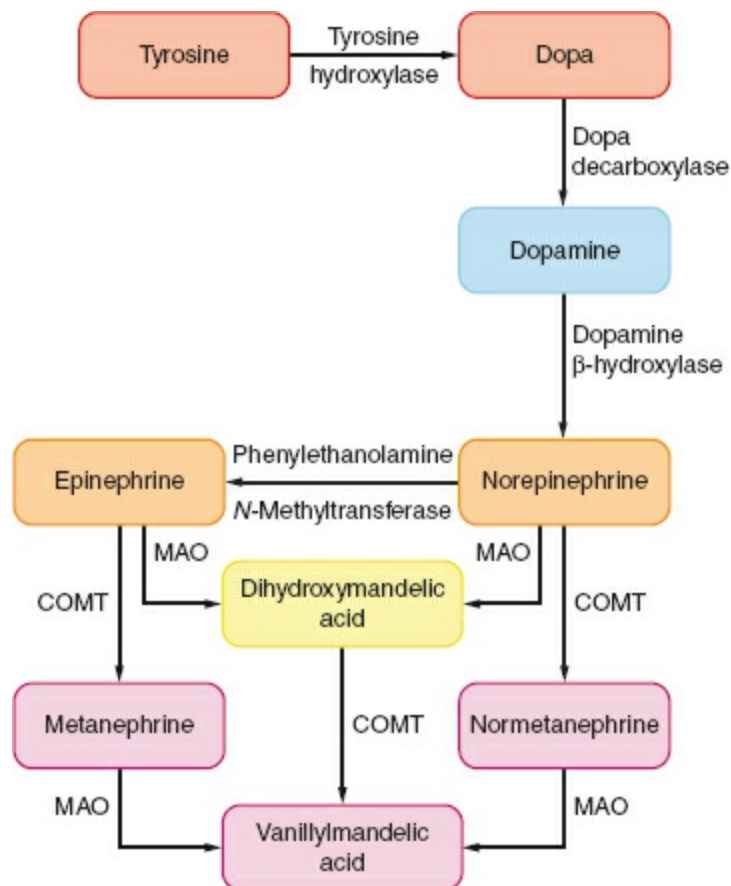

The synthesis of norepinephrine begins with hydroxylation of  tyrosine to dopa (Fig. 47-5). This rate-limiting step in catecholamine biosynthesis is regulated so synthesis is coupled to release. In the adrenal medulla and in those rare central neurons using epinephrine as a neurotransmitter, most of the norepinephrine is converted to epinephrine by the enzyme phenylethanolamine-*N*-methyltransferase. It is likely that the capacity of the adrenal medulla to synthesize epinephrine is influenced by the

flow of glucocorticoid-rich blood from the adrenal cortex through the intra-adrenal portal system because it is known that high concentrations of glucocorticoid are able to induce the enzyme phenylethanolamine-*N*-methyltransferase.

**Table 47-8** Glucocorticoid Preparations

Generic Name	Anti-inflammatory	Mineralocorticoid	Approximate Equivalent Dose (mg)
<b>Short-acting</b>			
Hydrocortisone	1.0	1.0	20.0
Cortisone	0.8	0.8	25.0
Prednisone	4.0	0.25	5.0
Prednisolone	4.0	0.25	5.0
Methylprednisolone	5.0	—	4.0
<b>Intermediate-acting</b>			
Triamcinolone	5.0	—	4.0
<b>Long-acting</b>			
Dexamethasone	30.0	—	0.75

Relative milligram comparisons with cortisol. The glucocorticoid and mineralocorticoid properties of cortisol are set as 1.0.

**Figure 47-5** Synthesis and metabolism of endogenous catecholamines. COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase. (Adapted from Stoelting RK, Dierdorf SF, eds. *Anesthesia and Co-existing Disease*. New York, NY: Churchill-Livingstone; 1983.)

In the adrenal medulla, catecholamines are stored in chromaffin granules

complexed with adenosine triphosphate and  $\text{Ca}^{2+}$ . The normal adrenal releases epinephrine and norepinephrine by exocytosis in response to stimulation by preganglionic sympathetic neurons. The circulatory half-life (10 to 30 seconds) of these catechols is considerably longer than the brief receptor activity of norepinephrine released as a neurotransmitter from postganglionic sympathetic nerve endings. Biotransformation of circulating norepinephrine and epinephrine is accomplished chiefly by the enzyme catechol-*O*-methyltransferase, located in the liver and kidney. Monoamine oxidase is of less importance in the metabolism of circulating catechols. Metanephrine and vanillylmandelic acid are the major end products of catecholamine metabolism. These metabolites and a small amount of unchanged catecholamine (1%) appear in the urine.

The outflow of postganglionic sympathetic neurotransmitters and circulating catecholamine from the adrenal medulla is coordinated by higher cortical centers connected to the brainstem. The intrinsic activity of the brainstem sympathetic areas is modulated by higher cortical functions, emotional reactions (anger, fear), and various physiologic stimuli, including changes in the physical and chemical properties of the extracellular fluid (hypoglycemia, hypotension). The adrenal medulla and sympathetic nervous system are often stimulated together in a generalized fashion, although many physiologic conditions exist in which they act independently.

## *Pheochromocytoma*

The only important endocrine disease process associated with the adrenal medulla is pheochromocytoma. These tumors produce, store, and secrete catecholamines. Paragangliomas are tumors that arise from autonomic ganglia and behave pathophysiologically like pheochromocytomas. Most pheochromocytomas secrete both epinephrine and norepinephrine, with the fraction of secreted norepinephrine being greater than that secreted by the normal gland. Although pheochromocytomas occur in less than 0.2% of hypertensive patients, it is important to aggressively evaluate the patient with clinically suspect symptoms because surgical extirpation is curative in over 90% of patients and complications are often lethal in undiagnosed cases.<sup>42</sup> Postmortem series have reported high perioperative mortality rates in undiagnosed patients undergoing relatively minor surgical procedures. Most deaths are from cardiovascular causes. Perioperative morbidity is related to tumor size and the degree of catecholamine secretion.<sup>43</sup>

Most (85% to 90%) pheochromocytomas are solitary tumors localized to a single adrenal gland, usually the right. Approximately 10% of adults and 25% of children have bilateral tumors. The tumor may originate in extra-adrenal sites (10%), anywhere along the paravertebral sympathetic chain; however,

95% of the tumors are located in the abdomen, and a small percentage are located in the thorax, urinary bladder, or neck. Malignant spread of these highly vascular tumors occurs in approximately 10% of cases.

In approximately 5% of cases, this tumor is inherited as a familial autosomal dominant trait. It may be part of the polyglandular syndrome referred to as multiple endocrine neoplasia (MEN) IIA or IIB. Type IIA includes medullary carcinoma of the thyroid, parathyroid hyperplasia, and pheochromocytoma; type IIB consists of medullary carcinoma of the thyroid, pheochromocytoma, and neuromas of the oral mucosa. Pheochromocytomas may also arise in association with von Recklinghausen neurofibromatosis or von Hippel–Lindau disease (retinal and cerebellar angiomas). The pheochromocytoma of the familial syndromes is rarely extra-adrenal or malignant. Bilateral tumors occur in approximately 75% of cases. When these patients present with a single adrenal pheochromocytoma, the chances of subsequent development of a second adrenal pheochromocytoma are sufficiently high that bilateral adrenalectomy should be considered. Every member of a MEN family should be considered at risk for pheochromocytoma.

## **Clinical Presentation**

Pheochromocytoma may occur at any age, but it is most common in young to middle adult life. The clinical manifestations are mainly due to the pharmacologic effects of the catecholamines released from the tumor. These tumors are not innervated, and catecholamine release is independent of neurogenic control. Most patients have sustained hypertension, although occasionally it is paroxysmal.<sup>44</sup> When true paroxysms occur, the blood pressure may rise to alarmingly high levels, placing the patient at risk for cerebrovascular hemorrhage, heart failure, dysrhythmias, or myocardial infarction. Headache, palpitations, tremor, profuse sweating, and either pallor or flushing may accompany an attack. Pheochromocytoma can masquerade as malignant hyperthermia. Physical examination of the patient with pheochromocytoma may be unrevealing during the period between attacks, unless the patient presents with symptoms and signs of sequelae related to longstanding hypertension. A catecholamine-induced cardiomyopathy may be accompanied by heart failure and cardiac dysrhythmias. Paroxysms are commonly not associated with clearly defined events, but may be precipitated by displacement of the abdominal contents or, in the case of a bladder tumor, by micturition.

## **Diagnosis**

Biochemical determination of free catecholamine and catecholamine

metabolites in the urine is the most common screening test used to establish the diagnosis of pheochromocytoma.<sup>45</sup> Urinary vanillylmandelic acid and unconjugated norepinephrine and epinephrine levels are measured in a 24-hour urine collection and are expressed as a function of the creatinine clearance (Fig. 47-6). Excess production of catecholamines is diagnostic for pheochromocytoma. Free catecholamines represent less than 1% of the originally released hormone, and urinary levels are not always elevated to a significant degree. Hence, differentiation from normal subjects may be difficult. A change in the ratio of unconjugated epinephrine to norepinephrine may be the only biochemical finding. Certain drugs interfere with urinary assays, and some patients with paroxysmal hypertension have normal values between attacks.

**Figure 47-6** Catabolism of norepinephrine and epinephrine.

Although routine laboratory data are unlikely to provide specific diagnostic insight, ECG, chest radiograph, and complete blood cell count can provide valuable information about end-organ damage to the clinician who entertains the diagnosis. Left ventricular hypertrophy and nonspecific T-wave changes are two of the more common ECG findings. Evidence of acute myocardial infarction or tachyarrhythmia has also been reported. The chest radiograph may reveal cardiomegaly, and the blood count often shows an elevated hematocrit consistent with a reduced intravascular volume and hemoconcentration. Standardized imaging methods such as CT and MRI are

used in the noninvasive localization of these tumors.<sup>46</sup> Ultrasound and MRI are especially useful in pregnant patients. <sup>131</sup>I-Metaiodobenzylguanidine scintigraphy is also effective in localizing recurrent or extra-adrenal masses.<sup>47</sup>

## Anesthetic Considerations

### *Preoperative Preparation*

Perioperative mortality rates have decreased from a high of 45% to 4 between 0% and 3% for excision of pheochromocytoma followed by the introduction of  $\alpha$ -antagonists for preoperative therapy. Perioperative blood pressure fluctuations, myocardial infarction, congestive heart failure, cardiac dysrhythmias, and cerebral hemorrhage all appear to be reduced in frequency when the patient has been treated before surgery with  $\alpha$ -blockers and the intravascular fluid compartment has been re-expanded. Extended treatment with  $\alpha$ -antagonists is also effective in treating the clinical manifestations of catecholamine myocarditis. However,  $\alpha$ -blocker therapy has never been studied in a controlled way, and there are some groups that question its necessity in light of the availability of potent titratable vasodilators for intraoperative use.<sup>48</sup> A list of drugs frequently used in the management of pheochromocytoma is given in [Table 47-9](#).

**Table 47-9** Drugs Used in the Management of Pheochromocytoma

Drug	Action	Preoperative Blood Pressure Control	Pressor Crisis	Comment
Phentolamine	Nonselective $\alpha$ -antagonist	—	1–5 mg IV; 0.5–1 mg/min IV	Short duration of action –5 min
Phenoxybenzamine	Nonselective $\alpha$ -antagonist	20 mg/day PO up to 160 mg/day in divided doses	—	Long half-life; may accumulate
Doxazosin (terazosin dosing similar)	Selective $\alpha_1$ -antagonist	1 mg/day PO up to 8 mg/day PO	—	First-dose phenomena; may cause syncope
Propranolol	Nonselective $\beta$ -antagonist	40 mg/day PO up to 480 mg/day in divided doses to control tachycardia	1–2 mg IV bolus	Should never be given without first creating $\alpha$ -blockade
Atenolol	Selective $\beta_1$ -antagonist	50–100 mg/day PO	—	Long-acting drug eliminated unchanged by kidney
Esmolol	Selective $\beta_1$ -antagonist	—	250–500 $\mu$ g/kg/min IV loading followed by maintenance infusion 25–250 $\mu$ g/kg/min	Short acting; elimination half-life –9 minute
Labetalol	$\alpha$ -antagonist and $\beta$ -antagonist	200 mg/day PO in divided doses up to 800 mg/day	10 mg IV bolus	A much weaker $\alpha$ -blocker than $\beta$ -blocker; may cause hypertensive response
Nitroprusside	Direct vasodilator	—	0.5–1.5 $\mu$ g/kg/minute initially, increased to maximum of 8 $\mu$ g/kg/min; titrate to effect	Powerful vasodilator; short acting
Magnesium sulfate	Direct vasodilator and membrane stabilizer	—	2–4 g IV bolus followed by 1–2 g/hour and additional 1–2 g boluses as needed	May potentiate neuromuscular blockade
Nicardipine	Calcium channel antagonist	—	1–2 $\mu$ g/kg/min increased to 7.5 $\mu$ g/kg/min; titrate to effect	—
$\alpha$ -Methyltyrosine	Inhibitor of biosynthesis of catecholamine	1–4 g/day PO in divided doses	—	Suitable for patients not amenable to surgery; may be nephrotoxic

$\alpha$ -Adrenergic blockade is initiated once the diagnosis of pheochromocytoma is established (see [Chapter 13](#)). Phenoxybenzamine, a long-acting (24 to 48 hours), noncompetitive presynaptic ( $\alpha_2$ ) and postsynaptic ( $\alpha_1$ ) blocker, has traditionally been used at doses of 10 mg every 8 hours. Increments are added until the blood pressure is controlled and paroxysms disappear. Most patients need between 80 and 200 mg/day. The absorption after oral administration is variable, and side effects are common. Certain cardiovascular reflexes such as the baroreceptor reflex are blunted, and postural hypotension is common. Selective competitive  $\alpha_1$ -blockers, such as doxazosin, terazosin, and prazosin, can also be used effectively with fewer side effects. Because postural hypotension can be pronounced with the commencement of therapy, the initial 1-mg dose is given at bedtime. Postural changes are also seen with maintenance therapy. A comparison of patients with pheochromocytoma receiving phenoxybenzamine or prazosin has shown both drugs to be equally effective in controlling blood pressure. Although the optimal period of preoperative treatment has not been established, most

clinicians recommend beginning  $\alpha$ -blockade therapy at least 10 to 14 days before the proposed surgery; however, periods as short as 3 to 5 days have been used.<sup>49</sup> During this time, the contracted intravascular volume and hematocrit return toward normal and the blood pressure is stabilized. Despite the real possibility of hypotension after vascular isolation of the tumor, most clinicians continue  $\alpha$ -blockers until the morning of surgery. Calcium channel blockers can also be used alone or in combination with  $\alpha$ -blockers.

$\beta$ -Adrenergic blockade is occasionally added after  $\alpha$ -blockade has been established. This addition is considered in patients with persistent tachycardia or cardiac dysrhythmias that may be caused by nonselective  $\alpha$ -blockade or epinephrine-secreting tumors.  $\beta$ -Blockers should not be given until adequate  $\alpha$ -blockade is ensured to avoid the possibility of unopposed  $\alpha$ -mediated vasoconstriction. There is no clear preoperative advantage of one  $\beta$ -antagonist over another, although the short half-life of esmolol may allow better control of heart rate and arrhythmias in the perioperative setting. Labetalol, a  $\beta$ -adrenergic antagonist with  $\alpha$ -blocking activity, is effective as a second-line medication, but can increase blood pressure when used alone.

$\alpha$ -Methyltyrosine is an agent that inhibits the enzyme tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. This medication is generally reserved for patients with metastatic disease or for situations in which surgery is contraindicated and long-term medical therapy is required though some institutions are including it as part of preoperative preparation. When  $\alpha$ -methyltyrosine is used in combination with  $\alpha$ -adrenergic-blocking agents, there is a significant reduction in catecholamine biosynthesis.

Unrecognized pheochromocytoma during pregnancy may be life-threatening to the mother and fetus. Although the safety of adrenergic-blocking agents during pregnancy has not been established, these agents probably improve fetal survival in pregnant patients with pheochromocytoma. The trend is to perform surgery during the first trimester or at the time of cesarean delivery. There is no reason to terminate an early pregnancy, but the patient should be aware of the risk of spontaneous abortion resulting from abdominal surgery to remove the tumor.<sup>50</sup>

### *Perioperative Anesthetic Management*

Symptomatic patients continue to receive medical therapy until tachycardia, cardiac dysrhythmias, and paroxysmal elevations in blood pressure are well controlled. If it is not possible to initiate  $\alpha$ -blocking therapy before surgery or if the patient has received less than 48 hours of intensive treatment, it may be necessary to infuse nitroprusside during the induction of anesthesia. A low-dose infusion is often initiated in anticipation of the marked blood pressure elevations that can occur with laryngoscopy and surgical stimulation.

Improvements in imaging now allow most patients with solitary tumors without evidence of metastases or local invasion to undergo a laparoscopic retroperitoneal approach. If the surgeon needs to assess for bilateral disease or the dissection is too difficult, then the procedure can be converted to an open one. During laparoscopic surgery, creation of the pneumoperitoneum may cause release of catecholamines and large changes in hemodynamics that can be controlled with a vasodilator.<sup>51</sup> Cortical sparing adrenalectomies are becoming more common to preserve adrenal function.

Continuous intra-arterial blood pressure monitoring is required for managing the patient with pheochromocytoma. Central venous access can be useful for secure administration of anticipated vasoactive medications. The presence of coexisting disease would dictate the need for more intensive monitoring.

Although there is no clear advantage to one anesthetic technique over another, drugs that are known to liberate histamine are avoided. Dopamine antagonists such as droperidol and metoclopramide can provoke catecholamine release and should not be used. A potent sedative hypnotic, in combination with an opioid analgesic, is used for induction. It is extremely important to achieve an adequate depth of anesthesia before proceeding with laryngoscopy to minimize the sympathetic nervous system response to this maneuver. Maintenance is provided with an opioid analgesic and a potent **5** inhalation agent. Manipulation of the tumor may produce a marked elevation in blood pressure. Acute hypertensive crises are treated with IV infusions of nitroprusside or phentolamine or any vasodilator mentioned later. Phentolamine is a short-acting  $\alpha$ -adrenergic antagonist that may be given as an IV bolus (2 to 5 mg) or by continuous infusion. Tachydysrhythmia is controlled with IV boluses of propranolol (1-mg increments) or by a continuous infusion of the ultrashort-acting selective  $\beta_1$ -adrenergic antagonist esmolol. The disadvantage of long-acting  $\beta$ -blockers may be persistence of bradycardia and hypotension after the tumor is removed. Even esmolol may be problematic because there are cases of cardiac arrest after clamping of the venous drainage in patients receiving large doses of esmolol. Almost every vasodilator has been tried and recommended as an adjuvant to control hypertension. Magnesium sulfate given as an infusion with intermittent boluses has successfully controlled blood pressure.<sup>52</sup> Nicardipine, clevidipine,<sup>53</sup> nitroglycerin, diltiazem, fenoldopam, and prostaglandin E<sub>1</sub> have all been used anecdotally. The reduction in blood pressure that may occur after ligation of the tumor's venous supply can be dangerously abrupt and should be anticipated through close communication with the surgical team. Restitution of any intravascular fluid deficit is the initial therapy in this situation. After replenishment of the intravascular volume, if the patient remains hypotensive, phenylephrine is administered. Norepinephrine or

vasopressin may also be needed.<sup>53</sup> After surgery, catecholamine levels return to normal over several days. Approximately 75% of patients become normotensive within 10 days. Hypoglycemia must be watched for as insulin levels rise from loss of catecholamine-induced  $\beta$ -cell suppression.

## Diabetes Mellitus

A fasting glucose level below 100 mg/dL is considered normal. Individuals with documented fasting glucose levels above 126 mg/dL (HbA1c  $\geq$ 6.5%) are considered diabetics, whereas those with levels between 100 and 125 mg/dL (HbA1c 5.7 to 6.4) are considered prediabetics.<sup>54</sup> An estimated 29.1 million Americans (7% of the U.S. population) have DM and about 40 million Americans have prediabetes.<sup>55</sup> DM is the most commonly occurring endocrine disease found in surgical patients, and 25% to 50% of diabetics will require surgery at some point in their lives. Although the most serious complications of DM are related to its character as a chronic disease, it can cause difficulties in the short-term management of acute illness. DM can remain clinically unapparent until exacerbated by the stress of trauma or surgery.<sup>56</sup> Some observational studies report that hyperglycemia is present in 32% to 38% of patients in community hospitals, 41% of critically ill patients with acute coronary syndromes, and 80% of patients after cardiac surgery.<sup>57</sup> In these reports, approximately one-third of nonintensive care unit (non-ICU) patients and approximately 80% of ICU patients had no history of diabetes before admission.<sup>57</sup>

The principles of the treatment of DM will be easier to understand if one reviews the physiology of glucose metabolism and the stress response and then considers some of the specific pathologic entities that comprise the clinical picture of DM.

### Classification

DM primarily manifests as a disease of glucose metabolism; however, it significantly affects lipid and protein metabolism and has an impact on a wide range of endocrinologic functions. Despite a variety of etiologic factors, its hallmark is a deficiency, either absolute or relative, in the amount of insulin effect to the tissues.

DM is classified into four broad types: type 1 diabetes, type 2 diabetes, gestational DM, and diabetes due to other causes.<sup>54</sup>

Type 1 is due to pancreatic  $\beta$ -cell destruction, usually leading to absolute insulin deficiency. It accounts for 5% to 10% of all DM cases and is distinguished from type 2, which accounts for the remaining 90% to 95% of all DM cases. Most patients with type 1 DM typically experience the onset of

disease early in life. Consequently, this form was also referred to as juvenile-onset diabetes. However, type 1 diabetes and type 2 diabetes are heterogeneous diseases in which clinical presentation and disease progression may vary considerably. The traditional paradigms of type 2 diabetes presenting only in adults and type 1 diabetes only in children are no longer accurate, as both diseases occur in both cohorts.<sup>58</sup> Classification is important for determining therapy. Hyperglycemia in patients with type 1 diabetes cannot be controlled with diet or oral hypoglycemic agents; rather, it mandates treatment with insulin as there is an absolute deficiency of insulin. It is difficult to maintain an optimal glucose level in patients with type 1 DM. They are more likely to become ketotic and sustain progressive end-organ complications of diabetes.<sup>54</sup>

Patients with type 2 DM, also called adult-onset diabetes, typically experience a gradual onset of the disease later in life. It is due to a progressive loss of insulin secretion in the background of insulin resistance. However, type 2 form can occur in young people, and many older adults can acquire a severe and brittle form of type 1 diabetes. Because of the obesity epidemic, many adolescents and teenagers are presenting more frequently with this disorder.<sup>54</sup> Patients with type 2 DM are often obese, have resistance to the effects of insulin (commonly referred to as insulin resistance), and, hence, may have normal or even elevated levels of insulin, initially. In milder forms, this version of diabetes can often be treated with diet, lifestyle modifications, and oral hypoglycemic agents. Because these patients are relatively resistant to ketosis, their disease may not be clinically apparent until exacerbated by the stress of surgery or intercurrent illness.

Other types of DM can be a result of a disease that damages the pancreas and thus impairs insulin secretion. Pancreatic surgery, chronic pancreatitis, cystic fibrosis, and hemochromatosis can damage the pancreas and impair insulin secretion sufficiently to produce clinical DM. DM can also result from one of the endocrine diseases that produces a hormone that opposes the action of insulin. Hence, a patient with a glucagonoma, pheochromocytoma, or acromegaly may develop diabetes. An increased effect of glucocorticoids, from either Cushing disease or steroid or tacrolimus therapy (after organ transplantation), may also oppose the effect of insulin enough to elicit clinical diabetes and would certainly complicate the management of pre-existing diabetes. Thiazide diuretic and atypical antipsychotics (clozapine, olanzapine, risperidone, ziprasidone, quetiapine) increase the risk of diabetes.<sup>59</sup> Treatment of human immunodeficiency virus/acquired immunodeficiency syndrome, genetic defects in  $\beta$ -cell function, and genetic defects in insulin action can also induce diabetes (monogenic diabetes).<sup>54</sup> Gestational diabetes is typically diagnosed in the second or third trimester of pregnancy and may presage future type 2 DM. Different diagnostic criteria are used to diagnose

gestational diabetes.<sup>54</sup>

## Physiology

Insulin has multiple and complex interactions with lipid, protein, and glucose metabolism. It also has many nonmetabolic functions.<sup>60</sup> For our purposes, it is easiest to regard the effects of insulin on glucose metabolism as primary and to view its effects on other metabolic functions only as they relate to glucose.

Insulin is a small protein produced by the  $\beta$  cells of the islets of Langerhans in the pancreas. The basal rate of insulin secretion is about 1 unit/hr, which can increase by 5- to 10-fold after ingestion of food. Normal production in the adult human is approximately 40 to 50 units/day. Insulin acts through its specific receptor on cells. The half-life of insulin in the circulation is 5 minutes. However, it may clinically appear to have a longer duration of action, due to delays in binding and release from the cellular receptors.<sup>61</sup> These facts lead us to the important principle that once a high level of insulin saturates all the binding sites, insulin will not have a more potent effect, just a more long-lasting effect.

Insulin is metabolized in the liver and kidneys. In patients with hepatic dysfunction, the loss of gluconeogenesis and a prolongation of insulin effect increase the risk of hypoglycemia. Similarly, in patients with renal disease, the action of insulin is prolonged. They are more prone to hypoglycemia, and exogenous insulin should be administered judiciously in diabetic patients with renal disease.

Insulin release is related to a number of events. First is the direct effect of glucose and amino acids to stimulate insulin release. The mechanism involves interaction with hormones from the GI tract released during enteral feeding. The autonomic nervous system, also through vagal stimulation, increases insulin release, as does  $\beta$ -adrenergic stimulation and  $\alpha$ -adrenergic blockade. Nitric oxide stimulates insulin secretion, and potassium depletion decreases insulin secretion.

The most fundamental action of insulin is to stimulate cellular uptake of glucose in skeletal muscle cells, adipose tissue, and cardiac cells. This is particularly important in skeletal muscle cells, where muscle activity also increases glucose uptake and is an important variable in the management of the physically active diabetic patient. The brain, liver, and immune cells are exceptions, where insulin does not affect glucose transport. Hence, the patient with diabetes has hyperglycemia because of inadequate cellular uptake of glucose in muscle and adipose tissue. Along with glucose, potassium enters the cells under the influence of insulin, so the diabetic patient is also likely to have an imbalance of potassium concentrations across cell membranes.

Other important metabolic functions of insulin include the stimulation of

glycogen formation, as well as the suppression of gluconeogenesis and lipolysis. The patient with insulin deficiency has low glycogen stores and active gluconeogenesis. This implies that in the diabetic patient, because of an absence of glycogen, protein must be broken down to make glucose. Insulin also increases the uptake of amino acids into muscle cells. Hence, an insulin deficiency leads to catabolism and negative nitrogen balance.

Fat metabolism is also abnormal in the diabetic state, with acceleration of lipid catabolism and increased formation of ketone bodies. A deficiency of insulin leads to increased fatty acid liberation from adipose tissue. These fatty acids have multiple metabolic effects, including interference with carbohydrate phosphorylation in muscle, which leads to further hyperglycemia. Low concentrations of insulin, which may be inadequate to prevent hyperglycemia, are often sufficient to block lipolysis. This effect explains the common clinical situation in which a patient is hyperglycemic without being ketotic.

Glucagon is a polypeptide released from the  $\alpha$  cells of the pancreas and acts both to stimulate the release of insulin and to oppose some of the effects of insulin. It has both a direct and an indirect ability to increase circulating glucose levels. In some patients, after total pancreatic resection, glucose balance is not as poor as might be expected because of the concomitant absence of glucagon. Glucagon release is stimulated by hypoglycemia, epinephrine, and cortisol and is suppressed by glucose ingestion.

The metabolic effects of stress are intricately involved with the same pathways as those involved in DM. During stress, elevations in the circulating levels of cortisol, glucagon, catecholamines, and growth hormone all act to stimulate gluconeogenesis and glycogenolysis and cause hyperglycemia. In addition, glucagon and adrenergic stimulation exert a suppressive effect on insulin release. Furthermore, inflammatory mediators released during stress enhance the release of the counter-regulatory hormones and directly affect the intracellular signaling pathways of insulin, culminating in significant insulin resistance.<sup>62,63</sup> Hence, mild hyperglycemia may occur in the stressed patient who does not have DM. In a patient with minimal or subclinical DM before the stressful episode, the hyperglycemia may become difficult to manage during the stress-related event and many patients require additional insulin to manage hyperglycemia.

## **Diagnosis**

For decades, the diagnosis of diabetes was based on plasma glucose criteria, either the fasting plasma glucose (FPG) or the 2-hour value in the 75-g oral glucose tolerance test (OGTT). Starting in 2009, the criteria to diagnose DM was amended and now includes hemoglobin A1c (HbA1c) above 6.5%.<sup>54</sup>

Correlation of HbA1c with average glucose levels is presented in Figure 47-7. Other criteria for diagnosing DM are listed in Table 47-10. As with most diagnostic tests, a test result diagnostic of diabetes should be repeated to rule out laboratory error, unless the diagnosis is clear on clinical grounds.<sup>54,64</sup>

## Treatment

Patients with type 1 DM require exogenous insulin to survive. Further, the risk of microvascular complications can be decreased if glycemic control is maintained near normal levels of blood glucose (HbA1c <7%).<sup>54,65</sup> Patients may be on a range of doses of short-acting and long-acting insulin, with doses given three to four times per day, depending on the desire for tight control. In some clinical situations, an insulin pump may be used to administer a constant level of insulin. Intensive treatment of hyperglycemia in *newly* diagnosed patients may reduce long-term cardiovascular disease rates; however, intensive glycemic control (HbA1c <6.5% for 3.5 to 5.6 years) in patients with longstanding diabetes (8 to 11 years) showed no reduction in cardiovascular outcomes.<sup>66</sup>

**Figure 47-7** Correlation of hemoglobin A1c with average glucose. (Mean plasma glucose values above the line are in mg/dL and below the line and italic are in mmol/dL.) Estimates are based on 2,700 glucose measurements over 3 months per A1c measurement in 507 adults with type 1, type 2, and no diabetes. The correlation between A1c and average glucose was 0.92. (Data from Nathan DM, Kuenen J, Borg R, et al. A1c-derived average glucose study group: translating the A1c assay into estimated average glucose values. *Diabetes Care*. 2008;31:1473–1478.)

Patients with type 2 DM may initially be treated with diet control, exercise, and metformin therapy.<sup>67</sup> Metformin is a biguanide that decreases

hepatic glucose output and enhances the sensitivity of both hepatic and peripheral tissues to insulin.<sup>68</sup> If this fails to control glucose levels or the diabetes worsens, therapy with insulin and additional oral agents are indicated.<sup>54</sup> The goal is to decrease HbA1c levels below 7% safely, without causing hypoglycemia. Each new class of noninsulin agents added to initial therapy is expected to reduce HbA1c by 0.9% to 1.1%.<sup>69</sup> Selected properties of noninsulin glucose-lowering drugs are noted in [Table 47-11](#). Sulfonylureas (glyburide, glipizide, glimepiride) and glinides (repaglinide, nateglinide) enhance  $\beta$ -cell insulin secretion. Rosiglitazone (Avandia) and pioglitazone (Actos) are thiazolidinediones that increase insulin sensitivity.  $\alpha$ -Glucosidase inhibitors (acarbose, miglitol) decrease postprandial glucose absorption. Amylin analogs (pramlintide) suppress glucagon secretion and slow gastric emptying. Incretin mimetics (exenatide), as the name implies, emulate natural incretin hormones (glucagon-like peptide-1 [GLP-1], glucose-dependent insulinotropic polypeptide [GIP]) and increase insulin production, inhibit glucagon secretion, and decrease glucose absorption. Dipeptidyl-peptidase-4 inhibitors (sitagliptin) also slow degradation of incretin hormones, increase endogenous incretin hormone levels, and improve postprandial hyperglycemia. Sodium-glucose cotransporter 2 (SGLT2) inhibitors provide insulin-dependent glucose lowering by blocking glucose reabsorption in the proximal renal tubule by inhibiting SGLT2. There is an increased risk of ketoacidosis in patients with type 1 and type 2 diabetes who are treated with SGLT2 inhibitors.<sup>70</sup> Bariatric surgery may be considered for adults with a body mass index higher than 35 kg/m<sup>2</sup> and type 2 diabetes, especially if the diabetes or associated comorbidities are difficult to control with lifestyle and pharmacologic therapy.<sup>54</sup> Although small trials have shown a glycemic benefit of bariatric surgery in patients with type 2 diabetes with BMI 30 to 35 kg/m<sup>2</sup>, there is currently insufficient evidence to generally recommend surgery in patients with BMI 35 kg/m<sup>2</sup> or lower.<sup>71</sup>

**Table 47-10** Criteria for the Diagnosis of Diabetes

A1c  $\geq 6.5\%$ . The test should be performed in a laboratory using a method that is certified and standardized.<sup>a</sup>  
Fasting plasma glucose  $\geq 126$  mg/dL (7 mmol/L). Fasting is defined as no caloric intake for at least 8 h.<sup>a</sup>  
2-h plasma glucose  $\geq 200$  mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.<sup>a</sup>  
In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose  $\geq 200$  mg/dL (11.1 mmol/L).

<sup>a</sup>In the absence of unequivocal hyperglycemia, result should be confirmed by repeat testing.

## Anesthetic Management

Successful management of diabetic patients is as dependent on, or more dependent on, chronic complication management than acute hyperglycemia.

### Preoperative

Preoperative evaluation and management has three important goals: One is determining end-organ complications of DM. This requires a thorough history and physical, a recent ECG, blood urea nitrogen, potassium, creatinine, glucose, and urinalysis. Second is determining the patient's glucose-lowering regimen. Patients may be on different types of insulin regimens and oral hypoglycemic agents. Preoperative counseling has to be specific to the patient's glucose-lowering regimen. The third goal is to determine patient glycemic control and the need for preoperative intervention to control glucose levels.

**Table 47-11** Properties of Selected Glucose-lowering Drugs

Class	Compounds	Mechanism	Actions
Biguanides	Metformin	Activate AMP-kinase	Decrease hepatic glucose production Decrease intestinal glucose absorption Increase insulin action
Sulfonylureas (second generation)	Glibenclamide/glyburide Glipizide Gliclazide Glimepiride	Close KATP channels on $\beta$ -cell plasma membranes	Increase insulin secretion
Meglitinides (glinides)	Repaglinide Nateglinide	Close KATP channels on $\beta$ -cell plasma membranes	Increase insulin secretion
Thiazolidinediones (glitazones)	Pioglitazone Rosiglitazone	Activate the nuclear transcription factor PPAR- $\gamma$	Increase peripheral insulin sensitivity
$\alpha$ -Glucosidase inhibitors	Acarbose Miglitol	Inhibit intestinal $\alpha$ -glucosidase	Intestinal carbohydrate digestion (consequently, absorption is slowed)
GLP-1 receptor agonists (incretin mimetics)	Exenatide Exenatide extended release Liraglutide Albiglutide Dulaglutide	Activate GLP-1 receptors ( $\beta$ -cells/ endocrine pancreas; brain/ autonomous nervous system)	Increase insulin secretion (glucose dependent) Decrease glucagon secretion (glucose dependent) Slow gastric emptying Increase satiety
DPP-4 inhibitors (incretin enhancers)	Sitagliptin Vildagliptin Saxagliptin Linagliptin Alogliptin	Inhibit DPP-4 activity, increasing postprandial, endogenously released, active incretin hormone concentration	Increase active GLP-1 concentration Increase active GIP concentration Increase insulin secretion Decrease glucagon secretion
Bile acid sequestrants	Colesevelam	Bind bile acids in the intestinal tract, increasing bile acid production	Decrease hepatic glucose production Increase incretin levels
Dopamine-2 agonists	Bromocriptine	Activate dopaminergic receptors	Alter hypothalamic regulation of metabolism Increase insulin sensitivity
SGLT2 inhibitors	Canagliflozin Dapagliflozin Empagliflozin	Inhibits SGLT2 in the proximal nephron	Block glucose reabsorption by the kidney, increasing glucosuria
Amylin mimetics	Pramlintide	Activates amylin receptors in the pancreas	Decrease glucagon secretion Slow gastric emptying Increase satiety

AMP, adenosine monophosphate; KATP, adenosine triphosphate potassium; PPAR, peroxisome proliferator-activated receptor; GLP, glucagon-like peptide; DPP, dipeptidyl peptidase; SGLT, sodium-glucose transport protein.

## End-organ Complications of Diabetes

**6** Atherosclerosis develops earlier and is more widespread in diabetic patients compared with nondiabetics. Manifestations include coronary artery disease, peripheral vascular disease, cerebrovascular disease, and renovascular disease. The incidence of postoperative myocardial infarction is increased in diabetic patients, and the complication rate is higher. Coronary artery disease can manifest at a young age or atypically in type 1 diabetics. Silent myocardial ischemia and infarction occur more commonly in diabetic patients, perhaps because of sensory neuropathy of the visceral afferents to the heart. DM may be associated with a cardiomyopathy in the face of angiographically normal coronary arteries, possibly with diffuse disease in

arteries too small to be visualized. The American College of Cardiology (ACC)/American Heart Association guidelines recognize DM as a risk factor when evaluating patients for noncardiac surgery.<sup>72</sup> Preoperative hyperglycemia, as documented by increased HbA1c, has consistently been associated with poor perioperative outcomes in a variety of clinical situations.<sup>61,73</sup>

Diabetic nephropathy occurs in 20% to 40% of patients with diabetes and is the leading cause of end-stage renal disease (ESRD). Albuminuria usually precedes a steady decline in renal function. Microalbuminuria (30 to 299 mg/24 hrs) has been shown to be the earliest stage of diabetic nephropathy in type 1 diabetes and a marker for development of nephropathy in type 2 diabetes.<sup>52,74</sup>

Patients with diabetes can develop heterogeneous types of neuropathies with diverse clinical manifestations. Most common among the neuropathies are chronic sensorimotor distal symmetric polyneuropathy and autonomic neuropathy.<sup>75</sup> Cardiovascular autonomic neuropathy is clinically the most important. It presents as resting tachycardia, exercise intolerance, and orthostatic hypotension. Autonomic function may be tested by measuring the beat-to-beat variation in heart rate during breathing, heart rate response to a Valsalva maneuver, and orthostatic changes in diastolic blood pressure and heart rate. Diabetic patients with autonomic neuropathy are at increased risk for intraoperative hypotension, requiring vasopressor support, and perioperative cardiorespiratory arrest.<sup>76–78</sup> There may be an exaggerated pressor response to tracheal intubation.<sup>79</sup> Autonomic neuropathy predisposes to intraoperative hypothermia.<sup>80</sup>

Diabetic patients may also have GI neuropathies (e.g., esophageal enteropathy, gastroparesis, constipation, diarrhea, fecal incontinence). They may have delayed gastric emptying, and therefore they may be at increased risk of pulmonary aspiration of gastric contents. Autonomic function tests can predict the presence of solid food particles in gastric contents, but not increased gastric volume or acidity. Metoclopramide or erythromycin may be useful in emptying the stomach of solid food.<sup>54</sup>

In up to 40% of juvenile patients with DM presenting for renal transplantation, direct laryngoscopy can be difficult.<sup>81</sup> This may be due to diabetic stiff joint syndrome, a frequent complication of type 1 DM, leading to decreased mobility of the atlanto-occipital joint. The “prayer sign,” an inability to approximate the palmar surfaces of the interphalangeal joints, is associated with stiff joint syndrome and may predict difficult laryngoscopy. Diabetic patients are at an increased risk of cognitive decline, dementia, fractures, cancer, obstructive sleep apnea, and hearing disorders.<sup>54</sup>

### *Determining Glucose-lowering Regimen and Preoperative Counseling*

Though specific protocols vary from institution to institution, a typical protocol followed at our institution is as follows.<sup>82</sup> Patients who are on oral antihyperglycemic medications are advised to discontinue their medications the night before surgery. No oral hypoglycemic medications are administered or advised on the morning of surgery. Medications are reinstated after the patient has resumed a normal diet. Patients who are on sulfonylureas are particularly at risk for developing hypoglycemia. Like other oral hypoglycemics, metformin should be discontinued preoperatively. Though it has been associated with severe lactic acidosis during episodes of hypotension, poor perfusion, or hypoxia, similar perioperative outcomes have been reported in patients who have undergone surgery without discontinuing metformin.<sup>83</sup>

For patients who are taking short- or long-acting insulin preparations, adjustment of the insulin should take into account the timing of their insulin regimen (Table 47-12). Patients who take both evening and morning doses of insulin should take their usual dose of evening short-acting insulin, but reduce their intermediate- or long-acting insulin dose by 20% the night before surgery. On the morning of surgery, they should omit their morning short-acting insulin and reduce the intermediate- or long-acting dose by 50% (and take this only if the fasting glucose is >120 mg/dL). If patients are using a premixed insulin, they are instructed to reduce their evening dose prior to surgery by 20% and hold insulin completely on the morning of the procedure.<sup>82</sup> Patients with type 1 diabetes need some basal insulin at all times. An estimated 400,000 patients with DM in the United States are receiving continuous subcutaneous insulin infusion (CSII) therapy (also called insulin pump therapy) to achieve optimal glucose control. Though insulin pumps have been safely utilized during surgery, there is no consensus regarding their management in the perioperative period. Specialized endocrinologic expertise may be needed in the care of patients with an insulin pump.<sup>84</sup> Blood glucose should be checked every hour if insulin infusion pump is continued during surgery.

**Table 47-12** Properties of Common Insulin Preparations

Insulin/Insulin Analogue Preparation	Onset	Peak	Duration
Lispro, Aspart, Glulisine (sc)	10–15 min	1–2 hr	3–5 hr
Regular (sc)	0.5–1 hr	2–4 hr	4–8 hr
Regular (iv)	15 min	15–30 min	0.5–1 hr
NPH (sc)	1–3 hr	4–10 hr	10–18 hr
Glargine (sc)	2–3 hr	none	24+ hr
Detemir (sc)	1 hr	none	Up to 24 hr

sc, subcutaneous; iv, intravenous.

### *Preoperative Glycemic Control*

It is axiomatic that the patient should attain the best possible preoperative metabolic control; however, no randomized control study has documented that achieving a certain glycemic range preoperatively for a certain period of time will improve perioperative outcome.<sup>85</sup> Currently, no evidence-based guidelines exist regarding when to cancel a surgical procedure due to hyperglycemia. Given the multitude of patient factors involved as well as the variety of surgical procedures and procedure urgency, it is unlikely that recommendations based on outcomes will be forthcoming. Providers need to weigh several issues when considering this question. First, the urgency of surgery should be considered. Second, hyperglycemia could represent an unstable metabolic state, such as diabetic ketoacidosis (DKA), which should be rapidly assessed in the preoperative area. Elective surgery in an unstable metabolic state is not recommended (see “Emergencies”). Furthermore, the chronic glycemic state of the patient should be considered. If the patient has chronically elevated glucose values, this represents poor glucose control, as opposed to a new illness. In this situation, there are opportunities for providers to identify and address the problem prior to the patient arriving in the preoperative area. The value of canceling elective surgery in this situation is unclear. Another consideration is that the hyperglycemia may be caused by the illness for which the patient presented for surgery (e.g., wound infection, intra-abdominal sepsis, osteomyelitis), which would not be expected to improve until the patient undergoes surgery and source control is achieved. Providers must therefore assess the patient for stability, the need for the procedure, the risks of the procedure, and the ability of the patient to achieve glucose control if the surgery is postponed. Some institutions have used a cutoff value of 300 mg/dL as a trigger in the preoperative area for evaluation for ketoacidosis via either urine ketone dipstick or whole blood chemistry. In other institutions it is left to the discretion of the physician.<sup>82</sup> However, it is

recommended to postpone nonurgent or elective surgery if there is an acute rise in glucose to above 400 mg/dL.<sup>82</sup>

## **Intraoperative**

The details of the anesthetic plan depend intimately on the end-organ complications. Invasive monitoring may be indicated for the patient with heart disease, awake intubation may be necessary if a difficult intubation is predicted, fluid management and drug choices may depend on renal function, and aspiration must be considered if there is gastroparesis.

Blood glucose levels should be measured before, during, and after surgery. Blood glucose should be monitored every 4 to 6 hours while the patient is NPO.<sup>54</sup> The need for additional measurements is determined by the duration and magnitude of surgery, as well as the brittleness of the diabetes. Hourly measurements are reasonable in high-risk patients, especially those receiving continuous insulin through either an insulin pump or infusion.

The standard glucose dosage for an adult patient is 5 to 10 g/hr (100 to 200 mL of 5% dextrose solution hourly). Intraoperative administration of glucose should be guided by the patient's glucose level with the goal of preventing hypoglycemia or hyperglycemia. Routine administration of additional glucose-containing IV fluids is not recommended. It is best to separately record dextrose administration and fluids given.

Monitoring of the patient who arrives in the operating room with significant metabolic impairment, such as DKA, is similar to management in the medical ICU, including hourly determinations of blood glucose, arterial pH, electrolytes, and fluid balance. Frequent reassessments with medical consultation as necessary guide the use of fluids and electrolytes, especially potassium, insulin, phosphate, and glucose.

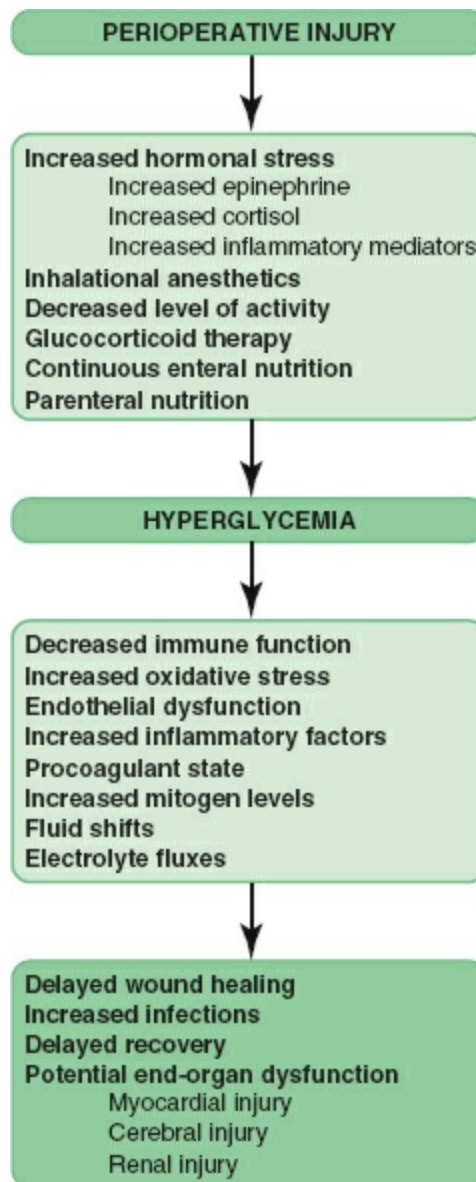

Another area of monitoring that is extremely important in the diabetic patient is positioning on the operating table. Injuries to the limbs or nerves are more likely in the patient who arrives in the operating room already compromised by diabetic peripheral vascular disease or neuropathy. The peripheral nerves may already be partly ischemic and therefore particularly vulnerable to pressure or stretch injuries.<sup>86</sup>

## ***Hyperglycemia and Perioperative Outcomes***

Prior to the past decade, little attention was paid to the control of hyperglycemia in the perioperative period or in the acute phase of critical illness managed in the ICU. Permissive or stress-induced hyperglycemia was generally accepted as the norm. Stress-induced hyperglycemia is defined as a transient response to the stress of an acute injury or illness.<sup>57</sup> Observational

studies have reported significant prevalence of hyperglycemia in hospitalized patients. Seventy percent of diabetic patients with acute coronary syndrome and 80% of cardiac surgery patients in the perioperative period may develop hyperglycemia.<sup>67</sup> Hyperglycemia in a hospital setting is defined as any blood glucose higher than 140 mg/dL.<sup>87</sup> Hyperglycemia significantly impairs chemotaxis, phagocytosis, generation of reactive oxygen species, and intracellular killing of bacteria.<sup>88</sup> Vascular reactivity is also decreased by hyperglycemia and is proposed to be related to decreased nitric oxide production. Acute hyperglycemia has also been shown to lead to poor outcomes in the setting of myocardial infarction and stroke.<sup>88</sup> There is evidence that hyperglycemia in hospitalized patients leads directly to adverse consequences.<sup>88</sup>

In surgical patients, *postoperative* hyperglycemia is associated with an increased risk of infection, renal and pulmonary complications, and also mortality (Fig. 47-8).<sup>61,89-93</sup> Many studies have addressed the effects of hyperglycemia *perioperatively* and confirmed similar associations.<sup>85,94-96</sup> One study demonstrated that for every 20 mg/dL increase in the mean intraoperative glucose, the risk of an adverse outcome increased by more than 30%.<sup>94</sup>

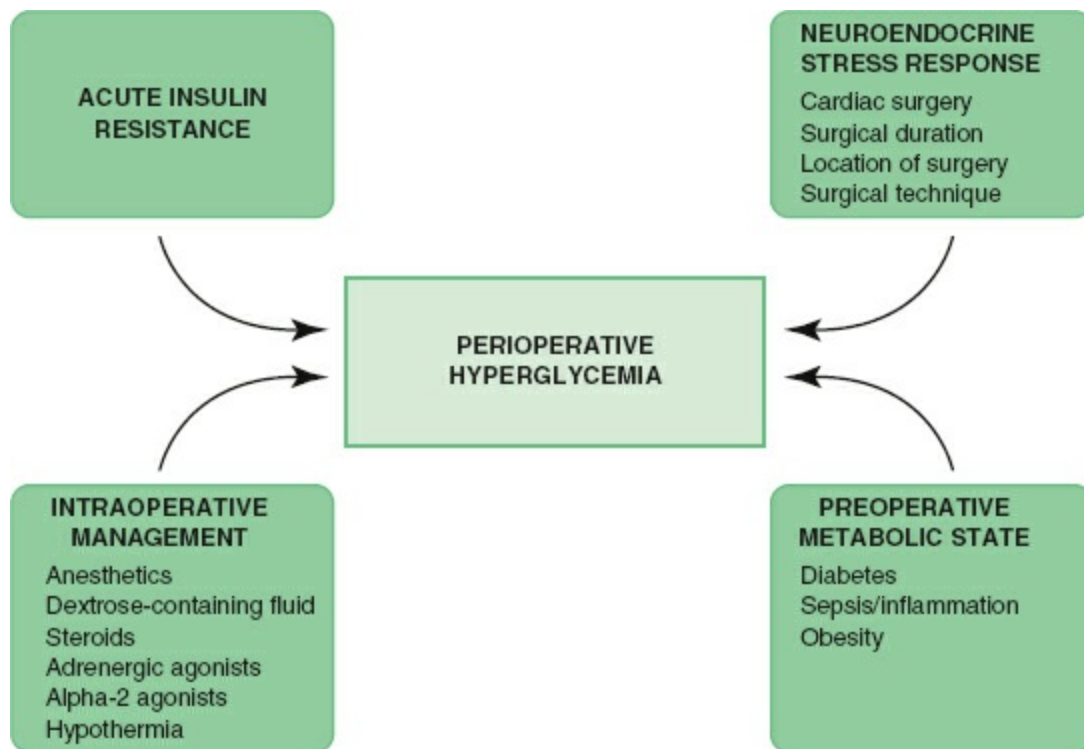

**Figure 47-8** Relation among perioperative injury, hyperglycemia, and outcomes. (Reprinted with permission from Akhtar S, Barash PG, Inzucchi SE. Scientific principles and clinical implications of perioperative glucose regulation and control. *Anesth Analg.* 2010;110[2]:478–497.)

Two other glycemic factors are also associated with poor perioperative outcomes. Hypoglycemia is a rare occurrence compared to hyperglycemia, but it is the principal factor limiting optimization of glycemic control and is associated with increased mortality.<sup>97,98</sup> Finally, glucose variability (changes in the measured level of blood glucose) is an independent predictor of mortality.<sup>99</sup> This indicates that measures of glycemia, other than glucose concentration, may be important in the pathophysiology of hyperglycemia. Three different methods of expression of glucose variability are utilized: standard deviation (SD) of glucose, the mean amplitude of glycemic excursions (MAGE), and the glycemic lability index (GLI). MAGE is the mean of absolute values of any change in glucose (consecutive values) that are more than 1 SD of the entire set of glucose values. GLI is the squared

difference between consecutive glucose measures per unit of actual time between those samples. Of these three methods, the GLI may be the best discriminator for mortality.<sup>100</sup> However, no prospective trials have determined whether decreased glucose variability with insulin results in improved perioperative outcomes.

**Figure 47-9** Modulators of perioperative hyperglycemia. (Reprinted with permission from Akhtar S, Barash PG, Inzucchi SE. Scientific principles and clinical implications of perioperative glucose regulation and control. *Anesth Analg*. 2010;110[2]:478–497.)

### Perioperative Glycemic Control

Many factors influence the glucose levels in the perioperative period (Fig. 47-9). Endogenous insulin secretions, exogenous insulin administration, insulin resistance, endogenous glucose production, exogenous glucose administration, and overall glucose consumption are some of the key factors that determine glucose levels in a patient.

Insulin secretion can be decreased because of the direct effects of anesthetics, whereas significant insulin resistance develops postoperatively. Degree of insulin resistance is directly related to surgical trauma (Fig. 47-10). Insulin resistance not only can be modified by the stress of surgery and the inflammatory state but also may be affected by nutritional intake and level of activity. Postoperative ambulation and physical activity can alter glucose consumption acutely. Intraoperative and postoperative hyperglycemia are predictable in patients who present for cardiac and high-risk noncardiac surgery and/or have poor glycemic control preoperatively (e.g., diabetics, or

patients who have an ongoing metabolic insult secondary to trauma or sepsis).<sup>61</sup>

**Figure 47-10** Time course for postoperative insulin resistance in patients undergoing open cholecystectomy. Relative insulin sensitivity represented as a percentage that is calculated as postoperative insulin sensitivity/perioperative insulin sensitivity  $\times$  100. Insulin sensitivity was determined within 5 days preoperatively and at days 1 ( $n = 9$ ), 5, 9, and 20 ( $n = 5$ ) postoperatively. \*Statistically significant difference. Op, day of the operation. (Reprinted with permission from Thorell A, Efendic S, Gutnaik M, et al. Insulin resistance after abdominal surgery. *Br J Surg*. 1994;81:59–63.)

## Glycemic Goals

In 2001, van den Berghe et al.<sup>101</sup> published a landmark paper that demonstrated a mortality benefit of tight glucose control in critically ill patients in the surgical ICU. From this study originated the concept of intensive insulin therapy (IIT) as a means of normalizing elevated glucose levels in critically ill patients. IIT was defined by a target glucose range of 80 to 110 mg/dL, and standard care implied a target glucose range of 180 to 200 mg/dL.<sup>101</sup> Although the study by van den Berghe et al. was a single-center, nonblinded trial, other retrospective studies also supported their findings and many centers adopted IIT protocols for management of hyperglycemia in the ICU. Furthermore, numerous studies documented clinical benefit of glycemic control in patients who underwent cardiac surgery.<sup>61</sup> However, most of the evidence was from prospective observational or retrospective studies. Over the course of the next few years, several studies comparing IIT to standard care failed to demonstrate a difference with respect to mortality. The IIT groups also demonstrated high incidences of hypoglycemia (8% to 28%), which was six times higher than the control group.<sup>102–105</sup>

The largest study to date, the NICE-SUGAR study, a multicenter, multinational randomized controlled trial, compared the effect of intensive glycemic control (target 81 to 108 mg/dL, mean blood glucose attained 115 mg/dL) to standard glycemic control (target 144 to 180 mg/dL,

mean blood glucose attained 144 mg/dL) on outcomes among 6,104 critically ill participants, almost all of whom required mechanical ventilation.<sup>106</sup> Surprisingly, 90-day mortality was significantly higher in the intensive versus the conventional group in both surgical and medical patients, as was mortality from cardiovascular causes. Severe hypoglycemia was also more common in the intensively treated group (6.8% vs. 0.5%). The results of this study were in stark contrast to the van den Berghe et al. study, which reported a 42% relative reduction in ICU mortality in critically ill surgical patients treated to a target blood glucose of 80 to 110 mg/dL.

One situation where tight glucose control with insulin may be beneficial is in patients who are administered exogenous glucose via total parenteral nutrition.<sup>107</sup> This was the case in the van den Berghe et al. study, where patients received significant exogenous glucose early in the ICU. Furthermore, the control group in the NICE-SUGAR trial had reasonably good blood glucose management and was maintained at a mean glucose of 144 mg/dL, only 29 mg/dL above the intensively managed patients. Accordingly, this study's findings do not negate the concept that glycemic control in the ICU is important. However, they do strongly suggest that it may not be necessary to target blood glucose values to a highly stringent target of less than 110 mg/dL, and that it may actually be dangerous to control glucose too tightly.

Several studies published subsequent to the NICE-SUGAR trial underscored the findings of that investigation. Annane et al.<sup>108</sup> found no reduction in mortality and increased hypoglycemia in a randomized controlled trial of IIT with glucocorticoids in the treatment of septic shock. The control group was given standard insulin therapy plus glucocorticoids. Meta-analyses of randomized trials investigating IIT demonstrated no overall effect on mortality and increased hypoglycemia rates in the IIT groups compared with controls.<sup>107,109–111</sup> An observational cohort study published prior to the NICE-SUGAR trial compared outcomes before and after institution of an IIT policy. Hypoglycemia was increased and no survival benefit was noted with the institution of IIT.<sup>112</sup>

In summary, association between perioperative hyperglycemia and poor outcomes is strong. Though hyperglycemia develops frequently in patients who undergo cardiac or high-risk noncardiac surgery, the value of controlling glucose levels tightly *intraoperatively* has not been proven conclusively. Poor glycemic control is probably a marker of significant metabolic perturbation, which is beyond the regulatory capacity of the body. Given that in the NICE-SUGAR trial the standard insulin therapy control group (140 to 180 mg/dL range) had similar outcomes (if not better) than the IIT group, the 140 to 180 mg/dL range is now generally accepted as the new goal. In 2009, the American Association of Clinical Endocrinologists and the American Diabetes Association (AAACE/ADA) released formal recommendations for the

management of hyperglycemia in the ICU.<sup>113</sup> The recommended threshold to initiate an insulin infusion is no higher than 180 mg/dL. Once insulin therapy has been initiated, the 140 to 180 mg/dL goal range is targeted.

In addition to the AACE/ADA, various other professional organizations have published guidelines for the management of glucose levels in the ICU.<sup>114</sup> The Surviving Sepsis Campaign<sup>115</sup> recommends maintaining glucose levels below 180 mg/dL; the Institute for Healthcare Improvement target is less than 180 mg/dL; the 2014 European Society of Cardiology guidelines for perioperative cardiac management in noncardiac surgery patients do take into account the results of the NICE-SUGAR study and recommend maintaining glucose levels less than 180 mg/dL in postsurgery patients.<sup>116</sup> The Society of Thoracic Surgeons (for cardiac surgery) targets 150 to 180 mg/dL, whereas the guidelines from the American College of Physicians recommend keeping glucose below 180 mg/dL in critically ill patients (Table 47-13).<sup>117</sup>

Hyperglycemia in hospitalized patients has been defined as blood glucose above 140 mg/dL (7.8 mmol/L). In noncritically ill hospitalized patients, the goal is to keep the glucose level between 140 and 180 mg/dL. This should ideally be achieved by basal plus bolus insulin dosing rather than sliding scale insulin. Practitioners should also keep in mind that target glucose levels for terminally ill, elderly, frail, and nursing home patients have not been established. There is general consensus that in these populations, the risk of hypoglycemia outweighs the risk of hyperglycemia and less stringent targets may be more appropriate.<sup>52,118</sup>

### *Management of Perioperative Hyperglycemia*

In view of the complex nature of glycemic control in the perioperative period, maintaining glucose levels within a specific range can be demanding. The narrower the desired glycemic range, the more resource intensive the protocol will be.

There are multiple insulin preparations, with varying duration of actions, which can be administered in many different ways.<sup>119</sup> The simplest way is to administer short-acting insulin subcutaneously. Only a few studies have adopted this route and have not been very successful in maintaining glucose in the desired range (40% to 60% of the time) and achieving it in a timely manner. In the perioperative setting, the state of peripheral perfusion is extremely variable and vasoconstriction is very common, often secondary to hypovolemia or hypothermia. Hence, absorption of any drug administered subcutaneously can be erratic and unreliable. Similarly, sliding scale protocols have also been disappointing. Most study protocols that have demonstrated desirable glycemic control in the acute care setting have used continuous IV insulin infusion combined with IV bolus injections. Targeted glucose levels are

achieved successfully and promptly using these dynamic scale protocols combined with frequent blood glucose determinations. Once a certain requirement of insulin in a 24-hour period is known, the patient can be transitioned to basal–bolus insulin protocol. This requires giving a certain amount of long-acting insulin (which provides a fraction of basal insulin requirement), supplemented by three or four doses of short-acting insulin bolus based on blood glucose measurements.<sup>57</sup> A randomized controlled trial has shown that basal–bolus treatment improved glycemic control and reduced hospital complications compared with sliding scale insulin in general surgery patients with type 2 diabetes.<sup>120</sup>

**Table 47-13** Current Recommendations for Glycemic Control in Critically Ill Patients

Organization	Year	Patient Population	Treatment Threshold (mg/dL)	Target Glucose Level (mg/dL)
Society of Thoracic Surgeons	2009	Cardiac surgery in ICU	150	150–180
Institute for Healthcare Improvement	2009	ICU patients	180	<180
American College of Physicians	2011	ICU patients	180	140–180
Surviving Sepsis Campaign	2013	ICU patients	180	<180
European Society of Cardiology	2014	Patients after major noncardiac surgery	180	140–180
American Diabetes Association	2016	ICU patients	180	140–180

Blood glucose can be determined by central laboratory, blood–gas analysis machines, or various point-of-care testing devices that use capillary blood (fingerstick). Point-of-care devices are most commonly used in many acute care areas for glucose monitoring and management. Practitioners should keep in mind that the accuracy of these handheld meters can vary by 20%.<sup>121</sup> Glucose meter analysis (arterial and capillary blood) may provide higher glucose values, whereas blood–gas meter analysis of arterial blood may yield lower glucose values compared with central laboratory values. The hemodynamic state of the patient may also affect the accuracy of the blood glucose measurement by the point-of-care devices. Furthermore, whole blood glucose values and plasma glucose values are different, and the same is true for arterial and venous blood. Therefore, a real possibility exists of overdosing or underdosing a patient with insulin. Hence, aberrant glucose values should be verified by central laboratory measurements, and practitioners should be aware of the performance of the point-of-care devices used in their institutions.<sup>122</sup>

## Type 1 Diabetes

Type 1 diabetics require exogenous insulin or they will rapidly develop ketoacidosis and its complications. This can be given by administering one-half to two-thirds of the patient’s usual intermediate-acting insulin

subcutaneously on the morning of surgery. In addition to this basal insulin, a regular insulin sliding scale (RISS) can be added and titrated to blood glucose measurement.<sup>123</sup> Alternatively, an insulin infusion of 0.5 to 2 units/hr (100 units of regular insulin in 1,000 mL normal saline at 5 to 20 mL/hr) can meet basal metabolic needs and be adjusted to maintain blood glucose at the desired level.<sup>119</sup> With either method, a slow glucose infusion (5% dextrose in water at 75 to 125 mL/hr) will prevent hypoglycemia while the patient is fasting.

## **Type 2 Diabetes**

Patients who are on oral antihyperglycemic medications are advised to discontinue their medications the night before surgery. No oral hypoglycemic medications are administered or advised on the morning of surgery. Patients on chronic insulin are treated based on their insulin regimen. Perioperative glucose control can be achieved by insulin infusion titrated to blood glucose (typically in the ICUs) or basal long-acting insulin supplemented by an RISS. The use of an RISS as the sole method of control is to be discouraged, because it can predispose to wide glucose variations.<sup>57</sup>

Postoperatively, as the patient resumes oral intake, therapy can be transitioned to the patient's chronic regimen. Type 2 diabetics who have had a gastric bypass procedure can have rapid resolution of their glucose intolerance and will often need their oral agents and insulin reduced or even discontinued in the postoperative period. This effect appears to be due to changes in the incretin hormones such as GIP and GLP-1, rather than weight loss.<sup>124</sup>

## **Emergencies**

Hyperglycemic hyperosmolar state (HHS) and DKA represent two extremes in the spectrum of decompensated DM. DKA is more common than HHS and accounts for 1% of diabetes-related emergencies. The mortality rate for HHS (10% to 20%) is greater than the mortality from DKA (5%).<sup>125</sup> Patients may present with a diabetic emergency, or it may develop perioperatively because stress, trauma, and infection may all lead to increased insulin requirements and insulin resistance.<sup>126</sup>

## **Hyperosmolar Nonketotic Coma**

An occasional elderly patient with minimal or mild DM may present with remarkably high blood glucose levels (>600 mg/dL) and profound dehydration (9 to 12 L). Such patients usually have enough endogenous

insulin activity to prevent lipolysis and ketosis; even with blood sugar concentrations of 1,000 mg/dL, they are not in ketoacidosis. It takes only *one-tenth* as much insulin to suppress lipolysis as it does to stimulate glucose utilization. Presumably, it is the combination of an impaired thirst response and mild renal insufficiency that allows the hyperglycemia to develop. The marked hyperosmolarity may lead to coma and seizures, with the increased plasma viscosity producing a tendency to intravascular thrombosis. It is characteristic of this syndrome that the metabolic disturbance responds quickly to rehydration and small doses of insulin. If there are no cardiovascular contraindications, 1 to 2 L (or 15 to 30 mL/kg) of normal saline should be infused over 1 hour. Insulin, by bolus or infusion, should be administered after initial volume has been administered.<sup>127</sup> Administering insulin before adequate fluid replacement can result in cardiovascular collapse. Insulin-mediated glucose uptake moves water out of the intravascular space and into cells causing severe hypovolemia. With rapid correction of the hyperosmolarity, cerebral edema is a risk, and recovery of mental acuity may be delayed after the blood glucose level and circulating volume have been normalized.<sup>128</sup>

## **Diabetic Ketoacidosis**

DKA is defined by the biochemical triad of ketonemia, hyperglycemia, and acidemia.<sup>129</sup> If the diabetic patient has insufficient insulin effect to block lipolysis and the metabolism of free fatty acids, the metabolic by-products acetoacetate and  $\beta$ -hydroxybutyrate accumulate. These ketone bodies are organic acids and cause a metabolic acidosis with an increased unmeasured anion gap.<sup>130</sup> Clinically, the patient often presents because of intercurrent illness, trauma, or the untoward cessation of insulin therapy. Although hyperglycemia is almost always present, the degree of hyperglycemia does not correlate with the severity of acidosis. Blood sugar levels are often in the 250- to 500-mg/dL range. The patient is always dehydrated because of the combination of the hyperglycemia-induced osmotic diuresis and the nausea and vomiting typical of this syndrome. Because leukocytosis, abdominal pain, GI ileus, and mildly elevated amylase levels are all common in ketoacidosis, an occasional patient is misdiagnosed as having an intra-abdominal surgical problem.

**Table 47-14** Management of Diabetic Ketoacidosis

Regular insulin, 10-unit IV bolus, followed by an insulin infusion nominally at (blood glucose/150) units/h  
Isotonic IV fluids as guided by vital signs and urine output; anticipate 4–10 L deficit  
When urine output is more than 0.5 mL/kg/h, give potassium chloride, 10–40 mEq/h (with continuous electrocardiographic monitoring when the rate is >10 mEq/h)  
When serum glucose is decreased to 250 mg/dL, add dextrose 5% at 100 mL/h  
Consider sodium bicarbonate to correct pH <6.9

Diagnostic criteria for DKA include ketonemia or significant ketonuria; blood glucose above 250 mg/dL or known DM; and serum bicarbonate below 18 mmol/L or arterial pH less than 7.3.<sup>131</sup> Treatment of DKA includes insulin administration and fluid and electrolyte replacement (Table 47-14). Route of administration of insulin is determined by the severity of DKA. Mild to moderate DKA can be treated with subcutaneously administered insulin analogs. However, severe DKA requires IV insulin administration. Typically, a continuous infusion is started at 0.1 unit/kg/hr as long as serum potassium is above 3.3 mEq/L. If the blood glucose does not fall by 10% in the first hour, a bolus of 0.1 unit/kg is administered. Another alternative is to administer 0.1 unit/kg as a bolus followed by an infusion at 0.1 unit/kg/hr. When blood glucose levels decrease below 250 mg/dL, glucose should be added to the IV fluid while insulin therapy continues. Fluid requirements can be marked; 1 to 2 L of normal saline, or equivalent, should be given over 1 to 2 hours. After the first hour, they may need to be continued at 15 to 20 mL/kg/hr. Further deficits can be replaced more gradually. Potassium replacement is a key concern in patients with DKA. Because of the diuresis, the total-body potassium stores are reduced. However, acidosis by itself causes a shift of potassium ions out of the cell. Thus, the serum potassium concentration may be normal or even slightly elevated while the patient is acidotic. As soon as the metabolic acidosis is corrected, the potassium ions shift back into the cells. Consequently, the serum potassium concentration can decline acutely. Therefore, early and vigorous potassium replacement is required in these patients, with the exception of those patients in renal failure. Hypophosphatemia also occurs with the correction of the acidosis and, if severe, may cause impairment of ventilation, resulting from skeletal muscle weakness in the vulnerable patient. Instead of DKA, the diabetic patient with a metabolic acidosis may have lactic acidosis, which results from poor tissue perfusion or sepsis. It is diagnosed by the presence of an increased serum lactate concentration without an elevated ketone concentration. Several studies have shown that the use of bicarbonate in patients with DKA made no difference in resolution of acidosis or time to discharge.<sup>132</sup> Its use is not generally indicated unless the patient is hemodynamically unstable with pH

below 7.1 or has pH below 6.9.

DKA must also be distinguished from the syndrome of alcoholic ketoacidosis. This typically occurs in the poorly nourished alcoholic patient after acute intoxication. Except for the presence of chemical ketoacidosis, alcoholic ketoacidosis is not clinically related in any way to DM. The alcoholic patient may be hypoglycemic or mildly hyperglycemic. The predominant ketone in this syndrome is  $\beta$ -hydroxybutyrate, which tends to react less sensitively in the standard laboratory nitroprusside reaction measurement of ketones. Hence, the diagnosis may be obscured. Administration of dextrose and parenteral fluids is the specific treatment for alcoholic ketoacidosis; insulin is not indicated (except in the rare circumstance in which the patient also has clear-cut DM).

## Hypoglycemia

Hypoglycemia is the clinical occurrence most feared in the management of diabetic patients. The precise level at which symptomatic hypoglycemia occurs is variable. The normal, fasted patient may have blood sugar levels no higher than 50 mg/dL without symptoms. However, the diabetic patient who has a chronically elevated blood sugar level may be symptomatic at levels significantly above this glucose concentration. Hypoglycemia is almost impossible to diagnose clinically in the unconscious patient.

Clinically significant hypoglycemia is defined by Whipple triad: (a) Symptoms of neuroglycopenia, (b) simultaneous blood glucose concentration below 40 mg/dL, and (c) relief of symptoms with glucose administration. Although a subclinical stress response may be initiated at glucose levels below 70 mg/dL, a blood glucose level of approximately 55 mg/dL results in activation of the sympathetic nervous system and autonomic symptoms, which include sweating, palpitations, tremor, and hunger. Neuroglycopenic symptoms occur with blood glucose levels of approximately 45 mg/dL, and include behavioral and cognitive impairment, drowsiness, speech difficulty, blurred vision, seizures, coma, and death. Hypoglycemia in hospitalized patients has been defined as blood glucose below 70 mg/dL (3.9 mmol/L) and severe hypoglycemia as less than 40 mg/dL (2.2 mmol/L).<sup>133</sup> Many of the autonomic as well as the early neurologic symptoms are notably absent in the intubated, sedated, critically ill, or anesthetized patient. In the anesthetized patient, these signs of sympathetic hyperactivity can easily be misinterpreted as inadequate or “light” anesthesia. In the anesthetized, sedated, or seriously ill patient, the mental changes of hypoglycemia are also unrecognizable. Furthermore, in patients being treated with  $\beta$ -adrenergic-blocking agents or in patients with advanced diabetic autonomic neuropathy, the sympathetic hyperactivity of hypoglycemia may be obscured. Thus, the clinical diagnosis

of hypoglycemia in the surgical patient may be difficult to make, and only a high degree of suspicion and frequent blood glucose checks can prevent this complication. Treatment is with 25 g of IV dextrose (50 mL of dextrose 50% in water) or 1 mg of intramuscular glucagon if the patient is not alert, and 8 ounces of juice if the patient is alert. The goal is to achieve a blood glucose level above 100 mg/dL.

Hypoglycemia is more likely to occur in the diabetic surgical patient if insulin or sulfonylureas are given without supplemental glucose. With renal insufficiency, the action of insulin and oral hypoglycemic agents is prolonged.

## Pituitary Gland

The pituitary gland is located below the base of the brain in a bony structure called the sella turcica. The pituitary gland and the hypothalamus together form a central unit that regulates the release of various hormones. The pituitary gland is divided into two components. The *anterior pituitary* (adenohypophysis) secretes prolactin, growth hormone, gonadotropins (luteinizing hormone and follicle-stimulating hormone), TSH, and ACTH. The *posterior pituitary* (neurohypophysis) secretes the hormones vasopressin and oxytocin. Hormone release from the anterior and posterior pituitary is regulated by the hypothalamus. Regulatory peptides or preformed hormones from the hypothalamus are transported to the pituitary gland through vascular or tissue connections.

### Anterior Pituitary

Hyposecretion of anterior pituitary hormones is usually due to compression of the gland by tumor. This may begin as an isolated deficiency, but it usually develops into multiglandular dysfunction. Male impotence or secondary amenorrhea in the woman is an early manifestation of panhypopituitarism. Panhypopituitarism after postpartum hemorrhagic shock (Sheehan syndrome) is due to necrosis of the anterior pituitary gland. Radiation therapy delivered to the sella turcica or nearby structures and surgical hypophysectomy are other causes of panhypopituitarism. Panhypopituitarism is treated with specific hormone replacement therapy, which should be continued in the perioperative period. Stress doses of corticosteroids are necessary for patients receiving steroid replacement because of inadequate ACTH.

The hypersecretion of various anterior pituitary hormones is usually caused by an adenoma. Excess prolactin secretion with galactorrhea is a common hormonal abnormality associated with pituitary adenoma. Cushing disease may occur secondary to excess ACTH production, and gigantism or acromegaly may occur as a consequence of excess growth hormone

production in the child or adult, respectively. Excessive secretion of TSH is rare.

8 Acromegaly in the adult patient may pose several problems for the anesthesiologist.<sup>134</sup> Hypertrophy occurs in skeletal, connective, and soft tissues.<sup>135</sup> The tongue and epiglottis are enlarged, making the patient susceptible to upper airway obstruction. The incidence of difficult intubation is 20% to 30% and may be clinically unpredictable.<sup>136</sup> Hoarseness may reflect thickening of the vocal cords or paralysis of an RLN due to stretching. Dyspnea or stridor is associated with subglottic narrowing. Peripheral nerve or artery entrapment, hypertension, and DM are other common findings. The anesthetic management of these patients is complicated by distortion of the facial anatomy and upper airway. Induction of general anesthesia may put the patient at increased risk if mask fit is improper or vocal cord visualization is impaired. When the preoperative history suggests upper airway or vocal cord involvement, it is prudent to consider intubation of the trachea while the patient is awake.

## *Posterior Pituitary*

The posterior pituitary, or neurohypophysis, is composed of terminal nerve endings that extend from the ventral hypothalamus. Vasopressin (antidiuretic hormone [ADH]) and oxytocin are the two principal hormones secreted by the posterior pituitary. Both hormones are synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. They are bound to inactive carrier proteins, neurophysins, and transported by axons to membrane-bound storage vesicles located in the posterior pituitary. ADH is a nonapeptide that circulates as a free peptide after its release. The primary functions of ADH are maintenance of extracellular fluid volume and regulation of plasma osmolality. Oxytocin elicits contraction of the uterus and promotes milk secretion and ejection by the mammary glands.

### **Vasopressin**

ADH promotes resorption of solute-free water by increasing cell membrane permeability to water alone. The target sites for ADH are the collecting tubules of the kidneys. A decrease in free water clearance causes a decrease in serum osmolality and a corresponding increase in circulating blood volume. Under normal conditions, the primary stimulus for the release of ADH is an increase in serum osmolality.

Osmoreceptors located in the hypothalamus are sensitive to changes in the normal serum osmolality of as little as 1% (normal osmolality is approximately 285 mOsm/L). Stretch receptors in the left atrium and perhaps

pulmonary veins, which are sensitive to moderate reductions in the blood volume, are also capable of stimulating ADH secretion. The need to restore plasma volume may at times override osmotic inhibition of ADH release. Various physiologic and pharmacologic stimuli also influence the secretion of ADH. Positive-pressure ventilation of the lungs, stress, anxiety, hyperthermia,  $\beta$ -adrenergic stimulation, and any histamine-releasing stimulus can promote the release of ADH.

ADH also has other actions. It can increase blood pressure by constricting vascular smooth muscle (see [Chapter 39](#)). This activity is most significant in the splanchnic, renal, and coronary vascular beds, and provides the rationale for administering exogenous vasopressin in the management of hemorrhage due to esophageal varices. Caution must be taken when this drug is used in patients with coronary artery disease. ADH (even in small doses) can precipitate myocardial ischemia through vasoconstriction of the coronary arteries. It is unclear whether selective arterial infusion is safer than systemic administration with regard to cardiac and vascular side effects. ADH is also often used in vasodilatory shock as an adjuvant to other pressor agents.

ADH also promotes hemostasis through an increase in the level of circulating von Willebrand factor and factor VIII. Desmopressin (DDAVP), an analogue of ADH, is commonly used to treat some types of von Willebrand disease (see [Chapter 17](#)). DDAVP is also frequently used to reverse the coagulopathy of renal failure.

## **Diabetes Insipidus**

Diabetes insipidus results from inadequate secretion of ADH or resistance on the part of the renal tubules to ADH (nephrogenic diabetes insipidus). Failure to secrete adequate amounts of ADH results in polydipsia, hypernatremia, and a high output of poorly concentrated urine. Hypovolemia and hypernatremia may become so severe as to be life-threatening. This disorder usually occurs after destruction of the pituitary gland by intracranial trauma, infiltrating lesions, or surgery (see [Chapter 37](#)).<sup>137</sup> Patients in whom diabetes insipidus develops secondary to severe head trauma or subarachnoid hemorrhage often have impending brain death or are presenting for organ retrieval. Treatment of diabetes insipidus depends on the extent of the hormonal deficiency. During surgery, the patient with complete diabetes insipidus can be treated with DDAVP or vasopressin infusion combined with administration of an isotonic crystalloid solution.<sup>138</sup> The serum sodium and plasma osmolality are measured on a regular basis and therapeutic changes are made accordingly. If diabetes insipidus occurs postoperatively free access to water is often all that is needed. If persistent or severe, DDAVP administered intranasally has prolonged antidiuretic activity (12 to 24 hours). Nonhormonal agents that

have efficacy in the treatment of incomplete diabetes insipidus include the oral hypoglycemic chlorpropamide (200 to 500 mg/day). This drug stimulates the release of ADH and sensitizes the renal tubules to the hormone. Hypoglycemia is a serious side effect that limits the usefulness of the drug. Carbamazepine and clofibrate are also capable of stimulating ADH release and have been used in the outpatient setting. None of these medications are effective in the patient with nephrogenic diabetes insipidus. Paradoxically, the thiazide diuretics exert an antidiuretic action in patients with this disorder.

### **Inappropriate Secretion of Antidiuretic Hormone**

Inappropriate and excessive secretion of ADH may occur in association with a number of diverse pathologic processes, including head injuries, intracranial tumors, pulmonary infections, small cell carcinoma of the lung, and hypothyroidism (see [Chapter 37](#)). Surgery and trauma can cause transiently elevated ADH levels. The clinical manifestations occur as a result of a dilutional hyponatremia, decreased serum osmolality, and a reduced urine output with a high osmolality. Weight gain, skeletal muscle weakness, and mental confusion or convulsions are presenting symptoms. Peripheral edema and hypertension are rare. The diagnosis of the syndrome of inappropriate ADH secretion is one of exclusion, and other causes of hyponatremia must be ruled out first. The prognosis is related to the underlying cause of the syndrome.

The treatment for patients with mild or moderate water intoxication is restriction of fluid intake to 800 mL/day. Patients with severe water intoxication associated with hyponatremia (sodium <120 mEq/L) and central nervous system symptoms may require more aggressive therapy, with the IV administration of a hypertonic saline solution. This may be administered in conjunction with furosemide. Caution must be observed in patients with poor left ventricular function. Too-rapid correction of hyponatremia may induce osmotic demyelination and cause permanent brain damage. Serum sodium should not be raised by more than 9 mEq/L in 24 hours. Other drugs that may be used in the patient with syndrome of inappropriate ADH are demeclocycline and lithium. Demeclocycline interferes with the ability of the renal tubules to concentrate urine and is frequently used in outpatients. Lithium is usually not used because of the high incidence of toxicity. Vasopressin-2 receptor antagonists, such as conivaptan, may be useful in specific situations.

### **Endocrine Response to Surgical Stress**

Anesthesia, surgery, and trauma elicit a generalized endocrine metabolic

response characterized by an increase in the plasma levels of cortisol, ADH, renin, catecholamines, and endorphins and by metabolic changes such as hyperglycemia and a negative nitrogen balance.<sup>139,140</sup> There is also an increase in inflammatory markers such as C-reactive protein which would not be generally considered part of an endocrine response. Various neural and humoral factors (e.g., pain, anxiety, acidosis, local tissue factors, hypoxia) play a role in activating this stress response. There is an acute response to critical illness that is characterized by normal pituitary function, but targets organ insensitivity. During the chronic phase of critical illness, there is generalized endocrine hypofunction probably of a hypothalamic origin.<sup>141</sup>

The induction of anesthesia increases the levels of circulating catecholamines and is a form of metabolic stress. Regional anesthesia can block part, but not all, of the metabolic stress response during surgery, probably by blockade of the neural communication from the surgical area.<sup>142</sup> It is theorized that the persistently high levels of circulating catecholamines in trauma and critical illness lead to stress hyperglycemia through a direct inhibition of insulin release. Bypass of the gut hormonal actions in patients receiving IV glucose feedings, especially if given in large amounts, contributes to the impairment of insulin release during illness and can create a particularly difficult management problem for diabetic patients.

Endorphins are a group of endogenous peptides with opioid activity that have been isolated from the central nervous system. It is well documented that  $\beta$ -endorphin is released from the anterior pituitary, where it is contained as part of  $\beta$ -lipoprotein, a 91-chain amino acid, which is a cleavage product of the precursor peptide for ACTH. Large increases in the central nervous system and plasma concentrations of endorphins in response to emotional or surgical stimuli suggest that these substances play a role in the body's response to stress. These substances modulate painful stimuli by binding to opiate receptors located throughout the brain and spinal cord.

Numerous experiments have focused on the stress response and its relation to the depth of anesthesia. Regional anesthesia and general anesthesia appear to blunt the release of various stress hormones during the period of surgical stimulation in a dose-dependent fashion. Historically, anesthesiologists have relied on the indirect measurement of hemodynamic variables such as blood pressure and heart rate to evaluate the level of autonomic activity in response to anesthesia and surgery. It is assumed that the physiologic manifestations of stress are potentially harmful, especially in patients with limited functional reserve. As such, anesthetic techniques and pain management strategies are designed to limit this neurohormonal response in the hope of providing the patient with some benefit. Further investigations are needed to assess the impact of these efforts on perioperative morbidity and mortality.

## Acknowledgments

## KEY POINTS

- 1 The restricted spaces in the airway require an understanding and cooperative relationship between surgeon and anesthesiologist, and the use of specially adapted equipment suitable to these cramped areas.
- 2 Despite only mild-to-moderate tonsillar enlargement on physical examination, children with obstructive sleep apnea have upper airway obstruction while awake and apnea during sleep. The clinician should not underestimate the severity of the problem based on tonsillar size alone.
- 3 Patients with obstructive sleep apnea have increased sensitivity to opioids and consequently the dose administered should be reduced by as

much as 50%.

- 4 Post-tonsillectomy hemorrhage may result in unappreciated large volumes of swallowed blood originating from the tonsillar fossa. These patients must be considered to have a full stomach, and anesthetic precautions addressing this situation must be taken.
- 5 The middle ear and sinuses are air-filled, nondistensible cavities. During procedures in which the eardrum is replaced or perforation is patched, nitrous oxide should be discontinued or, if this is not possible, limited to a maximum of 50% during the application of the tympanic membrane graft to avoid pressure-related displacement.
- 6 Systemic absorption of vasoconstrictive agents during functional endoscopic sinus surgery may cause hypertension, bradycardia, tachycardia, and arrhythmias. Preoperative evaluation should include a thorough investigation of the patient's cardiovascular status. Rapid response by the anesthesiologist to these effects is necessary in preventing complications.
- 7 Patients with a history of head and neck cancer may have undergone prior chemotherapy, which can affect specific organ systems, or radiation, which can lead to fibrosis and ankylosis in the temporomandibular joint, rendering direct laryngoscopy difficult.
- 8 Facial trauma is commonly associated with other injuries such as cervical spine and head injuries, which can have implications for patient care beyond airway management.

## Evaluating the Airway

Air flows through the upper respiratory passages into the trachea, bronchi, bronchioles, and alveoli in the healthy human. Airflow occurs seemingly without either thought or effort, and the actual work of respiration in the unobstructed airway is minimal. However, airway obstruction due to malformation, tumor, infection, or trauma may significantly alter the clinical presentation and make gas exchange a laborious, energy-consuming process. The increased work of breathing can leave the patient exhausted, incapable of maintaining adequate gas exchange, and finally succumbing to ventilatory failure. Significant obstruction and anatomic distortion may be present in a patient with minimal evidence of disease because clinically evident upper airway obstruction is a late sign. It is a most unwelcome experience for the anesthesiologist to unexpectedly discover an obstructed upper airway at the time of anesthetic induction or attempted tracheal intubation.

In the presence of tumor, other mass lesions, or infection in the airway, it may be useful to obtain radiologic evaluation of the airway with plain films of the tracheal and laryngeal air columns, computed tomography, or magnetic

resonance imaging (MRI) studies of the airway. Significant anatomic distortion may be appreciated and help the anesthesiologist determine the most appropriate technique for securing the airway.

## Anesthesia for Pediatric Ear, Nose, and Throat Surgery

The safe management of the pediatric patient undergoing surgery of the ear, nose, and throat is particularly challenging to the anesthesiologist. 1 The restricted spaces in the airway of the child require an understanding and cooperative relationship between surgeon and anesthesiologist, and the use of specially adapted equipment suitable to these cramped areas.

### *Tonsillectomy and Adenoidectomy*

Untreated adenoidal hyperplasia may lead to nasopharyngeal obstruction, causing failure to thrive, speech disorders, obligate mouth breathing, sleep disturbances, orofacial abnormalities with a narrowing of the upper airway, and dental abnormalities. Surgical removal of the adenoids is usually accompanied by tonsillectomy; however, purulent adenoiditis, despite adequate medical therapy, and recurrent otitis media with effusion secondary to adenoidal hyperplasia are improved with adenoidectomy alone.

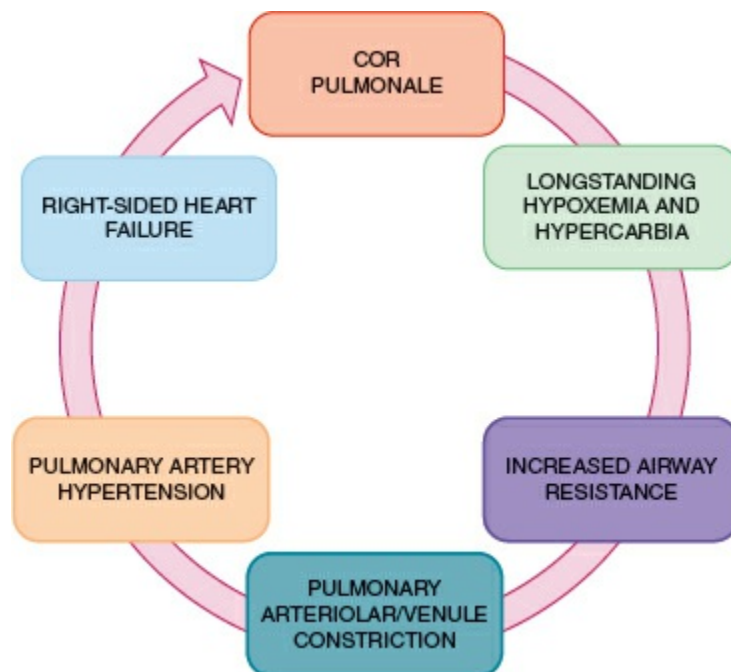

Tonsillectomy is one of the more commonly performed pediatric surgical procedures.<sup>1</sup> Chronic or recurrent acute tonsillitis, peritonsillar abscess, tonsillar hyperplasia, and obstructive sleep apnea syndrome (OSAS) are the major indications for surgery. In addition, patients with cardiac valvar disease are at risk for endocarditis from recurrent streptococcal bacteremia secondary to infected tonsils. Tonsillar hyperplasia may lead to chronic airway obstruction resulting in sleep apnea, carbon dioxide (CO<sub>2</sub>) retention, cor pulmonale, failure to thrive, swallowing disorders, and speech abnormalities. These risks are eliminated with removal of the tonsils.

Obstruction of the oropharyngeal airway by hypertrophied tonsils leading to apnea during sleep is an important clinical entity referred to as *obstructive sleep apnea syndrome*. Despite only mild-to-moderate tonsillar enlargement on physical examination, these patients have upper airway obstruction while awake and apnea during sleep. The goals of treatment are to relieve airway obstruction and increase the cross-sectional area of the pharynx.<sup>2</sup> Some patients require the use of nasal continuous positive airway pressure during sleep, whereas others may require a tracheostomy to bypass the chronic upper airway obstruction that is present. The two most frequent levels of obstruction during sleep are at the soft palate and the base of the tongue.<sup>3,4</sup> Most children have tremendous improvement in their symptoms after tonsillectomy.

In children with longstanding hypoxemia and hypercarbia, increased airway resistance can lead to cor pulmonale (Fig. 48-1). Patients may have electrocardiographic evidence of right ventricular hypertrophy and radiographic evidence consistent with cardiomegaly. Each apneic episode causes progressively increased pulmonary artery pressure with significant systemic and pulmonary artery hypertension, leading to ventricular dysfunction and cardiac dysrhythmias.<sup>5</sup> These patients often have dysfunction in the medulla or hypothalamic areas of the central nervous system causing persistently elevated CO<sub>2</sub>, despite relief of airway obstruction as well as a hyperreactive pulmonary vascular bed. The increased pulmonary vascular resistance and myocardial depression in response to hypoxia, hypercarbia, and acidosis are far greater than what is expected for that degree of physiologic alteration in the normal population. Cardiac enlargement is frequently reversible with surgical removal of the tonsils and adenoids.

### *Preoperative Evaluation*

A thorough history is the basis for the preoperative evaluation. A history of sleep-disordered breathing (SDB) should be sought. The physical examination should begin with observation of the patient. The presence of audible respirations, mouth breathing, nasal quality of the speech, and chest retractions should be noted. Mouth breathing may be the result of chronic nasopharyngeal obstruction. An elongated face, a retrognathic mandible, and a high-arched palate may be present. The oropharynx should be inspected for evaluation of tonsillar size to determine the ease of mask ventilation and tracheal intubation (Fig. 48-2). The presence of wheezing or rales on auscultation of the chest may be a lower respiratory component of upper airway infection. The presence of inspiratory stridor or prolonged expiration may indicate partial airway obstruction from hypertrophied tonsils or adenoids.

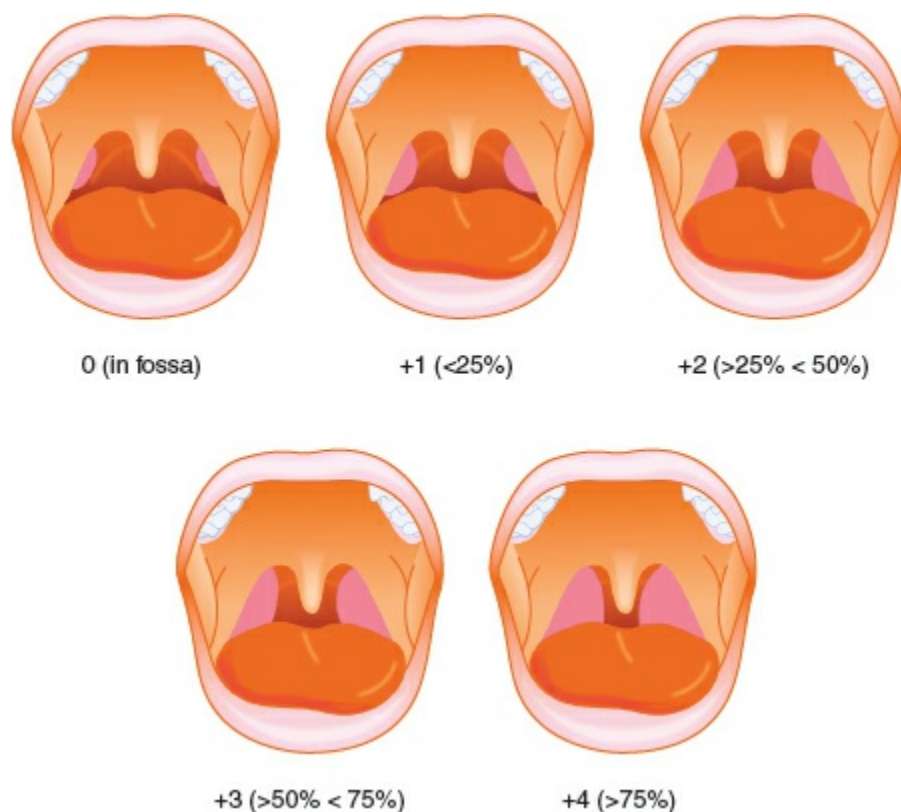

**Figure 48-1** Events leading to cor pulmonale.

Measurement of hematocrit and coagulation parameters is suggested. Because patients requiring tonsillectomy and adenoidectomy have frequent infections, the parent should be questioned for current use of antibiotics, antihistamines, or other medicines. Many nonprescription cold medications and antihistamines contain aspirin, which may affect platelet function, and this potential anticoagulation should be taken into consideration. Chest radiographs and electrocardiograms (ECGs) are not required unless specific abnormalities are elicited during the history, such as recent pneumonia, bronchitis, upper respiratory infection (URI), or history consistent with cor pulmonale, which is seen in children with OSAS. In those children with a history of cardiac abnormalities, an echocardiogram may be indicated.

### ***Sleep-disordered Breathing and Obstructive Sleep Apnea***

SDB is a spectrum of disorders ranging from primary snoring to OSAS. SDB affects 10% of the population, but only 1% to 4% will progress to OSAS. OSAS is characterized by periodic, partial, or complete obstruction of the upper airway during sleep.<sup>6-9</sup> Proper screening for and diagnosis of obstructive sleep apnea prior to surgery for both children and adults is essential in reducing the associated risks. The STOP-BANG questionnaire has been developed as a tool to screen adult patients for obstructive sleep apnea and includes information on Snoring, daytime somnolence and Tiredness, Observation of apnea during sleep and elevations in blood Pressure. Predicting risk in children, however, is far more complicated.<sup>10,11</sup> The STBUR questionnaire has been proposed as an alternative for pediatric patients. It evaluates Snoring, Trouble Breathing, and Un-Refreshed after sleep and has

the potential to be a reliable predictor of children at risk for perioperative respiratory events.<sup>12</sup>

**Figure 48-2** Classification of tonsil size, including percentage of oropharyngeal area occupied by hypertrophied tonsils.

Repetitive arousal from sleep to restore airway patency is a common feature, as are episodic sleep-associated oxygen desaturation, hypercarbia, and cardiac dysfunction as a result of airway obstruction. Individuals who experience obstruction during sleep may have snoring loud enough to be heard through closed doors or observed pauses in breathing during sleep. They may awaken from sleep with a choking sensation. Parents report restless sleep in affected children and frequent somnolence or fatigue while awake despite adequate sleep hours. These children fall asleep easily in nonstimulating environments and are difficult to arouse at usual awakening time. Type 1 OSAS is characterized by lymphoid hyperplasia without obesity, whereas type 2 OSAS patients are obese with minimal lymphoid hyperplasia. Approximately 10% of OSAS cases occur in preschool and school-aged children, and this number is thought to decline after 9 years of age.

Obesity changes craniofacial anthropometric characteristics. Therefore, a body mass index of 95% for age or greater is a predisposing physical characteristic that increases the risk of developing OSAS.<sup>13,14</sup> Children with craniofacial abnormalities including a small maxilla and mandible, a large tongue for a given mandibular size, and a thick neck have a similar increased risk. Many of these children have syndromes that are associated

with additional comorbidities. Anatomic nasal obstruction and class 4 touching tonsils reduce oropharyngeal cross-sectional area, which constitutes an additional risk. Pharyngeal size is determined by the soft tissue volume inside the bony enclosure of the mandible; an anatomic imbalance between the upper airway soft tissue volume and craniofacial size will result in obstruction. The magnitude of pharyngeal muscle contraction is controlled by neural mechanisms, and the interaction between the anatomic balance and neural mechanisms determines pharyngeal airway size. Increased neural mechanisms can compensate for the anatomic imbalance in obstructive sleep apnea patients during wakefulness. When these neural mechanisms are suppressed during sleep or anesthesia, pharyngeal dilator muscles do not contract maximally, and therefore the pharyngeal airway severely narrows because of the anatomic imbalance. Increasing bony enclosure size will provide relief of airway obstruction. This is only accomplished surgically by mandibular advancement. Increasing the distance between the mentum and the cervical column by positioning will transiently relieve the obstruction so long as the sniffing position is maintained. Similarly, the sitting position displaces excessive soft tissue outside the bony enclosure through the submandibular space.

The long-term effects of OSAS are not limited to the airway. Increased body mass index and obesity may lead to increased cognitive vulnerability, as illustrated by the increased frequency of hyperactivity and increased levels of C-reactive protein. The duration of OSA has no relation to reversibility of neurobehavioral impairment, because many believe that episodic hypoxia alters the neurochemical substrate of the prefrontal cortex, causing neuronal cell loss. Metabolic syndrome consists of insulin resistance, dyslipidemia, and hypertension. It is thought that OSAS is a risk factor for metabolic syndrome in obese children but not in nonobese patients. Cardiovascular and hemodynamic comorbidities are more common in OSAS patients. These consist of altered regulation of blood pressure as well as alterations in sympathetic activity and reactivity. Also present are endothelial dysfunction and initiation and propagation of inflammatory response facilitated by increases in levels of C-reactive protein. Systemic inflammation with use of interleukins as a marker is a component of OSAS in both obese and nonobese children and is reversed after tonsillectomy. Systemic hypertension, changes in left ventricular geometry, and intermittent hypoxia leading to pulmonary artery hypertension are well-described comorbidities present in patients with OSAS.

The mainstay of the management is surgical removal of tonsils and adenoids, which carries an 85% success rate in resolving OSAS. Recurrence may occur in children with craniofacial abnormalities and in others. If surgical intervention does not resolve the problem, nocturnal CPAP is the next

treatment modality.

Tonsillotomy, or partial tonsillectomy, is being increasingly utilized as an alternative therapy in patients with OSA as a result of evidence suggesting lower rates of postsurgical hemorrhage and decreased pain compared with tonsillectomy.<sup>15,16</sup> However, with tonsillotomy there remains concern for tonsillar regrowth, necessitating additional surgeries and inferior treatment of OSA because of subtotal removal of tonsillar tissue.<sup>15</sup>

For patients with severe or refractory OSA in whom corrective surgery is being considered or patients with persistent OSA after surgery, drug-induced sleep endoscopy (DISE) can be performed to better characterize the anatomic basis of obstruction. One study found that compared with clinical examination alone, information from DISE resulted in a change in surgical plan in 78% of cases.<sup>17</sup> During DISE, patients are sedated with the goal of reproducing obstructive symptoms that occur during sleep. One of the goals of sedation is maintenance of spontaneous respiration, and, because these patients are at high risk of obstruction, timely emergence is important for safe recovery and discharge. Coincident with these goals, agents with rapid offset such as propofol and dexmedetomidine infusion with or without ketamine bolus are typically used.<sup>18</sup> By nature, these patients are at increased risk of obstruction with sedation, and the anesthesiologist should have equipment immediately available (such as oral and nasal airways and laryngeal mask airways [LMAs]) to bypass and relieve obstruction. Once the patient is sedated, nasal endoscopic evaluation is performed to evaluate the upper airway for specific areas of obstruction that would be potentially corrected by surgical intervention.

## *Anesthetic Management*

The goals of the anesthetic management for tonsillectomy and adenoidectomy are to render the child unconscious, to provide the surgeon with optimal operating conditions, to establish intravenous access to provide a route for volume expansion and medications when necessary, and to provide rapid emergence so that the patient is awake and able to protect the recently instrumented airway. Premedication may be used sparingly; sedative premedication should be avoided in children with obstructive sleep apnea, intermittent obstruction, or very large tonsils. Use of an antisialagogue will minimize secretions in the operative field.

Anesthesia is commonly induced with a volatile anesthetic agent, oxygen, and nitrous oxide (N<sub>2</sub>O) by mask. Parental presence in the operating room (OR) during mask induction may be helpful in the anxious unpremedicated child. Tracheal intubation is best accomplished under deep inhalation anesthesia or aided by a short-acting nondepolarizing muscle relaxant. Many

clinicians may choose to eliminate the neuromuscular blocking agent in favor of enhancing the depth of anesthesia with the use of propofol. Acetaminophen can be used as part of a multimodal pain regimen to reduce opioid consumption, particularly for patients having surgery for treatment of OSA.

**3** One study demonstrated that patients undergoing adenotonsillectomy who received fentanyl, 1 to 2  $\mu\text{g}/\text{kg}$ , and acetaminophen, 15 mg/kg intravenously or 40 mg/kg rectally, had a median time to postoperative rescue analgesia of 7 and 10 hours, respectively.<sup>19</sup> The addition of 0.5 to 1  $\mu\text{g}/\text{kg}$  of dexmedetomidine infused during the procedure may help to attenuate emergence delirium in toddlers at the conclusion of the anesthetic.<sup>20</sup> Although intraoperative nonsteroidal anti-inflammatory drugs should be avoided intraoperatively to decrease the risk of postoperative hemorrhage, these agents have been shown to be safe and effective in the postacute recovery period.<sup>21</sup> Owing to the increased opioid sensitivity of patients with OSA, the standard dose of opioid should be reduced by 50%. Codeine should be avoided because of the possibility of rapid metabolism and conversion.<sup>22,23</sup> Blood in the pharynx may enter the trachea during the surgical procedure. For this reason, the supraglottic area may be packed with petroleum gauze, or a cuffed endotracheal tube may be used. If a cuffed endotracheal tube is selected, careful attention to the inflation pressure of the cuff is essential if postextubation croup is to be avoided. Monitoring tools include precordial stethoscope, ECG, automated blood pressure, pulse oximetry, and end-tidal capnography.

Emergence from anesthesia should be rapid, and the child should be alert before transfer to the recovery area. The child should be awake and able to clear blood or secretions from the oropharynx as efficiently as possible before removal of the endotracheal tube. Maintenance of airway and pharyngeal reflexes is essential in the prevention of aspiration, laryngospasm, and airway obstruction. There is no difference in the incidence of airway complications on emergence between patients who are extubated awake and those who are deeply anesthetized.<sup>24</sup>

The use of the LMA for adenotonsillectomy was described in 1990; however, it was not until the widespread availability of a streamlined flexible model that it was routinely used for this purpose.<sup>25,26</sup> There is an emerging trend to use the flexible LMA for tonsillectomy, which protects the vocal cords from blood or secretions that may be present in the oropharynx.<sup>27</sup> The wide, rigid tube of the standard LMA model does not fit under the mouth gag and is easily compressed or dislodged during full mouth opening. The flexible model has a soft, reinforced shaft that easily fits under the mouth gag without becoming dislodged or compressed. Adequate surgical access can be achieved, and the lower airway is protected from exposure to blood during the procedure.<sup>28,29</sup> Because the cuff is larger and occupies a greater percentage of

the posterior hypopharynx, there is a greater risk of airway fire if the electrocautery touches the LMA. Insertion is possible either after the intravenous administration of 3 mg/kg of propofol or when sufficient depth of anesthesia is achieved using a volatile agent administered by face mask. The same depth of anesthesia should be obtained during insertion of the LMA as would be required for performing laryngoscopy and endotracheal intubation. Positive-pressure ventilation should be avoided when the LMA is used during tonsillectomy, although gentle assisted ventilation is both safe and effective if peak inspiratory pressure is kept below 20 cm H<sub>2</sub>O.

Tonsillar enlargement can make LMA insertion difficult; therefore, care in placement is essential. Maneuvers to overcome this include increased head extension, lateral insertion of the mask, anterior displacement of the tongue, pressure on the tip of the LMA using the index finger as it negotiates the pharyngeal curve, or use of the laryngoscope if all else fails. Dislodgment of the device does not occur during extreme head extension, assuming good position and ventilation were obtained before changes in head position.<sup>30</sup>

Advantages of the LMA over traditional endotracheal intubation are a decrease in the incidence of postoperative stridor and laryngospasm and an increase in immediate postoperative oxygen saturation. If the child is breathing spontaneously at a regular rate and depth, the LMA may be removed before emergence from anesthesia. The oropharynx should be gently suctioned with a soft flexible catheter, the LMA deflated and removed, an oral airway inserted, and the respirations assisted with 100% oxygen delivered by face mask. It is often distressing for young children to awaken with the LMA still in place. Although the device is an appropriate substitute for an oral airway in the adult population, this is not so in children. If the practitioner wants to remove the LMA when the child has emerged from anesthesia, it should be deflated and removed as soon as possible after the return to consciousness. In addition, because it is not possible to pass a nasogastric tube beyond the LMA cuff even when deflated, the stomach cannot be emptied at the conclusion of surgery.

## **Complications**

The incidence of posttonsillectomy mortality within the first 48 hours in both children and adults has been reported to be increased in patients who are obese or have neurologic impairment or cardiopulmonary compromise.<sup>31</sup> The incidence of emesis after tonsillectomy ranges from 30% to 65%.<sup>32</sup> Whether emesis is due to irritant blood in the stomach or stimulation of the gag reflex by inflammation and edema at the surgical site remains unclear. Central nervous system stimulation from the gastrointestinal tract, as may be seen with gastric distention from the introduction of swallowed or insufflated air,

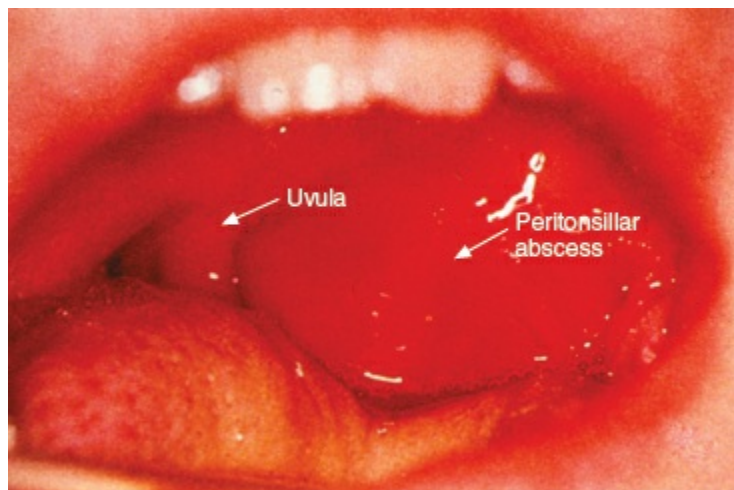

may trigger the emetic center of the brain. Decompressing the stomach with an orogastric tube may be helpful in preventing this response. Treatment with ondansetron, 0.10 to 0.15 mg/kg, either with or without dexamethasone, 0.5 mg/kg, has been shown to be very effective in reducing posttonsillectomy nausea and vomiting.<sup>33</sup> Dehydration secondary to poor oral intake as a result of nausea, vomiting, or pain can occur after tonsillectomy in 1% of cases. Vigorous intravenous hydration during surgery can offset the physiologic effects of lower postoperative fluid intake.

**4** The most serious complication of tonsillectomy is postoperative hemorrhage, which occurs at a frequency of 0.1% to 8.1%. The use of coblation tonsillectomy, which has recently increased in popularity, may result in an incidence of posttonsillectomy hemorrhage up to 11.1%.<sup>34,35</sup> Approximately 75% of postoperative tonsillar hemorrhage occurs within 6 hours of surgery. Most of the remaining 25% occurs within the first 24 hours of surgery, although bleeding may be noted until the sixth postoperative day (thus the “six hours or six days” guideline). Sixty-seven percent of postoperative bleeding originates from the tonsillar fossa, 26% in the nasopharynx, and 7% in both.<sup>31</sup> Initial attempts to control bleeding may be made using pharyngeal packs and cautery. If this fails, patients must return to the OR for exploration and surgical hemostasis.

Unappreciated large volumes of blood originating from the tonsillar bed may be swallowed. Patients must be considered to have a full stomach, and anesthetic precautions addressing this situation must be taken. A rapid-sequence induction accompanied by cricoid pressure and insertion of a styloleaded endotracheal tube is controversial but may be of benefit in some circumstances. Because the amount of blood swallowed can be considerable, blood pressure must be checked in both the erect and supine positions to exclude orthostatic changes resulting from decreases in vascular volume. Intravenous access and hydration must be established before the induction of anesthesia. A variety of laryngoscope blades and endotracheal tubes, as well as functioning suction apparatus, should be prepared in duplicate because blood in the airway may impair visualization of the vocal cords and cause plugging of the endotracheal tube.

Pain after adenoidectomy is usually minimal, but pain after tonsillectomy may be severe. This contributes to poor fluid intake and overall discomfort of patients. An increase in postoperative pain medication requirements has been noted in patients having laser or electrocautery as part of the operative tonsillectomy compared with those who have had sharp surgical dissection and ligation of blood vessels to achieve hemostasis. Intraoperative administration of corticosteroids may decrease edema formation and subsequent patient discomfort. Although infiltration of the peritonsillar space with local anesthetic and epinephrine has been shown to be effective in

reducing intraoperative blood loss, it does not significantly decrease postoperative pain.<sup>36</sup>

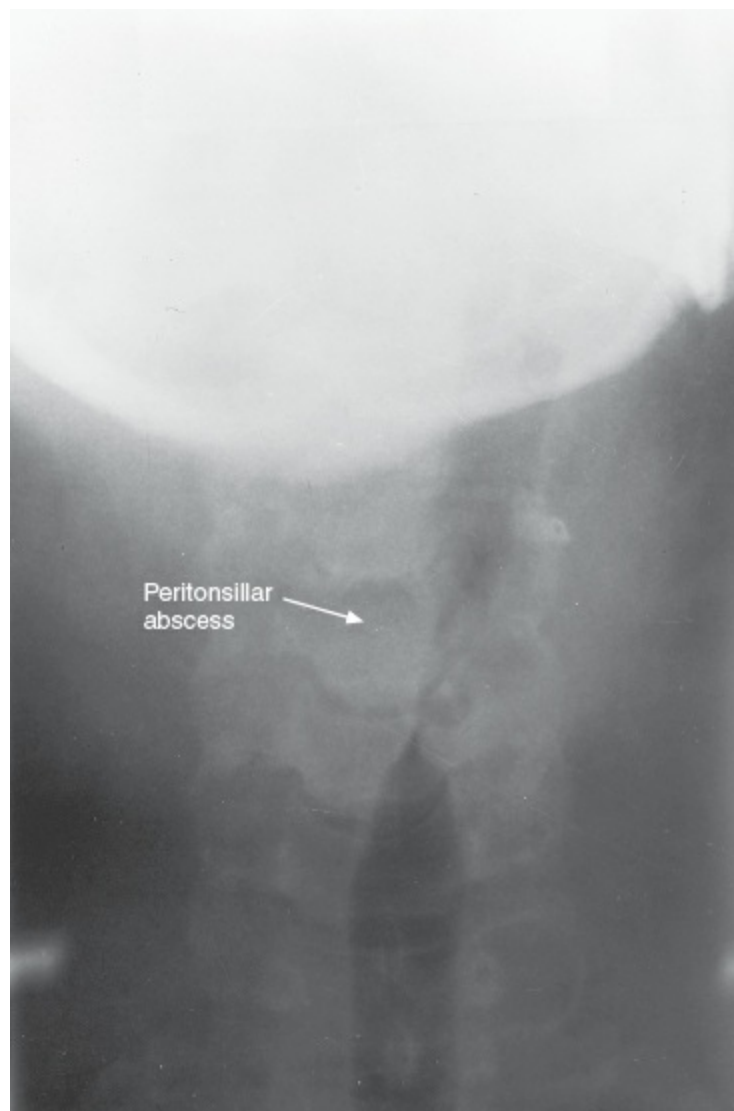

**Figure 48-3** Patient with a peritonsillar abscess on the left side. Note the displacement of the uvula. (Courtesy of Michael Cunningham, MD, Boston, MA.)

Peritonsillar abscess, or quinsy tonsil, is a condition that may require immediate surgical intervention to relieve potential or existing airway obstruction. An acutely infected tonsil may undergo abscess formation, producing a large mass in the lateral pharynx that can interfere with swallowing and breathing (Figs. 48-3 to 48-5). Fever, pain, and trismus are frequent symptoms. Treatment consists of surgical drainage of the abscess, either with or without tonsillectomy, and intravenous antibiotic therapy. Although the airway seems compromised, the peritonsillar abscess is usually in a fixed location in the lateral pharynx and does not interfere with ventilation of the patient by face mask after induction of general anesthesia. Visualization of the vocal cords should not be impaired because the pathologic process is supraglottic and well above the laryngeal inlet. Laryngoscopy must be carefully performed, avoiding manipulation of the larynx and surrounding structures. Intubation should be gentle because the tonsillar area is  tense and friable, and inadvertent rupture of the abscess can occur, leading to spillage of purulent material into the trachea. A head-down position may be useful during laryngoscopy to decrease risk of purulent aspiration in the event of abscess rupture.

Acute postoperative pulmonary edema is an infrequent but potentially life-threatening complication encountered when airway obstruction is suddenly relieved. One proposed mechanism is that during inspiration before adenotonsillectomy, the negative intrapleural pressure that is generated causes an increase in venous return, enhancing pulmonary blood volume. In the healthy child without airway obstruction, pleural pressure ranges from  $-2.5$  cm to  $-10$  cm  $H_2O$  during inspiration. Intrapleural pressure generated

in the child with airway obstruction can be as much as  $-30$  cm H<sub>2</sub>O, which causes disruption of the capillary walls of the pulmonary microvasculature when transmitted to the interstitial peribronchial and perivascular spaces. Concurrent with a negative transpulmonary gradient is an increase in venous return to the right side of the heart, thus increasing preload, which in the setting of “leaky capillaries” facilitates transudation of fluid into the alveolar space. To counterbalance this negative gradient, positive intrapleural and alveolar pressures are generated during exhalation, which decreases pulmonary venous return and blood volume. This phenomenon is similar to an expiratory “grunt” mechanism, in which the transpleural pressures generated are similar to those present during a Valsalva maneuver.

**Figure 48-4** Neck radiograph of a patient with a peritonsillar abscess (*arrow*).

The rapid relief of airway obstruction results in decreased airway pressure, an increase in venous return, an increase in pulmonary hydrostatic pressure, hyperemia, and finally pulmonary edema. The all-important counterbalance of the expiratory grunt in limiting pulmonary venous return is lost when the

obstruction is relieved. Contributing factors are the increased volume load on both ventricles as well as the inability of the pulmonary lymphatic system to remove acutely large amounts of fluid. The anesthesiologist may attempt to prevent this situation during induction of anesthesia by applying moderate amounts of continuous positive pressure to the airway, thus allowing time for circulatory adaptation to take place. This physiologic sequence is similar to that seen in patients with severe acute airway obstruction secondary to epiglottitis or laryngospasm.

**Figure 48-5** Computed tomography scan of a patient with a peritonsillar abscess (arrow).

Negative-pressure pulmonary edema is signaled by the appearance of frothy pink fluid in the endotracheal tube of an intubated patient or the presence of decreased oxygen saturation, wheezing, dyspnea, and increased respiratory rate in the immediate postoperative period in a previously extubated patient. Mild cases may present with minimal symptoms. The differential diagnosis of negative-pressure pulmonary edema includes aspiration of gastric contents, adult respiratory distress syndrome, congestive heart failure, volume overload, and anaphylaxis. A chest radiograph illustrating diffuse, usually bilateral interstitial pulmonary infiltrates combined with an appropriate clinical history will confirm the diagnosis.<sup>37,38</sup> Treatment is usually supportive, with maintenance of a patent airway, oxygen administration, and diuretic therapy in some cases. Endotracheal intubation

and mechanical ventilation with positive end-expiratory pressure may be necessary in severe cases. Resolution is usually rapid and may occur within hours of inception. Most cases resolve within 24 hours without treatment. There is currently no reliable method for predicting which children will experience this clinical syndrome after their airway obstruction has been resolved.

Adenoidectomy patients may be safely discharged on the same day after recovering from anesthesia. Although most tonsillectomy patients previously required postoperative admission to the hospital for observation, administration of analgesics, and hydration, many centers are discharging tonsillectomy patients on the day of surgery without adverse outcomes, and this trend will likely continue.<sup>38</sup> Patients should be observed for early hemorrhage for a minimum of 4 to 6 hours and be free from significant nausea, vomiting, and pain prior to discharge. The ability to take fluid by mouth is not a requirement for discharge home. However, intravenous hydration must be adequate to prevent dehydration. Excessive somnolence and severe vomiting are indications for hospital admission. There are patients for whom early discharge is not advised, and those patients should be admitted to the hospital after tonsillectomy. The characteristics of such patients are listed in [Table 48-1](#). Recently, the American Academy of Pediatrics has recommended that children who exhibit oxygen saturation less than 80% in the posttonsillectomy recovery period be admitted to an inpatient unit and monitored for respiratory depression.<sup>39</sup> Despite removal of hypertrophied lymphoid tissue in the hypopharynx, there are some children who remain at risk for postoperative obstruction.<sup>40</sup> Admission to an intensive care unit (ICU) is controversial and reserved for those children with very severe OSA, comorbidities that cannot be managed on the floor, and children who have demonstrated significant airway obstruction and desaturation in the initial postoperative period that required intervention beyond repositioning and oxygen supplementation.<sup>41</sup>

**Table 48-1** Tonsillectomy and Adenoidectomy Inpatient Guidelines: Recommendation of the American Academy of Otolaryngology—Head and Neck Surgery

Admit patients to the hospital after adenotonsillectomy if they meet any of the following criteria:

- Age  $\leq 3$  yrs
- Severe OSA with an apnea–hypopnea index of 10 or more obstructive events/hr, oxygen saturation nadir  $<80\%$ , or both
- Abnormal coagulation values with or without an identified bleeding disorder in the patient or family
- Systemic disorders that put the patient at increased preoperative cardiopulmonary, metabolic, or general medical risk
- Child with craniofacial or other airway abnormalities including, but not limited to, syndromic disorders such as Treacher Collins syndrome, Crouzon syndrome, Goldenhar syndrome, Pierre Robin anomaly, CHARGE syndrome, achondroplasia, and, most prominently, Down syndrome, as well as isolated airway abnormalities such as choanal atresia and laryngotracheal stenosis
- When extended travel time, weather conditions, and home social conditions are not consistent with close observation, cooperation, and ability to return to the hospital quickly at the discretion of the attending physician

CHARGE, coloboma of the eye, heart defects, atresia of the choanae, retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities.

## Laryngology

There have been great advances in knowledge regarding voice disorders and strategies for managing them. This developed in adult practice, and the subspecialty of phoniatrics emerged. This expertise is now prevalent in surgeons for both pediatric and adult patient populations. The most common disorder is vocal nodules as a result of laryngeal hyperfunction, producing hoarseness. Papillomatosis of the vocal cords is another cause of voice disorder along with vocal fold paralysis.<sup>42</sup> Treatment of papillomatosis includes laser ablation, which is easily performed with a laser-reflective endotracheal tube in adults, and spontaneous ventilation with a natural airway in children. Medialization of the vocal cord or injection laryngoplasty is also accomplished during spontaneous ventilation with a natural airway. Although there are many different methods for providing general anesthesia with a natural airway, total intravenous anesthesia (TIVA) with topicalization of the vocal cords during spontaneous ventilation provides the best view of the surgical field for the surgeon.<sup>43</sup>

## Ear Surgery

The ear and its associated structures are target organs for many pathologic conditions. General anesthesia for surgery of the ear has its own set of unique considerations that must be addressed.

### **Myringotomy and Tube Insertion**

Chronic serous otitis in children can lead to hearing loss. Drainage of accumulated fluid in the middle ear is an effective treatment for this condition. Myringotomy, which creates an opening in the tympanic membrane for fluid drainage, may be performed alone. During healing, the drainage path may become occluded; therefore, ventilation tube placement is usually included. The insertion of a small plastic tube in the tympanic membrane serves as a vent for the ostium and allows for continued drainage of the middle ear until the tubes are naturally extruded in 6 months to 1 year or surgically removed at an appropriate time.

Myringotomy with tube insertion is a relatively short procedure, and anesthesia may be effectively accomplished with a potent inhalation agent, oxygen, and N<sub>2</sub>O administered by face mask. Premedication is not recommended because most sedative drugs used for premedication will far outlast the duration of the surgical procedure. Patients with chronic otitis frequently have accompanying recurrent URI. It is often the eradication of middle ear fluid that resolves the concomitant URI. Because tracheal

intubation is not required for routine patients, the criteria for cancellation of surgery and anesthesia may be different for this procedure. Insertion of myringotomy tubes may be undertaken in most children with a concomitant URI provided that this can be completed with face mask anesthesia and endotracheal intubation is avoided. No significant difference in perioperative morbidity between asymptomatic patients and those fulfilling URI criteria has been demonstrated.<sup>44,45</sup> It is recommended that patients with URI symptoms receive supplemental postoperative oxygen.

## Middle Ear and Mastoid

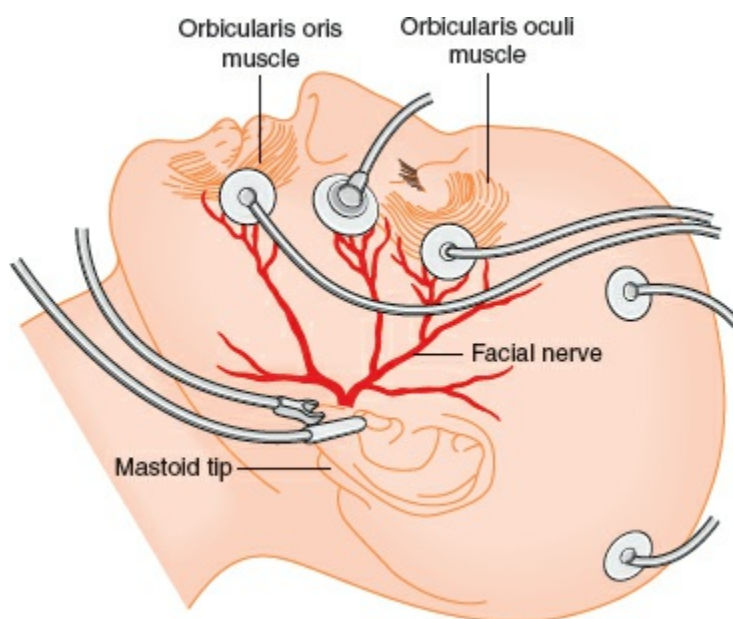

Tympanoplasty and mastoidectomy are two of the most common procedures performed on the middle ear and accessory structures. To gain access to the surgical site, the head is positioned on a headrest, which may be lower than the operative table, and extreme degrees of lateral rotation may be required. Extreme tension on the heads of the sternocleidomastoid muscles must be avoided. The laxity of the ligaments of the cervical spine and the immaturity of odontoid process in children make them especially prone to C1 to C2 subluxation.

Ear surgery often involves surgical identification and preservation of the facial nerve, which requires isolation of the nerve by the surgeon and verification of its function by means of electrical stimulation (Fig. 48-6). This is accomplished by brainstem auditory evoked potential and electrocochleogram monitoring, which requires that complete muscle relaxation be avoided.<sup>46</sup> However, if an opioid-relaxant technique is chosen, at least 30% of the muscle response, as determined by a twitch monitor, should be preserved. This fact suggests that it is not mandatory to avoid skeletal muscle relaxants in the anesthetic management of patients undergoing surgical procedures when monitoring of facial nerve function is necessary.

Bleeding must be kept to a minimum during surgery of the small structures of the middle ear. Minimizing excessive increases in blood pressure and normotension can be helpful in improving the surgical field. Relative hypotension can also be effective, though careful consideration should be given to the risks of lowered blood pressure against the potential benefit of reduced surgical bleeding, because even short periods of hypotension may be associated with perioperative morbidity.<sup>47</sup> Additional specific contraindications to this technique include intracranial hypertension, hypovolemia, or history of vascular, cerebrovascular, or other end-organ disease.<sup>48</sup> Concentrated epinephrine solution, often 1:1,000, can be injected in the area of the tympanic vessels to produce vasoconstriction, though concentrations as low as 1:400,000 may give equivalent reductions in local

blood flow with less potential for adverse effects from inadvertent intravascular injection.<sup>49,50</sup> Pay close attention to the volume of injected epinephrine so that dysrhythmias and wide swings in blood pressure may be avoided.

**Figure 48-6** Illustration of facial nerve and monitoring electrodes. (Courtesy of Steve Ronner, PhD, Boston, MA.)

**5** The middle ear and sinuses are air-filled, nondistensible cavities. An increase in the volume of gas in these structures results in an increase in pressure. N<sub>2</sub>O diffuses along a concentration gradient into the air-filled middle ear spaces more rapidly than nitrogen moves out. Passive venting occurs at 20 to 30 cm H<sub>2</sub>O pressure, and it has been shown that the use of N<sub>2</sub>O results in pressures that exceed the ability of the eustachian tube to vent the middle ear within 5 minutes, leading to pressure buildup.<sup>51</sup> During procedures in which the eardrum is replaced or a perforation is patched, N<sub>2</sub>O should be discontinued or, if this is not possible, limited to a maximum of 50% during the application of the tympanic membrane graft to avoid pressure-related displacement.

After N<sub>2</sub>O is discontinued, it is quickly reabsorbed, creating a void in the middle ear with resulting negative pressure. This negative pressure may result in serous otitis, disarticulation of the ossicles in the middle ear (especially the stapes), and hearing impairment, which may last up to 6 weeks after surgery. The use of N<sub>2</sub>O is related to a high incidence of postoperative nausea and vomiting, which is a direct result of negative middle ear pressure during recovery. The vestibular system is stimulated by traction placed on the round window by the negative pressure that is created. Although all patients have the potential for nausea and vomiting after surgery, children younger than 8 years of age seem to be most affected. If the use of N<sub>2</sub>O cannot be avoided,

vigorous use of antiemetics is warranted.

**Table 48-2** Causes of Stridor

Supraglottic Airway	Larynx	Subglottic Airway
Laryngomalacia	Laryngocele	Tracheomalacia
Vocal cord paralysis	Infection (tonsillitis, peritonsillar abscess)	Vascular ring
Subglottic stenosis	Foreign body	Foreign body
Hemangiomas	Choanal atresia	Infection (croup, epiglottitis)
Cysts	Cyst Mass Large tonsils Large adenoids Craniofacial abnormalities	

## Airway Surgery

### Stridor

Noisy breathing due to obstructed airflow is known as *stridor*. Inspiratory stridor results from upper airway obstruction; expiratory stridor results from lower airway obstruction; and biphasic stridor is present with midtracheal lesions. The evaluation of a patient with stridor begins with a thorough history. The age of onset suggests a cause: Laryngotracheomalacia is usually present at or shortly after birth, whereas cysts or mass lesions develop later in life (Table 48-2). Vocal cord paralysis may be congenital or acquired. Acquired vocal cord paralysis may be due to iatrogenic injury sustained during surgery, neurologic abnormalities such as Arnold–Chiari malformation, local invasion by tumors, and certain chemotherapy regimens. Information indicating positions that make the stridor better or worse should be obtained, and placing a patient in a position that allows gravity to aid in reducing obstruction can be of benefit during anesthetic induction.

Physical examination reveals the general condition of a patient and the degree of the airway compromise. Laboratory examination may include assessment of hemoglobin, a chest radiograph, and a barium swallow, which can aid in identifying lesions that may be compressing the trachea. Other radiologic examinations such as MRI and computed tomography may be indicated in isolated instances but are not routinely ordered. Specific note of the signs and symptoms listed in Table 48-3 should be made.

Laryngomalacia is the most common cause of stridor in infants. It is most often due to a long epiglottis that prolapses posteriorly and prominent

arytenoid cartilages with redundant aryepiglottic folds that obstruct the glottic opening during inspiration.<sup>52</sup> Many times, laryngomalacia will improve as patients grow older, though patients with severe obstructive symptoms may need surgical intervention.

**Table 48-3** Clinical Component of the Evaluation of Patients with Stridor

Respiratory rate	Chest retractions
Heart rate	Nasal flaring
Wheezing	Level of consciousness
Cyanosis	

Though the majority of patients with unilateral vocal cord paralysis (UVCP) are stridorous, they rarely have signs of overt airway obstruction, as would be the case with bilateral cord paralysis. Younger children with UVCP may have a weak cry and frequent aspiration from lack of ability to fully oppose their vocal cords and protect their airway, whereas older patients may have only symptoms of hoarseness and poor vocal projection.

The definitive diagnosis for both laryngomalacia and UVCP is obtained by direct laryngoscopy and rigid or flexible bronchoscopy. Preliminary examination is usually carried out in the surgeon's office. A small, flexible fiberoptic bronchoscope is inserted through the nares into the oropharynx, and the movement of the vocal cords is observed. Alternatively, it may be accomplished in the OR before anesthetic induction in an awake patient or in a lightly anesthetized patient during spontaneous respiration. Patients must be breathing spontaneously so that the vocal cords can move freely. After deepening of anesthesia and topicalization of the vocal cords is performed using 1% to 2% lidocaine, a rigid bronchoscope is inserted through the vocal cords, and the subglottic area is inspected; the lower trachea and bronchi are evaluated with a rigid or flexible fiberoptic bronchoscope. Treatment for laryngomalacia and UVCP can be performed in conjunction with direct laryngoscopy and bronchoscopy. During supraglottoplasty, redundant tissue is removed in a targeted manner to improve airflow mechanics. Interventional therapy for UVCP is aimed at medializing the paralyzed cord such that it can make contact with the contralateral functioning vocal cord and allow for airway protection. This can be accomplished with periodic injection laryngoplasty or with more permanent interventions such as medialization thyroplasty and reinnervation procedures. Reinnervation procedures do not return vocal cord mobility but restore tone such that the vocal cord assumes a more medial position.<sup>53</sup>

## Bronchoscopy

Small infants may be brought into the OR unpremedicated. Older children and adults may experience respiratory depression and worsening of airway obstruction if heavy premedication is administered, so only light sedation is suggested. The airway must be protected from aspiration of gastric contents during prolonged airway manipulation; therefore, premedication with the full regimen of acid aspiration prophylaxis may be indicated.

The goals of the anesthetic are analgesia, an unconscious patient, and a “quiet” surgical field. Coughing, bucking, or straining during instrumentation with the rigid bronchoscope may cause difficulty for the surgeon and result in damage to the patient’s airway. At the conclusion of the procedure, patients should be returned to consciousness quickly, with airway reflexes intact. For most patients, a pulse oximeter, blood pressure cuff, ECG leads, and precordial stethoscope are applied before induction of anesthesia. Inhalation induction by mask is accompanied by administration of oxygen and a volatile agent in increasing concentrations in children and intravenous drugs in adults. Patients should be placed in the position that produces the least adverse effect on airway symptoms (often the sitting position). An intravenously administered antisialagogue may help decrease secretions that might compromise the view through the bronchoscope.

The size of a bronchoscope refers to the internal diameter. Because the external diameter may be significantly greater than that of an endotracheal tube of similar size ([Table 48-4](#)), care must be taken to select a bronchoscope of proper external diameter to avoid damage to the laryngeal structures. A rigid bronchoscope can be used for ventilation of the lungs during examination of the airway. It is inserted through the vocal cords, and ventilation is accomplished through a side port, which can be attached to the anesthesia circuit. During ventilation with the viewing telescope in place, high resistance may be encountered as a result of partial occlusion of the lumen. High fresh gas flow rates, large tidal volumes, and high inspired volatile anesthetic concentrations are often necessary to compensate for leaks around the ventilating bronchoscope and the high resistance encountered when the viewing telescope is in place. Manual ventilation at higher-than-normal rates is most effective in achieving adequate ventilation. Adequate time for exhalation must be provided for passive recoil of the chest.<sup>54</sup>

**Table 48-4** Comparison of External Diameter of Standard Endotracheal Tubes versus Rigid Bronchoscope

Endotracheal Tube	Rigid Bronchoscope	
	External Diameter (mm)	Internal Diameter (mm)
3.5	4.2	2.5
4.3	5	3
4.9	5.7	3.5
5.5	6.7	4
6.8	7.8	5
8.2	8.2	6

An alternative method of ventilation is the jet ventilation technique, which involves intermittent bursts of oxygen delivered under pressure.<sup>55,56</sup> Intermittent flow is accomplished by use of a programmed jet ventilator but can alternatively be accomplished with manual controls. The use of jet ventilation techniques is associated with the additional risks of pneumothorax or pneumomediastinum due to rupture of alveolar blebs or a bronchus.<sup>57</sup> Because ventilation may be intermittent and at times suboptimal, oxygen should be used as the carrier gas during bronchoscopic examination. Intravenous drugs that cause excessive respiratory depression should be avoided. It is wise to ask the surgeon if movement of the vocal cords will be required at the conclusion of the procedure or if tracheal or bronchial dynamics will be evaluated during the procedure so that the anesthetic may be planned accordingly (i.e., spontaneous respirations preserved during light levels of anesthesia vs. no respiratory efforts and the use of short-acting muscle relaxants).

Maintenance of anesthesia is usually accomplished with a volatile anesthetic augmented by propofol infusion (100 to 300  $\mu\text{g}/\text{kg}/\text{min}$ ). Intravenous anesthetics combined with muscle relaxation best maintain a constant level of anesthesia because the delivery of volatile anesthetics through the bronchoscope may be interrupted, and anesthetic depth can vary. At the conclusion of rigid bronchoscopy, an endotracheal tube is usually placed in the trachea to control the airway during recovery of anesthesia. Securing the airway is particularly important if muscle relaxants have been used because passive regurgitation of gastric contents may be more likely to occur in paralyzed patients. An additional advantage of placing an endotracheal tube is that if the surgeon should want to examine the distal airways, a small, flexible fiberoptic bronchoscope can be passed through the endotracheal tube.

## Pediatric Airway Emergencies

Upper airway emergencies may be life-threatening and demand immediate treatment. Rapid respiratory failure can occur in patients with croup, epiglottitis, or foreign body aspiration, and few clinical situations are more challenging to the anesthesiologist.

## Epiglottitis

 Acute epiglottitis is one of the most feared infectious diseases in children and adults and is the result of *Haemophilus influenzae* type B. A conservative estimate of the incidence of epiglottitis is 10 to 40 cases per million people in the United States. Since 1985, with the widespread vaccination against *H. influenzae* type B (Hib), which was the most common organism related to epiglottitis, the overall incidence of the disease among children has dropped dramatically. It can progress with extreme rapidity from sore throat to airway obstruction to respiratory failure and ultimately to death if proper diagnosis and intervention are not rapidly implemented. Patients are usually between 2 and 7 years of age, although epiglottitis has been reported in younger children and in adults. Epiglottitis in the very young (younger than 1 year) is unusual and occurs in only about 4% of cases, and in adults it peaks between ages 20 to 40 years. Vaccination against *H. influenzae* type B polysaccharide is now recommended before 2 years of age to provide immunity before the greatest period of vulnerability in pediatric patients.

Characteristic signs and symptoms of acute epiglottitis include sudden onset of fever, dysphagia, drooling, thick muffled voice, and preference for the sitting position with the head extended and leaning forward. Retractions, labored breathing, and cyanosis may be observed in cases in which respiratory obstruction is present. However, in the early stages, the patient may be pale and toxic without respiratory distress. *Supraglottitis* may be a more appropriate designation because it is the tissues of the supraglottic structures—from the vallecula to the arytenoids—that are involved in the infectious process. At no time, especially in the emergency department or radiography suite, should direct visualization of the epiglottis be attempted in the unanesthetized patient. The differential resulting from negative pressure inside and atmospheric pressure outside the extrathoracic airway results in slight narrowing during normal inspiration. The pressure differential on inspiration is exaggerated in the patient with airway obstruction. This dynamic collapse of the airway may become life-threatening in the struggling, agitated patient, and every attempt should be made to keep the patient calm. Blood drawing, intravenous catheter insertion, and excessive manipulation of the patient, as well as sedation, should be avoided before securing the airway to avoid the possibility of total obstruction.

If the clinical situation allows, oxygen should be administered by mask, and lateral radiographs of the soft tissues in the neck may be obtained. Thickening of the aryepiglottic folds and swelling of the epiglottis may be noted (the “thumbprint” sign). Radiologic examination should be carried out only if skilled personnel and adequate equipment accompany the patient at all times. The patient with severe airway compromise should proceed from the emergency department directly to the operating suite accompanied by both the anesthesiologist and surgeon. Parental presence in this situation may calm an anxious and frightened child.

In all cases of epiglottitis, an artificial airway is established by means of tracheal intubation. In some centers in which personnel experienced in the management of the compromised airway are not available, tracheostomy is a less-favored alternative. In the OR, the child is kept in the sitting position while monitors are placed. A pulse oximeter and precordial stethoscope are essential. If it is believed to be helpful, one parent may accompany the child and remain in the OR during the induction of general anesthesia. The OR must be prepared with equipment and personnel for laryngoscopy, rigid bronchoscopy, and tracheostomy. Anesthetic induction is accomplished by inhalation of oxygen and increasing concentrations of sevoflurane. After loss of consciousness occurs, intravenous access should be secured and the child lowered into the supine position. Laryngoscopy followed by oral tracheal intubation is then accomplished without the use of muscle relaxants. The endotracheal tube chosen should be at least one size (0.5 mm) smaller than would normally be chosen, and a stylette is often useful. Once the surgeon has examined the larynx, noting the appearance of the epiglottis, aryepiglottic folds, and surrounding tissues, the endotracheal tube may be changed to a nasotracheal tube and secured. Tissue and blood cultures are taken, and antibiotic therapy is initiated. The child is then transferred to the ICU for continued observation and radiographic confirmation of tube placement. Sedation is appropriate at this time. Tracheal extubation is usually attempted 48 to 72 hours later in the OR, when a significant leak around the nasotracheal tube is present and visual inspection of the larynx by flexible fiberoptic bronchoscopy confirms reduction in swelling of the epiglottis and surrounding tissues.

### ***Laryngotracheobronchitis***

Laryngotracheobronchitis (LTB), or croup, occurs in children from 6 months to 6 years of age but is primarily seen in children younger than 3 years of age. It is usually viral in etiology, and its onset is more insidious than that of epiglottitis. The child presents with low-grade fever, inspiratory stridor, and a “barking” cough. Radiologic examination confirms the diagnosis, and

subglottic narrowing of the airway column secondary to circumferential soft tissue edema produces the “steeple” sign characteristic of LTB. Approximately 6% of patients with LTB require admission to the hospital. Treatment includes cool, humidified mist and oxygen therapy, usually administered in a tent for mild-to-moderate cases. More severe cases of LTB are accompanied by tachypnea, tachycardia, and cyanosis. Racemic epinephrine administered by nebulizer is beneficial. The use of steroids has been surrounded by a great deal of controversy, but current opinion is that a short course of steroids may be beneficial. In rare circumstances, thick secretions are present in the airway, and the child requires intubation to allow pulmonary toilet and suctioning to be performed. Management in the ICU and extubation are carried out in the same fashion as for epiglottitis.

### ***Foreign Body Aspiration***

A major cause of morbidity and mortality in children and adults is aspiration of a foreign body. Any history of coughing, choking, or cyanosis while eating should suggest the possibility of foreign body aspiration. Peanuts, popcorn, jelly beans, and hot dogs are some of the ingested items most commonly associated with pulmonary aspiration. Any patient who presents to the emergency department with refractory wheezing should be suspected of this diagnosis. Physical findings include decreased breath sounds, tachypnea, stridor, wheezing, and fever. These signs indicate an obstructive process with inflammation present in the airway. Some foreign bodies are identifiable on radiologic examination; however, 90% are radiolucent, and air trapping, infiltrate, and atelectasis are all that are noted.

**Figure 48-7** Aspirated foreign body in the right main stem bronchus.

The most common site of foreign body aspiration is the main stem bronchus, the right being more frequent than the left (Fig. 48-7). Food particles comprise the majority of aspirated items; however, beads, pins, and small toys are not unusual. Each type of aspirated item has potential complications associated with it. Vegetable items expand with moisture encountered in the respiratory tract and can fragment into multiple pieces, thus creating a situation in which the original foreign body is in one bronchus and, with coughing, a fragment is dislodged and transported to the other bronchus. Oil-containing objects, such as peanuts, cause a chemical inflammation, and sharp objects cause bleeding in addition to the obstruction.

All aspirated foreign bodies in the airway should be removed in the OR and considered to be emergency situations. No sedation should be administered to patients before removal of the foreign body. If the patient has recently eaten, full-stomach precautions must be taken, and anesthesia should be induced intravenously (topical anesthetic cream may be applied to the skin before intravenous catheter insertion in small children) by rapid sequence, with gentle cricoid pressure maintained during intubation of the trachea. If the child has not eaten recently, anesthesia may be induced by inhalation of sevoflurane in oxygen by mask. Inhalation induction can be prolonged secondary to obstruction of the airway, and N<sub>2</sub>O should be avoided to prevent air trapping distal to the obstruction. After evacuation of the stomach by

orogastric tube, the airway may be given over to the surgeon, who introduces a rigid bronchoscope and removes the aspirated object.

Spontaneous ventilation should be preserved until the location and nature of the foreign body have been determined. Ventilation via the bronchoscope requires careful attention. Hypoxia and hypercarbia may occur because of inadequate ventilation caused by an excessively large leak around the bronchoscope or, more commonly, inability to provide adequate gas exchange through a narrow-lumen bronchoscope fitted with an internal telescope. These conditions are remedied by frequent removal of the telescope and withdrawal of the bronchoscope to the midtrachea, allowing effective ventilation. Bronchospasm may occur during examination of the respiratory tract and should be treated with increasing depths of anesthesia, nebulized albuterol, or intravenous bronchodilators. Although rare, pneumothorax should be suspected if acute deterioration occurs during the procedure.

Once the foreign body has been removed, examination of the entire tracheobronchial tree is carried out to detect any additional objects or fragments. Often, vigorous irrigation and suctioning distal to the obstruction are required to remove secretions and prevent the possibility of postobstructive pneumonia. Steroids are administered if inflammation of the airway mucosa is observed. Close postoperative observation of the patient is required so that early intervention may be instituted in the event of respiratory compromise secondary to airway edema or infection.

## Pediatric and Adult Surgery

Certain surgical procedures are commonly performed in both adults and children, including nasal surgery and laser surgery of the airway.

### Laser Surgery of the Airway

One of the greatest advances in airway surgery has been the use of the laser (light amplification by stimulated emission of radiation). For use in the airway, the laser provides precision in targeting lesions, minimal bleeding and edema, preservation of surrounding structures, and rapid healing. The laser consists of a tube with reflective mirrors at either end and an amplifying medium between them to generate electron activity, resulting in the production of light.<sup>58</sup> The CO<sub>2</sub> laser is the most widely used in medical practice, having particular application in the treatment of laryngeal or vocal cord papillomas, laryngeal webs, resection of redundant subglottic tissue, and coagulation of hemangiomas. The laser is an especially useful modality for the surgeon because the invisible beam of light affords an unobstructed view of the lesion during resection. The energy

emitted by a CO<sub>2</sub> laser is absorbed by water contained in blood and tissues. Human tissue is approximately 80% water, and laser energy absorbed by tissue water rapidly increases the temperature, denaturing protein and vaporizing the target tissue. The thermal energy of the laser beam cauterizes capillaries as it vaporizes tissues; thus, bleeding and postoperative edema are minimized.

The properties that give the laser a high degree of specificity also supply the route by which a misdirected laser beam may cause injury to a patient or to unprotected OR personnel. The eyes are especially vulnerable, and all OR personnel should wear laser-specific eye goggles with side protectors to prevent injury. Because of the limited penetration (0.01 mm) of the CO<sub>2</sub> laser, it may cause injury only to the cornea. Other lasers such as the neodymium–yttrium-aluminum-garnet (Nd:YAG) have deeper penetration, and may cause retinal injury and scarring. The eyes of a patient undergoing laser treatment must be protected by taping them shut, followed by the application of wet gauze pads and a metal shield. Any stray laser beam is absorbed by the wet gauze, preventing penetration of the eyes. Laser radiation increases the temperature of the absorbent material, and flammable objects such as surgical drapes must be kept away from the path of the laser beam. To avoid cutaneous burns from deflected beams, wet towels should be applied to exposed skin of the face and neck when the laser is being used in the airway. Laser smoke plumes may cause damage to the lungs; interstitial pneumonia has been reported with long-term exposure. In addition, it has been postulated that cancer cells and virus particles, including human immunodeficiency virus, are vaporized during laser application, and the resultant smoke plume, if inhaled, may be a vehicle for spread. The use of specially designed surgical masks for filtering laser smoke is recommended.

Most anesthetic techniques are suitable for laser surgery, provided that patients are immobile and the laser beam can be directed at a target that is entirely still and in full view. Both N<sub>2</sub>O and oxygen support combustion; therefore, the primary gas for anesthetic maintenance should consist of blended air and oxygen or helium and oxygen. A pulse oximeter should be used at all times to ensure adequate oxygenation at the lowest possible inspired concentration of oxygen. Anesthesia during laser surgery may be administered with or without an endotracheal tube. The choice of endotracheal tube used during laser surgery can affect the safety of the technique. All standard polyvinyl chloride endotracheal tubes are flammable and can ignite and vaporize producing hydrochloric acid when in contact with the laser beam. Cuffed endotracheal tubes should be inflated with sterile saline to which methylene blue has been added so that a cuff rupture from a misdirected laser spark is readily detected by the blue dye and extinguished by the saline.<sup>59</sup> Endotracheal tubes have been manufactured

specifically for use during laser surgery. Some have a double cuff to ensure protection of the airway in the event of a cuff rupture, and some have a special matte finish that effectively prevents reflected laser beam scattering; some have both. Nonreflective flexible metal endotracheal tubes are also specifically manufactured for use during laser surgery. The outer diameter of each size of metal laser tube is considerably greater than the polyvinyl chloride counterpart, especially in the small sizes used for pediatric anesthesia (Table 48-5).

An apneic technique is preferred by some surgeons, especially when working on the airway of small infants and children. The advantage of this technique is an unobstructed surgical field owing to the absence of an endotracheal tube, which may obscure the surgical field. In this circumstance, a child is anesthetized and rendered immobile by the use of a muscle relaxant or deep inhalation of a volatile anesthetic. The patient's trachea is not intubated, and the airway is given over to the surgeon, who uses the laser for brief periods. Between laser applications, the patient's lungs are ventilated by mask. Because apnea is a component of this technique, it is prudent to ventilate the lungs with oxygen. Although this technique has been widely used with safety, there is a greater potential for debris and resected material to enter the trachea as well as the potential for airway trauma as a result of repeated endotracheal intubation.

**Table 48-5** Comparison of Standard Plastic versus Metal Endotracheal Tubes

Internal Diameter (mm)	External Diameter (mm)	
	<i>Plastic</i>	<i>Metal</i>
3 (uncuffed)	4.3	5.2
3.5 (uncuffed)	4.9	5.7
4 (uncuffed)	5.5	6.1
4.5 (cuffed)	6.2	7
5 (cuffed)	6.8	7.5
5.5 (cuffed)	7.5	7.9
6 (cuffed)	8.2	8.5

The use of a jet ventilator is a modification of the apneic technique that does not require tracheal intubation but does provide for oxygenation; ventilation during laser surgery uses a jet ventilator. The operating laryngoscope is fitted with a catheter through which oxygen is delivered under pressure through a variable reducing valve. Additional room air is entrained, and the patient's lungs are ventilated with this combination of gases. This technique produces a quiet surgical field because large chest excursions of the diaphragm are eliminated and ventilation is uninterrupted. In morbidly obese patients and those with severe small airway disease,

effective ventilation is difficult to impossible with this technique, and an alternate technique should be used.

The final technique that may be used is spontaneous ventilation without the aid of an endotracheal tube (Fig. 48-8). In this technique, a surgical laryngoscope fitted with an oxygen insufflation port is inserted into the larynx. Anesthesia may be induced with a volatile agent by mask but is maintained with total intravenous agents without muscle relaxant in the spontaneously breathing patient. Propofol may be infused with or without a short-acting narcotic, and the vocal cords may be sprayed with 4% lidocaine to decrease reactivity. This technique is advantageous in that longer periods of uninterrupted laser application may be provided. Disadvantages include the absence of complete control of the airway, limited protection from laryngospasm, limited protection from debris entering the airway, vocal cord motion, and difficult scavenging.

## Nasal Surgery

Close communication between the anesthesiologist and the otorhinolaryngologist during nasal surgery is essential for a successful outcome and avoidance of major complications. Functional endoscopic sinus surgery (FESS) is the most common procedure performed in the nasal area. Historically, nasal procedures were completed under topical or local anesthesia with sedation so that the patient could signal the surgeon if problems arose.<sup>60</sup> As endoscopic nasal surgery grew larger in scope and duration, general anesthesia became preferred, and local anesthesia with sedation was reserved for the simpler cases.

To achieve optimal visualization of the surgical field, bleeding must be kept to a minimum. Current anesthetic practice includes the use of vasoconstrictors, elevation of the head, and avoiding excessive increases in blood pressure. Preoperative evaluation of the patient includes a focused cardiovascular history to document coronary artery disease, peripheral artery disease, and cardiac arrhythmias, which might be exacerbated by the use of sympathomimetic agents used for local vasoconstriction. Positive findings may alter the degree of head elevation, the use of topical constrictors, the anesthetic technique, and the lower limit of blood pressure that can be safely tolerated.

Intranasal vasoconstriction has been accomplished by the use of local anesthetics combined with cocaine, epinephrine, and phenylephrine. Systemic absorption of these agents can cause hypotension, hypertension, bradycardia, tachycardia, and arrhythmias.<sup>61,62</sup> For patients on  $\beta$ -blocker or calcium channel blocker therapy,  $\alpha$ -agonist-induced hypertension may lead to pulmonary edema and cardiac failure. Prompt treatment is needed to prevent

serious complications.

**Figure 48-8** **A:** The surgical laryngoscope and the jet ventilator needle. **B:** The surgical view of the laryngoscope positioned in the patient's pharynx and connected to a continuous flow of oxygen through the jet ventilator needle. **C:** View of the anesthetized, spontaneously breathing patient. **D:** Laser-aided resection of vocal cord lesion.

The patient is positioned with the head elevated 15 degrees to facilitate venous drainage. This position may give some modest hypotension; however, there is the potential for venous pooling in the lower extremities. General anesthesia is maintained with either inhalation-based anesthesia or TIVA. Many surgeons now prefer TIVA because it has been shown to reduce blood loss and improve visualization of the surgical field. A comparison of isoflurane/fentanyl anesthesia to remifentanyl/propofol TIVA resulted in better visualization and less blood loss for the TIVA group at equal reduction in blood pressure.<sup>63,64</sup> TIVA may also have the added benefit of reducing both coughing on emergence and postoperative nausea and vomiting.

### **Skull Base Surgery**

Skull base surgery may be considered the logical extension of nasal surgery involving the practices of otorhinolaryngology, neurosurgery, and

anesthesiology. The majority of adult patients undergoing skull base surgery have malignant tumors with a smaller group of patients having benign tumors, congenital malformations, or other abnormalities. These patients often require radiologic procedures to determine the location and extent of the lesion prior to surgery. Noninvasive tests include CAT scans and MRIs to ascertain the extent of bony and soft tissue abnormalities, whereas more invasive angiography may be needed to determine tumor location and blood supply. These studies may then be used to program intraoperative localizing systems to help guide the surgical dissection.<sup>65</sup> Finally, embolization of lesions may be performed a day or two prior to surgery to shrink the lesion and decrease blood loss during the operative procedure.<sup>66</sup>

Special attention during the preoperative assessment should be given to prior surgical procedures, which may affect the airway, chemotherapy, and radiation treatment. Prior surgical procedures may alter a previously **7** easy airway, which subsequently may require advanced airway management techniques to intubate the trachea. Prior chemotherapy can have anesthetic implications depending on the agents used. Patients who have received cardiotoxic agents in which effects are dose dependent may require a cardiac evaluation including an echocardiogram. Decreased cardiac function may affect the type of anesthetic agents used and require invasive blood pressure monitoring with an arterial catheter. Prior treatment with neurotoxic agents may decrease the dose of muscle relaxants or cause their duration of action to be prolonged, requiring neuromuscular monitoring. Prior radiation therapy usually does not cause systemic problems unless the pituitary gland is damaged, which can give rise to the problems of panhypopituitarism leading to hypothyroidism, hypoadrenocorticism, and diabetes insipidus. Prior radiation therapy may lead to fibrosis and ankylosis in the temporomandibular joint, rendering direct laryngoscopy difficult. Previous radiation to the operative site may also increase blood loss and results in poor wound healing. Secondary radiation fibrosis may make the surgical dissection more difficult and time consuming. It may also necessitate the use of free or vascularized grafts to close the surgical site. In addition, the location of the donor site and potential anastomotic sites must be considered when positioning the patient.

Close attention must be paid to the evaluation of the head and neck during the physical examination. Usually these patients do not have a difficult airway or require special techniques for intubation. For lesions requiring a midline surgical approach, oral intubation is the preferred route. If the lesion does not cross the midline, an oral or nasal approach may be used. Nasal endotracheal tubes may be secured by use of a heavy suture through the nasal septum and around the tube. Oral endotracheal tubes may be secured by wiring the endotracheal tube to the teeth, suturing it to the gingival periosteum, or using

a circummandibular wire.

There are two noteworthy points for anesthetic consideration: the use of muscle relaxation and blood conservation strategies. Similar to other procedures in which the facial nerve is at risk for injury or transection during dissection, it is necessary to avoid paralysis so that the facial nerve may be periodically stimulated to verify its integrity. Muscle relaxants may be given if nerve stimulation is no longer required. Minimizing blood loss and creating a plan for replacement with blood products must be considered. If there is anticipation for large-volume blood loss, various approaches can be utilized to potentially reduce the need for transfusion. Anemia identified preoperatively can be treated with iron and erythropoietin. Acute normovolemic hemodilution can be used to minimize blood loss during the procedure. Recently, antithrombotic therapy has been used with success in craniofacial procedures and may be of benefit in these cases.<sup>67,68</sup> Directed donor or autologous blood donation have been used to minimize or decrease the exposure to allogenic blood products. Blood salvage techniques, such as cell saver, are usually not appropriate given that most surgical sites are not reached through sterile approaches, and they would also be relatively contraindicated in surgeries involving resection of tumors.

### *Upper Airway Infections*

Infectious processes of the upper airway can occur in the adult and present the same problems of airway compression, distortion, and compromise. Inflammation of the upper airway caused mainly by gram-negative bacteria may present with the same symptoms as epiglottitis in the pediatric age group. Although these patients present with fever, chills, drooling, and difficulty in speaking and swallowing, they do not usually appear with critical airways from swelling. These same symptoms may occur with Ludwig angina, which is a generalized cellulitis of the submandibular region.<sup>69</sup> The infection is often the result of dental abscesses and extends into the submandibular, submental, and sublingual areas. Involvement of the sublingual spaces pushes the tongue upward and backward and can lead to asphyxiation due to obstruction of the airway. Should this occur, emergent surgical interventions may be required to drain the abscess and relieve the airway obstruction.

 Airway management can be very difficult in these cases.<sup>70</sup> Awake tracheostomy with local anesthesia has been considered the safest in these patients. If awake tracheostomy is performed, positive-pressure ventilation should be avoided until confirmation of proper tracheal tube placement, because insufflation into a false or blind passage can lead to significant patient morbidity. Alternative techniques of intubation include fiberoptic nasal intubation and direct laryngoscopy after inhalational

anesthesia. These patients require care in an ICU whether they have a tracheotomy or an endotracheal tube once the abscess has been drained because increased swelling may develop. The trachea should not be extubated until there is some resolution of the swelling.

## **Maxillofacial Trauma**

Traumatic disruption of the bony, cartilaginous, and soft tissue components of the face and upper airway challenges the anesthesiologist to recognize the nature and extent of the injury and consequent anatomic alteration, create a plan for securing the airway safely, implement the plan without doing further damage, maintain the airway during the administration of an anesthetic, and determine when and how to extubate the patient's trachea. Also necessary is the creation of a comfortable environment for both surgeon and anesthesiologist in a limited workspace.

It is conventional to divide the facial skeleton into thirds. The lower third consists of the mandible, with its subdivisions of midline symphysis, body, angle, ramus, condyle, and coronoid process. The mandible has a unique, horseshoe shape that causes forces to gather at its points of vulnerability, often distant from the point of impact. Consequently, fractures of the mandible typically occur posteriorly where the cortex is also thinner—at the angle of the mandible, the ramus, and the condyle.<sup>71,72</sup> With a condylar fracture, there is potential for temporomandibular joint involvement and resulting limitations in jaw mobility. Another common point of fracture is in the body of the mandible at the level of the first or second molar. Clinical experience indicates that this distribution occurs after high-velocity, high-impact trauma, such as occurs in an automobile accident. After trauma inflicted by a fist, a blunt weapon, or a fall, there is a greater tendency for a fracture of the symphysis, parasymphysis, and body to occur.<sup>73</sup> Fractures of the mandible typically do not extend into the skull base. The middle third contains the zygomatic arch of the temporal bone, blending into the zygomaticomaxillary complex, the maxillae, nasal bones, and orbits. Force from a blow to the midface, especially from in front and above, does not follow a normal vector of force dispersion and redistribution. Rather, it tends to create an abnormal shearing force, which may tear the facial skeleton from the cranial skeleton and extend the fracture into the base of the skull. Therefore, in any patient with severe midfacial trauma, a fracture of the base of the skull must be considered. The superior third consists of the frontal bone.

In 1901, Rene Le Fort of Lille, France, determined the common lines of midface fracture, which are thus eponymous and called Le Fort I, Le Fort II, and Le Fort III fractures.

The Le Fort I fracture is a horizontal fracture of the maxilla, passing above the floor of the nose but involving the lower third of the septum, mobilizing the palate, maxillary alveolar process, and the lower third of the pterygoid plates and parts of the palatine bones. The fracture segment may be displaced posteriorly or laterally or rotated about a vertical axis. The Le Fort II fracture is pyramidal, beginning at the junction of the thick upper part of the nasal bone, with the thinner portion forming the upper margin of the anterior nasal aperture. The fracture crosses the medial wall of the orbit, including the lacrimal bone beneath the zygomaticomaxillary suture; crosses the lateral wall of the antrum; and passes posteriorly through the pterygoid plates. The fracture segment may be displaced posteriorly or rotated about an axis. In a Le Fort III fracture, the line of fracture parallels the base of the skull, separating the midfacial skeleton from the base of the cranium. The line of fracture passes through the base of the nose and the ethmoid bone in its depth and through the orbital plates. The cribriform plate of the ethmoid may or may not be fractured. The fracture line crosses the lesser wing of the sphenoid, then passes downward to the pterygomaxillary fissure and sphenopalatine fossa. From the base of the inferior orbital fissure, the fracture extends laterally and upward to the frontozygomatic suture and downward and backward to the root of the pterygoid plates. A Le Fort III fracture results from massive force applied to the midface. The zygomata are displaced, applying rotational force to the zygomatic arches. The arches are usually fractured as a result.

In a patient with a Le Fort III fracture, the midface is mobilized and often distracted posteriorly. The normal convexity of the face becomes concave, giving rise to the characteristic “dish face deformity” of a Le Fort III fracture. Even if this facial concavity is not clinically evident, the presence of a Le Fort III fracture should be suspected if the incisive edges of the maxillary and mandibular teeth are apposed instead of being in the normal position, in which the maxillary incisors shingle over the mandibular incisors. This apposition serves as a subtle clue to minimal posterior displacement of the midface.

Nasotracheal intubation is contraindicated in Le Fort II or III fractures when the cribriform plate of the ethmoid bone may be involved. Foreign material from the nasopharynx may result in meningitis or, even more devastating, the endotracheal tube can enter the cranial cavity. Even positive-pressure bag and mask ventilation can force foreign material or air into the skull.<sup>74</sup> Radiographic studies should be done prior to nasotracheal intubation whenever trauma to the skull base is suspected.

In the patient with facial trauma, concomitant injuries may not be apparent. One study revealed that in patients with maxillofacial injury due to low-velocity, low-impact blows, 4% had additional major life-threatening

injuries and 10% had additional minor injuries. With high-velocity, high-impact accidents, 32% had major additional injuries and 31% had minor additional injuries.<sup>75</sup> Of great importance, cervical spine fractures occurred in 1.2% of high-velocity injuries. Multiple studies report cervical spine and significant head injury in patients with facial skeletal trauma, with incidence as high as 10.8% and 88.7%, respectively.<sup>76,77</sup> The area of cervical injury is frequently related to the site of maxillofacial trauma. Upper face injuries are associated with mid to lower cervical spine injuries, whereas unilateral mandibular injuries involve the upper cervical spine.<sup>76</sup>

To the extent that the patient's clinical situation allows, the degree of facial trauma and concomitant injuries should be assessed and incorporated into any plan for airway management. Patients with known or suspected cervical spine injuries should have appropriate protective precautions in place **8** during airway management. Intubating patients with facial trauma can be potentially challenging owing to distorted or even disrupted anatomy, which can also be obscured by blood or emesis and displaced.<sup>78</sup> For cases in which there is concern about difficult airway management, intubation with a flexible fiberoptic bronchoscope should be considered, provided the patient is both cooperative and clinically stable. Fiberoptic bronchoscopy and videolaryngoscopy can also be used to assess the airway and as part of a rescue technique for failed direct laryngoscopy. Surgical airway placement may be required for patients with extensive airway injury that does not permit intubation, or for conditions such as laryngotracheal disruption that can be worsened with conventional intubation techniques such as direct laryngoscopy.<sup>79</sup>

If a patient cannot open the mouth during the preoperative evaluation, one must ascertain whether the restriction to mouth opening is the result of pain, trismus, or mechanical problem or some combination of the three. Simple fractures of the mandible can be very painful; however, once the patient is anesthetized, the mouth can be opened and tracheal intubation can proceed without difficulty. There may be mechanical interference with opening due to injury to the temporomandibular area either directly or indirectly. Direct trauma to the mandibular condyle or zygomatic arch may cause fractures that interfere with normal function of the temporomandibular joint. Indirect trauma is caused by transmittal of force up the body and ramus to the condyles. Compression fractures of condyles in the glenoid fossa and greenstick fractures of the condyles may result, impeding opening.

Trismus, spasm of the muscles of mastication, can result from trauma or infection and interfere with mouth opening. It too is usually overcome by general anesthesia and muscle relaxation. The caveat here is that should the trismus be of long standing, some degree of joint immobility will occur. If the trismus is caused by a facial infection, the affected muscles may become

edematous and swell, causing a mechanical interference with opening.

## Acknowledgments

The authors acknowledge Ms. Jessie Barnes Hurley for her tireless assistance in the preparation of this manuscript. They also would like to acknowledge the prior contributions of Drs. Alexander Gotta and Charles Nargozian to this chapter in previous editions.

## KEY POINTS

- 1 Cataract surgery is one of the most frequently performed surgical procedures worldwide but represents just one aspect of the various ophthalmic subspecialties, which include cornea, retina, glaucoma, uveitis, strabismus, oculoplastic, and oncology surgeries.
- 2 Eye surgery patients are often at the extremes of age, ranging from premature babies with retinopathy of prematurity to nonagenarians with multiple coexisting diseases in which age-related anesthetic considerations are key.
- 3 With intraocular procedures, globe akinesia, patient movement, and control of intraocular pressure (IOP) are important variables; however, with extraocular surgery, the significance of IOP fades, whereas elicitation of the oculocardiac reflex becomes a concern.
- 4 Inhalation anesthetics cause dose-related reductions in IOP. The exact mechanisms are unknown, but postulated causes include depression of a control center in the diencephalon, reduction of aqueous humor production, enhancement of aqueous outflow, or relaxation of the extraocular muscles.
- 5 The oculocardiac reflex is triggered by pressure on the globe and by traction on the extraocular muscles as well as on the conjunctiva or on the orbital structures. This reflex, whose afferent limb is trigeminal and efferent limb is vagal, may also be elicited by performing a regional eye block, by ocular trauma, and by direct pressure on tissue remaining in the orbital apex after enucleation.
- 6 Ophthalmic drugs may significantly alter the patient's reaction to anesthesia. Similarly, anesthetic drugs and maneuvers may dramatically influence intraocular dynamics.
- 7 Several anesthetic options are available for many types of ocular procedures, including general anesthesia, retrobulbar (intraconal) block, peribulbar (extraconal) anesthesia, sub-Tenon block, topical analgesia, and intracameral injection.

8 The complications of ophthalmic anesthesia can be both vision- and life-threatening.

1 Cataract surgery is one of the most frequently performed surgical procedures worldwide but represents just one aspect of the ophthalmic subspecialties, which include cornea, retina, glaucoma, uveitis, strabismus, oculoplastic, and oncology surgeries. Anesthesia for ophthalmic surgery presents many unique challenges (Table 49-1). In addition to possessing technical expertise, the anesthesiologist must have detailed knowledge of ocular anatomy, physiology, and pharmacology. It is essential to appreciate that ophthalmic drugs may significantly alter the reaction to anesthesia and that concomitantly anesthetic drugs and maneuvers may dramatically influence intraocular dynamics. Patients undergoing ophthalmic surgery 2 may represent extremes of age. They may have coexisting diseases (e.g., diabetes mellitus, coronary artery disease, essential hypertension, chronic lung disease), and they are likely to be elderly. Indeed, the elderly constitute the most rapidly growing subset of the U.S. population, with the census projecting that by 2030, one in five Americans will be age 65 or older. Furthermore, “the elderly” is a uniquely vulnerable group with reduced functional reserve and a myriad of age-related diseases. The economic implications are staggering. For example, age-related macular degeneration is the leading cause of blindness in individuals older than 65 years in the United States, affecting more than 1.75 million people. Because of the rapid aging of our population, this number will increase to almost 3 million by 2020.<sup>1</sup>

**Table 49-1** Requirements of Ophthalmic Surgery

Safety  
Akinesia  
Analgesia  
Minimal bleeding  
Avoidance or obtundation of oculocardiac reflex  
Control of intraocular pressure  
Awareness of drug interactions  
Smooth emergence

One must be knowledgeable about the numerous surgical procedures that are unique to the specialty of ophthalmology. Although the list of ocular surgical interventions is lengthy, these procedures may, in general, be classified as *extraocular* or *intraocular*. This distinction is important because anesthetic considerations are different for these two major surgical categories.

3 For example, with intraocular procedures, globe akinesia, patient movement, and control of intraocular pressure (IOP) are important variables; however, with extraocular surgery, the significance of IOP fades, whereas elicitation of the oculocardiac reflex becomes a concern.

## Ocular Anatomy

The anesthesiologist should be knowledgeable about ocular anatomy as a basis for learning ophthalmic regional anesthesia and to enhance understanding of surgical procedures (Fig. 49-1). Salient subdivisions of ocular anatomy include the orbit, the eye itself, the extraocular muscles, the eyelids, and the lacrimal system.

The orbit is a bony pyramidal cavity housing the globe and its associated structures in the skull. The walls of the orbit are composed of the following bones: frontal, zygomatic, greater wing of the sphenoid, maxilla, palatine, lacrimal, and ethmoid. A familiarity with the surface relationships of the orbital rim aids performance of regional blocks.

The optic foramen, located at the orbital apex, transmits the optic nerve and the ophthalmic artery as well as the sympathetic nerves from the carotid plexus. The superior orbital fissure transmits the superior and inferior branches of the oculomotor nerve; the lacrimal, frontal, and nasociliary branches of the trigeminal nerve; the trochlear and abducens nerves; and the superior and inferior ophthalmic veins. The inferior orbital or sphenomaxillary fissure contains the infraorbital and zygomatic nerves and communication between the inferior ophthalmic vein and the pterygoid plexus. The infraorbital foramen, located about 4 mm below the orbital rim in the maxilla, transmits the infraorbital nerve, artery, and vein. The lacrimal fossa contains the lacrimal gland in the superior temporal orbit. The supraorbital notch, located at the junction of the medial one-third and temporal two-thirds of the superior orbital rim, transmits the supraorbital nerve, artery, and vein. The supraorbital notch, the infraorbital foramen, and the lacrimal fossa are all clinically palpable.

**Figure 49-1** Diagram of ocular anatomy.

The globe itself is actually one large sphere with part of a smaller sphere incorporated in the anterior surface, constituting a structure with two different radii of curvature. The coat of the eye is composed of three layers: sclera, uveal tract, and retina. The fibrous outer layer, or *sclera*, is protective, providing sufficient rigidity to maintain the shape of the eye. The anterior portion of the sclera, the cornea, is highly avascular and transparent, permitting light to pass into the internal ocular structures. The double-spherical shape of the eye exists because the corneal arc of curvature is steeper than the scleral arc of curvature. The focusing of rays of light to form a retinal image commences at the cornea.

The *uveal tract*, or middle layer of the globe, is vascular and in direct apposition to the sclera. A potential space, known as the *suprachoroidal space*, separates the sclera from the uveal tract. This potential space, however, may become filled with blood during an expulsive or suprachoroidal hemorrhage, often associated with surgical disaster. The iris, ciliary body, and choroid compose the uveal tract. The iris includes the pupil, which controls the amount of light entering the eye by contractions of three sets of muscles. The iris dilator is sympathetically innervated; the iris sphincter and the ciliary muscle have parasympathetic innervation. Posterior to the iris lays the ciliary body, which produces aqueous humor (see Formation and Drainage of Aqueous Humor, later). The ciliary muscles, situated in the ciliary body, adjust the shape of the lens to accommodate focusing at various distances. Large vessels and a network of small vessels and capillaries known as the *choriocapillaris* constitute the choroid, which supplies nutrition to the outer part of the retina.

The *retina* is a neurosensory membrane composed of 10 layers that convert light impulses into neural impulses. These neural impulses are then carried through the optic nerve to the brain. Located in the center of the globe is the vitreous cavity, filled with a gelatinous substance known as *vitreous humor*. This material is adherent to the most anterior 3 mm of the retina as well as to large blood vessels and the optic nerve. The vitreous humor may pull on the retina, causing retinal tears and retinal detachment.

The crystalline lens, located posterior to the pupil, refracts rays of light passing through the cornea and pupil to focus images on the retina. The ciliary muscle, whose contractile state causes tautness or relaxation of the lens zonules, regulates the thickness of the lens.

In addition, six extraocular muscles move the eye within the orbit to various positions. The bilobed lacrimal gland provides most of the tear film, which serves to maintain a moist anterior surface on the globe. The lacrimal drainage system—composed of the puncta, canaliculi, lacrimal sac, and lacrimal duct—drains into the nose below the inferior turbinate. Blockage of this system occurs frequently, necessitating procedures ranging from lacrimal duct probing to dacryocystorhinostomy, which involves anastomosis of the lacrimal sac to the nasal mucosa.

Covering the surface of the globe and lining the eyelids is a mucous membrane called the *conjunctiva*. Because drugs are absorbed across the membrane, it is a popular site for administration of ophthalmic drugs.

The eyelids consist of four layers: the conjunctiva, the cartilaginous tarsal plate, a muscle layer composed mainly of the orbicularis and the levator palpebrae, and the skin. The eyelids protect the eye from foreign objects; through blinking, the tear film produced by the lacrimal gland is spread across the surface of the eye, keeping the cornea moist.

Blood supply to the eye and orbit is by means of branches of both the internal and external carotid arteries. Venous drainage of the orbit is accomplished through the multiple anastomoses of the superior and inferior ophthalmic veins. Venous drainage of the eye is achieved mainly through the central retinal vein. All these veins empty directly into the cavernous sinus.

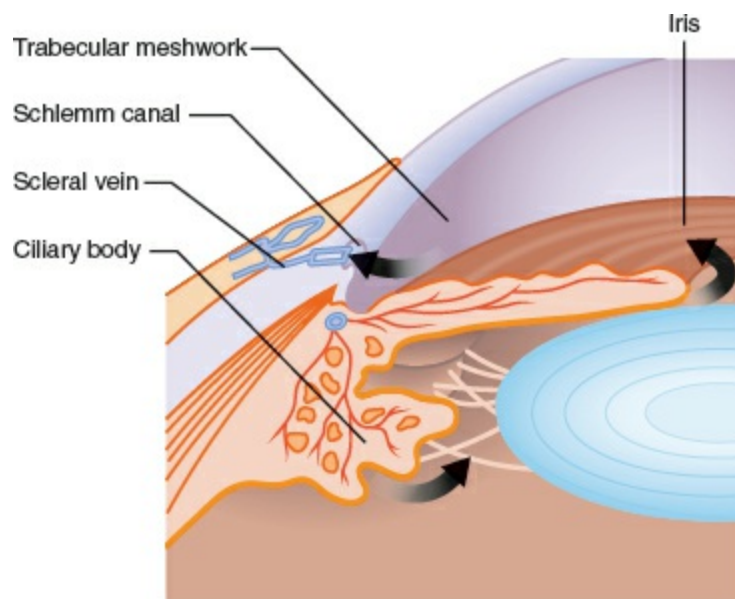

The sensory and motor innervations of the eye and its adnexa are very complex, with multiple cranial nerves supplying branches to various ocular structures. A branch of the oculomotor nerve supplies a motor root to the ciliary ganglion, which in turn supplies the sphincter of the pupil and the ciliary muscle. The trochlear nerve supplies the superior oblique muscle. The abducens nerve supplies the lateral rectus muscle. The trigeminal nerve constitutes the most complex ocular and adnexal innervation. In addition, the zygomatic branch of the facial nerve eventually divides into an upper branch, supplying the frontalis and the upper lid orbicularis, whereas the lower branch supplies the orbicularis of the lower lid.

## Ocular Physiology

Despite its relatively diminutive size, the eye is a complex organ, concerned with many intricate physiologic processes. The formation and drainage of aqueous humor and their influence on IOP in both normal and glaucomatous eyes are among the most important functions, especially from the anesthesiologist's perspective. An appreciation of the effects of various anesthetic manipulations on IOP requires an understanding of the fundamental principles of ocular physiology.

### *Formation and Drainage of Aqueous Humor*

Two-thirds of the aqueous humor is formed in the posterior chamber by the ciliary body in an active secretory process involving both the carbonic anhydrase and the cytochrome oxidase systems (Fig. 49-2). The remaining third is formed by passive filtration of aqueous humor from the vessels on the anterior surface of the iris.

**Figure 49-2** Ocular anatomy concerned with control of intraocular pressure.

At the ciliary epithelium, sodium is actively transported into the aqueous humor in the posterior chamber. Bicarbonate and chloride ions passively follow the sodium ions. This active mechanism results in the osmotic pressure of the aqueous humor being many times greater than that of plasma. It is this disparity in osmotic pressure that leads to an average rate of aqueous humor production of 2  $\mu\text{L}/\text{min}$ .

Aqueous humor flows from the posterior chamber through the pupillary aperture and into the anterior chamber, where it mixes with the aqueous formed by the iris. During its journey into the anterior chamber, the aqueous

humor bathes the avascular lens and, once in the anterior chamber, it also bathes the corneal endothelium. Then the aqueous humor flows into the peripheral segment of the anterior chamber and exits the eye through the trabecular network, Schlemm canal, and episcleral venous system. A network of connecting venous channels eventually leads to the superior vena cava and the right atrium. Thus, obstruction of venous return at any point from the eye to the right side of the heart impedes aqueous drainage, elevating IOP accordingly.

### *Maintenance of Intraocular Pressure*

IOP normally varies between 10 and 21.7 mmHg and is considered abnormal above 22 mmHg. This level varies from 1 to 2 mmHg with each cardiac contraction. Also, a diurnal variation of 2 to 5 mmHg is observed, with a higher value noted on awakening. This higher awakening pressure has been ascribed to vascular congestion, pressure on the globe from closed lids, and mydriasis—all of which occur during sleep. If IOP is too high, it may produce opacities by interfering with normal corneal metabolism.

During anesthesia, a rise in IOP can produce permanent visual loss. If the IOP is already elevated, a further increase can trigger acute glaucoma. If penetration of the globe occurs when the IOP is excessively high, rupture of a blood vessel with subsequent hemorrhage may transpire. IOP becomes atmospheric once the eye cavity has been entered, and any sudden rise in pressure may lead to prolapse of the iris and lens, and loss of vitreous. Thus, proper control of IOP is critical.

Three main factors influence IOP: (1) external pressure on the eye by the contraction of the orbicularis oculi muscle and the tone of the extraocular muscles, venous congestion of orbital veins (as may occur with vomiting and coughing), and conditions such as orbital tumor; (2) scleral rigidity; and (3) changes in intraocular contents that are semisolid (lens, vitreous, or intraocular tumor) or fluid (blood and aqueous humor). Although these factors affect IOP, the major control of intraocular tension is exerted by the fluid content, especially the aqueous humor.

Sclerosis of the sclera, not uncommonly seen in the elderly, may be associated with decreased scleral compliance and increased IOP. Other degenerative changes of the eye linked with aging can also influence IOP, the most significant being a hardening and enlargement of the crystalline lens. When these degenerative changes occur, they may lead to anterior displacement of the lens–iris diaphragm. A resultant shallowness of the anterior chamber angle may then occur, reducing access of the trabecular meshwork to the aqueous. This process is usually gradual, but if rapid lens engorgement occurs, angle-closure glaucoma may transpire.

Changes in the nature of the vitreous that affect the amount of unbound water also influence IOP. Myopia, trauma, and aging produce liquefaction of vitreous gel and a subsequent increase in unbound water, which may lower IOP by facilitating fluid removal. However, under different circumstances, the opposite may occur; that is, the hydration of more normal vitreous may be associated with elevation of IOP. Hence, it is often prudent to produce a slightly dehydrated state in the surgical patient with glaucoma.

Intraocular blood volume, determined primarily by vessel dilation or contraction in the spongy layers of the choroid, contributes importantly to IOP. Although changes in arterial or venous pressure may secondarily affect IOP, excursions in arterial pressure have much less importance than do venous fluctuations. In chronic arterial hypertension, ocular pressure returns to normal levels after a period of adaptation brought about by compression of vessels in the choroid as a result of increased IOP. Thus, a feedback mechanism reduces the total volume of blood, keeping IOP relatively constant in patients with systemic hypertension.

However, if venous return from the eye is disturbed at any point from Schlemm canal to the right atrium, IOP increases substantially. Trendelenburg position, a cervical collar, and even a tight necktie can produce increased intraocular blood volume and distention of orbital vessels as well as attenuated aqueous drainage.<sup>2</sup> Straining, vomiting, or coughing greatly increases venous pressure and raises IOP as much as 40 mmHg or more. The deleterious implications of these activities cannot be overemphasized. Laryngoscopy and tracheal intubation may also elevate IOP, even without any visible reaction to intubation, but especially when the patient coughs. Topical anesthesia of the larynx may attenuate the systemic hypertensive response to laryngoscopy but does not reliably prevent associated increases in IOP.<sup>3</sup> Ordinarily, the pressure elevation from such increases in blood volume or venous pressure dissipates rapidly. However, if the coughing or straining occurs during ocular surgery when the eye is open, as in penetrating keratoplasty, the result may be a disastrous expulsive hemorrhage, at worst, or a disconcerting loss of vitreous, at best.

Despite the notable role of venous pressure, scleral rigidity, and vitreous composition, maintenance of IOP is determined primarily by the rate of aqueous formation and the rate of aqueous humor outflow. The most important influence on formation of aqueous humor is the difference in osmotic pressure between aqueous humor and plasma. This fact is illustrated by the equation:

$$IOP = K[(OP_{aq} - OP_{pl}) + CP] \quad (49-1)$$

where  $K$  is the coefficient of outflow,  $OP_{aq}$  is the osmotic pressure of aqueous humor,  $OP_{pl}$  is the osmotic pressure of plasma, and  $CP$  is the capillary

pressure. Hypertonic solutions such as mannitol are used to lower IOP because a small change in the solute concentration of plasma can markedly influence the formation of aqueous humor and hence IOP.

Fluctuations in aqueous humor outflow may also produce a dramatic alteration in IOP. The most significant factor controlling aqueous humor outflow is the diameter of Fontana spaces, as illustrated by the equation:

$$A = \frac{r^2(P_{iop} - P_v)}{8\eta L} \quad (49-2)$$

where  $A$  is the volume of aqueous outflow per unit of time,  $r$  is the radius of Fontana spaces,  $P_{iop}$  is the IOP,  $P_v$  is the venous pressure,  $\beta$  is the viscosity, and  $L$  is the length of Fontana spaces. When the pupil dilates, Fontana spaces narrow, resistance to outflow is increased, and IOP rises. Because mydriasis is undesirable in both closed-angle glaucoma and open-angle glaucoma, miotics are applied conjunctivally in patients with glaucoma.

## Glaucoma

Glaucoma is a condition characterized by progressive optic nerve dysfunction and loss of vision. The terminology for glaucoma is complex because there are a number of variants, including acquired versus congenital, high-IOP versus normal pressure, acute versus chronic, and open-angle versus closed-angle. Angle-closure glaucoma may be either acute or chronic; notably, acute angle-closure glaucoma is an urgent condition, whereas chronic angle-closure disease is far more common and often asymptomatic.

With open-angle glaucoma, the elevated IOP exists within an anatomically open anterior chamber angle. It is believed that sclerosis of trabecular tissue results in impaired aqueous humor filtration and drainage. Treatment consists of medication to produce miosis and trabecular stretching. Commonly used eye drops are epinephrine, timolol, dipivefrin, and betaxolol. Closed-angle glaucoma is characterized by the peripheral iris moving into direct contact with the posterior corneal surface, mechanically obstructing aqueous humor outflow. People who have a narrow angle between the iris and the posterior cornea are predisposed to this condition. In these patients, mydriasis can produce such increased thickening of the peripheral iris that corneal touch occurs and the angle is closed. Another mechanism producing acute closed-angle glaucoma is swelling of the crystalline lens. In this case, pupillary block occurs, with the edematous lens blocking the flow of aqueous humor from the posterior to the anterior chamber. This situation can also develop if the lens is traumatically dislocated anteriorly, thus physically blocking the anterior chamber.

It was previously believed that intravenous atropine should not be administered to patients with glaucoma; however, atropine in the dose range used clinically has no effect on IOP in either open-angle or closed-angle glaucoma. When 0.4 mg of atropine is given parenterally to a 70-kg person, approximately 0.0001 mg is absorbed by the eye.<sup>4</sup> Garde et al.<sup>5</sup> reported, however, that scopolamine has a greater mydriatic effect than atropine and recommended not using scopolamine in patients with known or suspected closed-angle glaucoma.

Equation 49-2, describing the volume of aqueous outflow per unit of time, clearly demonstrates that outflow is exquisitely sensitive to fluctuations in venous pressure. Because a rise in venous pressure produces an increased volume of ocular blood and decreased aqueous outflow, it is obvious that considerable elevation of IOP occurs with any maneuver that increases venous pressure. Hence, in addition to preoperative instillation of miotics, consider avoiding IOP-elevating maneuvers such as overhydration, constriction around the patient's neck, prolonged Trendelenburg or prone position, and hypercapnia, which may induce choroidal vascular congestion. In some patients, such as those undergoing robotic-assisted laparoscopic prostatectomy with prolonged steep Trendelenburg position coupled with elevated CO<sub>2</sub>, the optic nerve may be at risk due to narrow-angle glaucoma. In these situations, one may contemplate preoperative ophthalmology consultation and intraoperative prophylactic administration of acetazolamide and/or mannitol.<sup>6</sup>

A small percentage of glaucoma patients experience a marked decrement in vision following surgery, termed visual field "wipe out." Although no distinct etiology is known, several surgical, anesthetic, and postoperative reasons have been postulated. Proposed, but not validated, anesthesia mechanisms include pressure on the optic nerve or its circulation by local anesthetic, blood, or a compression device; direct optic nerve injury by a needle; and hypoperfusion of the optic nerve due to hypotension during general anesthesia or vasoconstrictors admixed with local anesthetic.

Primary congenital glaucoma is classified according to age of onset, with the infantile type presenting any time after birth until 3 years of age. The juvenile type presents between the ages of 37 months and 30 years. Moreover, childhood glaucoma may also occur in conjunction with various eye diseases or developmental anomalies such as aniridia, mesodermal dysgenesis syndrome, and retinopathy of prematurity.

Successful management of infantile glaucoma depends critically on early diagnosis. Presenting symptoms include epiphora, photophobia, blepharospasm, and irritability. Ocular enlargement, termed *buphthalmos*, or "ox eye," and corneal haziness secondary to edema are common. *Buphthalmos* is rare, however, if glaucoma develops after 3 years of age because by then

the eye is much less elastic.

Because infantile glaucoma is frequently associated with obstructed aqueous humor outflow, management of it often requires surgical creation, by goniotomy or trabeculotomy, of a route for aqueous humor to flow into the canal of Schlemm. However, advanced disease may be unresponsive to even multiple goniotomies, and the more radical trabeculectomy or some other variety of filtering procedure may be necessary.

The juvenile form of glaucoma, in which the cornea and eye size are normal, is commonly associated with a family history of open-angle glaucoma and is treated similarly to primary open-angle glaucoma.

In cases of pediatric secondary glaucoma, goniotomy and filtering may be unsuccessful, whereas cyclocryotherapy may effect a reduction in IOP, pain, and corneal edema. The ciliary body is destroyed with a cryoprobe cooled to  $-70^{\circ}\text{C}$ , thus dramatically decreasing aqueous formation.

It is essential to appreciate that the high IOP frequently encountered in infantile glaucoma can be significantly reduced when a surgical plane of general anesthesia is achieved. Some clinicians maintain that ketamine is a useful drug to use for examination under anesthesia when infantile glaucoma is part of the differential diagnosis because ketamine does not appear to give a spuriously low reading from drug-induced decreased IOP. Moreover, even normal infants sporadically have pressures in the mid-20s. Hence, diagnosis is not based exclusively on the numerical pressure recorded under anesthesia. Other factors such as corneal edema and increased corneal diameter, tears in Descemet membrane, and cupping of the optic nerve are considered in making the diagnosis. If these aberrations are noted, surgical intervention may be mandatory, even in the setting of a reputedly normal IOP.

## Effects of Anesthesia and Adjuvant Drugs on Intraocular Pressure

### *Central Nervous System Depressants*

Inhalation anesthetics purportedly cause dose-related decreases in IOP. 4 The exact mechanisms are unknown, but postulated causes include depression of a central nervous system (CNS) control center in the diencephalon, reduction of aqueous humor production, enhancement of aqueous humor outflow, or relaxation of the extraocular muscles.<sup>4</sup> Moreover, virtually all CNS depressants—including barbiturates, neuroleptics, opioids, tranquilizers,<sup>4</sup> and hypnotics, such as etomidate and propofol—lower IOP in both normal and glaucomatous eyes. Etomidate, despite its proclivity to produce pain on intravenous injection and skeletal muscle movement, is associated with a significant reduction in IOP.<sup>7</sup> However, etomidate-induced

myoclonus may be hazardous in the setting of a ruptured globe.

Controversy surrounds the issue of ketamine's effect on IOP. Administered intravenously or intramuscularly, ketamine initially was believed to increase IOP significantly, as measured by indentation tonometry.<sup>8</sup> Corssen and Hoy<sup>9</sup> also reported a slight but statistically significant increase in IOP that appeared unrelated to changes in blood pressure or depth of anesthesia. However, nystagmus made proper positioning of the tonometer difficult and may have resulted in less-than-accurate measurements.

Conflicting results arose from a study in which 2 mg/kg of ketamine given intravenously to adults failed to have a significant effect on IOP.<sup>10</sup> Furthermore, a pediatric study reported no increase in IOP after an intramuscular ketamine dose of 8 mg/kg. Indeed, values obtained were similar to those reported with halothane and isoflurane.<sup>11,12</sup>

Some of the confusion may arise from differences in premedication practices and from the use of different instruments to measure IOP. More recent studies have used applanation tonometry rather than indentation tonometry. However, even if future studies should confirm that ketamine has minimal or no effect on IOP, ketamine's proclivity to cause nystagmus and blepharospasm makes it a less-than-optimal agent for many types of ophthalmic surgery.

## ***Ventilation and Temperature***

Hyperventilation decreases IOP, whereas asphyxia, administration of carbon dioxide, and hypoventilation have been shown to elevate IOP.

Hypothermia lowers IOP. On initial consideration, hypothermia might be expected to raise IOP because of the associated increase in viscosity of aqueous humor. However, hypothermia is linked with decreased formation of aqueous humor and with vasoconstriction; hence, the net result is a reduction in IOP.

## ***Adjuvant Drugs***

### **Hypertonic Solutions and Acetazolamide**

Intravenous administration of hypertonic solutions such as dextran, urea, mannitol, and sorbitol elevates plasma osmotic pressure, thereby decreasing aqueous humor formation and reducing IOP. As effective as urea is in reducing IOP, intravenous mannitol has the advantage of fewer side effects. Mannitol's onset, peak (30 to 45 minutes), and duration of action (5 to 6 hours) are similar to those of urea. Moreover, both drugs may produce acute intravascular volume overload. Sudden expansion of plasma volume

secondary to efflux of intracellular water into the vascular compartment places a heavy workload on the kidneys and heart, often resulting in hypertension and dilution of plasma sodium. Furthermore, mannitol-associated diuresis, if protracted, may trigger hypotension in volume-depleted patients.

Intravenous administration of acetazolamide inactivates carbonic anhydrase and interferes with the sodium pump. The resultant decrease in aqueous humor formation lowers IOP. However, the action of acetazolamide is not limited to the eye, and systemic effects include loss of sodium, potassium, and water secondary to the drug's renal tubular effects. Such electrolyte imbalances may then be linked to cardiac dysrhythmias during general anesthesia.

An advantage of acetazolamide is its relative ease of administration. Whereas large volumes of hypertonic solutions must be infused to reduce IOP, acetazolamide is easily dispensed from a single small vial. Acetazolamide may also be given orally, and topical carbonic anhydrase inhibitors are commercially available.

## Neuromuscular Blocking Drugs

Neuromuscular blocking drugs have both direct and indirect actions on IOP.

Equipotent paralyzing doses of all the nondepolarizing drugs directly lower IOP by relaxing the extraocular muscles (Fig. 49-3).<sup>13</sup> However, if paralysis of the respiratory muscles is accompanied by alveolar hypoventilation, the latter secondary effect may supervene to increase IOP.

**Figure 49-3** Mean intraocular pressure after administration of thiopental, 3 to 4 mg/kg, and pancuronium, 0.08 mg/kg at 0. A, loss of lid reflex; \* =  $p < 0.05$ . (Adapted with permission from Litwiller RW, DiFazio CA, Rushia EF. Pancuronium and intraocular pressure. *Anesthesiology*. 1975;42:75.)

In contrast to nondepolarizing drugs, the depolarizing drug succinylcholine elevates IOP. Lincoff et al.<sup>14</sup> reported extrusion of vitreous after succinylcholine administration to a patient with a surgically open eye. An average peak IOP increase of about 9 mmHg is produced within 1 to 4 minutes of an intravenous dose. Within 7 minutes, return to baseline usually transpires.<sup>15</sup> The ocular hypertensive effect of succinylcholine has been attributed to several mechanisms, including tonic contraction of extraocular muscles,<sup>4</sup> choroidal vascular dilation, and relaxation of orbital smooth muscle. One study speculates that the succinylcholine-induced increase in IOP is multifactorial but primarily the result of the cycloplegic action of succinylcholine, producing a deepening of the anterior chamber and increased outflow resistance.<sup>16</sup> Because they studied eyes with the extraocular muscles detached and still observed an elevation in IOP, these investigators proposed that changes in extraocular muscle tone do not contribute substantially to the increase in IOP observed after succinylcholine administration.

A variety of methods have been advocated to prevent succinylcholine-induced elevations in IOP. However, although some attenuation of the increase results, none of these techniques consistently and completely block the ocular hypertensive response. Prior administration of such drugs as acetazolamide, narcotics,  $\beta$ -blockers, and nondepolarizing neuromuscular blocking drugs has been suggested. The efficacy of pretreatment with nondepolarizing drugs is controversial.

In 1968, using indentation tonometry, Miller et al.<sup>17</sup> reported that pretreatment with small amounts of gallamine or *d*-tubocurarine prevented succinylcholine-associated increases in IOP. However, in 1978, using the more sensitive applanation tonometer, Meyers et al.<sup>18</sup> were unable to consistently circumvent the ocular hypertensive response after similar pretreatment therapy (Table 49-2). In addition, Verma<sup>19</sup> claimed that a “self-taming” technique in which a small dose of succinylcholine is administered prior to induction was protective, but in a controlled study using applanation tonometry, Meyers et al.<sup>20</sup> challenged this claim. Although intravenous pretreatment with lidocaine, 1 to 2 mg/kg, may blunt the hemodynamic response to laryngoscopy,<sup>3,21</sup> such therapy does not reliably prevent the ocular hypertensive response associated with succinylcholine and intubation.<sup>22</sup> However, Grover et al.<sup>23</sup> claimed that pretreatment with lidocaine, 1.5 mg/kg intravenously, 1 minute before induction with thiopental and succinylcholine offered protection from IOP increases because of succinylcholine and may therefore be of value in rapid-sequence induction for open eye injuries. 

In summary, succinylcholine is not the ideal agent for patients with penetrating ocular wounds, and one must carefully ponder giving it after the eye has been opened. Nonetheless, as explained in the later section, “Open-Eye, Full Stomach” Encounters, it is no longer valid to recommend that

succinylcholine be used only with extreme reluctance in ocular surgery.

The forced duction test (FDT) is an intraoperative maneuver that helps the ophthalmologist to determine whether strabismus is due to muscle paresis versus a restrictive force. It is discussed in detail in the strabismus section of this chapter. Jampolsky<sup>24</sup> warned that succinylcholine should be avoided in patients undergoing repeat strabismus surgery because the FDT does not return to baseline for approximately 30 minutes after administration of the drug. Quantitatively sophisticated studies by Dell and Williams<sup>25</sup> supported this caveat, although the latter investigators suggest waiting only 20 minutes after administration of succinylcholine before performing the FDT. However, in light of the black box warning issued by the U.S. Food and Drug Administration stating that use of succinylcholine in children may rarely be associated with hyperkalemia and cardiac arrest, it should be reserved for emergency intubation or when immediate airway control is needed, so the drug is typically avoided in pediatric strabismus surgery.

**Table 49-2** Effects of Succinylcholine on Intraocular Pressure: Double-Blind *d*-Tubocurarine or Gallamine Pretreatment

Pretreatment <sup>a</sup>	Mean Age (yr)	Intraocular Pressure (mmHg, MEAN ± SE)		
		Baseline	3 min after Pretreatment	1 min after Succinylcholine <sup>b</sup>
<i>d</i> -Tubocurarine	13.4	13 ± 1	12.3 ± 1.2	24 ± 1.3
Gallamine	8.7	10.9 ± 1.1	10.6 ± 1	23.4 ± 2.3

<sup>a</sup>*d*-Tubocurarine, 0.09 mg/kg, or gallamine, 0.3 mg/kg.

<sup>b</sup>1 to 1.5 mg/kg intravenously.

## Oculocardiac Reflex

 Bernard Aschner and Giuseppe Dagnini first described the oculocardiac reflex in 1908. This reflex is triggered by pressure on the globe and by traction on the extraocular muscles as well as on the conjunctiva or the orbital structures. Moreover, the reflex may also be elicited by performance of an eye block, by ocular trauma, and by direct pressure on tissue remaining in the orbital apex after enucleation. The afferent limb is trigeminal and the efferent limb is vagal. Although the most common manifestation of the oculocardiac reflex is sinus bradycardia, a wide spectrum of cardiac dysrhythmias may occur, including junctional rhythm, ectopic atrial rhythm, atrioventricular blockade, ventricular bigeminy, multifocal premature ventricular contractions, wandering pacemaker, idioventricular rhythm, asystole, and ventricular tachycardia.<sup>26</sup> This reflex may appear during either local or general anesthesia; however, hypercarbia and hypoxemia are believed

to augment the incidence and severity of the problem, as may inappropriate anesthetic depth.

Reports on the incidence of the oculocardiac reflex are remarkable in their striking variability. Berler<sup>27</sup> reported an incidence of 50%, but other sources quote rates ranging from 16% to 82%. Commonly, those articles disclosing a higher incidence included children, who tend to have more vagal tone, in the study population.

A variety of maneuvers to abolish or obtund the oculocardiac reflex have been promulgated. None of these methods have been consistently effective, safe, and reliable. Regional anesthesia can block the afferent limb of the reflex, but is not without other potential complications. Inclusion of intramuscular anticholinergic drugs such as atropine or glycopyrrolate in the usual premedication regimen for oculocardiac reflex prophylaxis is ineffective.<sup>28</sup> Atropine given intravenously within 30 minutes of surgery may reduce incidence of the reflex. For pediatric strabismus surgery, however, some anesthesiologists administer intravenous atropine, 0.02 mg/kg, before commencing surgery.<sup>29</sup> Alternatively, glycopyrrolate, 0.01 mg/kg administered intravenously, may be associated with less tachycardia than atropine in this setting. Moreover, some anesthesiologists claim that prior intravenous administration of atropine may yield more serious and refractory cardiac dysrhythmias than the reflex itself. Clearly, atropine may be considered a potential myocardial irritant. A variety of cardiac dysrhythmias<sup>30</sup> and several conduction abnormalities,<sup>31</sup> including ventricular fibrillation, ventricular tachycardia, and left bundle branch block, have been attributed to intravenous atropine.

It is generally believed that the aforementioned prophylactic measures, fraught with inherent hazards, are usually not indicated in adults. If a cardiac dysrhythmia appears, initially the surgeon should be asked to cease operative manipulation. Next, the patient's anesthetic depth and ventilatory status are evaluated. Commonly, heart rate and rhythm return to baseline within 20 seconds after institution of these measures. Moreover, Moonie et al.<sup>32</sup> noted that the reflex is attenuated with repeated manipulation. Bradycardia is less likely to recur, probably secondary to fatigue of the reflex arc at the level of the cardioinhibitory center. However, if the initial cardiac dysrhythmia is especially serious or if the reflex tenaciously recurs, atropine should be administered intravenously, but only after the surgeon stops ocular manipulation.

Delivery of chemotherapy via ophthalmic artery cannulation is a relatively new endovascular treatment modality for infants and children with retinoblastomas. This so-called superselective ophthalmic artery chemotherapy is performed under general anesthesia in a dedicated interventional radiology suite. The procedure involves insertion of a

microcatheter into the ophthalmic artery with subsequent infusion of high-concentration chemotherapeutic agent, typically melphalan, directly to the eye. Serious adverse cardiopulmonary responses to cannulation of the ophthalmic artery or injection of the agent have been described.<sup>33</sup> These responses are characterized by *abrupt drop in end-tidal CO<sub>2</sub>* followed by markedly reduced lung compliance akin to acute bronchospasm, profound hypoxia, systemic hypotension, and bradycardia. Harris reported an approximate 40% overall incidence,<sup>34</sup> whereas Phillips et al.,<sup>33</sup> who did not encounter the reaction during initial treatment, noted a 39% occurrence during the second or subsequent catheterization. Yamane et al.<sup>35</sup> confronted bradycardia with such frequency that they considered it to be an indicator of successful ophthalmic artery cannulation. Preoperative intravenous atropine did not alter the incidence or severity of the reaction. It has been postulated that superselective ophthalmic artery chemotherapy may trigger a trigeminal-afferent autonomic reflex response akin to the oculocardiac reflex. It has been referred to as a trigeminocardiac reflex (TCR) because the stimulus is decidedly posterior to the globe. Harris proposes that “trigeminal afferents, particularly in these young patients, act as exquisitely sensitive baroreceptors to the increased pressure during microcatheter insertion and infusion.”<sup>34</sup> Analogous to the oculocardiac reflex, the TCR is often self-limited and is suppressed by removal of the stimulus, in this case, withdrawal of the catheter from the ophthalmic artery. Profound or refractory TCR can be treated with intravenous epinephrine.

## Anesthetic Ramifications of Ophthalmic Drugs

**6** There is considerable potential for drug interactions during administration of anesthesia for ocular surgery. Topical ophthalmic drugs may produce undesirable systemic effects or may have deleterious anesthetic implications. Systemic absorption of topical ophthalmic drugs may occur from either the conjunctiva or the nasal mucosa after drainage through the nasolacrimal duct. In addition, from spillover, some percutaneous absorption through the immature epidermis of the premature infant may transpire. Occluding the nasolacrimal duct by pressing on the inner canthus of the eye for a few minutes after each instillation greatly decreases systemic absorption. Some of the potentially worrisome topical ocular drugs include anticholinesterases, cocaine, cyclopentolate, epinephrine, phenylephrine, and timolol. In addition, intraocular sulfur hexafluoride and other intraocular gases have important anesthetic ramifications. Furthermore, certain ophthalmic drugs given systemically may produce untoward sequelae germane to anesthetic management. Drugs in this category include glycerol, mannitol, and acetazolamide.

## Anticholinesterase Agents

Echothiophate, also known as *phospholine iodide*, is a long-acting anticholinesterase miotic that lowers IOP by decreasing resistance to the outflow of aqueous humor. It is used to treat glaucoma that is refractory to other therapies and also to treat some children with accommodative esotropia. It is absorbed into the systemic circulation after instillation in the conjunctival sac. Any of the long-acting anticholinesterases may prolong the action of succinylcholine because, after at least 1 month of therapy, plasma pseudocholinesterase activity may be below 5% of normal. It is said, moreover, that normal enzyme activity does not return until 4 to 6 weeks after discontinuation of the drug.<sup>36</sup> Hence, the anesthesiologist should anticipate prolonged apnea after a usual dose of succinylcholine. In addition, a delay in metabolism of ester local anesthetics should be expected.

## Cocaine

Cocaine, introduced to ophthalmology in 1884 by Koller, has limited topical ocular use because it can cause corneal pits and erosion. However, as the only local anesthetic that inherently produces vasoconstriction and shrinkage of mucous membranes, cocaine has been used in nasal packs during dacryocystorhinostomy. The drug is so well absorbed from mucosal surfaces that plasma concentrations are achieved that are comparable to those after direct intravenous injection. Because cocaine interferes with catecholamine uptake, it has a sympathetic nervous system potentiating effect.

The usual maximal dose of cocaine used in clinical practice is 200 mg for a 70-kg adult, or 3 mg/kg. Although 1 g is considered to be the usual lethal dose for an adult, considerable variation occurs. Furthermore, systemic reactions may appear with as little as 20 mg. Meyers<sup>37</sup> described two cases of cocaine toxicity during dacryocystorhinostomy, underscoring that cocaine is contraindicated in hypertensive patients or in patients receiving drugs such as tricyclic antidepressants or monoamine oxidase inhibitors. In addition, sympathomimetics, such as epinephrine or phenylephrine, should not be given with cocaine. The use of cocaine has largely been abandoned owing to its toxicity profile and potential for drug abuse. So-called pseudococaine solutions consisting of lidocaine 4%, oxymetazoline 0.05%, and peppermint oil are nearly as effective.

Obviously, before administering cocaine or another potent vasoconstrictor for dacryocystorhinostomy, doses of dilute solutions should be meticulously calculated and carefully administered. If serious cardiovascular effects occur, labetalol should be used to counteract them.<sup>38</sup>  $\beta$ -Blocking agents should not be administered in this situation owing to the potential to exacerbate

hypertension as a result of unopposed  $\alpha$ -adrenergic stimulation. Labetalol offers the advantages of combined  $\alpha$ -blockade and  $\beta$ -blockade. In addition, labetalol is preferable to esmolol because of its longer duration of action. It is important to appreciate, however, that labetalol has not been shown to reverse coronary artery vasoconstriction in humans. In the setting of cocaine-associated chest pain and/or myocardial infarction,  $\beta$ -blockers should not be administered acutely. Rather, nitroglycerin should be given.

### **Cyclopentolate**

Despite the popularity of cyclopentolate as a mydriatic, it is not without side effects, which include CNS toxicity. Manifestations include dysarthria, disorientation, and frank psychotic reactions. Purportedly, CNS dysfunction is more likely to follow use of the 2% solution as opposed to the 1% solution. Furthermore, cases of convulsions in children after ocular instillation of cyclopentolate have been reported. Hence, for pediatric use, 0.5% to 1% solutions are recommended. At higher concentrations, cyclopentolate also causes cycloplegia.

### **Epinephrine**

Although topical epinephrine has proved useful in some patients with open-angle glaucoma, the 2% solution has been associated with such systemic effects as nervousness, hypertension, angina pectoris, tachycardia, and other dysrhythmias. Consequently, dipivefrin hydrochloride, a prodrug of epinephrine formed by the diesterification of epinephrine and pivalic acid, is often used instead. The addition of pivaloyl groups to the epinephrine molecule enhances its lipophilic character, greatly facilitating its penetration into the anterior chamber, where it reduces aqueous production and augments outflow. The prodrug delivery system is a more efficient way of delivering the therapeutic benefits of epinephrine, with less drug and with fewer side effects than conventional epinephrine therapy. Dipivefrin 0.1% is less irritating than 1% or 2% epinephrine, and, unlike cholinergic agents used to treat glaucoma, it does not produce miosis or accommodative spasm. Dipivefrin should not be used, however, in patients with narrow angles because any dilation of the pupil may trigger an attack of angle-closure glaucoma.

### **Phenylephrine**

Pupillary dilation and capillary decongestion are reliably produced by topical

phenylephrine. Although systemic effects secondary to topical application of prudent doses are rare,<sup>39</sup> severe hypertension, headache, tachycardia, and tremulousness have been reported.

In patients with coronary artery disease, severe myocardial ischemia, cardiac dysrhythmias, and even myocardial infarction may develop after topical 10% eye drops. Those with cerebral aneurysms may be susceptible to cerebral hemorrhage after phenylephrine in this concentration. In general, a safe systemic level follows absorption from either the conjunctiva or the nasal mucosa after drainage by the tear ducts. However, phenylephrine should not be given in the eye after surgery has begun and venous channels are patent.

Children are especially vulnerable to overdose and may respond in a dramatic and adverse fashion to phenylephrine drops. Hence, the use of only 2.5%, rather than 10%, phenylephrine is recommended in infants and the elderly, and the frequency of application should be strictly limited in these patient populations.

### *Timolol and Betaxolol*

Timolol, a nonselective  $\beta$ -adrenergic blocking drug, historically has been a popular antiglaucoma drug. Because significant conjunctival absorption may occur, timolol should be administered with caution to patients with known obstructive airway disease, congestive heart failure, or greater than first-degree heart block. Life-threatening asthmatic crises have been reported after the administration of timolol drops to some patients with chronic, stable asthma.<sup>40</sup> The development of severe sinus bradycardia in a patient with cardiac conduction defects (left anterior hemiblock, first-degree atrioventricular block, and incomplete right bundle branch block) has been reported after timolol.<sup>41</sup> Moreover, timolol has been implicated in the exacerbation of myasthenia gravis<sup>42</sup> and in the production of postoperative apnea in neonates and young infants.<sup>43</sup>

In contrast to timolol, betaxolol, a  $\beta_1$ -blocker, is said to be more oculospecific and have minimal systemic effects.<sup>44</sup> However, patients receiving an oral  $\beta$ -blocker and betaxolol should be observed for potential additive effect on known systemic effects of  $\beta$ -blockade. Caution should be exercised in patients receiving catecholamine-depleting drugs. Although betaxolol has produced only minimal effects in patients with obstructive airway disease, caution should be exercised in the treatment of patients with excessive restriction of pulmonary function. Moreover, betaxolol is contraindicated in patients with sinus bradycardia, congestive heart failure, greater than first-degree heart block, cardiogenic shock, and overt myocardial failure.

## Intraocular Perfluorocarbons

For a patient with a retinal detachment, a relatively insoluble expandable gas may be injected into the vitreous to mechanically tamponade reattachment. By varying the concentration, volume, and type of gas used, bubbles can be produced that last from 5 to 70 days before being completely absorbed. Nitrous oxide is manyfold more diffusible than perfluorocarbons, can readily expand the size of a gas bubble, and so should be discontinued 15 minutes prior to injection of a gas bubble.

Should the patient need another operation of any sort, it must be remembered that perfluorocarbons may linger in the eye for a protracted period.<sup>45</sup> If nitrous oxide is administered during this interval, the bubble can rapidly expand, risking retinal and optic nerve ischemia secondary to central retinal artery occlusion. Nitrous oxide should be avoided for 5 days after air injection, for 10 days after sulfur hexafluoride injection, and for 70 days following perfluoropropane (Table 49-3).<sup>46</sup> A MedicAlert bracelet is placed on the patient to warn against administration of nitrous oxide during the window of vulnerability (see section on Retinal Detachment Surgery).

**Table 49-3** Differential Solubilities of Gases

Gas	Blood–Gas Partition Coefficients
Perfluoropropane	0.001
Sulfur hexafluoride	0.004
Nitrogen	0.015
Nitrous oxide	0.468

## Systemic Ophthalmic Drugs

In addition to topical and intraocular therapies, various ophthalmic drugs given systemically may result in complications of concern to the anesthesiologist. These systemic drugs include glycerol, mannitol, and acetazolamide. For example, oral glycerol may be associated with nausea, vomiting, and risk of aspiration. Hyperglycemia or glycosuria, disorientation, and seizure activity may also occur after oral glycerol.

The recommended intravenous dose of mannitol is 1.5 g/kg given over a 30- to 60-minute interval. However, serious systemic problems may result from rapid infusion of large doses of mannitol. These complications include renal failure, congestive heart failure, pulmonary congestion, electrolyte imbalance, hypotension or hypertension, myocardial ischemia, and, rarely, allergic reactions. Clearly, the patient's renal and cardiovascular status must be thoroughly evaluated before mannitol therapy.

Acetazolamide, a carbonic anhydrase inhibitor with renal tubular effects,

should be considered contraindicated in patients with marked hepatic or renal dysfunction or in those with low sodium levels or abnormal potassium values. As is well known, severe electrolyte imbalances can trigger serious cardiac dysrhythmias during general anesthesia. Furthermore, people with chronic lung disease may be vulnerable to the development of severe acidosis with long-term acetazolamide therapy. Topically active carbonic anhydrase inhibitors have been developed, are now commercially available, and appear to be relatively free of clinically important systemic effects.

## Preoperative Evaluation

### *Establishing Rapport and Assessing Medical Condition*

Preoperative preparation and evaluation of the patient begin with the establishment of rapport and communication among the anesthesiologist, the surgeon, and the patient. Most patients realize that surgery and anesthesia entail inherent risks, and they appreciate a candid explanation of potential complications, balanced with information concerning probability or frequency of permanent adverse sequelae. Such an approach also fulfills the medicolegal responsibilities of the physician to obtain informed consent.

A thorough history of the patient and physical examination are the foundation of safe patient care. Questionnaires in lieu of medical evaluation lack sensitivity to detect pertinent medical issues.<sup>47</sup> A complete list of medications that the patient is currently taking, both systemic and topical, must be obtained so potential drug interactions can be anticipated and essential medication will be administered during the hospital stay. Naturally, a history of any allergies to medicines, foods, or tape should be documented. Clearly, knowledge of any personal or family history of adverse reactions to anesthesia is mandatory. The requisite laboratory data vary, depending on the medical history and physical status of the patient, as well as the nature of the surgical procedure. Indeed, the American Society of Anesthesiologists (ASA) task force on preoperative evaluation concluded that routine preoperative tests are commonly not useful in assessing and managing patients' perioperative experience. Schein et al.,<sup>48</sup> for example, demonstrated that "routine" testing does not improve cataract patient safety or outcome. Some physicians and laypersons misinterpreted the results and conclusions of this investigation, believing that patients having cataract surgery need no preoperative evaluation. It is vital to note that all patients in this trial received regular medical care and were evaluated by a physician preoperatively. Patients whose medical status indicated a need for preoperative laboratory tests were excluded from the study. Clearly, testing should be based on the results of the history and physical examination. The

favorable economic impact of a “targeted” approach is obvious, because “routine” testing for the more than 1.5 million annual U.S. cataract operations neither decreases adverse events nor improves outcomes but is estimated to cost \$150 million.<sup>49</sup>

The dilemma whether to continue or suspend antithrombotic therapy prior to surgery is not unique to the ophthalmic patient population. Many elderly eye surgery patients are on antiplatelet or anticoagulant therapy because of a history of coronary or vascular pathology. These individuals are at higher risk for perioperative hemorrhagic events, including retrobulbar hemorrhage, circumorbital hematoma, intravitreous bleeding, and hyphema. Although prior discontinuation of antithrombotic agents may diminish the potential for perioperative ocular bleeding, such strategy may increase the risk of adverse events like myocardial ischemia, infarction, cerebrovascular accident, and deep venous thrombosis.

The consensus of studies exploring this controversial issue suggest that cataract and other ophthalmic procedures can be safely performed under regional anesthesia without discontinuing antithrombotic agents.<sup>50–52</sup> A multicenter study of almost 20,000 elderly cataract patients attempted to establish the risks and benefits of continuing aspirin or warfarin therapy.<sup>53</sup> Despite the large population studied, the rate of complications was so low that absolute differences in risk were minimal. Patients who continued therapy did not have more ocular hemorrhage; those who discontinued treatment did not have a greater incidence of medical events. A meta-analysis of 11 studies revealed that continuing warfarin therapy for cataract patients was associated with an increased risk of bleeding, but almost all instances were self-limiting and not clinically relevant. No patient had bleeding-related compromise of visual acuity.<sup>54</sup>

Recent articles in the *Annals of Surgery*<sup>55</sup> and the *New England Journal of Medicine*<sup>56</sup> categorized retina surgery as being distinctly apart from other ophthalmic procedures owing to the high risk for intraoperative hemorrhage. However, contemporary ophthalmic literature suggests otherwise.<sup>57,58</sup> Retrospective studies of hemorrhagic complications in patients undergoing retina surgery taking antithrombotics demonstrate equivalent or higher rates of bleeding compared to controls. Nonetheless, in nearly all of these studies bleeding did not cause long-term visual sequelae; most were self-limited vitreous hemorrhages that rarely required returning to the operating room. Evolving surgical techniques including smaller gauge vitrectomy may further decrease the risk of perioperative hemorrhage.

Regional anesthesia for eye surgery also presents another bleeding risk. Traditionally, some physicians held that patients taking antithrombotic medications should not receive a regional eye block owing to increased hemorrhagic risk. Significantly, there are no data that conclusively

substantiate this. In fact, the risks have been shown to be comparable regardless of antithrombotic continuation or interruption.<sup>53,59</sup>

The introduction of newer antithrombotic agents such as the anticoagulants dabigatran, rivaroxaban, and apixaban, as well as the antiplatelet medications prasugrel and ticagrelor, adds further complication because their efficacy cannot be monitored with conventional clotting assays.

The continuing evolution of this debate emphasizes the need to evaluate the systemic risk of stopping antithrombotics against the consequences associated with potential surgical/anesthetic hemorrhage. Currently, it is advocated to tailor guidelines such that most patients continue their antithrombotic medication regimens prior to ophthalmic surgery.

Another area of potential concern involves coronary artery disease patients with drug-eluting stents. Although bare-metal stents are susceptible to in-stent restenosis, drug-eluting stents are more vulnerable to stent thrombosis, a complication with a high mortality rate. Thus, patients with drug-eluting stents are typically on dual antiplatelet therapy with aspirin and clopidogrel, for example, for extended periods of time. A conclusion that is emerging is that the risk of thrombotic complications in patients with drug-eluting stents appears to outweigh the risk of bleeding complications. Therefore, given current information, a convincing case can be made for continuing dual antiplatelet therapy in the perioperative period and for delaying elective surgery for at least 4 to 6 weeks after placement of a bare metal stent and for 6 months after drug-eluting stent placement.<sup>54,60,61</sup>

Eye surgery patients are often at the extremes of age, ranging from premature babies with retinopathy of prematurity to nonagenarians. Hence, special age-related considerations such as altered pharmacokinetics and pharmacodynamics apply. In addition, elderly patients frequently have multiple comorbidities, including thyroid dysfunction, cardiopulmonary, and renal diseases. Hypertension is encountered in the majority of geriatric patients. Those with poorly controlled blood pressure should not receive dilating eye drops, such as phenylephrine, without consulting an anesthesiologist. Systemic absorption of high concentrations (e.g., >2.5% phenylephrine) or improperly instilled mydriatics can precipitate a hypertensive crisis with potentially devastating consequences.

As our society becomes increasingly geriatric, the number of ophthalmic surgery patients presenting with implanted cardiac defibrillators (ICDs) and pacemakers grows. The theoretical possibility of eye injury from patient movement in the event of ICD discharge during surgery exists. Although there is a broad spectrum of ophthalmic surgical procedures, the majority of cases use minimal bipolar cautery. For some, such as clear-corneal cataract surgery, no cautery is used. Thus, there is low risk of electromagnetic interference precipitating device discharge. Despite millions of procedures performed each

year, there have not been any case reports of ICD activation during ophthalmic surgery and none of the device manufacturers have documented such an incident.<sup>62,63</sup> A retrospective survey of ophthalmic anesthesia providers found that over 80% did not use a magnet to reprogram or inactivate an ICD before surgery.<sup>62</sup>

Perioperative movement is a possible cause of patient eye injury and potential anesthesiologist liability. An analysis of ophthalmic monitored anesthesia care (MAC) closed claims cases that resulted in blindness or poor visual outcome found that more than 80% were associated with inadequate anesthesia and/or patient movement either during the block or intraoperatively.<sup>64</sup> Cough, orthopnea, and restlessness are the most common precipitators of excessive motion. Propofol sedation for eye block is associated with sneezing. Midazolam, fentanyl, and alfentanil given prior to propofol abate the sneeze reflex.<sup>65</sup> Intraoperative movement during general anesthesia may also induce dire visual consequences. Because most ophthalmic surgical procedures are elective, should an enhanced risk of perioperative movement be noted during the preoperative assessment, the prudent course may be to postpone surgery until the patient is in optimal condition to remain relatively still<sup>66</sup> or to perform the procedure under general anesthesia. Deliberate patient selection is requisite in order to prescribe the optimal anesthesia care plan.

The anesthesiologist must be aware of the anesthetic implications of congenital and metabolic diseases with ocular manifestations. Diabetic patients often present with ocular complications, and the anesthesiologist must be knowledgeable about the systemic disturbances of physiology that affect these patients. Indeed, the list of congenital and metabolic diseases associated with ocular pathologic effects that have important anesthetic implications is lengthy. A partial summary includes syndromes such as Crouzon, Apert, Goldenhar (oculoauriculovertebral dysplasia), Sturge–Weber, Marfan, Lowe (oculocerebrorenal syndrome), Down (trisomy 21), Wagner–Stickler, and Riley–Day (familial dysautonomia). Other diseases in this category are homocystinuria, myotonia dystrophica, and sickle cell disease.<sup>67</sup>

## **Anesthesia Options**

The requirements of ophthalmic surgery include safety, akinesia, analgesia, minimal bleeding, avoidance or obtundation of the oculocardiac reflex, prevention of intraocular hypertension, awareness of drug interactions, and a smooth emergence devoid of vomiting, coughing, or retching (Table 49-1). Moreover, the exigencies of ophthalmic anesthesia mandate that the anesthesiologist be positioned remote from the patient's airway, sometimes creating certain logistic problems.

**7** A number of anesthetic options exist, including general anesthesia, retrobulbar (intraconal) block, peribulbar (extraconal) anesthesia, sub-Tenon block, topical anesthesia, and intracameral injection. General anesthesia is typically administered for infants and children. Some adolescent and most adult patients can be cared for with regional or topical anesthesia and MAC, with or without sedation. The choice of anesthesia technique should be individualized on the basis of the patient's needs and preferences, the nature and duration of the procedure, and the preferences and skills of the anesthesiologist and the surgeon.

The retrobulbar block has traditionally been the most popular regional anesthetic technique for eye surgery. Since the mid-1990s, owing to a presumed superior safety profile, peribulbar injection has surpassed retrobulbar block in popularity. Recently, however, topical analgesia has prevailed for cataract surgery in the United States,<sup>68</sup> whereas use of sub-Tenon blocks has surged in the United Kingdom and New Zealand.<sup>69</sup> Although cataract surgery embodies the majority of eye procedures, there are a variety of other subspecialty operations, including corneal transplant and procedures for glaucoma, strabismus, and tumor, as well as oculoplastic, orbital, vitreoretinal, and eye trauma procedures. Most of these continue to be accomplished primarily with a regional eye block and sedation,<sup>70</sup> although some warrant general anesthesia. Anesthesiologists have had increasing interest in administering ocular anesthesia, so workshops in ophthalmic regional anesthesia are often conducted at major regional and national meetings. Many ophthalmologists and administrators encourage anesthesiologists to administer the blocks to facilitate operating room efficiency.

When a regional anesthetic of the orbit is administered, by either the anesthesiologist or the ophthalmologist, it is the responsibility of the anesthesiologist to monitor the patient's vital signs, electrocardiogram (ECG), and oxygen saturation. Sedation may be administered before performance of the block and/or initiation of surgery. The anesthesiologist must be vigilant for the oculocardiac reflex, signs of brainstem anesthesia, and the need for airway support or other interventions.

### *Side of Anesthesia and Surgery*

In an attempt to ensure proper patient, side, site, and procedure selection, The Joint Commission (formerly known as the Joint Commission on Accreditation of Healthcare Organizations) held a "Wrong Site Summit" in May 2003 in which they developed a universal protocol for preventing wrong site, wrong procedure, wrong person surgery. The policy is tripartite, involving preoperative verification, marking of the

intended site, and a “time-out” immediately before the start of surgery.<sup>71</sup> Patient involvement and effective communication are key components.

Ophthalmologic surgery and regional anesthesia confer greater risk than many other surgical procedures owing to the potential for laterality errors. Patients (and medical staff) may be confused as to the side, site, or actual procedure. Sedatives or anesthetic agents may enhance the likelihood of error. Some patients, such as children and infants, may lack the competence to intervene. Similarity of names can be conducive to mistakes. Procedural factors may be contributory; a wrong side may be draped or prepared, a patient’s cap may obscure a clearly marked surgical site. Human factors play a key role in the problem. Failure to cross-check consent forms, patient charts, and patients, tragically, occasionally still occurs. Our distraction-rich environment, coupled with dysfunctional oral/written communication and lack of proper adherence to safety protocols, also plays a role.

## **Anesthesia Techniques**

In the past, ophthalmic procedures commonly involved large ocular incisions. General endotracheal anesthesia, with deep and sustained neuromuscular paralysis and placement of sandbags to surround the patient’s head, were typical strategies to ensure perioperative immobility. Currently, general anesthesia typically is reserved for children and adults who are unable to communicate, cooperate, or remain suitably stationary. Supraglottic airways (SGAs) have been increasingly accepted as a means to secure the airway in patients with minimal risk for aspiration who are having eye surgery with general anesthesia.<sup>72</sup> The SGA is not only safe and effective in this setting but also offers the advantage of less increase in IOP on insertion and removal than is encountered with an endotracheal tube.<sup>73</sup> Similarly, less bucking and coughing on emergence and during the recovery phase have been noted.<sup>74</sup> Vigilance must be maintained, however, to detect initial misplacement or intraoperative displacement of the SGA. In addition, intraoperative laryngospasm in infants and neonates is not uncommon with an SGA.

## **Retrobulbar (Intraconal) and Peribulbar (Extraconal) Blocks**

In 1844, Knapp described one of the first techniques for ophthalmic regional anesthesia.<sup>75</sup> In the early 20th century, Atkinson<sup>76</sup> introduced the retrobulbar block, a practical needle-based means to achieve analgesia and profound akinesia of the globe. For a retrobulbar block, the needle tip is situated behind (retro) the globe (bulbar). The peribulbar block, a more recently introduced needle-based technique, varies from the retrobulbar block in terms of the depth and angulation of needle placement within the orbit. Here, the

needle tip is placed around (peri) the globe (bulbar). The terminology is inadequate because “retro” and “peri” only vaguely describe the difference between the two techniques. The four rectus muscles, along with connective tissue septae, create a defined compartment known as the *orbital cone*, which extends from the rectus muscle origins around the optic foramen at the apex of the orbit to the attachment of the muscles onto the globe anteriorly. Retrobulbar blocks are accomplished by directing a needle through the eyelid or via the conjunctiva toward the orbital apex with sufficient depth and angulation such that the needle passes through the muscle cone (Figs. 49-4 and 49-5).<sup>77</sup> Local anesthetic is then instilled. The term intraconal injection is therefore a better, more descriptive name for the procedure than the older, retrobulbar block.<sup>78</sup>

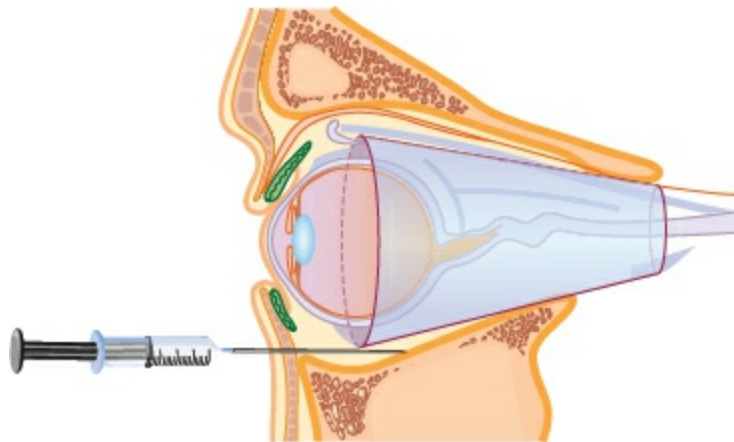

**Figure 49-4** Intraconal (retrobulbar) block and schematic representation of the intraorbital muscle cone.

Cadaveric dissections have shown that there is no complete intermuscular septum encircling the rectus muscles, linking them together to form an impermeable conal compartment behind the globe.<sup>79</sup> Ripart et al.<sup>80</sup> clearly demonstrated that extraconal injections of dye into cadaveric specimens diffused into the intraconal space, and solutions placed within the cone distributed to the extraconal space. Thus, the peribulbar or, more properly termed, extraconal block is executed by directing a needle through the eyelid or via the conjunctiva to less depth and with minimal angulation, parallel to the globe, toward the greater wing of the sphenoid bone (Figs. 49-6 and 49-7). Local anesthetic instilled in this extraconal space will eventually penetrate toward the optic nerve and other structures, establishing conduction anesthesia. The extraconal block may be theoretically safer because the needle tip is kept at a greater distance from vital intraorbital structures and brain.

**Figure 49-5** Needle placement for intraconal (retrobulbar) block.

**Figure 49-6** Extraconal (peribulbar) block and schematic representation of the intraorbital muscle cone.

The didactic classification of block nomenclature based on the relationship of the needle and the muscle cone is a useful means to conceptualize the differences between two types of needle-based eye blocks. It is important to emphasize, though, that needle path cannot always be predicted by clinical evaluation alone. Radiologic studies have shown that some percentage of intraconal blocks administered by experienced physicians is, in fact, extraconal, and vice versa.<sup>81</sup>

Again, a retrobulbar block is more precisely described as an intraconal injection. It positions local anesthetics deep within the orbit proximate to the nerves and muscle origins. Thus, it requires low volume, has rapid onset, and yields intense depth of anesthesia. The peribulbar or, more accurately labeled, extraconal block is placed further from the optic and other orbital nerves, requires larger volumes of local anesthetic, and has longer latency of onset. The needle entry point for both blocks is at the same inferotemporal location. The junction of the lateral third and medial two-thirds of the inferior orbital rim in line with the lateral limbal margin has been the conventional access point. However, locating the needle entry point more laterally may serve to

decrease the likelihood of injecting local anesthetics into the delicate inferior rectus or inferior oblique muscles. This is important because intramuscular injection of anesthetics has been postulated as a potential cause of postoperative strabismus.<sup>82</sup> Medial approaches at the caruncle have also been popularized.<sup>83</sup> Supplementation of anesthesia with an injection above the globe may not be prudent because the preponderance of vessels lie in the superior orbit. In addition, the belly of the superior oblique muscle and the trochlear muscle can be encountered superonasally.

**Figure 49-7** Needle placement for extraconal (peribulbar) block.

Katsev et al.<sup>84</sup> demonstrated that the tips of commonly used 1.5-in (38-mm) needles can reach critical structures in the densely packed apex of the orbit in almost 20% of classic retrobulbar blocks. Consequently, needles 1.25 inches (31-mm) or shorter are appropriate. Controversy exists over the advantages of sharp versus dull needles. Dull needles may require more force to penetrate the globe. However, sharp needles are less painful to insert and may cause less damage in the face of inadvertent globe puncture.<sup>85</sup> In the past, patients were asked to gaze superonasally while a block was conducted. Unsold et al.<sup>86</sup> found that this maneuver caused the optic nerve to stretch directly in the path of the incoming needle during intraconal injection, exposing it to risk of needle trauma. Patients should be instructed to maintain gaze in the neutral position, leaving the optic nerve lax within the orbit in the course of needle insertion.<sup>87</sup> Elevations in IOP after an eye block can be minimized by application of gentle noncontinuous digital pressure or use of an ocular decompression device.<sup>88</sup>

Akinesia of the eyelids is obtained by blocking the branches of the facial nerve supplying the orbicularis muscle. Lid akinesia is often a direct consequence of the larger volume of local anesthetic used for extraconal blocks. Intraconal blocks, in contrast, often leave the orbicularis oculi fully functional. Thus, a facial nerve block is performed in conjunction with

retrobulbar block to prevent squeezing of the eyelid, which could result in extrusion of intraocular contents during corneal transplantation, for example. Since facial nerve block was first used for ophthalmic surgery by Van Lint in 1914, numerous methods of facial nerve blockade have been described. These techniques block the facial nerve after its exit point from the skull in the stylomastoid foramen. Moving distally to proximally to the foramen, the techniques include the Van Lint, Atkinson, O'Brien, and Nadbath–Rehman methods. Although each has advantages and disadvantages, the Nadbath–Rehman approach can potentially produce the most serious systemic consequences. With this approach, a 27-gauge, 12-mm needle is inserted between the mastoid process and the posterior border of the mandibular ramus. Because of the proximity of the jugular foramen (10 mm medial to the stylomastoid foramen) to the injection site, ipsilateral paralysis of cranial nerves IX, X, and XI can occur, producing hoarseness, dysphagia, pooling of secretions, agitation, respiratory distress, or laryngospasm. Moreover, because the Nadbath–Rehman block produces complete hemifacial akinesia, which interferes with oral intake, this approach is not recommended for outpatients.

**8** Complications associated with needle-based ophthalmic anesthetics may be local or systemic and may result in blindness or even death ([Table 49-4](#)). Bleeding may be superficial or deep, arterial or venous. Superficial hemorrhage may produce an unsightly circumorbital hematoma. Retrobulbar hemorrhage, when arterially based, may produce precipitous bleeding and a palpable, dramatic increase in IOP, as well as globe proptosis and entrapment of the upper lid. With the globe's vascular supply in jeopardy, the patient's long-term ultimate visual acuity may be quickly compromised. Consultation with an ophthalmologist should be immediately sought, and fundoscopic examination, tonometric measurement of IOP, ultrasound to assess presence/location of blood, and even a lateral canthotomy may be warranted. Continuous ECG monitoring is indicated because the oculocardiac reflex may occur as blood extravasates from the muscle cone. The decision to proceed with surgery in the presence of a mild or moderate hemorrhage depends on numerous factors, including the degree of bleeding, the nature of the planned ophthalmologic surgery, and the patient's condition.

**Table 49-4** Complications of Needle-based Ophthalmic Anesthesia

Stimulation of oculocardiac reflex arc
Superficial hemorrhage → circumorbital hematoma
Retrobulbar hemorrhage ± retinal perfusion compromise → loss of vision
Globe penetration ± intraocular injection → retinal detachment, loss of vision
Trauma to optic nerve or orbital cranial nerves → loss of vision
Optic nerve sheath injection → orbital epidural anesthesia
Extraocular muscle injury, leading to postoperative strabismus, diplopia
Intra-arterial injection, producing immediate convulsions
Central retinal artery occlusion
Inadvertent brainstem anesthesia → contralateral amaurosis, mydriasis, muscle paresis
Neurocardiopulmonary compromise

Penetration of the sclera is a distinct, although rare, possibility with needle-based anesthesia techniques. Mechanical trauma, with potential retinal detachment, and chemical injury to delicate retina tissue caused by local anesthetics can occur. Blindness or very poor vision may be the result. Globe puncture is defined as a single entry into the eye, whereas perforation is caused by two full-thickness wounds—an entry and a subsequent exit. The globe's posterior pole is the most commonly penetrated area. Risk factors for posterior pole needle injury include presence of an elongated globe, recessed orb, and/or atypical-shaped eye. The anteroposterior distance of an eye may be long because of myopia or presence of globe-enveloping intraorbital hardware such as a scleral buckle. Some patients have an abnormal outpouching of the eye, termed *staphyloma*. Most staphylomata are located at the posterior of the globe, surrounding the juncture of the eye with the optic nerve. By definition, an intraconal (retrobulbar) anesthetic is administered by purposefully angling the needle steeply and deeply within the orbit behind the globe. If the globe is longer than one assumes, it is at greater risk of penetration or puncture by the needle. In one study, ultrasound detection determined that the tip of the needle, placed in classic retrobulbar fashion, can be much closer to the posterior pole of the globe than presupposed by physicians.<sup>89</sup> Extraconal (peribulbar) anesthesia entails shallower placement of the needle without directing the needle inward toward the orbital apex; thus, it is associated with a lower incidence of globe needle injury. Be aware, however, that it is still possible to engage the needle with sclera laterally.

The risk of penetrating the sclera with a needle is also inversely proportional to the anesthesiologist's education and experience. This notion is affirmed by several reports of globe injuries rendered by inadequately educated or trained personnel in the early 1990s.<sup>90</sup> In a survey of 284 directors of anesthesiology and ophthalmology programs, no formal training or education in ophthalmic regional anesthesia techniques was provided to

anesthesia residents in most academic programs.<sup>91</sup> This survey concluded that anesthesiologists who perform needle-based ophthalmic blocks should have knowledge of orbital anatomy and the ocular risk factors that were noted previously. Thus, appropriate preanesthesia history taking includes direct interrogation concerning myopia or previous scleral buckle surgery, because both imply increased globe length. Bayes et al.<sup>92</sup> showed that a history of correction for myopia as a child or young adult was both highly sensitive and highly specific for having an elongated axial length. Physical examination of surface anatomy should note the position of the globe within the orbit and whether enophthalmos is present. A recessed eye is at greater risk of needle-tip misadventure. The most important laboratory examination is the preoperative ultrasound. For patients undergoing cataract surgery, an ultrasound is *always* performed to calculate the appropriate intraocular lens to insert intraoperatively. In addition, it reveals the length and shape of the eye. An axial length greater than 26 mm confers greater risk of penetration or perforation. In the event that the ultrasound report is not found in the patient's chart, the anesthesiologist should inquire about the results before embarking on a needle-based block.

In the future, portable real-time ultrasonography may have a role in reducing the risk of penetrating injury (Fig. 49-8).<sup>93</sup> Needle-based eye blocks are "blind" techniques primarily dependent on surface anatomy landmarks to position the needle correctly. Ultrasound-guided direct visualization of both the needle and the spread of local anesthetic may improve the quality and safety of these blocks.

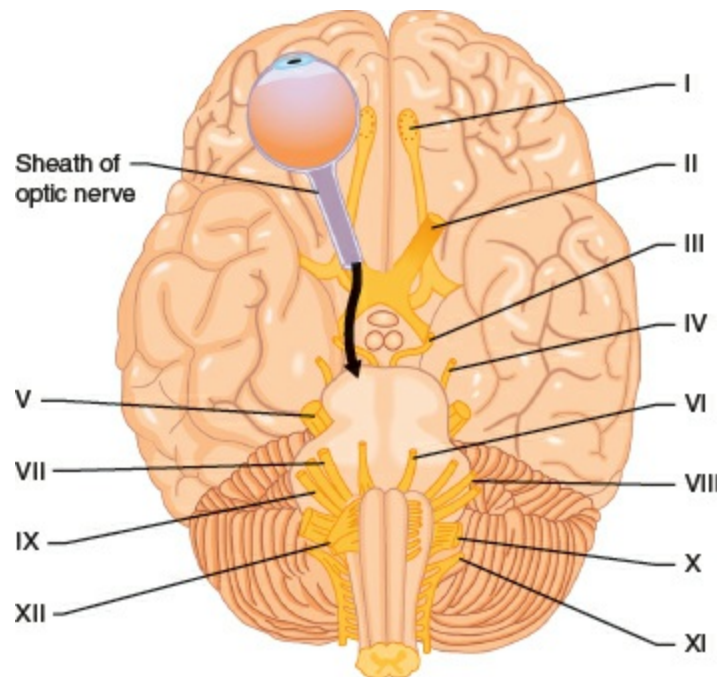

The eye is easily accessible, and its geometry and surrounding elements are relatively straightforward. Additionally, the tissue contents of the orbit lack gas-filled or osseous structures, making this a suitable area for ultrasonic imaging. Sonography of the eye, however, is not without risk. Owing to potential thermal and mechanical bioeffects, the U.S. Food and Drug Administration has imposed stricter physical parameters for ophthalmic ultrasound. In particular, limits on mechanical index and thermal index have been reduced to 0.23 and less than 1, respectively. Commercial ultrasound transducers marketed to anesthesiologists may not comply with these recommendations. A recent rabbit model study that compared thermal and mechanical changes induced by exposure to ophthalmic- and nonophthalmic-rated transducers showed significant changes in intraorbital temperature after moderate exposure to a nonophthalmic-rated device, emphasizing the need to ensure that proper eye-appropriate ultrasound equipment is employed for these blocks.<sup>94</sup>

Brainstem anesthesia and inadvertent intravascular injection of local anesthetics are two additional potentially devastating consequences of needle-based ocular anesthesia. In the course of accidental intravascular arterial

injection, local anesthetics flow from the needle via a branch of the ophthalmic artery in retrograde fashion to the internal carotid artery and then to the circle of Willis. Rapid redistribution of local anesthetic to the brain results in immediate onset of convulsions. Cardiopulmonary instability may also occur.

**Figure 49-8** Ultrasound-guided block with overlay. **A:** Globe. **B:** Needleshaft. **C:** Needle tip. **D:** Optic nerve.

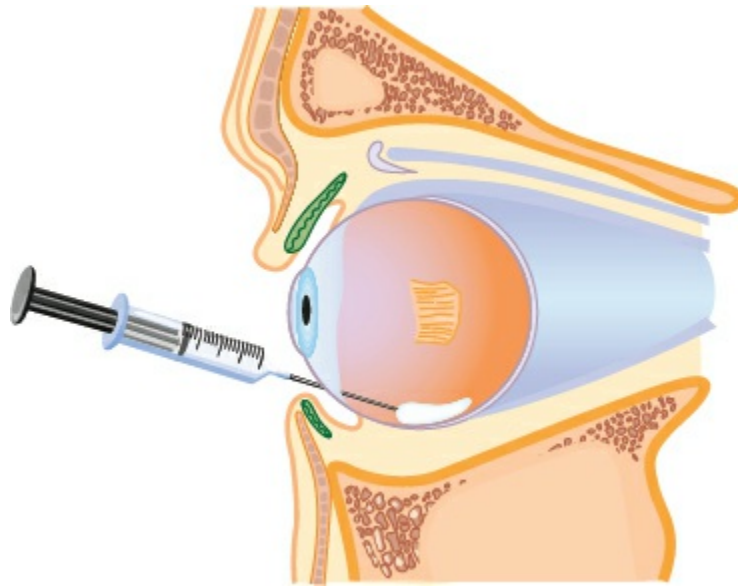

**Figure 49-9** Base of the brain and the path that local anesthetic agents might follow if inadvertently injected into the subarachnoid space. This route includes the cranial nerves, pons, and midbrain. (Adapted with permission from Javitt JC, Addiego R, Friedberg HL, et al. Brain stem anesthesia after retrobulbar block. *Ophthalmology*. 1987;94:718.)

Although the incidence of brainstem anesthesia is rare, it is even less

common with extraconal versus intraconal blocks. Brainstem anesthesia is a consequence of the direct spread of local anesthetic agents to the brain along the meningeal sheath surrounding the optic nerve. In contradistinction to intra-arterial injection, symptoms are typically not immediate. There is a continuum of sequelae dependent on the concentration and volume of drug that gains access centrally, as well as the specific areas into which the anesthetic spreads (Fig. 49-9).<sup>95</sup> Nicoll et al.<sup>96</sup> reported 16 cases of apparently central spread of anesthetics in a series of 6,000 intraconal blocks. Eight patients developed respiratory arrest. Examination of the conscious patient's contralateral, nonblocked eye for amaurosis, mydriasis, and extraocular muscle paresis may confirm the diagnosis of brainstem anesthesia. The abducens and oculomotor nerves are more commonly affected than the superior oblique muscle's trochlear nerve. Other protean CNS signs may include violent shivering, eventual loss of consciousness, apnea, and hemiplegia, paraplegia, quadriplegia, or hyperreflexia. Blockade of cranial nerves VIII to XII results in deafness, vertigo, vagolysis, dysphagia, aphasia, and loss of neck muscle power. It is axiomatic that personnel skilled in airway maintenance and ventilatory and circulatory support should be immediately available whenever ophthalmic anesthetic blocks are administered.

### **Cannula-based Techniques**

Cannula-based ophthalmic regional anesthesia was formally described by Swan<sup>97</sup> in 1956 and then rediscovered and popularized in the 1990s as another practical means to achieve analgesia and akinesia of the globe, while offering potential advantages in certain circumstances over needle-based blocks.<sup>98</sup> Imaging studies have shown that local anesthetics instilled beneath Tenon capsule spread into the posterior orbit.<sup>99</sup> The block is accomplished by inserting a blunt cannula through a small incision in the conjunctiva and Tenon capsule, also known as the *episcleral membrane*, with subsequent infusion of local anesthetics (Fig. 49-10). Onset of analgesia is rapid. The ultimate extent of globe akinesia is proportional to the volume of local anesthetic injected. One large prospective study by Guise<sup>69</sup> of 6,000 such blocks found this technique to be highly effective. Advantages, particularly for very myopic patients who have elongated axial lengths, include decreased risk of posterior pole penetration or perforation because needles are not placed into the posterior orbit.

**Figure 49-10** Sub-Tenon (episcleral) block with blunt cannula.

After application of topical anesthetic, the episcleral space can be accessed from all quadrants with blunt-tipped scissors; however, the incision is most commonly made in the inferonasal quadrant. The cannula is guided through the opening with the aid of a toothless forceps. It is common for local anesthetics to leak retrogradely out of the incision site. Conjunctival bleeding, chemosis, and ballooning of the conjunctiva are also common. Fortunately, these are cosmetic issues that rarely affect outcome. Guise<sup>69</sup> estimated the incidence of minor hemorrhage to be below 10% and had to abandon only one case because of a large subconjunctival hemorrhage that was not sight threatening. Thus, the sub-Tenon block may be a prudent ocular anesthesia technique for the anticoagulated patient at risk for retrobulbar hemorrhage.

Major complications of sub-Tenon anesthesia include globe perforation,<sup>100</sup> hemorrhage, rectus muscle trauma, postoperative strabismus, orbital cellulitis, optic nerve neuritis, and brainstem anesthesia.<sup>101</sup> More complications are reported with longer (18 to 25 mm) rigid metallic cannulae. Shorter (12 mm), more flexible plastic cannulae may be preferable; however, they are associated with a higher incidence of conjunctival hemorrhage and chemosis. Variations of sub-Tenon blocks include use of ultrashort cannulae (6 mm) and needle-based episcleral block techniques.<sup>102</sup> A new technique of an incisionless sub-Tenon block has been pioneered by Allman et al.<sup>103</sup> There has been a report of a death associated with a sub-Tenon block, potentially secondary to central spread of local anesthetic.<sup>104</sup> However, the definitive pathogenesis remains an enigma.<sup>105</sup>

## Topical Analgesia

Ophthalmologists have also been returning to a technique that was popularized during the early 1900s—the use of topical anesthetic agents,

particularly when the surgical incision is made through clear cornea. Indeed, surface analgesia was the technique of choice for cataract surgery until the evolution of effective needle-based methods of regional anesthesia and improved safety of general anesthesia in the 1930s. Multiple advances in cataract surgery that have enabled faster operations with greater control and less trauma have allowed ophthalmologists to re-examine the use of topical anesthesia for this procedure.

Fully anticoagulated patients may be excellent candidates for topical analgesia, as are monocular patients who are spared the trauma of prolonged local anesthetic-induced postoperative amaurosis. Potential disadvantages of topical anesthesia include eye movement during surgery, patient anxiety or discomfort, and, rarely, allergic reactions. Patient selection is critical and should be restricted to individuals who are alert and able to follow instructions, and who can refrain from eye movement and lid squeezing. Patients who are demented or photophobic, or who cannot communicate, may be inappropriate candidates, as are those with active infection. Similarly, patients with dense cataracts or small pupils who may require significant iris manipulation or those who need large scleral incisions may be contraindicated for topical anesthesia.

Topical analgesia can be achieved with local anesthetic drops or gels. Anesthetic gels produce greater levels of drug in the anterior chamber than equal doses of drops and may afford superior surface analgesia.<sup>106</sup> Concerns about increased potential for postoperative endophthalmitis with gel-based topical analgesia exist because gels might theoretically form a barrier to bactericidal agents. Therefore, if administered, gels should be applied after antiseptic solutions, taking care to apply anesthetic drops before the use of caustic bactericidal preps.

Analgesia can be supplemented with intracameral injection of 0.1 to 0.2 mL of 1% preservative-free lidocaine into the anterior chamber. So-called shugarcaine, an intracameral admixture of 4% preservative-free lidocaine and 1:1000 bisulfite-free epinephrine in salt solution, provides analgesia, dilates the pupil, and stabilizes the iris.<sup>107</sup> It is employed for cataract surgery patients with benign prostatic hyperplasia who typically exhibit symptoms of floppy iris intraoperatively. This syndrome has strong association with oral  $\alpha_1$ -selective adrenergic antagonists, particularly the  $\alpha_{1a}$  class that includes tamsulosin and silodosin. It manifests as a triad of poor pupillary dilation, floppy iris tissue, and a tendency for the iris to prolapse during surgery, resulting in a higher rate of cataract surgical complications.<sup>108</sup> Of note, symptoms can persist for over a year after discontinuation of  $\alpha_1$  antagonists.

## **Choice of Local Anesthetics, Block Adjuvants, and Adjuncts**

Anesthetics for ocular surgery are selected on the basis of onset and duration needed. Fast-onset, brief-duration local anesthetics are optimal for procedures such as cataract surgery or pterygium excision. Longer-acting agents are indicated for lengthier operations such as vitreoretinal surgery. Ophthalmic anesthesia has a tradition of mixing different local anesthetics to produce a block with shorter latency of onset yet longer duration of effect, although clinically there may not be true advantage to combining agents.<sup>109</sup> Bupivacaine 0.75% concentration has been shown to have potential to cause extraocular muscle toxicity. Lower concentrations do not have such a propensity.<sup>110</sup> Ropivacaine 0.75% or 1%, either alone or admixed with lidocaine, is an effective agent for eye block that has less cardiotoxic effects than 0.75% bupivacaine.<sup>111,112</sup>

Sodium bicarbonate, morphine sulfate, clonidine, and even vecuronium have been used as local anesthetic adjuvants in ophthalmic surgery. Vasoconstrictors may improve the quality of the block by delaying washout of drug from the orbit. There is concern, however, that epinephrine, the most common vasoconstrictor additive, may compromise retinal perfusion<sup>113</sup>; it is best avoided in patients with glaucomatous optic nerve damage.

Without question, however, hyaluronidase has been the most popular ancillary agent used to modify ocular local anesthetic actions since it was introduced by Atkinson in 1949. It acts by hydrolyzing hyaluronic acid, a natural substance that binds cells together, keeping them cohesive. Thus, hyaluronidase, in doses of 0.75 to 300 International Units per milliliter increases tissue permeability, serves to promote dispersion of local anesthetics through tissues within the orbit, reduces the increase in orbital pressure associated with the volume of injected anesthetics, and enhances the quality of orbital blockade.<sup>114</sup> Furthermore, hyaluronidase may reduce the risk of local anesthetic-induced extraocular muscle injury because clustered increases of postoperative diplopia were reported after national shortages of the drug in 1998 and 2000.<sup>115</sup> Studies since that time have supported these findings.<sup>116</sup> However, it is possible that technique was altered in response to the absence of hyaluronidase by placing needles deeper, using more injections, or depositing larger volumes of local anesthetics. Perhaps as a consequence of past national shortages, many facilities choose to obtain hyaluronidase from local compounding labs. In recent years, tainted medications from compounding facilities have led to multiple deaths due to fungal meningitis in chronic pain patients and permanent blindness in macular degeneration patients. Hyaluronidase is currently widely available in a human recombinant formulation, obviating the need for compounded formulations.

Digital pressure and mechanical devices have been used to soften the globe prior to surgery. Essentially, they are all variations on a ball, balloon, or bag theme. The Super Pinky ball and the Honan Intraocular Pressure

Reducer (The Lebanon Corporation, Lebanon, Indiana) are examples.<sup>88</sup> Immediately after administration of regional orbital anesthesia, the compression device may be positioned on the eye for 5 to 20 minutes. Reduction of IOP to below baseline levels is not uncommon. However, excessive pressure on the globe by these devices may impede blood flow, causing ischemic optic neuropathy (ION) or central retinal artery occlusion, possibly leading to blindness.<sup>117</sup> The Honan device addresses this potentially catastrophic complication with a pneumatic bellows that maintains even compression of the globe coupled to a manometric gauge that indicates a numeric value of applied pressure. A safety valve limits the amount of inflation of the bellows. With the increasing popularity of smaller incisions, lower-profile prosthetic lenses, and topical analgesia for cataract surgery, there is less need for IOP-reducing devices.

### **General Principles of Monitored Anesthesia Care**

Many advocate the intravenous administration of an appropriate agent immediately prior to ocular regional anesthesia to provide comfort and amnesia. Polypharmacy and deep sedation in the form of high doses of opioids, benzodiazepines, and hypnotics may be unwise because of the pharmacologic vagaries in the geriatric population and the attendant risks of respiratory depression, airway obstruction, hypotension, CNS aberrations, and prolonged recovery time. This undesirable technique has all the disadvantages of a general anesthetic in the absence of an endotracheal tube or SGA without the advantage of controllability that general anesthesia offers. After the block has been performed, the patient should be relaxed but sufficiently responsive to avoid head movement associated with snoring or sudden abrupt movement on awakening. Perioperative patient movement is a leading cause of patient eye injury and anesthesiologist liability.<sup>64</sup> Clearly, patients under monitored sedation must be capable of remaining relatively still, responding rationally to commands, and maintaining airway patency. Undersedation should likewise be avoided because tachycardia and hypertension may have deleterious effects, especially in patients with coronary artery disease. Curiously, a significant fraction of patients who have had cataract extraction on both eyes perceive the second eye surgery as being longer in duration, more painful, and/or generally more unpleasant.<sup>118</sup> Moreover, patients with orthopedic deformities or arthritis must be meticulously positioned and given comfortable padding on the operating table. Adequate ventilation about the face is essential to avoid carbon dioxide accumulation, particularly because supplemental oxygen can delay signs of desaturation and hypoventilation.<sup>119</sup> Use of exogenous oxygen can also contribute to surgical fire, particularly during oculoplastic surgery performed with electrocautery. Consider air or

mixed air/oxygen instead of oxygen for these procedures. Tightly occluded drapes may also promote accumulation of oxygen. In fact, burn injuries during facial surgery with supplemental oxygen account for nearly one-third of MAC closed claims cases.<sup>120</sup> Patients must be comfortably warm because the hazards of shivering in patients having delicate eye surgery are well known. Further, shivering causes a risk for patients with coronary artery disease. Continuous ECG monitoring is vital, lest performance of the ophthalmic regional block, pressure on the orbit, or tugging on the extraocular muscles stimulates the oculocardiac reflex arc and produces dangerous cardiac dysrhythmias. Likewise, pulse oximetry is essential. The adequacy of the sedated patient's ventilation should be assessed by clinical signs as well as exhaled carbon dioxide. Unequivocally, MAC should reflect "maximum anesthesia caution, not minimal anesthesiology care."<sup>121</sup>

Studies have confirmed that most cataract operations performed in the United States are conducted with the patient under some form of local anesthesia (either retrobulbar, peribulbar, sub-Tenon, intracameral, or topical analgesia), with monitoring equipment used in 97% of cases and an anesthesiologist present in 78% of cases.<sup>122</sup> An international survey of ophthalmologists reported routine use of anesthesia-trained personnel in 96% and 97% of cases in the United States and Australia, respectively.<sup>123</sup> On the other side of the spectrum, ophthalmologists from Malaysia and Thailand had anesthesia monitoring 31% and 18% of the time, respectively. Indeed, many anesthesiologists fear that the Centers for Medicare and Medicaid Services will decide not to reimburse for MAC for "routine" cataract cases.

An important study by Rosenfeld et al.<sup>124</sup> assessed the need for MAC in cataract surgery. These investigators prospectively studied the incidence and nature of interventions required by anesthesia personnel in 1,006 consecutive cataract operations (both phacoemulsification and extracapsular techniques were included) performed under peribulbar block. They also analyzed germane information, including patient demographic data, medical history, and preoperative laboratory tests, for ability to predict those patients at greatest risk for intervention. They found that 37% of patients required some type of intervention and that in general the majority of those interventions could not have been predicted before surgery. Patients younger than 60 years required intervention in over 60% of cases. The interventions ranged from minor forms, such as verbal reassurance and hand holding, to administering such intravenous medications as supplemental sedation or antihypertensive, pressor, or antiarrhythmic agents, or to providing respiratory assistance. Although hypertension, lung disease, renal disease, and a diagnosis of cancer were related to interventions, these four conditions combined accounted for only a small portion of the needed interventions. Moreover, although many of the interventions were relatively minor, several were more serious, and 30%

of the interventions were considered (by the involved anesthesia personnel) to be critical to the success of the operation. The investigators concluded that MAC by qualified anesthesia personnel is reasonable and justified and contributes to the quality of patient care when cataract surgery is performed with local anesthesia. Fung et al.<sup>125</sup> examined satisfaction scores for community-based cataract surgery via topical anesthesia and discovered that patients' value and regard for the anesthesiologist's role actually increased from the preoperative to the postoperative interview. In view of the fact that topical anesthesia produces analgesia that is less profound and provides operating conditions that are less ideal than regional or general anesthesia, it seems likely that anesthesia care is equally appropriate to provide comfort, support, and indicated drugs for these patients as well. For both ethical and surgical reasons, the ophthalmologist's attention must not be distracted from the microsurgical field.

## Anesthetic Management in Specific Situations

### *“Open-Eye, Full-Stomach” Encounters*

The anesthesiologist involved in caring for a patient with a penetrating eye injury and a full stomach confronts special challenges. He or she must weigh the risk of aspiration against the risk of blindness in the injured eye that could result from elevated IOP and extrusion of ocular contents.

As in all cases of trauma, attention should be given to the exclusion of other injuries, such as skull and orbital fractures, intracranial trauma associated with subdural hematoma formation, and the possibility of thoracic or abdominal bleeding.

Although regional anesthesia is often a valuable alternative for the management of nonfasted trauma patients, this option had traditionally been considered contraindicated with penetrating eye injuries because of the potential to extrude intraocular contents via pressure generated by injection of local anesthetics. Needle instrumentation of the orbit, squeezing of the eyelids, and pressure due to bleeding are additional reasons that regional anesthesia was typically avoided in open-globe scenarios. Nonetheless, some anecdotal case reports of successful use of ophthalmic blocks in this setting have been published.<sup>126</sup> Recognizing that there are several distinct permutations of eye injuries, Scott et al.<sup>127</sup> developed techniques to safely block patients with *select* open-globe injuries. In a 4-year period, 220 disrupted eyes were repaired via regional anesthesia. A significant number of injuries were caused by intraocular foreign bodies and dehiscence of cataract or corneal transplant incisions. Blocked eyes tended to have more anterior, smaller wounds than those repaired via general anesthesia. There was no

outcome difference—that is, change of visual acuity from initial evaluation until final examination—between the eyes repaired via regional versus general anesthesia. Moreover, combined topical anesthesia and sedation for *selected* patients with open-globe injuries has also been reported.<sup>128</sup> Ophthalmologists' shift from the hospital operating room suite to ambulatory surgery facilities and specialty eye-care surgery centers has unbound their ties to hospitals. Many no longer maintain hospital privileges, creating impetus to operate on eye injury patients on an ambulatory surgical basis in their own facilities. For some patients, general anesthesia in an ambulatory surgery center may confer an unacceptable level of systemic risk. In those scenarios, selection of regional or topical anesthesia for repair of traumatic eye injuries may be a prudent alternative.

Nonetheless, general anesthesia remains the accepted modality for many traumatic eye injury patients. Preoperative prophylaxis against aspiration may involve administering H<sub>2</sub> receptor antagonists to elevate gastric fluid pH and to reduce gastric acid production. Metoclopramide may be given to induce peristalsis and enhance gastric emptying.

Traditionally, an induction agent with nondepolarizing neuromuscular blocking drug technique was described as the method of choice for the emergency repair of an open eye injury; however, this method has its disadvantages, including risk of aspiration and difficult airway. Performance of the Sellick maneuver may afford some protection. Furthermore, a premature attempt at intubation of the trachea produces coughing, straining, and a dramatic rise in IOP, emphasizing the need to confirm the onset of drug effect with a peripheral nerve stimulator while appreciating, nonetheless, that muscle groups vary in their response to muscle relaxants. Several studies have explored the use of large doses of nondepolarizing muscle relaxants to accelerate the onset of adequate relaxation for endotracheal intubation. Moreover, the cardiovascular side effects of tachycardia and hypertension may prove worrisome in patients with coronary artery disease.

Succinylcholine offers the distinct advantages of swift onset, superb intubating conditions, and brief duration of action. Although the advisability of this technique has been debated vociferously, McGoldrick<sup>129</sup> pointed out that the 1957 watershed article of Lincoff et al.<sup>14</sup> states: "Various communications have been received from ophthalmologists who have used succinylcholine in surgery. This includes several reports of cases in which succinylcholine was given to forestall impending vitreous prolapse only to have a prompt expulsion of vitreous occur." Under such desperate circumstances, it is extremely difficult to attribute the expulsion of vitreous directly to succinylcholine.<sup>129</sup>

Rocuronium, with its rapid onset, is a useful drug in these circumstances, provided adequate doses (1.2 mg/kg intravenously) are administered.

Unfortunately, it has an intermediate duration of action that could be disadvantageous, compared with succinylcholine, in a patient with an unrecognized difficult airway. Sugammadex may provide a solution. It is an oligosaccharide chelating agent that rapidly reverses the effects of aminosteroid neuromuscular blocking agents, particularly rocuronium. Recovery of over 90% train-of-four responses may be accomplished in less than 120 seconds.<sup>130</sup> Thus, a new paradigm for the “open-globe, full-stomach” scenario may entail rapid-sequence induction with high-dose rocuronium to achieve swift onset of superb intubating conditions, followed by quick termination of neuromuscular blocking effect by sugammadex if one cannot intubate or cannot ventilate.<sup>131</sup> Sugammadex was approved for use in the United States in December 2015.

It was hoped that rapacuronium, with its swift onset, would emerge as a viable alternative to succinylcholine. However, rapacuronium is no longer available in the United States because of its role in triggering intractable bronchospasm in some patients. New ultrashort-acting nondepolarizing alternatives to succinylcholine are currently undergoing clinical investigation in human volunteers.

When confronted with a patient whose airway anatomy or anesthetic history suggests potential difficulties, the anesthesiologist should consult with the ophthalmologist concerning the probability of saving the injured eye. In selected instances, general anesthesia may be avoided by using topical or regional anesthesia. If this approach is not feasible, awake fiberoptic laryngoscopy and intubation may be the safest option, realizing that substantial increases in IOP may occur if the patient gags or coughs. These risks, which can be minimized by thorough topical anesthesia of the airway, assume relative unimportance when balanced against the risk of being unable to ventilate and oxygenate the patient.

### *Intraocular Surgery*

Advances in both anesthesia and in technology now permit a level of controlled intraocular manipulation that was previously not possible (Table 49-5).

Proper control of IOP is crucial for intraocular procedures such as glaucoma drainage surgery, open sky vitrectomy, penetrating keratoplasty (corneal transplantation), and traditional intracapsular cataract extraction. Before scleral incision (when IOP becomes equal to atmospheric pressure), a low-normal IOP is essential because abrupt decompression of a hypertensive eye could result in iris or lens prolapse, vitreous loss, or expulsive choroidal hemorrhage. Available data have not demonstrated a major difference in the rate of complications such as vitreous loss and iris prolapse between local

anesthesia and general anesthesia.

Vitreectomy is generally considered to be a low-risk procedure; however, in recent years, both the anesthesiology and ophthalmology literature have reported cases of sudden death during retina surgery. The presumed etiology is venous air embolism from air introduced into the choroid blood flow via a malpositioned infusion cannula.<sup>132</sup> An in vitro study of pars plana vitrectomy has confirmed the capacity for air infusion into the choroidal space, through the vortex veins, and on to the central circulation.<sup>133</sup> The majority of retina surgery has migrated to ambulatory facilities that are not typically capable of effective resuscitation from profound venous air embolism. It is important for anesthesiologists to confirm that vitreoretinal surgeons are aware of this rare phenomenon such that they ascertain the proper position of the infusion cannula prior to and during air infusion throughout vitrectomy.

Maximal pupillary dilation is important for many types of intraocular surgery and can be induced by continuous infusion of epinephrine 1:200,000 in a balanced salt solution, delivered through a small-gauge needle placed in the anterior chamber. Almost simultaneous with its administration, the drug is removed by aspirating it from the anterior chamber. The iris usually dilates immediately on contact with the epinephrine infusion, and drug uptake is presumably limited by the associated intense vasoconstriction of the iris and ciliary body. However, epinephrine may also be potentially absorbed by drainage through the canal of Schlemm into the venous system or by spillover of the infusion into the conjunctival vessels or drainage to the nasal mucosa.

**Table 49-5** Concerns with Various Ocular Procedures

Procedure	Concerns
Strabismus repair	Oculocardiac reflex Oculogastric reflex Forced duction testing Malignant hyperthermia
Intraocular surgery	Proper control of IOP Akinesia Drug interactions Associated systemic disease
Retinal detachment surgery	Nitrous oxide interaction with air, sulfur hexafluoride, or perfluorocarbon gas bubble Venous air embolism Oculocardiac reflex Proper control of IOP

IOP, intraocular pressure.

## Retinal Detachment Surgery

Surgery to repair retinal detachments involves procedures affecting

intraocular volume, frequently using a synthetic silicone band or sponge to produce a localized or encircling scleral indentation (Table 49-5). Furthermore, internal tamponade of the retinal break may be accomplished by injecting an expandable gas such as sulfur hexafluoride into the vitreous. Because of blood gas partition coefficient differences, the administration of nitrous oxide may enhance the internal tamponade effect of the perfluorocarbon intraoperatively, only to be followed by a dramatic drop in IOP and volume on discontinuation of nitrous oxide. The injected bubble, in the presence of concomitant administration of nitrous oxide, can cause a rapid and dramatic rise in IOP, reaching a peak within 20 minutes<sup>46,134</sup> (see earlier section on Intraocular Perfluorocarbons). Because the resultant rise in IOP may compromise retinal circulation, Stinson and Donlon<sup>134</sup> recommended cessation of nitrous oxide administration 15 minutes before gas injection to prevent significant changes in the volume of the intravitreal gas bubble. Furthermore, Wolf et al.<sup>46</sup> stated that if a patient requires anesthesia after intravitreal gas injection, nitrous oxide should be omitted for 5 days after an air injection and for 10 days after sulfur hexafluoride injection. In cases in which perfluoropropane has been injected, the nitrous oxide proscription should be in effect for longer than 70 days. Alternatively, silicone oil, a vitreous substitute, may be injected to achieve internal tamponade of a retinal break. Moreover, it should be pointed out that cervicofacial subcutaneous emphysema and pneumomediastinum have been reported after the injection of pressurized gas during retinal detachment surgery.<sup>135</sup> Although the precise mechanism of injury remains speculative, it was hypothesized that the pressure indicator for the perfluorocarbon gas injection may have malfunctioned.

It should be emphasized that resorption time is not always uniform or predictable. For example, a diabetic 19-year-old woman was injected with sulfur hexafluoride 25 days before subsequent surgery and a diabetic 37-year-old man was injected with perfluoropropane gas 41 days before subsequent surgery. They were given nitrous oxide and developed central retinal artery occlusion and permanent blindness in the affected eye.<sup>136</sup> Because the pressure in the retinal arterial vessels is lower in patients with diabetes, the elderly, and those with atherosclerosis, these patients are likely at higher risk for this devastating complication.<sup>137,138</sup> The international distributors of medical-grade gases, in cooperation with the American distributors and the FDA, have begun to provide warning bracelets for patients who receive intraocular gas injection to alert health professionals to the presence of the bubble and the need to avoid nitrous oxide administration.

A scleral buckle procedure is basically an extraocular circumglobal placement of a band. During globe manipulation, rotation of the globe with traction on the extraocular muscles may elicit the oculocardiac reflex. The

anesthesiologist must be vigilant about potential cardiac dysrhythmias. Intravenous acetazolamide or mannitol to lower IOP may be requested to soften the globe during buckling.

Anesthesiologists are sometimes faced with the unpopular duty of triaging the order of unscheduled cases. Clearly salvage of life takes priority over salvage of limb, but where do nonelective eye operations fit in? A rhegmatogenous retinal detachment is the most common posterior segment emergency. It occurs when a break or tear in the retina allows vitreous fluid to dissect underneath the retina. There are two types: fovea-sparing and fovea-involving. For the former, the macula remains attached, preserving central vision and retaining high likelihood of ultimately achieving excellent visual acuity. In fovea-involving detachments, the macula is separated, so the prognosis for ultimate visual acuity of 20/40 or better is much lower. Although it seems logical that the sooner the retina is reattached, the better the prognosis, clinical evidence suggests that duration of macular detachment has little to no effect on visual outcome so long as the repair is accomplished within about 1 week.<sup>139</sup> It is generally considered safe to delay surgery to the next available elective surgical slot.<sup>139</sup> Fovea-sparing detachments, however, are more urgent, though still not emergent, and can likely be deferred for 1 to 3 days following the detachment without affecting ultimate visual acuity.<sup>140</sup>

There is debate regarding the urgency of removal of an intraocular foreign body. Studies have suggested that surgery within 72 hours reduces the incidence of vision-threatening endophthalmitis. Recent literature challenges this guiding principle, because not a single case of endophthalmitis or other deleterious side effects arose during Operation Iraqi Freedom and Operation Enduring Freedom despite a 21-day median time to foreign body removal.<sup>141</sup>

## **Strabismus Surgery**

Approximately 3% of the population has malalignment of the visual axes, which may be accompanied by diplopia, amblyopia, and loss of stereopsis (Table 49-5). Indeed, strabismus surgery is the most common pediatric ocular operation performed in the United States, and it entails a variety of techniques to weaken an extraocular muscle by moving its insertion on the globe (recession) or to strengthen an extraocular muscle by eliminating a short strip of the tendon or muscle (resection).

Infantile strabismus occurs within the first 6 months of life and is often observed in the neonatal period. Although most patients with strabismus are healthy, normal children, the incidence of strabismus is increased in those with CNS dysfunction such as cerebral palsy and meningomyelocele with hydrocephalus. Moreover, strabismus may be acquired secondary to

oculomotor nerve trauma or sensory abnormalities such as cataracts or refractive aberrations.

In addition to the well-known propensity of strabismus surgery to trigger the oculocardiac reflex (previously discussed), strabismus or ptosis patients are thought to have an increased incidence of malignant hyperthermia.<sup>142</sup> This observation is consistent with the impression that people susceptible to malignant hyperthermia often have localized areas of skeletal muscle weakness or other musculoskeletal abnormalities. Although recent studies have challenged this belief, anesthesiologists providing care for eye muscle surgery patients must be cognizant of the theoretically enhanced risk. Other aspects of strabismus surgery of interest to anesthesiologists include succinylcholine-induced interference with the FDT and an increased incidence of postoperative nausea and vomiting.

In formulating a surgical treatment plan for strabismus, ophthalmologists often find the FDT to be exquisitely helpful in differentiating between a paretic muscle and a restrictive force preventing ocular motion. To perform the FDT, the surgeon grasps the sclera of the anesthetized eye with a forceps near the corneal limbus and moves the eye into each field of gaze, concomitantly assessing tissue and elastic properties. This simple test provides valuable clues to the presence and site of mechanical restrictions of the extraocular muscles and is most valuable in patients who have previously undergone strabismus surgery, in those who may have paralysis of one of the extraocular muscles, and in those who have sustained orbital trauma.

France et al.<sup>143</sup> quantitated the magnitude and duration of change of the FDT after succinylcholine administration. They demonstrated that quantification of the force necessary to rotate the globe remained notably increased over control for 15 minutes, even though the rise in IOP and the skeletal muscle paralysis lasted less than 5 minutes. Because succinylcholine interferes with FDT, its use is contraindicated less than 20 minutes before testing. Hence, France et al.<sup>143</sup> suggested performing the FDT on the anesthetized patient while mask inhalation anesthesia is being administered, before intubation of the trachea; after intubation, facilitated by nondepolarizing neuromuscular blocking drugs; or after intubation under moderately deep inhalation anesthesia, unaided by succinylcholine. (As previously discussed, succinylcholine is widely avoided in elective pediatric surgical cases as a result of the FDA warning of rare reports of acute rhabdomyolysis, subsequent hyperkalemia, dysrhythmia, and potential cardiac arrest.)

During surgery, should bradycardia occur, the surgeon is asked to discontinue ocular manipulation, and the patient's ventilatory status and anesthetic depth are quickly assessed. If additional intravenous atropine is indicated, it is not given while the oculocardiac reflex is active in case even

more dangerous cardiac dysrhythmias are triggered.

The SGA is gaining popularity for strabismus surgery in the United States, provided the patient is at minimal risk for aspiration. The laryngeal mask can be inserted without the use of muscle relaxants, causes less hemodynamic perturbation, and is associated with less straining and coughing on removal.

Vomiting after eye muscle surgery is common, giving credibility to the existence of the oculogastric reflex. The administration of droperidol, 0.075 mg/kg at induction of anesthesia before manipulation of the eye, has been shown to reduce the incidence of vomiting after strabismus surgery to a clinically acceptable level of approximately 10% without prolonging recovery time.<sup>144</sup> Moreover, a lower dose of droperidol, 0.02 mg/kg intravenously, administered immediately after anesthetic induction in patients with strabismus may decrease both the incidence and severity of nausea and vomiting.<sup>145</sup> Many physicians stopped using droperidol owing to the FDA's "black box" warning about QT-interval prolongation. However, the droperidol doses used for postoperative nausea and vomiting are extremely low and unlikely to be associated with notable cardiovascular events. Indeed, considerable concern has been expressed about the quality and quantity of evidence and the validity of the FDA conclusion.<sup>146</sup>

Prophylactic intravenous administration of a serotonin receptor antagonist such as ondansetron, dolasetron, or granisetron also appears to be efficacious. Combination therapy consisting of one or two antiemetics, each with a different mechanism of action, plus a glucocorticoid such as dexamethasone has been shown to be efficacious and safe in patients at high risk for postoperative nausea and vomiting.<sup>146</sup> Moreover, a total intravenous technique with propofol has also been associated with a low incidence of emesis after strabismus surgery.<sup>147</sup> In addition, avoiding narcotics may be helpful, although a recent paper found no difference in postoperative nausea or vomiting in children who received a remifentanil–sevoflurane mixture versus sevoflurane without the narcotic.<sup>148</sup> One study demonstrates that the nonopioid analgesic ketorolac, in a dose of 0.75 mg/kg intravenously, provides analgesia comparable with that of morphine in pediatric patients with strabismus, but with a much lower incidence of nausea and vomiting in the first 24 hours.<sup>149</sup>

## *Principles of Laser Therapy*

In 1957, in a laboratory at Columbia University, the first design for the laser was born. The invention has revolutionized industry, refined scientific measurements, provided therapy for countless medical and surgical conditions, and inspired 13 Nobel Prizes. The principle is based on the consequences of a photon meeting an electron in an excited state. Sometimes

the collision produces a second photon that has the same color and direction as the original. When repeated on a large scale, this process creates an orderly beam of light. The term *laser* was coined to describe this photon-cloning effect, and the acronym signifies light amplified by stimulated emission of radiation.

Laser radiation has many notable properties. Because it is monochromatic, all the photons have the same wavelength, energy, and frequency. It is coherent, with all the photons in phase. Moreover, laser radiation is collimated, so its beam is nondivergent. These properties allow the precision that is associated with laser surgery. The amount of radiant energy (joules) absorbed by tissues is the product of power (watts) multiplied by duration (seconds). Surgical lasers typically are used in either a continuous or a pulsed mode.

The effect that a particular laser beam exerts on tissue depends predominantly on its wavelength and power density. A specific laser's wavelength depends on its lasing medium, which also gives the laser its name. In general, the longer the wavelength, the more strongly absorbed the light. The converse is true; the shorter the wavelength, the more scattered the light. The power of the laser beam is converted to heat at a shallow depth. Coherent light of high-power density excels in cutting or vaporizing tissue. Lower-power densities are used to photocoagulate tissue and promote hemostasis. Of course, another variable that can be manipulated to produce a given effect is the duration of contact between laser beam and tissue. Additional uses of lasers of low-power density include the photoactivation of systemically administered dyes to precisely treat localized disease sites, such as with age-related macular degeneration.

Lasers are used to treat a wide spectrum of eye conditions, including three of the most common causes of visual loss in the United States: diabetic retinopathy, glaucoma, and age-related macular degeneration. The use of lasers expanded to include the rapidly growing field of refractive surgery. Argon, krypton, diode, dye-tuned, neodymium: yttrium-aluminum-garnet (Nd:YAG), and excimer lasers are among those commonly used for ophthalmic surgery. Owing to concerns that indirect exposure to laser energy could cause ocular damage to operating room personnel, staff working with or near the laser wear protective goggles designed to block the particular wavelength of light emitted by the laser in use.

The argon laser emits blue-green light with a wavelength of approximately 488 to 515 nm (approximately 0.5  $\mu\text{m}$ ). This laser has low maximum power and is easily transmitted by fiberoptic bundles. Light from the argon laser is strongly absorbed by hemoglobin, melanin, and other pigments, rendering it useful in retinal detachment surgery to photocoagulate or cauterize pigment epithelium and the adjacent neurosensory retina, thus creating an adhesion

between the retina and the “wall of the eye” to keep the retina attached. This photocoagulative property of the argon and similar lasers achieves its therapeutic effect in the treatment of diabetic retinopathy by focal and controlled necrosis of a limited amount of ischemic retina. The argon laser is also used with some efficacy to treat the late complications that can develop in the natural history of retinal vein occlusion. Because emissions of the argon laser can penetrate the cornea and lens, causing severe retinal damage, personnel in the vicinity of the argon laser should wear orange protective goggles.

The Nd:YAG, commonly called the *YAG laser*, emits light in the infrared range (wavelength 1,064 nm [1.06  $\mu\text{m}$ ]) and is useful in posterior lens capsule surgery. The Nd:YAG laser has high-power density and is efficacious in creating an opening in opacified posterior capsule membranes that develop in approximately one-third of cases after phacoemulsification or other extracapsular cataract surgery. Personnel working in the vicinity of this laser should wear green goggles and realize that their ability to detect cyanosis will be impaired.

An excimer laser (sometimes, and more correctly, called an *exciplex laser*) is a form of high-power, ultraviolet chemical laser frequently used in the delicate refractive surgery commonly referred to as *laser corrective surgery* or *LASIK*. The term *excimer* is short for “excited dimer,” and *exciplex* is short for “excited complex.” An excimer laser generally uses a combination of inert gas (argon, krypton, or xenon) and a reactive gas (fluorine or chlorine). Under appropriate conditions of electrical stimulation, a pseudomolecule called a *dimer* is generated, which can exist only in an energized state and gives rise to laser light in the ultraviolet range, typically with wavelengths of 125 to 200 nm. The ultraviolet light from an excimer laser is well absorbed by biologic matter and organic compounds. Instead of burning or cutting material, the excimer laser supplies enough energy to disrupt the molecular bonds of surface tissue through ablation. This property allows removal of exceptionally fine layers of surface material with almost no heating or change to neighboring tissue. These lasers are usually operated with a pulse rate of around 100 Hz and a pulse duration of 10 ns, although some may operate as high as 8 kHz and 30 ns.

Age-related macular degeneration is the most common cause of blindness in the elderly and has become alarmingly prevalent. The treatment of the generally more severe wet form of age-related macular degeneration has interestingly progressed over the years from the initial photocoagulation of the neovascular membrane that develops in the central retina or macula. Cauterization obliterates this membrane but can also damage the adjacent healthy macular tissue. The next modality used to treat age-related macular degeneration was the cold laser to photoactivate an intravenously injected

drug, verteporfin, which chemically changed on light exposure of 693 nm in the presence of oxygen. By precisely applying the cold laser light to the area of the neovascular membrane, the photoactivated verteporfin produced highly reactive oxygen radicals and “selectively” necrosed the diseased tissue. Because of ill effects on nearby healthy tissue, this approach has been superseded by a more effective, nonlaser treatment with intravitreal injection of monoclonal antibody drugs such as ranibizumab (FDA-approved) or bevacizumab (off-label).

## Postoperative Ocular Complications

The incidence of eye injuries associated with nonocular surgery is low. In a study by Roth et al.<sup>150</sup> of 60,965 patients undergoing nonocular surgery from 1988 to 1992, the incidence of eye injury was 0.056% (34 patients). Twenty-one of these 34 patients sustained corneal abrasion, although other injuries included conjunctivitis, blurry vision, red eye, chemical injury, direct ocular trauma, and blindness. Independent risk factors for greater relative risk of ocular injury were protracted surgical procedures, lateral intraoperative positioning, head or neck surgery, general anesthesia, and (for some unknown reason) surgery on a Monday. A specific mechanism of injury could be identified in only 21% of cases. In the ASA Closed Claims Study published in 1992 (which analyzed only cases involving litigation), eye injuries represented merely 3% of all claims, but the serious nature of some of the injuries was reflected in large financial awards.<sup>151</sup> Similar to the findings of Roth et al., the specific mechanism of injury could be ascertained in only a minority of cases. Another Closed Claims Study, published in 2004, examining injuries associated with regional anesthesia, reported that the proportion of regional anesthesia claims linked to eye blocks increased from 2% in the 1980s to 7% in the 1990s.<sup>152</sup> These injuries were typically permanent and related to the anesthesiologist's block technique or patient movement. More than half of the claims resulted in blindness. As sub-Tenon and topical anesthesia for cataract removal became more common, it was thought that a reduction in claims would occur. This has not, in fact, been the case.<sup>153</sup>

Although infrequent and often transient, eye injuries occasionally can result in blindness or more limited but nonetheless permanent visual impairment. Postoperative complications after nonocular surgery include corneal abrasion and minor visual disturbances, chemical injuries, thermal or photic injury, and serious visual disturbances, including blindness. Serious injury may result from such diverse conditions as acute corneal epithelial edema, glycine toxicity and other visual disturbances associated with transurethral resection of the prostate, retinal ischemia, ION, cortical blindness, and acute glaucoma. It appears that certain types of surgery,

including complex spinal surgery in the prone position, operations involving extracorporeal circulation, and neck, nasal, or sinus surgery may increase the risk of serious postoperative visual complications.

## Corneal Abrasion

Although the most common ocular complication of general anesthesia is corneal abrasion,<sup>154</sup> the incidence varies widely, depending on the perioperative circumstances. In a prospective study, Cucchiara and Black<sup>155</sup> found a 0.17% incidence of corneal abrasion in 4,652 neurosurgical patients whose eyes were protected, whereas Batra and Bali<sup>154</sup> a decade earlier reported a 44% incidence of corneal abrasion when eyes were left unprotected and partly open. A more recent study of over 100,000 nonophthalmologic procedures found an incidence of 0.15%, which decreased to 0.079% following a teaching initiative.<sup>156</sup> A variety of mechanisms can result in corneal abrasion, including damage caused by the anesthetic mask, surgical drapes, and spillage of solutions. During intubation of the trachea, moreover, the end of plastic watch bands or hospital identification cards clipped to the laryngoscopist's vest pocket can injure the cornea. Ocular injury may also occur from loss of pain sensation, obtundation of protective corneal reflexes, and decreased tear production during anesthesia. Therefore, it may be prudent to tape the eyelids closed immediately after induction and during mask ventilation and laryngoscopy. In addition to taping the eyelids closed, applying protective goggles and instilling petroleum-based ointments into the conjunctival sac may provide protection. Disadvantages of ointments include occasional allergic reactions; flammability, which may make their use undesirable during surgery around the face and contraindicated during laser surgery; and blurred vision in the early postoperative period. The blurring and foreign body sensation associated with ointments may actually increase the incidence of postoperative corneal abrasions if they trigger excessive rubbing of the eyes while the patient is still emerging from anesthesia. Even water-based (methylcellulose) ointments may be irritating and cause scleral erythema. It would seem prudent, therefore, to close the eyelids with tape during general anesthesia for procedures away from the head and neck. For certain procedures on the face, ocular occluders or tarsorrhaphy may be indicated. Special attention should also be devoted to frequent checking of the eyes during procedures on a prone patient.

Patients with corneal abrasion usually complain of a foreign body sensation, pain, tearing, and photophobia. Pain is typically exacerbated by blinking and ocular movement. It is wise to consider early ophthalmologic consultation. Treatment typically consists of the prophylactic application of antibiotic ointment and patching the injured eye. Although permanent

sequelae are possible, healing usually occurs within 24 hours.

### ***Chemical Injury***

Spillage of solutions during skin preparation may result in chemical damage to the eye. The FDA has reported serious corneal damage from eye contact with Hibiclens, a 4% chlorhexidine gluconate solution formulated with a detergent. Again, with meticulous attention to detail, this misadventure is preventable. Treatment consists of liberal bathing of the eye with balanced salt solution to remove the offending agent. After surgery, it may be desirable to have an ophthalmologist examine the eye to document any residual injury or lack thereof.

### ***Photic Injury***

Direct or reflected light beams may permanently damage the eye. For patients undergoing nonocular laser surgery, the potential for serious injury to the cornea or retina from certain laser beams requires that the patient's eyes be protected with moist gauze pads and metal shields and that operating room personnel wear protective glasses. These goggles must be appropriately tinted for the specific wavelength they are intended to block. Clear goggles may be worn when working with the carbon dioxide laser, whereas for work with the argon, Nd:YAG, or Nd:YAG-KTP (potassium titanyl phosphate) laser, the goggles must be tinted orange, green, or orange-red, respectively.

### ***Mild Visual Symptoms***

After anesthesia, transient mild visual disturbances such as photophobia or diplopia are common. Blurred vision in the early postoperative period may reflect residual effects of petroleum-based ophthalmic ointments or ocular effects of anticholinergic drugs administered in the perioperative period (see Corneal Abrasion).

In contrast, the complaint of postoperative visual loss is rare and is cause for alarm. Several of the following conditions may be associated with visual loss after anesthesia and surgery, and should be included in the differential diagnosis: hemorrhagic retinopathy, retinal ischemia, retinal artery occlusion, ION, cortical blindness, and acute glaucoma.

### ***Hemorrhagic Retinopathy***

Retinal hemorrhages that occur in otherwise healthy people secondary to

hemodynamic changes associated with turbulent emergence from anesthesia or protracted vomiting are termed *Valsalva retinopathy*. Fortunately, these venous hemorrhages are usually self-limiting and resolve completely in a few days to a few months.

Because no visual changes occur unless the macula is involved, most cases are asymptomatic. However, if bleeding into the optic nerve occurs, resulting in optic atrophy, or if the hemorrhage is massive, permanent visual impairment may ensue. In some instances of massive hemorrhage, vitrectomy may offer some improvement.

Retinal venous hemorrhage has also been described after injections of local anesthetics, steroids, or saline into the lumbar epidural space, and these cases have been summarized by Purdy and Ajimal.<sup>157</sup> The patients all received large injections ( $\geq 40$  mL) into the epidural space, and they subsequently developed blurry vision or headaches. On funduscopic examination, retinal hemorrhage was consistently observed. Eight of the nine patients described had complete recovery. It is believed that the hemorrhage is produced by rapid epidural injection, which causes a sudden increase in intracranial pressure. This increase in cerebrospinal fluid pressure causes an increase of retinal venous pressure, which may cause retinal hemorrhages. It is possible that obesity, hypertension, coagulopathies, pre-existing elevated cerebrospinal fluid pressure (as seen in pseudotumor cerebri), and such retinal vascular diseases as diabetic retinopathy may be risk factors. Caution is recommended when injecting drugs or fluid into the epidural space; a slow injection rate and using the minimal volume necessary to accomplish the desired objective are strongly recommended.

Retinal bleeding may also originate from the arterial circulation. This bleeding may be associated with extraocular trauma. Funduscopic examination shows cotton-wool exudates, and this condition is known as *Purtscher retinopathy*. Purtscher retinopathy should be ruled out when a trauma patient complains of postanesthetic visual loss. This condition is associated with a poor prognosis, and most patients sustain permanent visual impairment.

### **Retinal Ischemia**

Retinal ischemia or infarction may also result from direct ocular trauma secondary to external pressure exerted by an ill-fitting anesthetic mask, especially in a hypotensive setting, from embolism during cardiac surgery, or from the intraocular injection of a large volume of sulfur hexafluoride or other gases in the presence of high concentrations of nitrous oxide. It may also result from increased ocular venous pressure associated with impaired venous drainage or elevated IOP.

The importance of carefully positioning patients and scrupulously monitoring external pressure on the eye cannot be overemphasized, especially when the patient is in the prone or jackknife position. When the head is dependently positioned, venous pressure may be elevated. If external pressure is applied to the globe from improper head support, perfusion pressure to the eye is likely to be reduced. An episode of systemic hypotension in this setting could further decrease perfusion pressure and thereby decrease intraocular blood flow, resulting in possible retinal ischemia.

It is imperative that a padded or foam headrest be used for procedures done with patients in the prone position. The patient's eyes must be in the opening of this headrest and they must be checked at frequent intervals for pressure. Alternatively, Mayfield tongs can be used. During some spine procedures, a steep head-down position may be used to decrease venous bleeding and enhance surgical exposure. This position, in combination with deliberate hypotension and infusion of large quantities of crystalloid, may increase the risk of compromising the ocular circulation. It seems prudent to avoid combining these three risk factors to any significant degree.

Central retinal arterial occlusion and branch retinal arterial occlusion are important, and frequently preventable, causes of postoperative visual loss. Most case reports follow spinal, nasal, sinus, or neck surgery, as well as coronary artery bypass graft (CABG) surgery. In addition to external pressure on the eye, causes can include emboli from carotid plaques or other sources as well as vasospasm or thrombosis after radical neck surgery complicated by hemorrhage and hypotension and after intranasal injection of  $\alpha$ -adrenergic agonists. Several cases have followed intra-arterial injections of corticosteroids or local anesthetics in branches of the external carotid artery, with possible retrograde embolization to the ocular blood supply.<sup>158</sup> Mabry<sup>159</sup> suggested that the mechanism of injury involves positioning the needle intra-arterially to produce retrograde flow into the branches of the ophthalmic artery, as well as the perfusion pressure that must be overcome during the injection. Therefore, when injecting in the nasal and sinus areas, topical vasoconstrictors should be applied to decrease the size of the vascular bed, and a small (25-gauge) needle on a low-volume syringe should be used to minimize injection pressure. Moreover, because some cases have followed injections of corticosteroids combined with other drugs, it is believed that this practice may predispose to formation of drug crystals and therefore should be discouraged.

In cases of central retinal arterial occlusion, signs of eye injury including proptosis, chemosis, hyphema, corneal abrasion, and lid bruising are apparent. Pathognomonic findings on funduscopic examination reveal a pale, edematous retina and a cherry-red spot. Platelet-fibrin, cholesterol, calcific, or crystalloid emboli may be found in narrowed retinal arterioles. Embolic or

arteritic causes may be discovered via echocardiogram, carotid ultrasound, and temporal artery biopsy. Computed tomography (CT) and magnetic resonance imaging (MRI) studies are usually negative.

Prevention is much more successful than treatment. It may be possible to apply ocular massage (contraindicated if glaucoma is a possibility) to dislodge an embolus to more peripheral sites, and intravenous acetazolamide and 5% carbon dioxide inhalation have been used to increase retinal blood flow. The prognosis, however, typically is poor, and approximately 50% of patients with central retinal arterial occlusion eventually have optic atrophy.

## **Ischemic Optic Neuropathy**

Ischemic optic neuropathy in the nonsurgical setting is the most common cause of *sudden* visual loss in patients older than 50 years, and it may be either arteritic or nonarteritic. Our discussion is limited to postoperative ION and contrasts the similarities and differences between anterior ION and posterior ION. Because of a perceived increase in the incidence of postoperative visual loss since the mid-1990s, the Committee on Professional Liability of the ASA established the Postoperative Visual Loss Database on July 1, 1999, to better identify associated risk factors so these tragic complications might be prevented in the future.<sup>160</sup> Because the incidence of postoperative vision loss after spine surgery in the prone position is estimated to range from 0.017% to 0.1%, and the condition can occur in healthy individuals of all ages, it would seem prudent to discuss this potential complication preoperatively with the patient during the informed consent process.

### **Anterior Ischemic Optic Neuropathy**

Although the multifactorial pathophysiology of anterior ION has not been completely established, it is believed to involve temporary hypoperfusion or nonperfusion of the vessels supplying the anterior portion of the optic nerve, although intra-axonal edema and disturbed autoregulation to the optic nerve head may also play a role.<sup>161</sup> Coexisting systemic disease, especially involving the cardiovascular system and (to a lesser extent) the endocrine system, is common in patients in whom anterior ION develops. Male gender also strongly predominates. Other risk factors for postoperative anterior ION include CABG and other thoracovascular operations, as well as spinal surgery. Although massive bleeding, anemia, and hypotension are commonly described intraoperative risk factors, a retrospective survey of surgeons who perform spinal fusion surgery disclosed that hypotension and anemia were equally prevalent in patients in whom ION developed and in those in whom it did

not.<sup>161</sup> Other possible risk factors are increased IOP or orbital venous pressure. Although emboli may also play a role, anterior ION is not usually caused by emboli because emboli preferentially lodge in the central retinal artery rather than in the short posterior ciliary arteries that supply the anterior optic nerve.

Increased IOP caused by extrinsic compression of the eye decreases retinal blood flow, which can produce both retinal and optic nerve injuries. Moreover, increased IOP can result from large infusions of crystalloid when the head is steeply dependent, as during many spinal operations.<sup>162</sup> Increased orbital venous pressure results in a decreased perfusion pressure gradient to the optic nerve head. Interestingly, one patient who had ischemic optic neuropathy despite perioperative normotension had marked facial edema after surgery of protracted duration.<sup>162</sup> Similarly, a study in cardiac surgery patients revealed that increases in IOP correlated with the degree of hemodilution and the use of crystalloid priming solution.<sup>163</sup> Patients with anterior ION were more likely to have significant weight gain within 24 hours of open heart surgery, again suggesting the role of elevated ocular venous pressure in impeding blood flow to the optic nerve.

According to Roth and Gillesberg,<sup>158</sup> a complex interaction of factors such as ocular venous pressure, hemodilution, hypotension, release of endogenous vasoconstrictors, and individual risk factors such as atherosclerosis and aberrant optic nerve circulation may be implicated in the development of anterior ION. Therefore, specific recommendations for preventative strategies are elusive. Clearly, however, external pressure on the eyes must be meticulously avoided. It also seems prudent to minimize time in the prone position when the head is notably dependent. In patients with pre-existing cardiovascular disease, significant hypertension, or glaucoma, it seems advisable to maintain systemic blood pressure as close to baseline as possible.<sup>158</sup>

Patients with anterior ION typically have painless visual loss that may not be noted until the first postoperative day (or possibly later), an afferent pupillary defect, altitudinal field defects, and optic disc edema or pallor. MRI or CT initially shows enlargement of the optic nerve. However, optic atrophy is detected by MRI later.

The prognosis for anterior ION varies but is often grim. Although there is no recognized treatment for anterior ION Williams et al.<sup>164</sup> reviewed the various therapies that may be instituted. These include intravenous acetazolamide, furosemide, mannitol, and steroids. Maintaining the head-up position could be helpful if increased ocular venous pressure is operative. Surgical optic nerve sheath fenestration or decompression is not only ineffective but may actually be harmful.<sup>165</sup>

## Posterior Ischemic Optic Neuropathy

The posterior optic nerve has a less luxuriant blood supply than the anterior optic nerve. Most perioperative ION cases associated with spine surgery occur in the posterior optic nerve where there is poor collateral flow, rendering the nerve vulnerable to prolonged pathophysiologic changes in blood flow. In contrast to anterior ION, relatively few cases have been reported after CABG, and posterior ION appears to be less related to coexisting cardiovascular disease. As with anterior ION, male patients outnumber female patients substantially. Many cases have been associated with surgery involving the neck, nose, sinuses, or spine. In approximately one-third of cases reported, facial edema has been noted.<sup>158</sup> Approximately 11% of cases were associated with cardiopulmonary bypass procedures.

Posterior ION is produced by reduced oxygen delivery to the retrolaminar part of the optic nerve. Compression of the pial vessels (supplied by small collaterals from the ophthalmic artery) or embolic phenomena have been postulated to produce ischemia.<sup>158</sup>

A hypoxic insult in this region results in a slower development of ischemic damage, so a symptom-free period often precedes the loss of vision. In some patients, the onset of symptoms may be delayed several days. Typical findings include an afferent pupillary defect or nonreactive pupil. Disc edema is not a feature of posterior ION because of its retro-orbital position. CT scan in the early postoperative period may reveal enlargement of the intraorbital portion of the optic nerve. Bilateral blindness is more common with posterior ION than with anterior ION, possibly indicating involvement of the optic chiasm. Concomitant disease of the eye or ocular blood supply may be related to posterior ION.<sup>158</sup> Some cases may show partial improvement spontaneously, but often no improvement is noted. Steroids may be considered for treatment. Preventive strategies are as outlined for anterior ION.

A review of the first 6 years of cases submitted to the ASA Postoperative Visual Loss Registry found that spinal surgery patients at greatest risk for ION and visual compromise include those with predisposing patient-specific factors, surgery exceeding 6 hours' duration, and blood loss of more than a liter.<sup>166</sup> In the 83 reported cases, there was no causative evidence of traumatic eye injury from edema or direct pressure on the globe. Mean blood pressures and hematocrits varied widely among those who developed postoperative blindness. However, 34% of cases had the lowest mean arterial blood pressure or systolic blood pressure at least 40% below baseline, and in only 6% of cases were the mean arterial or systolic pressures less than 20% below baseline. The ASA practice advisory for perioperative visual loss associated with spine surgery concludes that there is no established "transfusion threshold" and that deliberate intraoperative hypotension during surgery has not been proven as contributory to postoperative loss of vision.<sup>167</sup>

The consultants and specialty society members, however, expressed concern about the use of deliberate hypotension in high-risk patients and recommended that the use of this technique be determined on a case-by-case basis. Further, they recommended that high-risk patients should be positioned so that their heads are level with or higher than the heart, if possible. Patients' heads should be maintained in a neutral forward position, avoiding neck flexion, extension, lateral flexion, or rotation, if at all possible. Finally, consideration should be given to using *staged* spine procedures to avoid excessively protracted periods in the prone position for high-risk patients.

In 2012, the first multicenter study to identify risk factors for ION patients compared with patients without ION after prone spinal fusion surgery using detailed perioperative data was published.<sup>168</sup> Cases with anterior and posterior ION were combined. After multivariate analysis, risk factors for ION after spinal fusion surgery included male sex, obesity, Wilson frame use, prolonged anesthesia duration, greater estimated blood loss, and lower-percent colloid administration. No statistically significant independent effect on ION of older age, hypertension, atherosclerosis, smoking, or diabetes was identified. These findings suggest that the etiology of ION may be more heavily influenced by intraoperative factors than by any known pre-existing comorbidities or vasculopathy. Fully half of the risk factors strongly support the speculation that acute venous congestion of the optic canal is a potential contributor to ION in this setting.<sup>169</sup> Perhaps over time, investigators will be able to determine what role, if any, an inflammatory response, either locally or systemically, plays in the genesis of ION.<sup>169</sup>

## **Cortical Blindness**

Brain injury rostral to the optic nerve may cause cortical blindness. The impairment is produced by damage to the visual path beyond the lateral geniculate nucleus or the visual cortex in the occipital lobe. Similar to anterior ION, cortical blindness is a significant concern in patients undergoing CABG, and systemic disease is often present. Emboli and sustained profound hypotension are common causes. Other events implicated in the pathophysiology include cardiac arrest, hypoxemia, intracranial hypertension, exsanguinating hemorrhage, vascular occlusion, thrombosis, and vasospasm.

Differential diagnostic features include a normal optic disc on fundoscopy and normal pupillary responses. There is, however, loss of optokinetic nystagmus with normal eye motility. CT and MRI are helpful in delineating the extent of brain infarction associated with cortical blindness. Occipital lesions are frequently bilateral, and CT findings typically indicate posterior cerebral artery thrombosis, basilar artery occlusion, posterior cerebral artery branch occlusion, or watershed infarction. Lesions after CABG often include

the parieto-occipital area.

Whereas most cases of ION do not improve significantly or completely, visual recovery from cortical blindness in previously healthy patients may be considerable but prolonged. Preventive strategies include maintenance of adequate systemic perfusion pressure and, in cardiac surgery, minimizing manipulation of the aorta, meticulous removal of air and particulate matter during valvular procedures, and use of an arterial line filter in selected patients during bypass.

### **Acute Glaucoma**

Although topical application of mydriatic atropine and scopolamine is contraindicated in patients with known chronic glaucoma, the systemic use of anticholinergics in usual doses is safe for glaucomatous eyes. The atropine–neostigmine combination for reversal of neuromuscular blockade is also considered safe. Topical ophthalmic medications administered to control glaucoma should be continued through the perioperative period.

Acute angle-closure glaucoma typically occurs spontaneously but has been reported, albeit rarely, after both spinal and general anesthesia. Acute angle-closure glaucoma caused by pupillary block is a serious, multifactorial disease. Risk factors include genetic predisposition, shallow anterior chamber depth, increased lens thickness, small corneal diameter, female gender, and advanced age. One study<sup>170</sup> explored possible precipitating events in at-risk patients and found no evidence that the type of anesthetic agent, the duration of surgery, the volume of parenteral fluids, or the intraoperative blood pressure were related to the development of acute angle-closure glaucoma.

Despite its seriousness, acute angle-closure glaucoma may be difficult to recognize.<sup>171</sup> However, physicians should be knowledgeable about this potential complication because diagnostic delay may detrimentally affect visual outcome and cause permanent optic nerve damage. Those patients considered at risk should undergo a preoperative ophthalmic evaluation and perioperative miotic therapy. After surgery, these patients should be scrupulously watched for red eye or a fixed dilated pupil, as well as for complaints of pain and blurred vision. Acute glaucoma is a true emergency, and ophthalmologic consultation should be secured immediately to acutely decrease IOP with systemic and topical therapy. The intense periorbital pain typically described by these patients is an important aid in differential diagnosis.

### **Postcataract Ptosis**

Ptosis after cataract surgery is not uncommon, and multiple factors have been

implicated in its etiology.<sup>172,173</sup> These include the presence of a preexisting ptosis, injection of anesthetic solution into the upper lid when performing facial nerve block, injection of local anesthesia through the upper eyelid at the 12 o'clock position, ocular compression or massage, use of the eyelid speculum, placement of a superior rectus bridle suture with traction on the superior rectus–levator complex, creation of a large conjunctival flap, prolonged or tight patching in the postoperative period, and postoperative eyelid edema. Feibel et al.<sup>172</sup> believed that the development of postcataract ptosis is multifactorial and that no single aspect of cataract surgery is the sole contributor. Taylor et al.<sup>173</sup> used MRI immediately after diagnosis of diplopia in four patients who received extraconal block. They found peribulbar edema consistent with direct local anesthetic–induced myotoxicity after presumed inadvertent intramuscular injection. Although local anesthetics are clearly myotoxic, the local anesthetic injection cannot be isolated as the primary factor because postsurgical ptosis is also seen in patients undergoing surgery with general anesthesia.

## **KEY POINTS**

- 1 Renal filtration and reabsorption are susceptible to alterations by surgical illness and anesthesia. Autoregulation of renal blood flow (RBF) is effective over a wide range of mean arterial pressures (50 to 150 mmHg). Autoregulation of urine flow does not occur, but a linear relationship between mean arterial pressure above 50 mmHg and urine output is observed.
- 2 Renal medullary blood flow is low (2% of total RBF) but central to the kidneys' ability to concentrate urine. During periods of reduced renal perfusion, the metabolically active medullary thick ascending limb may be especially vulnerable to ischemic injury.
- 3 The physiologic response to surgical stress invokes intrinsic mechanisms for sodium and water conservation. Renal cortical vasoconstriction causes a shift in perfusion toward juxtamedullary nephrons, a decrease in glomerular filtration rate, and retention of salt and water result.
- 4 The stress response may induce a decrease in RBF and glomerular filtration rate, causing afferent arteriolar vasoconstriction. If this situation is not reversed, ischemic damage to the kidney may result in acute renal failure (ARF).
- 5 Anesthetic-induced reductions in RBF have been described for many agents but are usually clinically insignificant and reversible. Likewise, anesthetic agents have not been shown to interfere with the renal response to physiologic stress.
- 6 Isolated ARF carries a mortality of up to 80% in surgical patients, with

- acute tubular necrosis being the cause of ARF in most of these patients.
- 7 Surgical patients with non–dialysis-dependent chronic kidney disease are at higher risk of developing end-stage renal disease. The single most reliable predictor of new postoperative need for dialysis is preoperative renal insufficiency.
  - 8 Overall, there are no conclusive comparative studies demonstrating superior renal protection or improved renal outcome with general versus regional anesthesia.
  - 9 Maintaining adequate intravascular volume and hemodynamic stability with aggressive management of kidney hypoperfusion is a basic principle of anesthetic care to prevent acute kidney injury.
  - 10 Urologic patients are often elderly, have numerous comorbidities, and require critical evaluation prior to any urologic procedure.
  - 11 Combining epidural with general anesthetic techniques for some major urologic surgeries may offer advantages for accelerated recovery, improved analgesia, and even better outcomes, but these techniques must be conducted with respect for other perioperative issues, including thromboprophylaxis for prevention of deep venous thrombosis.
  - 12 Watchful waiting, minimally invasive principles, and technologic innovation (e.g., laparoscopy, robotics) have changed the favored approach to many kidney, bladder, and prostate disorders, in some cases reducing the number of high-risk surgeries, in others creating other safer and less morbid alternate treatments.
  - 13 Absorption of irrigating solution related most often to transurethral prostate or bladder tumor resections can cause “TUR syndrome,” a condition that while becoming less common has the potential to be serious and even life-threatening during the several hours following surgery. Knowledge of specific concerns relevant to the different irrigating solutions, vigilance of the anesthesiologist to factors that minimize absorption, recognition of signs and symptoms, and appropriate treatment, are key to favorable outcomes with this condition.

## Introduction and Context

The kidney plays a central role in implementing and controlling a variety of homeostatic functions; these include tight control of extracellular fluid volume and composition and efficient excretion of uremic toxins in the urine. Acute kidney injury (AKI) disturbs such functions and can occur as a result of systemic inflammation, nephrotoxin exposure, or prolonged reduction in renal oxygen delivery due to surgical or medical disease; practically speaking, several factors are often identified. The first part of this chapter reviews renal physiology and pathophysiologic states as they relate to anesthetic practice

and then addresses strategies to recognize and manage patients at risk for AKI and renal failure. The second part describes current urologic procedures and their attendant anesthetic management issues.

## Renal Anatomy and Physiology

### Gross Anatomy

The two normal *kidneys* are reddish-brown organs and are ovoid in outline, but the medial margin is deeply indented and concave at its middle, where a wide, vertical cleft (the hilus) transmits items entering and leaving the kidney (Fig. 50-1). The *hilus* lies at approximately the level of the first lumbar vertebra. The kidneys lie in the paravertebral gutters, behind the peritoneum, with the right kidney resting slightly lower than the left one owing to the presence of the liver. At its upper end, the ureter is dilated to give rise to the *renal pelvis*, which passes through the hilus into the kidney proper. There it is continuous with several short funnel-like tubes (calyces) that unite it with the renal parenchyma. The renal blood vessels lie anterior to the pelvis of the kidney, but some branches may pass posteriorly. Renal pain sensation is conveyed back to spinal cord segments T10 through L1 by sympathetic fibers. Sympathetic innervation is supplied by preganglionic fibers from T8 to L1. The vagus nerve provides parasympathetic innervation to the kidney, and the S2 to S4 spinal segments supply the ureters.

Each kidney is enclosed in a thick, fibrous capsule, itself surrounded by a fatty capsule that fills the space inside a loosely applied renal (Gerota) fascia. The developing kidney is first formed in the pelvis and then ascends to its final position on the posterior abdominal wall. During its ascent, the kidney receives blood supply from several successive sources, such that an accessory renal artery from the aorta may be found entering the lower pole of the kidney. When first formed, the rudimentary kidneys are close together and may fuse to give rise to a horseshoe kidney. This organ is unable to ascend, “held in place” by the inferior mesenteric artery, and thus when present it remains forever a pelvic organ.

The *bladder* is located in the retropubic space and receives its innervation from sympathetic nerves originating from T11 to L2, which conduct pain, touch, and temperature sensations, whereas bladder stretch sensation is transmitted via parasympathetic fibers from segments S2 to S4. Parasympathetics also provide the bladder with most of its motor innervation.

The *prostate*, *penile urethra*, and *penis* also receive sympathetic and parasympathetic fibers from the T11 to L2 and S2 to S4 segments, respectively. The pudendal nerve provides pain sensation to the penis via the dorsal nerve of the penis. Sensory innervation of the *scrotum* is via cutaneous

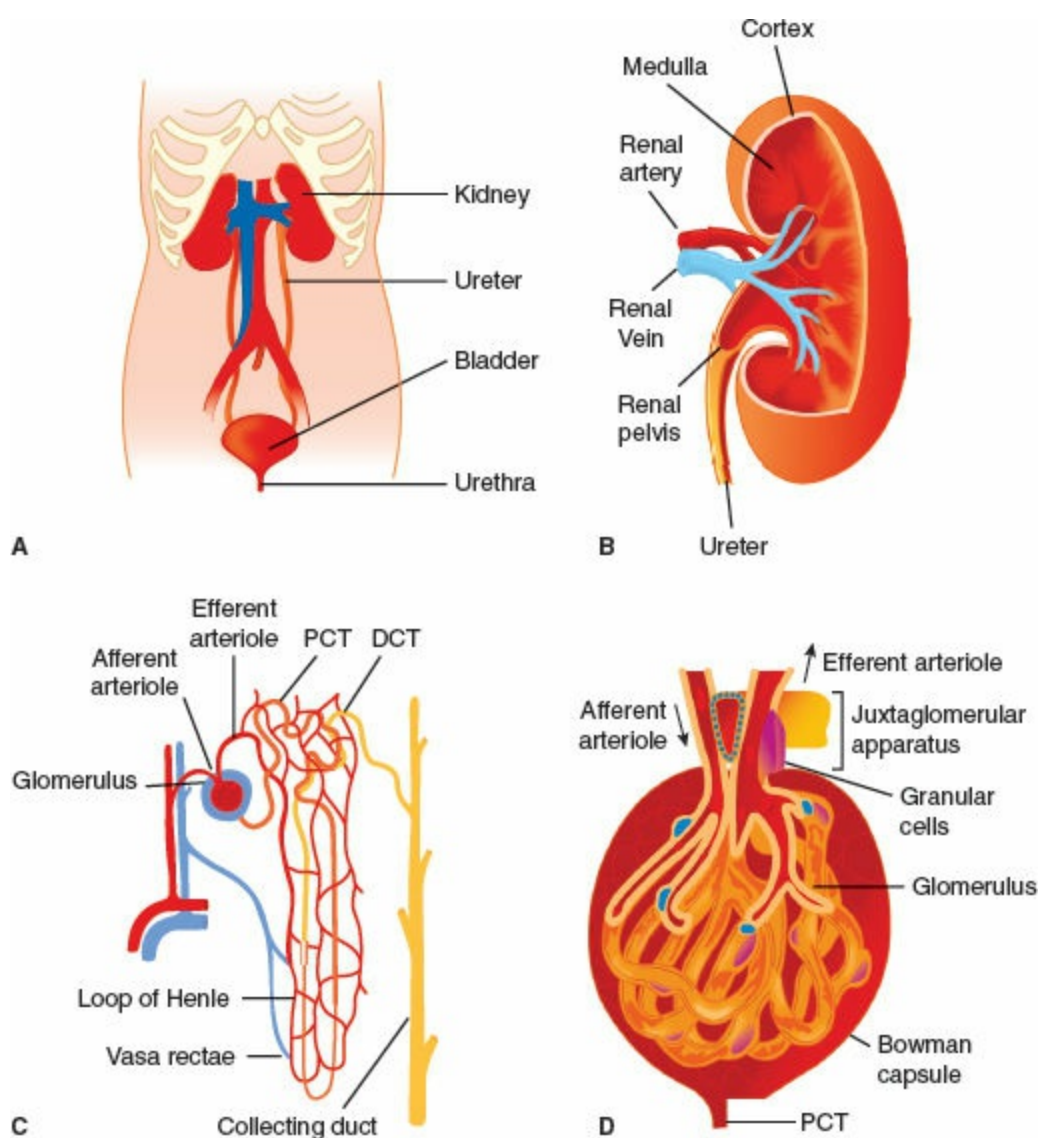

nerves, which project to lumbosacral segments, whereas testicular sensation is conducted to lower thoracic and upper lumbar segments.

## Ultrastructure

Inspection of the cut surface of the kidney reveals the paler *cortex*, adjacent to the capsule, and the darker, conical pyramids of the renal *medulla* (Fig. 50-1). The pyramids are radially striated and are covered with cortex, extending into the kidney as the renal columns. *Collecting tubules* from each lobe of the kidney (pyramid and its covering of cortex) discharge urine into the calyceal system via renal papillae at the entrance of each pyramid into the calyx proper. These collecting tubules originate deep within the radial striations (medullary rays) of the kidney and convey urine formed in the structural units of the kidneys, the *nephrons*. The parenchyma of each kidney contains approximately  $1 \times 10^6$  tightly packed nephrons, each one consisting of a tuft of capillaries (the *glomerulus*) invaginated into the blind, expanded end (glomerular corpuscle) of a long tubule that leaves the renal corpuscle to form the proximal convoluted tubule in the cortex. This leads into the straight tubule, which loops down into the medullary pyramid (*loop of Henle*) and hence back to the cortex to become continuous with the distal convoluted tubule. This then opens into a collecting duct that is common to a number of nephrons and passes through the pyramid to enter the lesser calyx at the papilla. It is in these parts of the nephron (proximal tubule, loop of Henle, distal tubule, and collecting duct) that urine is formed, concentrated, and conveyed to the ureters. The distal convoluted tubule comes into very close contact with the afferent glomerular arteriole, and the modified cells of each form the *juxtaglomerular apparatus*, a complex physiologic feedback control mechanism contributing in part to the precise control of intra- and extrarenal hemodynamics that is a hallmark feature of the normally functioning kidney.

As is the case for the renal tubules, the vasculature of the kidney is highly organized. The renal artery enters the kidney at the hilum and then divides many times before producing the arcuate arteries that run along the boundary between cortex and outer medulla. Interlobular arteries branch from arcuate arteries toward the outer kidney surface, giving rise as they pass through the cortex to numerous afferent arterioles, each leading to a single glomerular capillary tuft. The barrier where filtration from the vascular to tubular space within the glomerulus occurs is highly specialized and includes fenestrated negatively charged capillary endothelial cells and tubular epithelial cells (podocytes) separated by a basement membrane. Normally, selective permeability permits approximately 25% of the plasma elements to pass into the Bowman capsule; only cells and proteins more than 60 to 70 kDa cannot cross. However, abnormalities of this barrier can occur with disease, which

may permit filtration of much larger proteins and even red blood cells; these changes manifest as the *nephrotic syndrome* (proteinuria >3.5 g/24 hr) or *glomerulonephritis* (hematuria and proteinuria). The glomerular capillaries exit Bowman capsule and merge to form the efferent arteriole and peritubular capillaries that nourish the tubules. The renal vasculature is unusual in having this arrangement of two capillary beds joined in series by arterioles. Blood supply to the entire tubular system comes from the glomerular efferent arteriole, which branches into an extensive capillary network. Some of these peritubular capillaries, the *vasa recta*, descend deep into the medulla to parallel the loops of Henle. The vasa recta then return in a cortical direction with the loops, join other peritubular capillaries, and empty into the cortical veins.

**Figure 50-1** **A:** The gross anatomy and internal structure of the genitourinary system and kidney. **B:** Internal organization of the kidney includes cortex and medulla regions and the vasculature. **C:** The nephron is the functional unit of the kidney. **D:** Plasma filtration occurs in the glomerulus; 20% of plasma that enters the glomerulus passes through the specialized capillary wall into the Bowman capsule and enters the tubule to

be processed and generate urine. PCT, proximal convoluted tubule; DCT, distal convoluted tubule.

## Correlation of Structure and Function

Because renal tissue makes up only 0.4% of body weight but receives 25% of cardiac output, the kidneys are by far the most highly perfused major organs in the body, and this facilitates plasma filtration at rates as high as 125 to 140 mL/min in young adults. The functions of the kidney are many and varied, including waste filtration, endocrine and exocrine activities, immune and metabolic functions, and maintenance of physiologic homeostasis. As well as tight regulation of extracellular solutes such as sodium, potassium, hydrogen, bicarbonate, and glucose, the kidney also generates ammonia and glucose and eliminates nitrogenous and other metabolic wastes including urea, creatinine, bilirubin, and other uremic toxins (i.e., substances that have toxic effects when they accumulate due to renal impairment). Finally, circulating hormones secreted by the kidney influence red blood cell generation, calcium homeostasis, and systemic blood pressure.

The kidney fulfills its dual roles of toxin excretion and body fluid management by filtering large amounts of fluid and solutes from the blood and secreting waste products into the tubular fluid. Effects on the normal filtration and reabsorption processes of comorbid disease, surgery, and anesthesia are the focus of the next section.

## Glomerular Filtration

Production of urine begins with water and solute filtration from plasma flowing into the glomerulus via the afferent arteriole. The *glomerular filtration rate* (GFR) is a measure of glomerular function expressed as milliliters of plasma filtered per minute. The *ultrafiltration constant* ( $K_f$ ) is directly related to glomerular capillary permeability and glomerular surface area. The two major determinants of filtration pressure are glomerular capillary pressure ( $P_{GC}$ ) and glomerular oncotic pressure ( $p_{gc}$ ).  $P_{GC}$  is directly related to renal artery pressure and is heavily influenced by arteriolar tone at points upstream (afferent) and downstream (efferent) from the glomerulus. An increase in afferent arteriolar tone, as occurs with intense sympathetic or angiotensin II stimulation, causes filtration pressure and GFR to fall. Milder degrees of sympathetic or angiotensin activity cause a selective increase in efferent arteriolar tone, which tends to increase filtration pressure and GFR. The  $p_{gc}$  is directly dependent on plasma oncotic pressure. Afferent arteriolar dilatation enhances GFR by increasing glomerular flow, which in turn elevates glomerular capillary pressure. Recent general revisions of Starling's original

formula to incorporate the newly appreciated importance of the endothelial glycocalyx layer also appear to be relevant to glomerular filtration, particularly for pathologic states that involve proteinuria (e.g., diabetic nephropathy).<sup>1-3</sup>

## Autoregulation of Renal Blood Flow and Glomerular Filtration Rate

Renal blood flow (RBF) *autoregulation* maintains relatively constant rates of RBF and glomerular filtration over a wide range of arterial blood pressure. Renal autoregulation of blood flow and filtration is accomplished primarily by local feedback signals that modulate glomerular arteriolar tone to protect the **1** glomeruli from excessive perfusion pressure (Fig. 50-2).

In health, autoregulation of RBF is effective over a wide range of systemic arterial pressures. Several mechanisms for regulating blood flow to the glomerulus have been described, and all involve modulation of afferent glomerular arteriolar tone. The *myogenic reflex theory* holds that an increase in arterial pressure causes the afferent arteriolar wall to stretch and then constrict (by reflex); likewise, a decrease in arterial pressure causes reflex afferent arteriolar dilatation. The other proposed mechanism of RBF autoregulation is a phenomenon called *tubuloglomerular feedback*, which is also responsible for autoregulation of GFR.

**Figure 50-2** Renal blood flow (RBF) autoregulation maintains RBF and glomerular filtration rate (GFR) relatively constant with changes in systolic blood pressure from about 80 to 200 mmHg. (Adapted with permission from [http://www2.kumc.edu/ki/physiology/course/two/2\\_8.htm](http://www2.kumc.edu/ki/physiology/course/two/2_8.htm).)

Tubuloglomerular feedback allows the composition of distal tubular fluid to influence glomerular function through actions involving the juxtaglomerular apparatus. When RBF falls, the related decrease in GFR causes less chloride delivery to the juxtaglomerular apparatus, which in turn induces afferent arteriole dilation. As a result, glomerular flow and pressure

then increase, and GFR returns to previous levels. Chloride also acts as the feedback signal for control of efferent arteriolar tone. When GFR falls, declining chloride delivery to the juxtaglomerular apparatus triggers release of *renin*, which ultimately causes the formation of *angiotensin II*. In response to angiotensin, efferent arteriolar constriction increases glomerular pressure, which increases glomerular filtration. It is important to realize that autoregulation of urine flow does not occur, and that above a mean arterial pressure of 50 mmHg there is a linear relationship between mean arterial pressure and urine output.

## **Tubular Reabsorption of Sodium and Water**

Active, energy-dependent reabsorption of sodium begins almost immediately as the glomerular filtrate enters the proximal tubule. Here, an adenosine triphosphatase pump drives the sodium into tubular cells while chloride ions passively follow. Glucose, amino acid, and other organic compound reabsorption are strongly coupled to sodium in the proximal tubule. Normally, the proximal tubule reabsorbs two-thirds of the filtered sodium. Notably, no active sodium transport occurs in the loop of Henle until the medullary thick ascending limb is reached. Cells of the medullary thick ascending limb are metabolically active in their role of reabsorbing sodium and chloride and have a high oxygen consumption compared with the thin portions of the descending and ascending limbs. 2

Reabsorption of water is a passive, osmotically driven process tied to the reabsorption of sodium and other solutes. Water reabsorption also depends on peritubular capillary pressure; high capillary pressure opposes water reabsorption and tends to increase urine output. The proximal tubule reabsorbs approximately 65% of filtered water in an isosmotic fashion with sodium and chloride. The descending limb of the loop of Henle allows water to follow osmotic gradients into the renal interstitium. However, the thin ascending limb and medullary thick ascending limb are relatively impermeable to water and play a key role in the production of concentrated urine. Only 15% of filtered water is reabsorbed by the loop of Henle; the remaining filtrate volume flows into the distal tubule. There, and in the collecting duct, water reabsorption is controlled entirely by *antidiuretic hormone* (ADH) secreted by the pituitary gland. Conservation of water and excretion of excess solute by the kidneys would be impossible without the ability to produce concentrated urine. This is accomplished by establishing a hyperosmotic medullary interstitium and regulation of water permeability of the distal tubule and collecting duct via the action of ADH.

ADH increases the water permeability of the collecting ducts and allows for passive diffusion of water (under considerable osmotic pressure) back into

the circulation. The posterior pituitary gland releases ADH in response to an increase in either extracellular sodium concentration or extracellular osmolality. In addition, ADH release can be triggered by an absolute or relative reduction in intravascular fluid volume. The arterial baroreceptors are activated when hypovolemia leads to a decrease in blood pressure, whereas atrial receptors are stimulated by a decline in atrial filling pressure. Both of these circulatory reflex systems stimulate release of ADH from the pituitary and cause retention of water by the kidney in an effort to return the intravascular volume toward normal. ADH also causes renal cortical vasoconstriction when it is released in large amounts, such as during the physiologic stress response to trauma, surgery, or other critical illness. This induces a shift of RBF to the hypoxia-prone renal medulla.

### *The Renin–Angiotensin–Aldosterone System*

*Renin* release by the afferent arteriole may be triggered by hypotension, decreased tubular chloride concentration, or sympathetic stimulation. Renin enhances *angiotensin II* production, which in turn induces renal efferent arteriolar vasoconstriction. Angiotensin II also promotes ADH release from the posterior pituitary, sodium reabsorption by the proximal tubule, and aldosterone release by the adrenal medulla. *Aldosterone* stimulates the distal tubule and collecting duct to reabsorb sodium (and water), resulting in intravascular volume expansion. Sympathetic nervous system stimulation may also directly cause release of aldosterone. This leads to renal cortical vasoconstriction, a decrease in GFR, and salt and water retention.

### *Renal Vasodilator Mechanisms*

Opposing the saline retention and vasoconstriction observed in stress states are the actions of *atrial natriuretic peptide* (ANP), *nitric oxide*, and the renal *prostaglandin* system. ANP is released by the cardiac atria in response to increased stretch under conditions of volume expansion. Both natriuresis and aquaresis increase as ANP blocks reabsorption of sodium in the distal tubule and collecting duct. ANP also increases GFR, causes systemic vasodilatation, inhibits the release of renin, opposes production and action of angiotensin II, and decreases aldosterone secretion.<sup>4</sup> Likewise, nitric oxide produced in the kidney opposes the renal vasoconstrictor effects of angiotensin II and the adrenergic nervous system, promotes sodium and water excretion, and participates in tubuloglomerular feedback.

Prostaglandins are produced by the kidney as part of a complex system that modulates RBF and opposes the actions of ADH and the renin–angiotensin–aldosterone system. Stress states, renal ischemia, and hypotension stimulate the production of renal prostaglandins through the

enzymes phospholipase A<sub>2</sub> and cyclooxygenase. Prostaglandins produced by cyclooxygenase activity cause dilatation of renal arterioles (antiangiotensin II), whereas their distal tubular effects result in an increase in sodium and water excretion (anti-ADH and aldosterone). The renal prostaglandin system is important in maintaining RBF and sodium and water excretion during times of high physiologic stress and poor renal perfusion.

## Clinical Assessment of the Kidney

Most agree that immediate perioperative measures such as urine output correlate poorly with perioperative renal function<sup>4</sup>; however, much about the kidneys can be learned from knowing how effectively they clear circulating substances and inspection of the urine (i.e., urinalysis).

### Renal Function Tests

Filtration is a useful method to clinically assess kidney function. As a key indicator of disease, knowledge of limited filtration capacity is important to guide drug dosing for agents cleared by the kidneys and helps with preoperative risk stratification. Also, acute declines in filtration capacity indicate kidney injury and predict a more complicated clinical course.<sup>5</sup> *GFR*, as previously mentioned, refers to the plasma volume filtered per unit time by the kidneys, and normal values range from 90 to 140 mL/min. Normal GFRs relate to the patient age, size, and gender. In general, GFR declines 10% per decade after age 30 and is approximately 10 mL/min higher in men than women. A GFR below 60 mL/min meets criteria for chronic kidney disease (CKD) and is considered impaired, whereas values lower than 15 mL/min are often associated with uremic symptoms and may require dialysis.

An “ideal” substance to assess GFR through its clearance from the circulation must have specific properties, including a steady supply, free filtration, and no tubular reabsorption or excretion; ideally, it is also cheap and easy to measure. Unfortunately, the perfect ideal substance is yet to be identified. The gold standard GFR tools involve expensive and cumbersome measurements (e.g., inulin, <sup>51</sup>Cr-EDTA or <sup>99</sup>Tc-DTPA clearance), whereas the most practical and inexpensive test involves an imperfect ideal substance, *creatinine*. However, despite creatinine’s limitations, its relatively steady supply from muscle metabolism, modest tubular secretion, and proven usefulness in numerous clinical settings make it the most used renal filtration marker currently available. Although more ideal substances and other “early biomarkers” of AKI are being evaluated as clinical tools, current candidates (e.g., cystatin C) have yet to replace creatinine. The reader is referred to recent reviews on this subject.<sup>9,10</sup>

Estimates of GFR (eGFR) can be made by determining *creatinine clearance* (CrCl) from urine and blood creatinine tests. In stable, critically ill patients, 2-hour urine collections are sufficient to calculate CrCl,<sup>11</sup> using the following formula:

$$\text{CrCl (mL/min)} = \frac{(\text{U}_{\text{cr}} \text{ (mg/dl)} \times \text{V (ml)})}{(\text{P}_{\text{cr}} \text{ (mg/dl)} \times \text{time (min)})}$$

where  $\text{U}_{\text{cr}}$  = urine creatinine,  $\text{V}$  = total volume of urine collected,  $\text{P}_{\text{cr}}$  = plasma creatinine, and time = collection time.

However, if patient characteristics are known, GFR can also be estimated from a single steady-state serum creatinine value. Notably, predictive formulas are developed using data from stable (nonsurgical) populations, and factors such as fluid shifts, hemodilution, and hemorrhage add an “unsteadiness” to perioperative estimates of GFR using serum creatinine.

Nonetheless, serum creatinine remains, so far, an unsurpassed perioperative tool, particularly to reflect *trends* of change in renal filtration and to predict outcome, even during the perioperative period.<sup>12–14</sup> Of the predictive formulas, the Cockcroft–Gault equation is one of the oldest and most durable.<sup>15</sup> The Cockcroft–Gault equation uses patient gender, age (years), weight (kg), and serum creatinine (mg/dL):

$$\text{Cockcroft–Gault eGFR (mL/min)} = \frac{(140 - \text{age}) \times \text{weight (kg)}}{(\text{Cr} \times 72)(\times 0.85 \text{ for female patients})}$$

More recently, a method developed from the Modification of Diet in Renal Disease (MDRD) study that adds other factors including ethnicity (black versus nonblack) to Cockcroft–Gault equation has gained popularity.<sup>16</sup>

An abbreviated MDRD formula is available that can estimate GFR measured in milliliters per minute per 1.73 m<sup>2</sup>:

$$\text{GFR} = 186 \times (\text{serum creatinine} - \text{mg/dL})^{-1.154} \times (\text{age})^{-0.203} \\ (\times 0.742 \text{ for female patients}) \\ (\times 1.210 \text{ for black patients})$$

However, even a detailed MDRD eGFR under ideal conditions sometimes correlates poorly with a gold standard–determined GFR, with more than a 30% error in 10% of patients, and 2% deviating more than 50%.<sup>16</sup>

Some consensus definitions for significant perioperative renal dysfunction exist. The Society of Thoracic Surgeons defines postoperative AKI as either a new requirement for dialysis or a rise in serum creatinine to greater than 2 mg/dL involving at least a 50% increase in serum creatinine above baseline.<sup>17</sup> Another definition requires a creatinine rise of greater than 25% or 0.5 mg/dL (44 mmol/L) within 48 hours.<sup>18</sup> The Acute Dialysis Quality Initiative Group

definition for critically ill patients grades AKI by an acute creatinine rise of 50% as “risk,” 100% as “injury,” or 200% as “failure” (the RIFLE criteria).<sup>19</sup> The Acute Kidney Injury Network definition, a 1.5-fold or 0.3 mg/dL ( $\geq 26.4$  mmol/L) creatinine rise within a 48-hour period or more than 6 hours of oliguria ( $>0.5$  mL/kg/hr), is a modification of its RIFLE predecessor.<sup>19,20</sup> The most recent consensus definition for AKI comes from Kidney Disease Improving Global Outcomes (KDIGO): an increase in serum creatinine by at least 0.3 mg/dL ( $\geq 26.5$   $\mu$ mol/L) within 48 hours; or increase in serum creatinine to at least 1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or urine volume below 0.5 mL/kg/h for 6 hours.<sup>21</sup> Notably, serum creatinine does not usually rise significantly until GFR rates fall below 50 mL/min, so preoperative serum creatinine may be normal in patients even with some degree of renal dysfunction (Fig. 50-3).

*Blood urea nitrogen* (BUN) is sometimes used to assess renal function but possesses few of the characteristics of an ideal substance for such a task. Tubular urea transport changes with some conditions (e.g., dehydration), and urea generation can be highly variable, particularly during the postoperative period (i.e., catabolic state). In addition, hemodilution (e.g., cardiopulmonary bypass [CPB]) may affect circulating BUN levels.

### *Urinalysis and Urine Characteristics*

Urine inspection can reveal abnormal cloudiness or color and unexpected odors. Detailed descriptions of urine examination are available<sup>22</sup>; therefore, only a summary is provided here. Cloudy urine is due to suspended elements such as white or red blood cells and/or crystals. Lightly centrifuged urine sediment will normally contain  $80 \pm 20$  mg of protein per day and up to two red blood cells per high-power field ( $400\times$ ); higher levels of red blood cells or protein reflect abnormal kidney function. Urine protein electrophoresis can differentiate proteinuria from a glomerular (filtering), tubular (reuptake), overflow (supply that saturates the reuptake system), or tissue (e.g., kidney inflammation) abnormality. In contrast, color changes reflect dissolved substances; this occurs most commonly with dehydration, but other causes include food colorings, drugs, and liver disease (e.g., bilirubin). Unusual odors are less common but can also be diagnostic (e.g., maple syrup urine disease). Chromogenic dipstick chemical tests can determine urine pH and provide a semiquantitative analysis of protein, blood, nitrites, leukocyte esterase, glucose, ketones, urobilinogen, and bilirubin. In addition, microscopy can identify crystals, cells, tubular casts, and bacteria.

Urine *specific gravity* (the weight of urine relative to distilled water) normally ranges between 1.001 and 1.035 and can be used as a surrogate for osmolarity (normal 50 to 1,000 mOsm/kg), with 1.010 reflecting a specific gravity similar to that of plasma. High specific gravity ( $>1.018$ ) implies

preserved renal concentrating ability, unless high levels of glucose, protein, or contrast dye injection have raised specific gravity without significantly changing osmolarity.

Although poor urine output (e.g., <400 mL urine/24 hr) may reflect hypovolemia or impending *prerenal* renal failure, a majority of perioperative AKI episodes develop in the absence of oliguria.<sup>4</sup> The normal response to hypovolemia is renal solute retention; fluid and electrolyte retention produces a concentrated urine with a low sodium content (<20 mEq/L). In contrast, impaired concentrating ability due to AKI causes urine to approach plasma osmolarity (isosthenuria) with a higher sodium content (>40 mEq/L). The kidneys' ability to retain electrolytes is also reflected in the *fractional excretion of sodium* (FE<sub>Na</sub>), a test that uses a spot sample of urine and blood to compare sodium and creatinine excretion; this test can be useful to distinguish hypovolemia and renal injury:

$$FE_{Na} = \frac{U_{Na}}{P_{Na}} \times \frac{P_{Cr}}{U_{Cr}} \times 100$$

where U<sub>Na</sub> = urine sodium, P<sub>Na</sub> = plasma sodium, U<sub>Cr</sub> = urine creatinine, and P<sub>Cr</sub> = plasma creatinine.

**Figure 50-3** The nonlinear relationship between changes in renal filtration and serum creatinine level means that a large reduction (e.g., 75%, 120 to 30 mL/min) in glomerular filtration rate (GFR) may be associated with a modest rise in serum creatinine. Proportional reductions in GFR and (approximate) nephron loss (x axis) have an inverse logarithmic relationship with serum creatinine concentration (y axis).

(Modified with permission from Faber MD, Kupin WL, Krishna G, et al. The differential diagnosis of ARF. In: Lazarus JM, Brenner BM, eds. *Acute Renal Failure*. 3rd ed. New York, NY: Churchill Livingstone; 1993:133.)

$FE_{Na} < 1\%$  implies that sodium is being normally conserved, whereas values above 1% are consistent with acute tubular necrosis (ATN).

## Perioperative Nephrology

### Pathophysiology

Altered renal function can be thought of as a clinical continuum ranging from the normal compensatory changes seen during stress to frank renal failure. Clinically, there is considerable overlap between compensated and decompensated renal dysfunctional states. The kidney under stress reacts in a predictable manner to help restore intravascular volume and maintain blood pressure. The sympathetic nervous system reacts to trauma, shock, or pain by releasing norepinephrine, which acts much like angiotensin II on the renal arterioles. Norepinephrine also activates the renin–angiotensin–aldosterone system and causes ADH release. The net result of modest activity of the stress response system is a shift of blood flow from the renal cortex to the medulla, avid sodium and water reabsorption, and decreased urine output. A more intense stress response may induce a decrease in RBF and GFR by causing afferent arteriolar constriction. If this extreme situation is not reversed, ischemic damage to the kidney may result, and AKI may become clinically manifest.

### Electrolyte Disorders

#### Disorders of Sodium Balance

*Hyponatremia* is the most commonly occurring electrolyte disorder (see also [Chapter 16](#)).<sup>24,25</sup> Symptoms rarely occur unless sodium values are less than 125 mmol/L, and these include a spectrum ranging from anorexia, nausea, and lethargy to convulsions, dysrhythmias, coma, and even death due to osmotic brain swelling.<sup>26–28</sup> Hyponatremia may occur in the setting of an expanded (e.g., transurethral resection [TUR] syndrome), normal, or contracted extracellular fluid volume. Intravascular volume status and urinary sodium concentration are key markers in differentiating the large number of potential causes of hyponatremia. If water excess is a reason for hyponatremia, a dilute urine with a sodium concentration above 20 mmol/L is expected. Conversely, avid renal sodium retention (urine sodium  $< 20$  mmol/L) suggests sodium loss as a cause. If hyponatremia is acute, the risk of

neurologic complications is higher, and cautious treatment is indicated to prevent cerebral edema and seizures. This should be accomplished with intravenous hypertonic saline and furosemide to enhance water excretion and prevent sodium overload (see transurethral resection syndrome section).

*Hypernatremia* (serum sodium  $>145$  mmol/L) is generally the result of sodium gain or water loss, most commonly the latter. Dehydration of brain tissue can cause symptoms ranging from confusion to convulsions and coma. In cases of hypernatremia, laboratory studies often show evidence of hemoconcentration (increased hematocrit and serum protein concentrations). In addition, urine output is usually low ( $<500$  mL/day) and hyperosmolar ( $>1,000$  mOsm), with very low urinary sodium concentration and evidence of prerenal failure (elevations of BUN and serum creatinine). Occasionally, the urine is not maximally concentrated, suggesting an osmotic diuresis or an intrinsic renal disorder such as diabetes insipidus. The primary goal of treatment is restoration of serum tonicity, which can be achieved with isotonic or hypotonic parenteral fluids and/or diuretics unless irreversible renal injury is present, in which situation dialysis may be necessary.

## **Disorders of Potassium Balance**

Even minor variations in serum potassium concentration can lead to symptoms such as skeletal muscle weakness, gastrointestinal ileus, myocardial depression, malignant ventricular dysrhythmias, and asystole. Nearly 98% of total body potassium is intracellular. Circulating potassium levels are tightly controlled via renal and gastrointestinal excretion and reabsorption, but potassium also moves between the intra- and extracellular compartments under the influence of insulin and  $\beta_2$ -adrenoceptors. In the kidney, 70% of potassium reabsorption occurs in the proximal tubule and another 15% to 20% in the loop of Henle. The collecting duct is responsible for potassium excretion under the influence of aldosterone.

*Hypokalemia* may be due to a net potassium deficiency or transfer of extracellular potassium to the intracellular space. Notably, total body depletion may exist even with normal extracellular potassium levels (e.g., diabetic ketoacidosis). Causes of hypokalemia include extrarenal loss (e.g., vomiting, diarrhea), renal loss (impaired processing due to drugs, hormones, or inherited renal abnormalities), potassium shifts between the extra- and intracellular spaces (e.g., insulin therapy), and, occasionally, inadequate intake. Clinical manifestations of hypokalemia include electrocardiography (ECG) changes (flattened T waves—"no pot, no T," U waves, prodysrhythmic state) and skeletal muscle weakness. Hypokalemia treatment involves supplementation by either intravenous or oral route; however, extreme caution should be used with intravenous potassium administration because

overly rapid delivery can cause hyperkalemic cardiac arrest.

If a patient has *hyperkalemia* (elevated serum potassium level  $>5.5$  mEq/L), it is important to consider the duration of the condition because chronic hyperkalemia is far better tolerated than an acute rise. Other than laboratory artifacts (e.g., hemolyzed sample), causes of hyperkalemia include abnormal kidney excretion, abnormal cellular potassium release, or abnormal distribution between the intracellular and the extracellular space. Clinical manifestations of acute hyperkalemia include a range of ECG changes that can be clearly observed with the infusion of high-potassium cardioplegia immediately following aortic cross-clamp application during cardiac surgery. Peaked T waves, ST segment depression, and shortened QT interval are soon followed by manifestations of severe hyperkalemia, including QRS complex widening, prolonged PR interval, disappearance of the P wave, sine wave QRS, ventricular fibrillation, and asystole.

### **Disorders of Calcium, Magnesium, and Phosphorus**

Most of a grown adult's 1 to 2 kg of calcium is in bone (98%), with the remaining 2% in one of the three forms: ionized, chelated, or protein bound. Normal serum calcium values range between 8.5 and 10.2 mg/dL, but only the ionized fraction (50%) is biologically active and precisely regulated. Ionized extracellular calcium concentration ( $iCa^{++}$ ) is controlled by the combined actions of parathyroid hormone (PTH), calcitonin, and vitamin D and further modulated by dietary and environmental factors. The clinical manifestations of *hypocalcemia* include cramping, digital numbness, laryngospasm, carpopedal spasm, bronchospasm, seizures, and respiratory arrest. A positive Chvostek sign (facial muscle twitching in response to tapping the facial nerve) or Trousseau sign (carpal spasm induced by brachial artery occlusion) are the classic hallmarks of hypocalcemia but in practice are often absent. Mental status changes, including irritability, depression, and impaired cognition may also occur. Cardiac manifestations include QT interval prolongation and dysrhythmias. Hypocalcemia may be due to several mechanisms, including a decrease in PTH secretion or action, reduced vitamin D synthesis or action, resistance of bone to PTH or vitamin D effects, or calcium sequestration. Acute hypocalcemia due to citrate toxicity can develop from rapid infusion of citrate-stored packed red blood cells, particularly with citrate accumulation during the anhepatic phase of liver transplant procedures. Parathyroidectomy, either selectively or as a complication of thyroidectomy during neck surgery, can acutely reduce PTH levels and precipitate hypocalcemia. Citrate used for regional anticoagulation with chronic dialysis can also cause hypocalcemia and may lead to hypomagnesemia from decreased PTH secretion. Hypocalcemia due to

reduced serum protein levels is physiologically unimportant. Clinical symptoms of *hypercalcemia* correlate with its acuity and include constipation, nausea and vomiting, drowsiness, lethargy, weakness, stupor, and coma. Cardiovascular manifestations may include hypertension, shortened QT interval, heart block, and other dysrhythmias. The most frequent causes of hypercalcemia are primary hyperparathyroidism and malignancy. Other causes include thiazide (increases renal calcium reabsorption) or lithium (inhibits PTH release) therapy and rarer medical conditions including granulomatous disease, thyrotoxicosis, and multiple endocrine neoplasia types I and II.

Magnesium is a multifunctional cation that is found primarily in the intracellular space. Because extracellular magnesium represents only 0.3% of total (mainly intracellular) stores, normal serum levels (1.6 to 2.2 mg/dL) are a poor reflection of total body magnesium. *Hypomagnesemia* (<1.6 mg/dL) may sometimes be asymptomatic, but clinically important problems can and do manifest, including neuromuscular, cardiac, neurologic, and related electrolytic (hypokalemia and hypocalcemia) abnormalities. Causes of hypomagnesemia can be divided into four broad categories: decreased intake, gastrointestinal loss, renal loss, and redistribution. Nutritional hypomagnesemia can result from malabsorption syndromes in patients receiving parenteral nutrition, and it is also present in 25% of alcoholics. Redistribution occurs with acute pancreatitis, administration of catecholamines, and “hungry bone syndrome” after parathyroidectomy.<sup>29</sup> Magnesium can be supplemented orally or via the parenteral route. Clinical manifestations of *hypermagnesemia* (>4 to 6 mg/dL) are serious and potentially fatal. Minor symptoms include hypotension, nausea, vomiting, facial flushing, urinary retention, and ileus. In more extreme cases, flaccid skeletal muscular paralysis, hyporeflexia, bradycardia, bradydysrhythmias, respiratory depression, coma, and cardiac arrest may occur. Hypermagnesemia generally occurs in two clinical settings: compromised renal function (GFR < 20 mL/min) and excessive magnesium intake (e.g., excessive intravenous therapy in preeclampsia). Although mild hypermagnesemia in the setting of normal renal function can be treated with supportive care and withdrawal of the cause, in some cases dialysis is necessary.

Phosphorus is a major intracellular anion that plays a role in regulation of glycolysis, ammoniogenesis, and calcium homeostasis and is an essential component of adenosine triphosphate and red blood cell 2,3-diphosphoglyceric acid synthesis. *Hypophosphatemia* is clinically more important than hyperphosphatemia and can result in symptoms including muscle weakness, respiratory failure, and difficulty in weaning critically ill patients from mechanical ventilation when serum levels are less than 0.32

mmol/L. In addition, low phosphate levels may diminish oxygen delivery to tissues and rarely cause hemolysis. Hypophosphatemia can result from intracellular redistribution (from catecholamine therapy), from inadequate intake or absorption secondary to alcoholism or malnutrition, or from increased renal or gastrointestinal losses.<sup>30</sup> Intravenous and oral supplementation can be used to treat hypophosphatemia. *Hyperphosphatemia* (>5 mg/dL) is generally related to accompanying hypocalcemia although increased phosphate levels may also lead to calcium precipitation and decreased intestinal calcium absorption. Significantly elevated serum phosphate levels are most commonly due to reduced excretion from renal insufficiency but can also result from excess intake or redistribution of intracellular phosphorus. Treatment of chronic hyperphosphatemia includes dietary phosphate restriction and oral phosphate binders.

## Acid–Base Disorders

The primary determinant of serum pH is the balance between plasma bicarbonate ( $\text{HCO}_3^-$ ) concentration and the  $\text{PCO}_2$  in the extracellular space. Acid–base homeostasis involves tight regulation of  $\text{HCO}_3^-$  and arterial  $\text{PCO}_2$  ( $\text{PaCO}_2$ ). Primary extracellular pH derangements due to abnormal bicarbonate reabsorption and proton ( $\text{H}^+$ ) elimination by the kidney lead to metabolic acidosis or alkalosis, whereas factors that abnormally affect respiratory drive influence  $\text{PaCO}_2$ , leading to respiratory acidosis or alkalosis. Because combined problems are often seen in perioperative critically ill patients, an approach to both “pure” and “mixed” acid–base disorders is presented here.

### Metabolic Acidosis

The *anion gap* (AG) represents the total serum concentration of unmeasured anions and can be calculated as  $\text{AG} = (\text{Na}^+ + \text{K}^+) - (\text{HCO}_3^- + \text{Cl}^-)$ . It allows differentiation of the causes of metabolic acidosis into normal AG ( $12 \pm 4$ ) and increased AG (>16 mmol/L) varieties. Conditions that cause an increase in negatively charged ions other than bicarbonate and chloride (e.g., lactate, salicylate) increase the AG. In contrast, non-AG metabolic acidosis results from renal or gastrointestinal  $\text{HCO}_3^-$  loss and is associated with high chloride levels (hyperchloremic metabolic acidosis). The usual compensatory response to all types of metabolic acidoses is hyperventilation, which leads to a partial pH correction toward normal. Winter’s formula predicts expected  $\text{PaCO}_2$  for a metabolic acidosis as follows:  $\text{PaCO}_2 = (1.5 \times \text{HCO}_3^-) + 8$ .

### Metabolic Alkalosis

Metabolic alkalosis is a common primary acid–base disturbance associated with increased plasma  $\text{HCO}_3^-$ . Increased extracellular  $\text{HCO}_3^-$  is due to a net loss of  $\text{H}^+$  and/or addition of  $\text{HCO}_3^-$ . The most common cause of metabolic alkalosis is gastrointestinal acid loss due to vomiting or nasogastric suctioning; the resulting hypovolemia leads to secretion of renin and aldosterone and enhanced absorption of  $\text{HCO}_3^-$ . Thiazides and loop diuretics both induce a net loss of chloride and free water and can cause a volume “contraction” alkalosis.

## **Respiratory Acidosis**

If the lungs fail to eliminate  $\text{CO}_2$ , hypercapnia and respiratory acidosis result, characterized by increased  $\text{PaCO}_2$  and decreased blood pH. Acute and chronic causes can be differentiated by examining arterial pH,  $\text{PaCO}_2$ , and  $\text{HCO}_3^-$  values. In the early phase of respiratory acidosis, increased  $\text{PaCO}_2$  stimulates renal generation and secretion of  $\text{H}^+$ . The kidneys continue to adapt to the increased pH through greater titratable acid excretion (e.g., ammonium) and  $\text{HCO}_3^-$  generation. Therefore, acute respiratory acidosis is characterized by an elevated  $\text{PaCO}_2$ , acidemia, and a relatively normal  $\text{HCO}_3^-$ . In contrast, chronic respiratory acidosis is associated with an elevated  $\text{HCO}_3^-$  (often accompanied by a relatively normal pH) due to renal compensation.

## **Respiratory Alkalosis**

Increased minute ventilation is the primary cause of respiratory alkalosis, characterized by decreased  $\text{PaCO}_2$  and increased pH. Patients with acute, uncompensated respiratory alkalosis have normal plasma  $\text{HCO}_3^-$ . In chronic respiratory alkalosis, renal compensation leads to decreased plasma  $\text{HCO}_3^-$ . The causes of respiratory alkalosis relate to abnormal respiratory drive from stimulants or toxins (e.g., salicylate, caffeine, nicotine, progesterone), central nervous system abnormalities (e.g., anxiety, stroke, increased intracranial pressure), pulmonary abnormalities (e.g., pulmonary embolism, pneumonia), mechanical hyperventilation, or systemic conditions such as liver failure and sepsis.

## **Mixed Acid–Base Disorders**

It is not uncommon for a metabolic derangement to coexist with a respiratory derangement, particularly in critically ill patients. A general approach to the diagnosis of mixed acid–base disorders requires a stepwise approach that begins with a focused history and physical examination. An arterial blood gas and a concurrent serum chemistry panel (including  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , and total  $\text{CO}_2$  concentrations) should also be obtained, and the use of an acid–base map

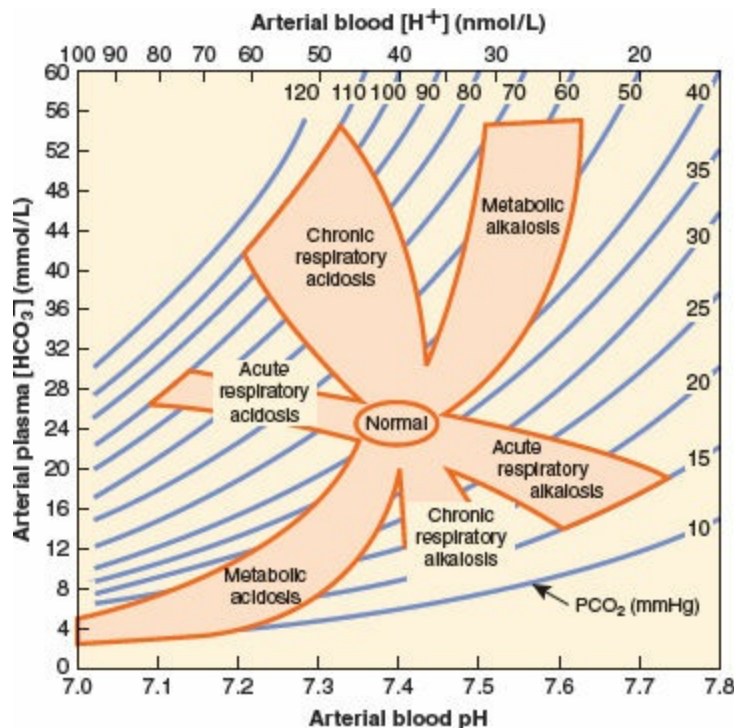

may help differentiate simple from mixed disorders (Fig. 50-4).

## Acute Kidney Conditions

### Acute Kidney Injury

AKI is now the preferred term for an acute deterioration in renal function. It is associated with a decline in glomerular filtration and results in inability of the kidneys to excrete nitrogenous and other wastes. This manifests as an accumulation of creatinine and urea in the blood (uremia) and is often accompanied by reduced urine production, although nonoliguric forms of postoperative AKI are common.<sup>31</sup> In surgical patients, ATN is the most common cause of AKI. AKI frequently occurs in the setting of critical illness with multiple organ failure when the mortality is alarmingly high (up to 80%).<sup>32</sup> Notably, extracorporeal renal support appears to have little impact in altering the generally poor outcome associated with AKI in critically ill surgical patients.<sup>32</sup> Even studies that advocate the use of extracorporeal technology report mortality of between 50% and 70%.<sup>33–35</sup>

AKI can be caused by *prerenal* factors causing renal hypoperfusion, *intrinsic* renal causes, or *postrenal* causes (obstructive uropathy). There are many pathophysiologic similarities between the various causes of kidney injury.

**Figure 50-4** Acid–base map. Plotting the PCO<sub>2</sub> and H<sup>+</sup> (from the arterial blood gas) against plasma HCO<sub>3</sub><sup>-</sup> (from the serum chemistry panel) for a patient can identify simple acid–base disorders. When mixed disorders exist, values may fall outside the shaded areas. (Adapted with permission from DuBose TD Jr. Acid-base disorders. In: Brenner BM, ed. *Brenner & Rector's The Kidney*. 7th ed. Philadelphia, PA: WB Saunders;

### *Prerenal Azotemia*

*Prerenal azotemia* is the increase in BUN associated with renal hypoperfusion or ischemia that has not yet caused renal parenchymal damage. The metabolically active cells of the medullary thick ascending limb of the loop of Henle are especially vulnerable to hypoxic damage because of their relatively high oxygen consumption. AKI ensues when necrosis of tubular cells releases debris into the tubules, causing flow obstruction, increased tubular back pressure, and leak of tubular fluid. Often, prerenal AKI is precipitated in patients with pre-existing renal vasoconstriction (e.g., volume depletion, heart failure, or sepsis) by nephrotoxin exposure or further reductions in cardiac output.

### *Intrinsic Acute Kidney Injury*

The term *intrinsic* not only implies a primary renal cause of AKI but also includes AKI due to ischemia, nephrotoxins, and renal parenchymal diseases. ATN remains the most common ischemic lesion and represents an extension of prerenal azotemia, whereas cortical necrosis may follow a massive renovascular insult such as prolonged suprarenal aortic clamping or renal artery embolism. Nephrotoxins often act in concert with hypoperfusion or underlying renal vasoconstrictive states to damage renal tubules or the microvasculature. Several common nephrotoxins, some of which are difficult to avoid in a hospitalized patient population, are listed in [Table 50-1](#).

### *Postrenal Acute Kidney Injury (Obstructive Uropathy)*

Downstream obstruction of the urinary collecting system is the least common pathway to established AKI, accounting for less than 10% of cases.<sup>37</sup> Because it can generally be corrected, it is extremely important to exclude with a renal ultrasound examination as a source of AKI. The obstructing lesion may occur at any level of the collecting system, from the renal pelvis to the distal urethra. Intraluminal pressure rises and is eventually transmitted back to the glomerulus, thereby reducing glomerular filtration pressure and rate.

**Table 50-1** Nephrotoxins Commonly Found in the Hospital Setting

<b>Exogenous</b>
Antibiotics (aminoglycosides, cephalosporins, amphotericin B, sulfonamide, tetracyclines, vancomycin)
Anesthetic agents (methoxyflurane, enflurane)
Nonsteroidal anti-inflammatory drugs (aspirin, ibuprofen, naproxen, indomethacin, ketorolac)
Chemotherapeutic-immunosuppressive agents (cisplatin, cyclosporin A, methotrexate, mitomycin, nitrosoureas, tacrolimus)
Contrast media
<b>Endogenous</b>
Calcium (hypercalcemia)
Uric acid (hyperuricemia and hyperuricosuria)
Myoglobin (rhabdomyolysis)
Hemoglobin (hemolysis)
Bilirubin (obstructive jaundice)
Oxalate crystals
Paraproteins

## Nephrotoxins and Perioperative Acute Kidney Injury

Nephrotoxin exposure is a common occurrence in hospitalized patients and frequently plays a role in the cause of AKI in this population. Nephrotoxins may take the form of drugs, nontherapeutic chemicals, heavy metals, poisons, and endogenous compounds (Table 50-1). The nephrotoxins most likely to contribute to renal dysfunction/failure in the perioperative period are certain antimicrobial and chemotherapeutic-immunosuppressive agents, radiocontrast media, nonsteroidal anti-inflammatory drugs (NSAIDs), and the endogenous heme pigments myoglobin and hemoglobin. These diverse groups of renal toxins share a common pathophysiologic characteristic: They disturb either renal oxygen delivery or oxygen utilization and thereby promote renal ischemia.

Antimicrobial and chemotherapeutic-immunosuppressive agents are effective because they are cellular toxins. When these drugs are filtered, reabsorbed, secreted, and eventually excreted by the kidney, toxic concentrations in renal cells can be reached. The aminoglycoside antibiotics and amphotericin B are particularly difficult to avoid because they are effective antimicrobials, with few available alternatives. Their effect can be additive with other nephrotoxic factors causing impairment of kidney function. Hypovolemia, fever, renal vasoconstriction, and concomitant therapy with other nephrotoxic agents should be avoided wherever possible. Electrolyte disorders such as hypercalcemia, hypomagnesemia, hypokalemia, and metabolic acidosis can further enhance nephrotoxic damage to the kidney.

Cyclosporin A and tacrolimus are indispensable components of many immunosuppressive drug regimens, but in combination with other nephrotoxins and clinical factors, they can cause acute and exacerbate chronic

kidney injuries in transplant recipients.<sup>34</sup>

Yacoub and colleagues<sup>38</sup> suggest that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) should not be given for 48 hours prior to routine cardiac surgery. In their meta-analysis of 29 retrospective studies (>50,000 procedures) these authors linked chronic ACE inhibitor or ARB use until the day of surgery with higher mortality risk (20%;  $p = 0.005$ ) and AKI rates (17%;  $p = 0.04$ ). ACE inhibitors and ARBs are also associated with increased AKI risk in patients receiving diuretic therapy; those with volume depletion, CHF, or diabetes; and the elderly.<sup>39,40</sup> Finally, although ACE inhibitors and ARBs are sometimes prescribed to slow the progression of CKD, their use with NSAIDs and other nephrotoxic agents such as cyclosporine, tacrolimus, and aprotinin is also associated with increased perioperative AKI risk.<sup>39,41,42</sup>

Discontinuing loop diuretic therapy on the day prior to surgery should also receive careful consideration. Two studies have linked chronic diuretic therapy with postoperative AKI,<sup>43,44</sup> with one differentiating loop (not thiazide) diuretics as having higher AKI and mortality risk.<sup>44</sup> Other retrospective studies report high furosemide dose as a risk factor for AKI following contrast exposure during coronary angiography and then subsequent off-pump cardiac surgery.<sup>45</sup> Short-term furosemide also worsened AKI in one randomized cardiac surgery trial and a retrospective study of noncardiac surgery patients.<sup>46,47</sup>

In contradistinction, patients taking statins prior to coronary artery bypass graft (but not isolated valve) surgery had lower dialysis and mortality rates in a meta-analysis of 17 studies (>47,000 patients) addressing this issue.<sup>48</sup>

Radiocontrast media pose a threat to the renal function of patients with diabetic nephropathy, pre-existing renal vasoconstriction (heart failure, hypovolemia), or renal insufficiency.<sup>49</sup> Radiocontrast dye has effects on renal function that develop 24 to 48 hours after exposure and peak at 3 to 5 days. Measures that may prevent AKI or lessen the severity of renal damage include prehydration, smaller contrast doses, and judicious withholding of other nephrotoxins, such as NSAIDs. Hu and colleagues<sup>50</sup> concluded that nonemergent cardiac procedures should be delayed for 24 hours after contrast administration to reduce the incidence of postoperative AKI in their meta-analysis of eight retrospective studies (>11,000 patients receiving dye within 3 days preoperatively).

NSAIDs produce reversible inhibition of prostaglandin synthesis and are well-known nephrotoxins.<sup>51</sup> Except in cases of massive overdose, NSAIDs produce renal dysfunction only in patients with coexisting renal hypoperfusion or vasoconstriction. Advanced age, hypovolemia, end-stage hepatic disease, heart failure, sepsis, chronic renal insufficiency, and major surgery are risk factors for development of NSAID-induced AKI.<sup>52</sup>

Myoglobin and hemoglobin are both capable of causing AKI in critically ill surgical patients. Myoglobin seems to be a more potent nephrotoxin than hemoglobin because it is more readily filtered at the glomerulus and can be reabsorbed by the renal tubules, where it chelates nitric oxide and thus induces medullary vasoconstriction and ischemia.<sup>53</sup> Hypovolemia and acidemia potentiate the toxicity of both pigments. Reduced intravascular volume causes a decrease in RBF and GFR, which results in a smaller volume of tubular fluid with a relatively higher concentration of pigment. There is also evidence suggesting that pigment precipitation inside the tubular lumen is enhanced under acidotic conditions and that tubular obstruction plays a role in the pathogenesis of AKI.<sup>53,54</sup>

Preventive treatment of pigment-induced AKI is directed at increasing RBF and tubular (urine) flow while correcting any existing acidosis. These goals may be accomplished by expanding the intravascular fluid volume with crystalloid infusion, stimulating an osmotic diuresis with mannitol, and increasing the urine pH with intravenous bicarbonate therapy.<sup>55</sup> Adequate systemic resuscitation from shock is a prerequisite if AKI is to be avoided, especially in massive crush injuries and electrical burns. Though high-quality evidence is lacking, forced mannitol-alkali diuresis is recommended as the second step in the preventive treatment of myoglobinuria, with urine flow rates of up to 300 mL/hour and a urine pH above 6.5 advocated for patients with massive crush injuries.<sup>55</sup>

The nephrotoxicity of volatile agents remains controversial. Inhalation anesthetics such as enflurane, isoflurane, and sevoflurane can generate free fluoride ions during their metabolism, which (when levels are >50 mm/L) may cause polyuric AKI by interfering with tubular concentrating ability. However, peak fluoride levels during administration of these agents seldom reach toxic levels, and there are few reports describing volatile agent-induced nephrotoxicity.<sup>56</sup> The potential of sevoflurane-induced nephrotoxicity has been related to the production of compound A during prolonged, low-fresh-gas-flow sevoflurane anesthesia.<sup>57</sup> Although there are insufficient data to conclude that sevoflurane-induced kidney injury occurs in the human population, even during low-gas-flow anesthesia, it is probably prudent to maintain a fresh gas flow of at least 2 L/min during sevoflurane anesthesia.<sup>58</sup>

Fluid resuscitation has also been associated with nephrotoxicity. Evidence of increased rates of renal replacement therapy in critically ill and septic patients receiving hydroxyethyl starches resulted in the elimination of these fluids from routine clinical practice.<sup>59,60</sup> In addition, excessive use of 0.9% “normal” saline (chloride liberal) was associated with higher risks of AKI and renal replacement therapy compared to a chloride-restrictive strategy in a prospective study of 1,543 critically ill patients.<sup>61</sup>

It appears that not only the type of fluid but also the amount of fluid can

influence the development of AKI. It is well known that hypoperfusion of the kidney can lead to AKI; however, fluid overload can also worsen kidney injury through intra-abdominal hypertension and venous and interstitial congestion within the kidney.<sup>62</sup> In addition, a meta-analysis examining renal function in randomized controlled perioperative goal-directed therapy studies revealed a very modest role for fluid management in effective goal-directed therapy protocols, with the most effective reduction in AKI rates coming from significant inotropic intervention and less fluid resuscitation.<sup>63</sup> Thus, optimal fluid management in the perioperative period, in both the type and amount of fluid, has significant effects on renal function.

## Chronic Kidney Disease

Patients with non-dialysis-dependent CKD are at increased risk of developing *end-stage renal disease* (ESRD). ESRD is the term used to describe a clinical syndrome characterized by renal dysfunction that would prove fatal without renal replacement therapy (i.e., dialysis). These patients have GFRs less than 25% of normal. Lesser degrees of renal dysfunction may be categorized as chronic renal insufficiency (25% to 40% of normal GFR) or decreased renal reserve (60% to 75% of normal GFR). Patients with decreased renal reserve **7** are often asymptomatic and frequently do not have elevated blood levels of creatinine or urea. Established renal insufficiency results in patently abnormal serum creatinine and BUN values, but nocturia (due to reduced concentrating ability) may be the only symptom.

The *uremic syndrome* represents an extreme form of chronic renal failure, which occurs as the surviving nephron population and GFR decreases below 10% of normal. It results in inability of the kidney to perform its two major functions: regulation of the volume and composition of the extracellular fluid and excretion of waste products. Water balance in ESRD becomes difficult to manage because the number of functioning nephrons is too small either to concentrate or to fully dilute the urine. This results in failure both to conserve water and to excrete excess water. Patients with uremic syndrome often require frequent or continuous dialysis.

**Table 50-2** Factors Contributing to Hyperkalemia in Chronic Renal Failure

<b>Potassium Intake</b>
Increased dietary intake
Exogenous IV supplementation
Potassium salts of drugs
Sodium substitutes
Blood transfusion
Gastrointestinal hemorrhage
<b>Potassium Release from Intracellular Stores</b>
Increased catabolism, sepsis
Metabolic acidosis
β-Adrenergic blocking agents
Digitalis intoxication (Na–K-ATPase inhibition)
Insulin deficiency
Succinylcholine
<b>Potassium Excretion</b>
Acute decrease in GFR
Constipation
Potassium-sparing diuretics
Angiotensin-converting enzyme inhibitors (decreased aldosterone secretion)
Heparin (decreased aldosterone effect)

IV, intravenous; Na–K-ATPase, Na–K-adenosine triphosphatase; GFR, glomerular filtration rate.

Life-threatening hyperkalemia may occur in CKD because of slower-than-normal potassium clearance. Situations predisposing patients with renal failure to hyperkalemia are presented in [Table 50-2](#). Derangements in calcium, magnesium, and phosphorus metabolism are also commonly seen in CKD ([Table 50-3](#)).

Metabolic acidosis occurs in two forms in ESRD: a hyperchloremic, normal AG acidosis and a high AG acidosis from inability to excrete titratable acids. Both render patients susceptible to an endogenous acid load such as may occur in shock states, hypovolemia, or with an increase in catabolism.

Cardiovascular complications of the uremic syndrome are primarily due to volume overload, high renin–angiotensin activity, autonomic nervous system hyperactivity, acidosis, and electrolyte disturbances. Hypertension due to extracellular fluid volume expansion, autonomic factors, and hyperreninemia is an almost universal finding in ESRD. Together with volume overload, acidemia, anemia, and possibly the presence of high-flow arteriovenous fistulae created for dialysis access, hypertension may contribute to the development of myocardial dysfunction and heart failure. Pericarditis may occur secondary to uremia or dialysis, with pericardial tamponade developing in 20% of the latter group.<sup>64</sup> Pulmonary problems associated with CKD are limited to changes in lung water and control of ventilation. Pulmonary edema and restrictive pulmonary dysfunction are commonly seen in patients with renal failure and are usually responsive to dialysis. Hypervolemia, heart failure, reduced serum oncotic pressure, and increased pulmonary capillary permeability are relevant factors in the development of pulmonary edema.

Chronic metabolic acidosis may be responsible for the hyperventilation seen in patients with ESRD, but increased lung water and poor pulmonary compliance can also stimulate hyperventilation.

**Table 50-3** The Uremic Syndrome

<b>Water Homeostasis</b>
Extracellular fluid expansion
<b>Electrolyte and Acid-Base</b>
Hyponatremia
Hyperkalemia
Hypercalcemia or hypocalcemia
Hyperphosphatemia
Hypermagnesemia
Metabolic acidosis
<b>Cardiovascular</b>
Heart failure
Hypertension
Pericarditis
Myocardial dysfunction
Dysrhythmias
<b>Respiratory</b>
Pulmonary edema
Central hyperventilation
<b>Hematologic</b>
Anemia
Platelet hemostatic defect
<b>Immunologic</b>
Cell-mediated and humoral immunity defects
<b>Gastrointestinal</b>
Delayed gastric emptying, anorexia, nausea, vomiting, hiccups, upper gastrointestinal tract inflammation/hemorrhage
<b>Neuromuscular</b>
Encephalopathy, seizures, tremors, myoclonus
Sensory and motor polyneuropathy
Autonomic dysfunction, decreased baroreceptor responsiveness, dialysis-associated hypotension
<b>Endocrine Metabolism</b>
Renal osteodystrophy
↓ Glucose intolerance
Hypertriglyceridemia, ↑ atherosclerosis

The anemia of CKD occurs as a result of reduced levels of erythropoietin, red cell damage, ongoing gastrointestinal blood loss, and iron or vitamin deficiencies. Platelet dysfunction may aggravate blood loss, but it is responsive to dialysis, cryoprecipitate administration, and desmopressin acetate (or 1-deamino-8-D-arginine vasopressin). Acquired defects in both cellular and humoral immunity probably account for the high prevalence of serious infections (60%) and high mortality from sepsis in CKD (30%).

## Drug Prescribing in Renal Failure

If a drug depends solely on the kidney for clearance, then a simple approach to prescribing might involve a calculated percentage reduction in drug dosage that matches the reduction in GFR. Although GFR can be accurately measured, an estimated clearance derived from serum creatinine is usually adequate for these purposes. Unfortunately, clearance of most medications involves a more complex combination of both hepatic and renal functions, and drug level measurement or algorithms for specific drugs are often recommended.

AKI may affect absorption of a drug. For example, a reduced first-pass effect through the gastrointestinal tract and liver is associated with increased serum levels of oral  $\beta$ -blockers and opioids in patients with AKI. Also, an increase in the volume of distribution is seen in most patients with CKD owing to increased plasma volume and decreased plasma protein binding. However, plasma protein binding is highly variable, with acidic drugs having reduced binding and basic agents (e.g., amide local anesthetics) having increased binding. Importantly, for drugs with less binding, “normal” drug levels may reflect dangerously high active (unbound) drug levels. For example, therapeutic phenytoin levels are typically reported as being in the range of 10 to 20 mg/mL normally but 4 to 10 mg/mL in cases of renal failure. Finally, hepatic metabolism of drugs is difficult to predict in the setting of renal failure because some hepatic enzymes are inhibited whereas others are induced, and accompanying liver disorders may alter the relationship of drug clearance with GFR.

## **Anesthetic Agents in Renal Failure**

With the exception of methoxyflurane and possibly enflurane, anesthetic agents do not directly cause renal dysfunction or interfere with the normal compensatory mechanisms activated by the stress response. The nephrotoxicity of methoxyflurane appears to be due to its metabolism, which results in release of the fluoride ions believed responsible for the renal injury.<sup>65</sup> It has been suggested that renal, not hepatic, metabolism of methoxyflurane may be responsible for generating fluoride ions locally that contribute to nephrotoxicity.<sup>66</sup> Enflurane nephrotoxicity may also occur<sup>67</sup> but is of minor clinical importance, even in patients with pre-existing renal dysfunction. Although direct anesthetic effects on the kidney are usually not harmful, indirect effects may combine with hypovolemia, shock, nephrotoxin exposure, or other renal vasoconstrictive states to produce renal dysfunction. If the chosen anesthetic technique causes a protracted reduction in cardiac output or sustained hypotension that coincides with a period of intense renal vasoconstriction, renal dysfunction or failure could result. This is true for either general or regional anesthesia. There are no comparative studies demonstrating superior renal protection or improved renal outcome with

general versus regional anesthesia.

Significant renal impairment may affect the disposition, metabolism, and excretion of the commonly used anesthetic agents. Inhalation anesthetics are, of course, an exception to the rule that drugs with central nervous system activity (which generally are lipid soluble) must be converted to more hydrophilic compounds by the liver before being excreted by the kidney. The water-soluble metabolites of agents that are not inhaled may accumulate in renal failure and display prolonged pharmacodynamic effects if they possess even a small percentage of the pharmacologic activity of the parent drug. Drugs that are eliminated unchanged by the kidneys (e.g., certain nondepolarizing muscle relaxants, the cholinesterase inhibitors, many antibiotics, digoxin) have a prolonged elimination half-life when given to patients with kidney failure. Many drugs used in anesthesia are highly protein bound and may demonstrate exaggerated clinical effects when protein binding is reduced by uremia.

### **Induction Agents and Sedatives**

Although now rarely used, sodium thiopental serves as a good illustrative example of how reduced protein binding in CKD may affect the clinical use of an anesthetic agent. Burch and Stanski<sup>68</sup> showed that the free fraction of an induction dose of thiopental is almost doubled in patients with renal failure. This accounts for the exaggerated clinical effects seen with thiopental in CKD patients and the substantial reduction in the necessary induction dose of this agent in uremic patients when compared with patients with normal renal function.

Ketamine is less extensively protein bound than thiopental, and renal failure appears to have less influence on its free fraction. Redistribution and hepatic metabolism are largely responsible for termination of the anesthetic effects, with less than 3% of the drug excreted unchanged in the urine. Norketamine, the major metabolite, has one-third the pharmacologic activity of the parent drug and is further metabolized before it is excreted by the kidney.<sup>69</sup>

Etomidate, although only 75% protein bound in normal patients, has a larger free fraction in patients with ESRD.<sup>70</sup> The decrease in protein binding does not seem to alter the clinical effects of etomidate anesthetic induction in patients with renal failure.

Propofol undergoes extensive rapid hepatic biotransformation to inactive metabolites that are renally excreted. Its pharmacokinetics appear to be unchanged in patients with renal failure,<sup>71</sup> and there are no reports of prolongation of its effects in ESRD.

The benzodiazepines, as a group, are extensively protein bound. CKD

increases the free fraction of benzodiazepines in the plasma, and this potentiates their clinical effect. Certain benzodiazepine metabolites are pharmacologically active and have the potential to accumulate with repeated administration of the parent drug to anephric patients. For example, 60% to 80% of midazolam is excreted as its (active)  $\alpha$ -hydroxy metabolite,<sup>72</sup> which accumulates during long-term infusions in patients with renal failure.<sup>72</sup> AKI appears to slow the plasma clearance of midazolam, whereas repeated diazepam or lorazepam administration in CKD may carry a risk of active metabolite-induced sedation. Alprazolam is one of the few drugs related to anesthesia practice that has undergone pharmacodynamic studies in patients with CKD. Schmith et al.<sup>73</sup> found that when decreased protein binding and increased free fraction of alprazolam are taken into account, patients with CKD are actually more sensitive to its sedative effects than healthy persons.

Dexmedetomidine is primarily metabolized in the liver. Volunteers with renal impairment receiving dexmedetomidine experienced a longer-lasting sedative effect than subjects with normal kidney function. The most likely explanation is that less protein binding of dexmedetomidine occurs in subjects with renal dysfunction.<sup>74</sup>

## Opioids

Single-dose studies of the pharmacokinetics of morphine in renal failure demonstrate no alteration in its disposition. However, chronic administration results in accumulation of its 6-glucuronide metabolite, which has potent analgesic and sedative effects.<sup>75</sup> There is also a decrease in protein binding of morphine in ESRD, which mandates a reduction in its initial dose. Meperidine is remarkable for its neurotoxic, renally excreted metabolite (normeperidine) and is not recommended for use in patients with poor renal function. Hydromorphone is metabolized to hydromorphone-3-glucuronide, which is excreted by the kidneys. This active metabolite accumulates in patients with renal failure and may cause cognitive dysfunction and myoclonus.<sup>76</sup> Codeine also has the potential for causing prolonged narcosis in patients with renal failure and cannot be recommended for long-term use.<sup>75</sup>

Fentanyl appears to be a better choice of opioid for use in ESRD because of its lack of active metabolites, unchanged free fraction, and short redistribution phase.<sup>77</sup> Small-to-moderate doses, titrated to effect, are well tolerated by uremic patients.

Alfentanil has been shown to have reduced protein binding but no change in its elimination half-life or clearance in ESRD and is extensively metabolized to inactive compounds.<sup>78</sup> Therefore, caution should be exercised in administering a loading dose, but the total dose and infusion dose should be similar to those for patients with normal renal function. The free fraction of

sufentanil is unchanged in ESRD; however, its pharmacokinetics are variable, and it has been reported to cause prolonged narcosis.<sup>79</sup>

Remifentanil is rapidly metabolized by blood and tissue esterases to a weakly active (about 4,600 times less potent) *m*-opioid agonist and renally excreted metabolite, remifentanil acid. Renal failure has no effect on the clearance of remifentanil, but elimination of the principal metabolite, remifentanil acid, is markedly reduced. However, the clinical implications of this metabolite are likely limited.<sup>80</sup>

## Muscle Relaxants

Muscle relaxants are the most likely group of drugs used in anesthetic practice to produce prolonged effects in ESRD because of their dependence on renal excretion (Table 50-4). Only succinylcholine, atracurium, *cis*-atracurium, and mivacurium appear to have minimal renal excretion of the unchanged parent compound. Most nondepolarizing muscle relaxants must be either hepatically excreted or metabolized to inactive forms in order to terminate their activity. Some muscle relaxants have renally excreted active metabolites that may contribute to their prolonged duration of action in patients with ESRD. Although the following discussion focuses on the pharmacology of individual muscle relaxants, coexisting acidosis and electrolyte disturbances as well as drug therapy (e.g., aminoglycosides, diuretics, immunosuppressants, magnesium-containing antacids) may alter the pharmacodynamics of muscle relaxants in patients with renal failure.<sup>81</sup>

Succinylcholine has a long history of use in CKD that has been somewhat confused by conflicting reports of plasma cholinesterase activity in renal failure.<sup>82,83</sup> Provided the serum potassium concentration is not dangerously elevated, its use can be justified as part of a rapid-sequence anesthesia induction technique because its duration of action in ESRD is not significantly prolonged. However, use of a continuous succinylcholine infusion raises concerns because the major metabolite, succinylmonocholine, is weakly active and excreted by the kidney. The rise in serum potassium following succinylcholine administration (0.5 mEq/L in normal subjects) implies that levels of this electrolyte should be normalized to the best extent possible in patients with renal failure, but clinical experience suggests that the potassium rise following succinylcholine administration is usually well tolerated in patients with *chronically* elevated serum potassium levels. Use of the long-acting muscle relaxants doxacurium, pancuronium, and pipecuronium might also be questioned in patients with known renal insufficiency. In a single-dose study of doxacurium, Cook et al.<sup>84</sup> demonstrated an increased elimination half-life, reduced plasma clearance, and prolonged duration of effect in patients with renal failure. Similar findings have been reported for the

pharmacokinetics of pipecuronium. Intermediate-acting muscle relaxants (atracurium, *cis*-atracurium, vecuronium, and rocuronium) have a distinct advantage in ESRD because of their shorter duration. The risk of a clinically significant prolonged block is much reduced. Atracurium and its derivative, *cis*-atracurium, undergo enzymatic ester hydrolysis and spontaneous nonenzymatic (Hoffman) degradation with minimal renal excretion of the parent compound. Their elimination half-life, clearance, and duration of action are not affected by renal failure,<sup>85</sup> nor have they been reported to cause prolonged clinical effects in ESRD. These characteristics strongly support their use in patients with renal disease. One potential concern is that an atracurium metabolite, laudanosine, may cause seizures in experimental animals and may accumulate with repeated dosing or continuous infusion.<sup>86</sup> However, this has not been realized in intensive care patients with renal failure receiving prolonged infusions of atracurium. Consistent with its greater potency and lower dosing requirements, *cis*-atracurium metabolism results in lower laudanosine blood levels than does atracurium in ESRD patients.

**Table 50-4** Nondepolarizing Muscle Relaxants in Renal Failure

Drug	% Renal Excretion	Half-life (hr) Normal/ ESRD	Renally Excreted Active Metabolite	Use in ESRD
<i>D</i> -Tubocurarine	60	1.4–2.2	–	Avoid
Metocurine	45–60	6/11.4	–	Avoid
Pancuronium	30	2.3/4–8	+	Avoid
Gallamine	>85	2.5/6–20	–	Avoid
Pipecuronium	37	1.8–2.3/4.4	+	Avoid
Doxacurium	30	1.7/3.7	–	Avoid
Vecuronium	30	0.9/1.4	+	Avoid infusion
Rocuronium	30	1.2–1.6/1.6–1.7	–	Variable duration
Atracurium/ <i>cis</i> -atracurium	<5	0.3/0.4	–	Normal
Mivacurium	<7	2 min/2 min	–	Duration 1.5× normal
Rapacuronium	<12	0.5/0.5	++	Normal single dose

ESRD, end-stage renal disease.

Initial reports suggested that the pharmacokinetics of vecuronium are unchanged in renal failure, but it has subsequently emerged that its duration of action is prolonged as a result of reduced plasma clearance and increased elimination half-life.<sup>85</sup> An intubating dose lasts approximately 50% longer in patients with ESRD.<sup>87</sup> In addition, the active metabolite, 3-desmethylvecuronium, accumulates in anephric patients receiving a continuous vecuronium infusion, producing a prolonged neuromuscular blockade.

Rocuronium has a pharmacokinetic profile in normal subjects similar to that of vecuronium.<sup>88</sup> Single-dose pharmacokinetic studies in patients with renal failure have reported conflicting results. Szenohradzky et al.<sup>89</sup> reported

that renal failure increased the volume of distribution and elimination half-life of rocuronium but had no effect on its clearance. Cooper et al.<sup>90</sup> found that its clearance was reduced, and the duration of block was widely variable in patients with renal failure, although the mean duration of relaxation and spontaneous recovery was not statistically different from that in control subjects.

The short-acting muscle relaxant mivacurium is enzymatically eliminated by plasma pseudocholinesterase at a somewhat slower rate than succinylcholine. Low pseudocholinesterase activity correlates with slower recovery from a bolus dose of mivacurium in anephric patients.<sup>83</sup> The maintenance infusion dose has been reported to be both lower than<sup>91</sup> and similar<sup>92</sup> to that in normal control subjects.

The pharmacokinetics of the clinically available anticholinesterases are affected by renal failure.<sup>93</sup> They have a prolonged duration of action in ESRD because of their heavy reliance on renal excretion. The anticholinergic agents atropine and glycopyrrolate, used in conjunction with the anticholinesterases, are similarly excreted by the kidney. Therefore, no dosage alteration of the anticholinesterases is required when antagonizing neuromuscular blockade in patients with reduced renal function.

Sugammadex provides a novel approach to the reversal of muscle relaxants. This agent is a modified  $\gamma$ -cyclodextrin that encapsulates aminosteroidal neuromuscular blocking agents (e.g., rocuronium, vecuronium, pancuronium), which leads to a swift decline of free muscle relaxant in the plasma and rapid reversal.<sup>94</sup> A study has revealed that sugammadex-rocuronium complexes are cleared more slowly in patients with ESRD; however, reversal of neuromuscular blockade by sugammadex is still as timely and effective in these patients as in healthy controls.<sup>95</sup>

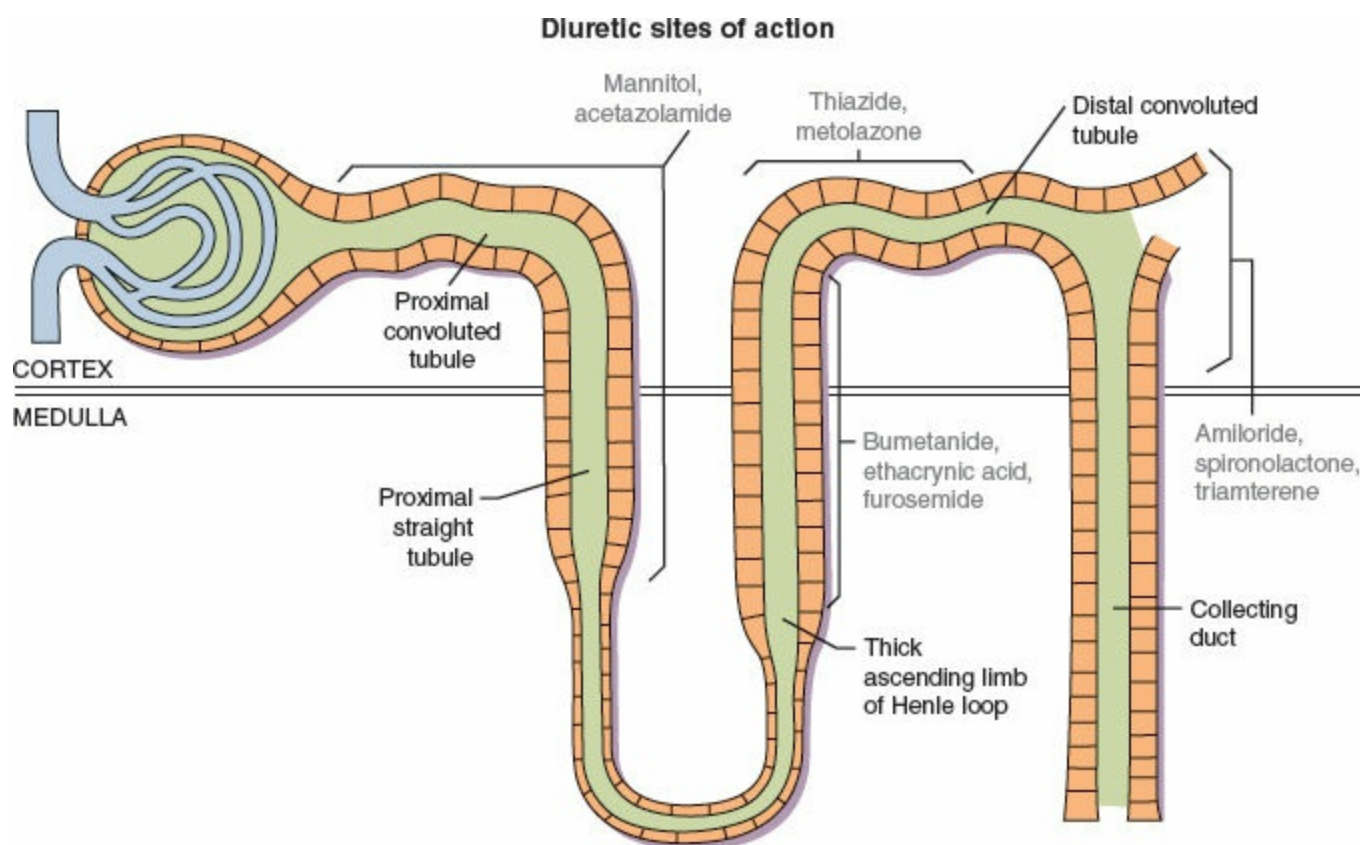

## **Diuretic Drugs: Effects and Mechanisms**

When salt or water intake exceeds renal and extrarenal losses fluid overload results, leading to excess total body water and usually sodium. Fluid overload may be evenly distributed among the body compartments (e.g., congestive heart failure), or the interstitial space may be increased (i.e., edema) while the circulating blood volume may be normal or even decreased (e.g., posttraumatic or postoperative). Edema results when Starling forces favor passage of fluid into the interstitial space. Fluid overload due to a variety of chronic conditions (congestive heart failure, renal failure, or hepatic cirrhosis) may be first recognized during preoperative assessment and may require that elective surgery be delayed for treatment to reduce operative risk. The first line of therapy for fluid overload that includes all body compartments involves restriction of salt and water ingestion; however, diuretic therapy is

often indicated.

### The Physiologic Basis of Diuretic Action

Diuretics are typically grouped according to their site and mechanism of action (Fig. 50-5). Under normal conditions, kidney function assures that less than 1% of the filtered  $\text{Na}^+$  load enters the urine (i.e., the  $\text{FE}_{\text{Na}}$  is  $<1\%$ ). The  $\text{Na}^+/\text{K}^+$ -ATPase pump on the basolateral surface (blood side) of renal tubular cells is primarily responsible for active pumping of  $\text{Na}^+$  out of cells into blood in exchange for  $\text{K}^+$ . This pump causes a net movement of positive charge out of the cell (2  $\text{K}^+$  in, for every 3  $\text{Na}^+$  out) creating an electrochemical gradient that also causes  $\text{Na}^+$  to enter the luminal (urine) side of the cell. Renal tubular cells in different portions of the nephron have different luminal “systems” to allow this  $\text{Na}^+$  influx. These systems are the sites of action where the different diuretics work.

**Figure 50-5** Site of action of commonly available diuretics. (Adapted with permission from Mende CW. Current issues in diuretic therapy. *Hosp Pract.* 1990;25[Suppl 1]:15.)

### Proximal Tubule Diuretics

In the proximal tubule, a specialized luminal transporter exchanges protons ( $\text{H}^+$ ) for sodium ions; the result is sodium reabsorption and acidification of the urine. The excreted  $\text{H}^+$  combines with bicarbonate ( $\text{HCO}_3^-$ ) in the tubule to form carbonic acid:  $\text{H}^+ + \text{HCO}_3^- \rightarrow \text{H}_2\text{CO}_3$ . Carbonic acid converts to water ( $\text{H}_2\text{O}$ ) and carbon dioxide ( $\text{CO}_2$ ) in a reaction catalyzed by carbonic

anhydrase:  $\text{H}_2\text{CO}_3 \rightarrow \text{H}_2\text{O} + \text{CO}_2$ . The same enzyme, carbonic anhydrase, allows this reaction to occur in reverse within tubular cells, converting  $\text{H}_2\text{CO}_3$  to  $\text{HCO}_3^-$  and  $\text{H}^+$ , generating more  $\text{H}^+$  for countertransport with  $\text{Na}^+$  and releasing bicarbonate, which passes into the circulation. Carbonic anhydrase inhibitors are drugs that inhibit this enzyme; the net effect of these agents is that sodium and bicarbonate, which would otherwise have been reabsorbed, remain in the urine and result in an alkaline diuresis.

Although patients may develop a metabolic acidosis when taking these agents, compensatory processes in the tubules accommodate the effects of carbonic anhydrase inhibitors so that their long-term use rarely causes this problem. However, these agents can be useful, for example, with contraction alkalosis from aggressive diuresis with loop diuretics (see later discussion); administration of these drugs can reduce  $\text{PaCO}_2$  and improve  $\text{PaO}_2$  for patients with little accompanying change in blood pH. Specific uses for carbonic anhydrase inhibitors include treating mountain sickness and open-angle glaucoma and increasing respiratory drive in patients with central sleep apnea.<sup>96,97</sup>

### *Osmotic Diuretics*

Substances such as mannitol that are freely filtered at the glomerulus but poorly reabsorbed by the renal tubule will cause an osmotic diuresis. In the water-permeable segments of the proximal tubule and loop of Henle, fluid reabsorption occurs, and filtered mannitol is concentrated. Eventually oncotic pressure in the tubular fluid resists further fluid reabsorption. Mannitol also draws water from cells into the plasma and effectively increases RBF.

Mannitol has been widely used for the treatment of increased intracranial pressure (see [Chapter 35](#)), but also as a strategy to prevent AKI. Although animal studies warranted hope, apart from AKI prophylaxis in kidney transplantation, there is no evidence to suggest mannitol is effective for either the prevention or treatment of AKI.<sup>98,99</sup> Even in cadaveric kidney transplant recipients, the data are modest to support a beneficial effect.<sup>100</sup> In a controlled trial of mannitol prophylaxis in patients with mild chronic renal failure, it was less effective than hydration alone for prevention of contrast-associated nephropathy.<sup>99</sup> Mannitol therapy is not without complications. As mannitol shifts water between fluid compartments, there can be effects on plasma and intracellular electrolyte concentrations, including hyponatremia and hypochloremia and intracellular increases in  $\text{K}^+$  and  $\text{H}^+$ . Patients with normal renal function quickly correct these changes, but patients with renal impairment may develop significant circulatory overload with hemodilution and pulmonary edema, hyperkalemic metabolic acidosis, central nervous system depression, and even severe hyponatremia requiring urgent hemodialysis.<sup>101</sup>

## *Loop Diuretics*

The electrochemical gradient established by the  $\text{Na}^+/\text{K}^+$ -ATPase in the loop of Henle drives the transport of one  $\text{Na}^+$ , one  $\text{K}^+$ , and two  $\text{Cl}^-$  ions into the tubule cells from the tubular fluid. Because the thick ascending limb segment of the loop of Henle is water impermeable, reabsorption of solute concentrates the interstitium and dilutes the tubular fluid. Loop diuretics, such as furosemide, bumetanide, and torsemide, directly inhibit the electroneutral transporter, preventing salt reabsorption from occurring. Because 25% of filtered  $\text{NaCl}$  is normally reabsorbed in the loop of Henle, loop diuretics cause a large salt load to pass to the distal convoluted tubule that is beyond the extra reserve of this tubular segment to reabsorb; consequently, large volumes of dilute urine ensue.

Loop diuretics are a first-line therapeutic modality for treatment of acute decompensated congestive heart failure. Although loop diuretics have no proven mortality benefit, they reduce left ventricular filling pressures and very effectively relieve the symptoms of congestion, pulmonary edema, extremity swelling, and hepatic congestion. Adverse effects of loop diuretics include hypokalemia, hyponatremia, and AKI. Heart failure patients with atrial fibrillation may also be prescribed digitalis, which in combination with furosemide can lead to hypokalemia-induced dysrhythmias. Loop diuretics, especially furosemide, may cause ototoxicity, particularly in patients with renal insufficiency.<sup>102</sup>

## *Distal Convoluted Tubule Diuretics*

Distal convoluted tubule diuretics, such as thiazides (e.g., hydrochlorothiazide) and metolazone, act in the early part of this segment to block the  $\text{NaCl}$  cotransport mechanism across apical plasma membranes. Because the distal tubule is relatively water-impermeable, net  $\text{NaCl}$  absorption causes urinary dilution. Clinically, distal convoluted tubule diuretics are used for the treatment of hypertension (often as sole therapy) and volume overload disorders and to relieve the symptoms of edema in pregnancy.

Adverse reactions associated with distal tubule diuretics include electrolyte disturbances and volume depletion. Hydrochlorothiazide specifically has been associated with a number of other side effects including pancreatitis, jaundice, diarrhea, and aplastic anemia.

## *Distal (Collecting Duct) Acting Diuretics*

Unlike in the more proximal nephron segments,  $\text{NaCl}$  absorption in the collecting duct cells is not electroneutral. That is, a net electrical gradient is maintained both by the  $\text{Na}^+/\text{K}^+$ -ATPase  $\text{Na}^+$  ion channels and in the luminal

membranes. As a result, the tubule lumen is negatively charged with respect to the blood. This normally causes  $K^+$  secretion into the tubular lumen through  $K^+$ -specific ion channels. Distal  $K^+$ -sparing diuretics (e.g., amiloride and triamterene) directly inhibit luminal  $Na^+$  entry, blocking this mechanism and resulting in a  $K^+$ -“sparing” effect. In addition,  $H^+$  secretion is inhibited.

A second class of distal-acting, potassium-sparing diuretics is the competitive aldosterone antagonists (e.g., spironolactone and eplerenone). Ordinarily, the mineralocorticoid hormone aldosterone is released by the body in response to angiotensin II or hyperkalemia. Aldosterone normally stimulates  $Na^+$  reabsorption and  $K^+$  excretion by the collecting duct. Inhibition of the aldosterone effect by these drugs causes a mild natriuresis and  $K^+$  retention. Distal  $K^+$ -sparing agents are used primarily for  $K^+$ -sparing diuresis (e.g., in patients with volume overload receiving digitalis or with hypokalemic alkalosis). In addition, these drugs are especially useful in treating disorders involving secondary hyperaldosteronism, such as cirrhosis with ascites. Spironolactone treatment has been shown to improve survival with volume overload and left ventricular dysfunction or heart failure.<sup>103</sup> Hyperkalemia and hyperkalemic, hyperchloremic metabolic acidoses are significant complications of the injudicious use of spironolactone, triamterene, or amiloride.

### *Dopaminergic Agonists*

Intravenous infusion of low-dose dopamine (1 to 3 mg/kg/min) is natriuretic owing primarily to a modest increase in the GFR and reduction in proximal  $Na^+$  reabsorption mediated by dopamine type 1 ( $DA_1$ ) receptors.<sup>104</sup> Fenoldopam is a selective  $DA_1$  receptor agonist with little cardiac stimulation. At higher doses, the pressor response to dopamine is beneficial in patients with hypotension, but it has little or no renal effect in critically ill or septic patients.<sup>104,105</sup> The so-called “renal-dose” dopamine for the treatment of AKI, although widely used, has not been demonstrated to have significant renoprotective properties in numerous studies<sup>106–108</sup> and can cause worsened splanchnic oxygenation, impaired gastrointestinal function, impaired endocrine and immunologic system function, blunting of ventilatory drive, and increased risk of postcardiac surgery atrial fibrillation.<sup>109–111</sup>

## **High Renal Risk Surgical Procedures**

### **Cardiac Surgery**

Cardiac operations requiring CPB can be expected to result in AKI or renal failure in up to 7% of patients.<sup>112,113</sup> There are numerous risk factors associated with the development of postoperative AKI in this population (Fig.

50-6).<sup>114</sup> Interestingly, patients with preoperative CKD appear to tolerate surgery and CPB remarkably well.<sup>115</sup> Renal ischemia-reperfusion, inflammatory mediators, and toxin exposure are considered to be primary pathologic mechanisms involved in AKI. Renal risk factors contributing to each of these mechanisms include preoperative left ventricular dysfunction, duration of CPB, pulse pressure hypertension,<sup>116</sup> and aprotinin therapy.<sup>117</sup>

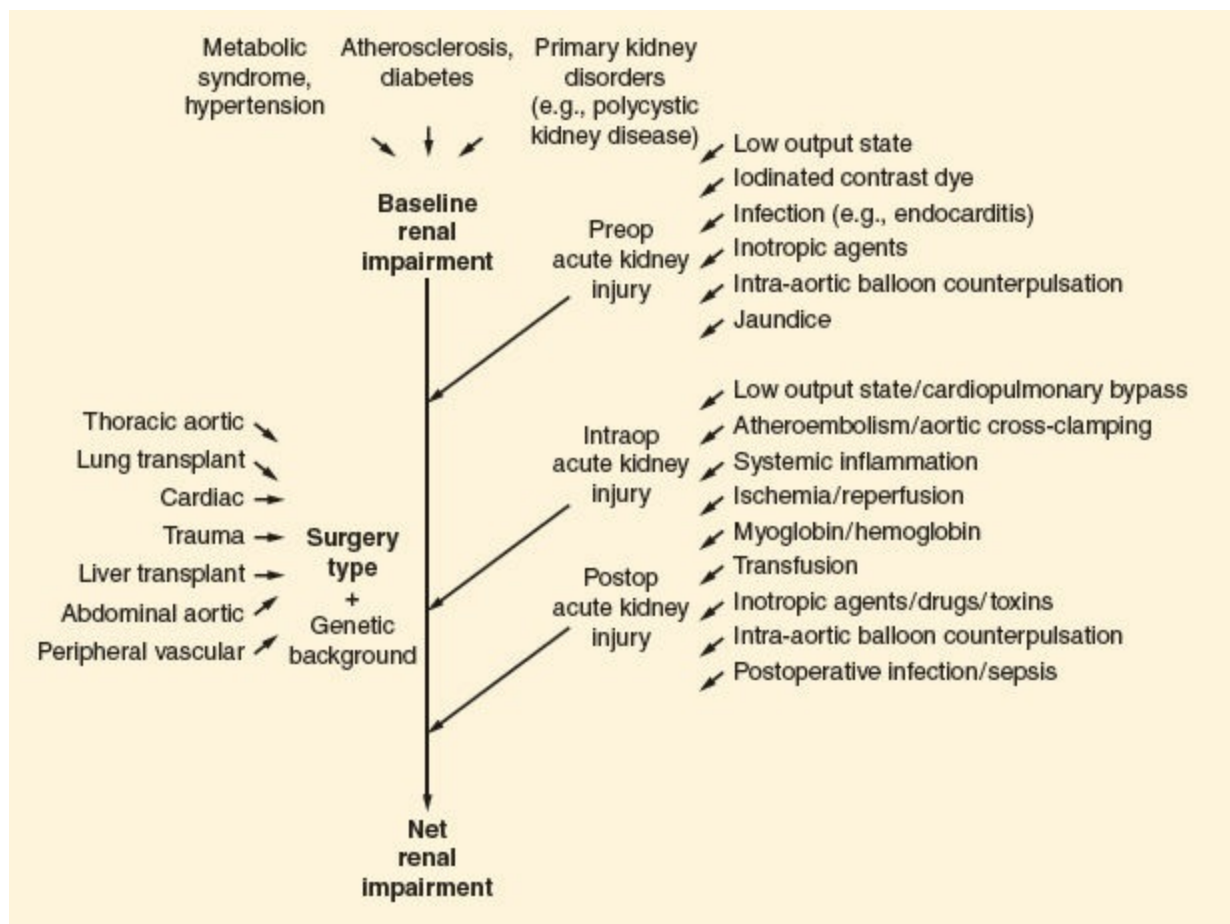

Although some retrospective studies suggest that “beating heart” off-pump coronary artery bypass grafting lowers renal risk compared with the traditional CPB techniques,<sup>118</sup> randomized studies have been inconclusive. However, despite the fact that pulsatile CPB suppresses plasma renin activity, postoperative renal function in patients with normal kidneys undergoing pulsatile or nonpulsatile CPB is equivalent.

Numerous agents have been used intraoperatively without success in attempts to protect the kidney during cardiac surgery. Mannitol use during CPB is partly aimed at avoiding hemoglobin-induced AKI by promoting urine flow and reducing renal cell swelling. Dopamine is infused at low doses (<5 mg/kg/min) as a renal vasodilator without benefit. Costa et al.<sup>119</sup> administered low-dose dopamine during CPB to patients with preoperative renal dysfunction and were able to induce a saluresis without affecting GFR or protecting the kidney from ischemic injury. Dopexamine improved CrCl and systemic oxygen delivery in one cardiac surgery study,<sup>120</sup> but a systemic review of 21 randomized controlled trials failed to confirm benefit.<sup>121</sup> Other studies examining the renal protective effects of fenoldapam, ANP, and insulin-like growth factor 1 in this population have not shown a consistently protective effect.

## Noncardiac Surgery

Several common noncardiac surgical procedures can compromise previously normal renal function. Emergency surgery has been reported as a risk factor for AKI, with trauma surgery figuring as a prominent subgroup of emergency procedures.<sup>122</sup> ATN is the typical renal lesion associated with trauma, and it may be produced by a number of ischemic mechanisms. Most often, hypovolemic shock, pigmenturia, multiple organ failure, or exogenous nephrotoxins are responsible for sequential or simultaneous insults to the kidney. AKI that develops in the trauma patient may be characterized by an early oliguric picture related to inadequate volume resuscitation or by a later, sometimes nonoliguric syndrome associated with multiple organ failure, nephrotoxin exposure, or sepsis. The outcomes of these two posttraumatic AKI scenarios are dramatically different. The early form is associated with high mortality rates, whereas only 20% to 30% of patients will die in the case of nonoliguric AKI.<sup>123</sup> Not surprisingly, trauma victims with pre-existing

renal insufficiency experience much higher mortality than previously healthy patients.<sup>124</sup>

**Figure 50-6** Clinical risk factors that predict perioperative acute kidney injury and renal dysfunction. Preop, preoperative; Intraop, intraoperative; Postop, postoperative. (Adapted with permission from Stafford-Smith M, Patel UD, Phillips-Bute BG, et al. Acute kidney injury and chronic kidney disease after cardiac surgery. *Adv Chronic Kidney Dis.* 2008;15:257–277.)

Preventing AKI in patients presenting for emergency surgery begins with proper management of intravascular volume depletion and shock. Restoring euvolemia while maintaining cardiac output and systemic oxygen delivery is an important goal. Urine flow, once established, is maintained at 0.5 mL/kg/hr or more. Invasive hemodynamic monitoring may be required to guide intraoperative management of ongoing cardiovascular instability due to surgical manipulation, blood loss, fluid shifts, and anesthetic effects. Intraoperative transesophageal echocardiography provides excellent assessment of left and right ventricular functions as well as guidance of fluid resuscitation. Nephrotoxin exposure should be kept to a minimum in the unstable trauma victim. Radiocontrast media, NSAIDs, and myoglobin pose the greatest threat in this patient group. There is no place for either furosemide or mannitol therapy in the early, resuscitative phase of trauma

management, except in the case of head injury with elevated intracranial pressure or when massive rhabdomyolysis is suspected.

Vascular surgery requiring aortic clamping has deleterious effects on renal function regardless of the level of clamp placement. Suprarenal clamping results in an attenuated ATN-like lesion.<sup>125</sup> Infrarenal clamping causes a smaller, short-lived reduction in GFR and is associated with a lower risk of AKI, whereas surgery involving the thoracic aorta has a 25% incidence of AKI.<sup>126</sup> Two major predictors of AKI following aortic surgery are pre-existing renal dysfunction and perioperative hemodynamic instability.<sup>127</sup> Olsen et al.<sup>128</sup> reported in a large series of patients undergoing abdominal aortic aneurysm repair that the overall incidence of AKI was 12%. Patients who had emergency surgery for ruptured aneurysm had a very high incidence of hemodynamic instability, and AKI developed in 26%; in contrast, elective aortic surgery was associated with good hemodynamic control and a 4% incidence of renal failure. Atheromatous renal artery emboli and prolonged aortic clamp time may contribute to ischemic renal injury in these patients.

The endovascular approach (endostent) to major aortic surgery has gained popularity.<sup>129</sup> The etiology of AKI after endovascular and open repair of aortic aneurysm is multifactorial (renal ischemia, atheroembolism, hemodynamic instability). Although hemodynamic changes during endovascular procedures on the aorta may be less dramatic than those accompanying open repair, the prevalence of renal complications appears to be similar. During endovascular procedures, patients may be exposed to substantial amounts of radiocontrast dye, which can exacerbate postoperative renal dysfunction, especially in those with pre-existing renal insufficiency. The long-term incidence of renal insufficiency/failure (followed up to 24 months postoperatively) is similar after endovascular and open repair of aortic aneurysm. It is thus important that before endovascular procedures, patients are adequately hydrated, and the total dose of radiocontrast dye is limited.

Most efforts to preserve renal function in aortic surgery have centered on diuretic and renal vasodilator therapies, although a large body of evidence no longer supports the use of either intravenous mannitol or dopamine to prevent AKI in this setting. Indeed, a clinical study of infrarenal aortic clamping found that combined mannitol and low-dose dopamine treatment was no more effective in preventing AKI than volume expansion with saline. Although increased urine flow rate is a consistent finding with low-dose infusion of dopamine, there is no evidence in collective analysis of numerous randomized studies that this is associated with preservation of renal function during aortic surgery. Other agents are being investigated for use as renoprotective drugs. Nifedipine attenuated a postoperative decrease in GFR in a small, placebo-controlled study of aortic surgery patients.<sup>130</sup> Insulin-like

growth factor 1 has been shown to speed healing in experimental ischemic AKI<sup>131</sup> and to improve renal function in patients with ESRD<sup>132</sup> and in those undergoing aortic or renal artery surgery.<sup>133</sup> A synthetic form of ANP may be useful in managing established oliguric acute renal failure,<sup>134</sup> but it has not been used prophylactically in high-risk surgical patients. Fenoldopam, a selective dopamine-1 receptor agonist, showed some promise as a renal protective agent but has not been tested in large multicenter prevention trials in the perioperative setting. A new generation of early biomarker tests may soon be available, capable of recognizing AKI much earlier than possible with accumulation of serum creatinine. The hope is that earlier AKI recognition will improve the effectiveness of current interventions.

As previously discussed, patients with hepatic failure or cholestatic jaundice are particularly susceptible to AKI. When the serum conjugated bilirubin exceeds 8 mg/dL, endotoxins from the gastrointestinal tract are absorbed into the portal circulation, causing intense renal vasoconstriction. Intravenous mannitol and/or oral administration of bile salts in the preoperative period may limit renal dysfunction in patients with cholestatic jaundice. This phenomenon may contribute to the high incidence of AKI after liver transplantation and biliary surgery. AKI occurs in up to two-thirds of liver transplant recipients.<sup>135</sup> Many liver transplant candidates have overt hepatorenal syndrome, renal dysfunction, and presumably underlying renal vasoconstriction. When such patients are exposed to intraoperative hemodynamic instability, massive transfusion, and nephrotoxins, AKI frequently follows.<sup>136</sup>

## **Anesthetic Considerations for Urologic Procedures**

A review of urologic surgical procedures follows, including sections on nephrectomy, cystectomy, prostatectomy, TUR procedures, and therapies for urolithiasis. For each section, general disease principles and treatment rationales are briefly discussed, perioperative management and potential complications reviewed, and then important aspects related to specific procedures within the section highlighted (e.g., simple versus radical **10** nephrectomy). Selected additional topics are outlined at the end of the section. Notably, a deliberate approach has been taken to minimize repetition by referring the reader to other chapter sections whenever appropriate.

## **Nephrectomy**

Nephrectomy procedures involve partial, radical, or simple resection of the kidney. Each year in the United States, there are approximately 46,000

nephrectomies for benign or malignant disease, and an additional 5,500 donor surgeries for renal transplant. Although radical nephrectomy is the standard for resectable kidney cancer, simple nephrectomy is typical for benign disease. Some kidney tumors invade the renal vein, extending as far as the inferior vena cava (IVC) or right atrium; these tumors require additional procedures to safely retrieve their intravascular component. Kidney transplant donor nephrectomy involves simple nephrectomy with measures to avoid organ trauma and optimize graft function. The so-called nephron-sparing or partial nephrectomy is indicated for limited benign disease but increasingly is being considered for wider indications, including selected cancerous lesions.

The approach and incision for nephrectomy are based on surgical priorities and surgeon preference. Retroperitoneal approaches require a flank incision and lateral decubitus positioning with flank extension ([Fig. 50-7](#)), allowing access to the kidney with avoidance of the peritoneal cavity. This approach has obvious advantages for treatment of infection but also simplifies procedures in those with prior abdominal surgery or obesity. Difficulties with the retroperitoneal approach include access to the vena cava, risk of unintentional pneumothorax, and the adverse effects of lateral decubitus position and flank extension on respiratory vital capacity, which can be reduced up to 20% (see [Chapter 29](#)).

Anterior approaches to nephrectomy involve supine positioning and breach of the peritoneal cavity through midline, subcostal, or thoracoabdominal incisions that provide direct access to both the kidney and major vascular structures. Although transperitoneal approaches add the risk of visceral injury and peritonitis, they improve access to the renal pedicle (e.g., trauma, hemorrhage) with best access to both kidneys being through midline incisions (e.g., bilateral nephrectomy for end-stage polycystic kidney disease). The thoracoabdominal approach enters both the peritoneal and pleural spaces and rarely may require single-lung ventilation.

In recent years, *laparoscopic* retro- and transperitoneal approaches to nephrectomy have surpassed their open equivalents in popularity, particularly for simple and donor procedures, but these techniques are even being used for nephron-sparing partial nephrectomy. Other recent innovations include robotic-assisted, single-port laparoscopic, and even transvaginal minimally invasive nephrectomies.

### **Preoperative Considerations**

Recruits for donor nephrectomy surgery are typically healthy individuals; however, perioperative risk for other nephrectomy procedures often relates to the indication for surgery. Although smoking and obesity are the most important risk factors for renal cancer, many other cardiovascular risk factors

are also strongly associated with renal cancer risk including advanced age, male gender, chronic renal disease or ESRD, and hypertension. Hence, protocols for assessment and management of perioperative cardiac risk are particularly relevant to nephrectomy surgery.<sup>137</sup>

Simple nephrectomy for infectious indications is uncommon but most often involves diabetic patients and can be grouped into two categories. Elective procedures involve irreversible kidney damage due to chronic pyelonephritis (e.g., xanthogranulomatous).<sup>138</sup> In contrast, emergent procedures are associated with very high mortality rates (up to 43%) and generally involve critically ill patients with acute emphysematous pyelonephritis unresponsive to antibiotics.

**Figure 50-7** Common positioning options for urologic surgery include right lateral decubitus with waist extension (A), lithotomy (B), supine with steep (30 to 45 degrees) Trendelenburg (C), and exaggerated lithotomy (D). (A, reproduced with permission from <http://www.opitek.dk/en/products/pedistirrup>.)

Several hereditary conditions that are associated with kidney cancer also have attributes that must be considered in anesthetic planning;<sup>139</sup> for

example, individuals with Birt–Hogg–Dubé syndrome have pulmonary cysts, which increase the risk of intraoperative spontaneous pneumothorax, whereas patients with von Hippel–Lindau syndrome, the commonest of these disorders, have high rates of pheochromocytoma and neuroendocrine tumors.

Ten to forty percent of patients presenting with renal cancer have associated paraneoplastic syndromes.<sup>140</sup> Beyond fever, cachexia, and weight loss, these subdivide into endocrine and nonendocrine categories. Tumor-related endocrine effects include hypercalcemia (PTH-like effects), hypertension (renin), anemia/polycythemia (erythropoietin), nonmetastatic hepatic dysfunction (Stauffer syndrome), galactorrhea, Cushing syndrome, and ectopic insulin and glucagon production, whereas nonendocrine effects include amyloidosis, neuromyopathies, vasculopathy, nephropathy, coagulopathy, and elevated prostaglandin levels. Of renal cancers presenting with hypercalcemia, 50% are paraneoplastic in origin. Renal tumors may also be associated with a hypercoagulable state; sudden intraoperative clot formation has been reported.<sup>141</sup>

As for most major urologic surgeries, other investigations for nephrectomy include routine ECG, chest x-ray, complete blood cell count, electrolyte profile with serum BUN and creatinine values, liver function tests, serum calcium assessment, coagulation testing, and urine analysis. Although normal serum creatinine level and evidence of contralateral function by means of intravenous pyelography are sometimes considered sufficient assessment to predict adequate postoperative renal function, a noninvasive differential renal scan (iodine-131 or technetium-99m computerized isotope renograph) is often performed for more precise prediction of postoperative GFR.

Urologic surgery patients often present with additional disease workup that can provide a wealth of information beyond routine studies and assessment of their urinary tract. Abdominal computed tomography (CT) scans detail tumor size and location and invasion of the renal collecting system or perirenal fat, whereas magnetic resonance imaging is most valuable to assess for vena caval and/or cardiac chamber involvement.

Standard recommended preoperative management of chronic drug therapies is all that is necessary for most nephrectomy procedures, although dose adjustment may be considered if significant changes in renal function are anticipated.

### *Intraoperative Considerations*

Preparation for even the most straightforward nephrectomy surgery demands sufficient monitoring and vascular access to respond to complications, most notably significant hemorrhage, an uncommon but ever-present risk in such procedures. Beyond standard monitoring (e.g., American Society of

Anesthesiologists guidelines) and two large-bore peripheral intravenous catheters, requirements for intravascular access and additional monitoring are dictated by patient condition and complexity of the procedure and may include a peripheral intra-arterial catheter for continuous blood pressure recording and repeated blood gas assessment and sometimes central venous access.

Although central venous line placement is not essential for most nephrectomy surgeries, patient and procedural factors such as comorbidities (e.g., cardiac history) and bleeding risk (e.g., tumor extension into venous structures) may warrant such access. If placement of a central venous catheter is deemed necessary, selection of the side *ipsilateral* to the nephrectomy surgery for subclavian or internal jugular central venous puncture should be considered to minimize the risk of bilateral pneumothorax.

Assessment of infection, bony metastases, and bleeding risk may influence the decision to include neuraxial procedures in the anesthesia plan. Sometimes spinal imaging from CT and magnetic resonance imaging scans can provide added detail useful when contemplating epidural catheter placement. If a lumbar or thoracic epidural catheter is placed, this is usually done prior to anesthesia induction to allow for a meaningful test dose sequence and to facilitate preincision administration of epidural opiates. Varied opinions regarding intraoperative local anesthetic dosing of the epidural catheter involve concerns over hemodynamic stability and the likelihood of significant blood loss during the procedure.

Neuraxial injection or catheter placement prior to anesthesia induction (e.g., epidural catheter insertion) can be followed by placement of intra-

**11** arterial and central venous access after anesthesia induction in most cases. Bladder catheter placement is essential for all nephrectomy procedures; urinary output monitoring provides information on intravascular volume status in the absence of central venous pressure monitoring, avoids the possibility of urinary retention, and also provides valuable information postoperatively regarding renal function, bleeding sources, and the possibility of clot-related urinary tract obstruction. Noninvasive cardiac output monitoring (e.g., esophageal Doppler, LiDCO [LiDCO Group plc, London, UK], noninvasive cardiac output) techniques may be useful in selected patients.

Standard preanesthesia induction considerations include postoperative planning (e.g., postanesthesia care unit versus stepdown versus intensive care unit disposition) and administration of intravenous antibiotic prophylaxis within 1 hour prior to surgical incision. Plans for postoperative analgesia strategy may dictate disposition particularly to involve a care team capable of recognizing and treating potential complications of the various analgesia strategies.

Anesthesia induction agent selection to achieve hypnosis, paralysis, and blunting of the hemodynamic intubation response should be matched to any use of regional anesthesia, the anticipated duration of the procedure, and the patient's renal function. Intraoperative and postoperative pain management can be accomplished by intravenous or other opioid therapies such as patient-controlled analgesia or neuraxial analgesia. Continuous epidural analgesia attenuates the neuroendocrine response but may also improve postoperative ventilatory mechanics and resolve ileus sooner, and has been associated with improved survival in intermediate- to high-risk noncardiac surgery.<sup>142</sup>

Potential intraoperative complications include injury to major blood vessels (e.g., IVC, aorta) or gastrointestinal organs (e.g., spleen, liver, pancreas) and unrecognized entry into the pleural space with resultant pneumothorax. Complications associated with hemorrhage during nephrectomy are uncommon but mandate preparatory steps beyond monitoring and generous intravenous access. Confirmation that blood products are present or readily available should occur immediately prior to surgery. Routine fluid and patient warming technology, availability of colloid volume expanders, and even a rapid transfusion device for selected cases should also be considered. Because unexplained changes in pulmonary mechanics or hypotension during a nephrectomy procedure may reflect diaphragmatic injury and pneumothorax, such changes should be discussed with the surgeon to facilitate prompt intervention. This may require direct repair of a rent in the diaphragm as well as needle decompression of a pneumothorax and chest tube insertion.

Particularly in the setting of limited renal reserve, in addition to consideration of transfusion triggers and strict avoidance of unjustifiable blood product administration, a note of caution is warranted regarding the potential for resuscitation "overshoot" in response to acute hemorrhage. Strict attention to appropriate monitors during fluid resuscitation and appropriate use of arterial blood gas assessment, assisted by good communication with the surgeon, will help avoid the risk of pulmonary edema from fluid overload.

### ***Postoperative Considerations***

Up to 20% of patients undergoing nephrectomy develop postoperative complications, and operative mortality rates following radical nephrectomy are as high as 2%. Added to standard concerns, such as hemorrhage and unrecognized visceral injury, are atelectasis, ileus, superficial and deep wound infections, temporary or permanent renal failure, and incisional hernia. The most common radical nephrectomy complications are adjacent organ (4% bowel, spleen, liver, diaphragm, or pancreas) and vascular injury (2%). Overall complication rates are similar whether an open or laparoscopic

approach is used.<sup>143–145</sup> Bleeding requiring transfusion occurs in up to 5.7% of all cases.<sup>146–148</sup> Other less common major complications include myocardial infarction, congestive heart failure, pulmonary embolism, cerebrovascular accident, pneumonia, and thrombophlebitis.

A logical expectation of nephrectomy surgery would be the need to adjust postoperative dosing of drug therapies to accommodate the anticipated decrease in GFR associated with an approximate 50% loss of kidney tissue. Although a drop in GFR can be anticipated, interestingly, adaptation of the remaining kidney usually results in a modest 25% decline postoperatively.

The pain of nephrectomy, laparoscopic or open, is significant. Analgesia can be achieved with epidural or spinal analgesia strategies, systemic opioids, and nonopioid adjuncts. Recent findings of improved recovery using epidural analgesia for major abdominal surgeries<sup>149</sup> have not been assessed specifically for nephrectomy surgery.

## **Specific Procedures**

### **Simple and Donor Nephrectomies**

Simple nephrectomy is sufficient intervention for irreversible nonmalignant disease such as untreatable infection, unsalvageable kidney trauma, or a nonfunctioning kidney due to calculi or hypertensive disease. In up to 86% of patients with hypertension that is presumed to be renovascular in origin with noncorrectable unilateral renal artery disease, hypertension control improves after simple nephrectomy.

During donor procedures, several steps are added to simple nephrectomy, including administration of drugs intravenously just prior to explant to achieve low-level anticoagulation (e.g., 3,000-USP heparin units) and forced diuresis (e.g., mannitol, 12.5 g; furosemide, 40 mg), extension of (laparoscopic) incisions to ensure atraumatic organ extraction, and postharvest protamine administration. Procured organs are infused with cold preservative (e.g., University of Wisconsin or histidine–tryptophan–ketoglutarate solutions) and stored on ice and/or cold machine perfused. Just over one-third of renal transplants in the United States are from living donors, and, compared to cadavers, living kidney donation is associated with improved short- and long-term outcomes (i.e., recipient and graft survival).

### **Radical Nephrectomy**

Renal cell carcinoma is the main indication for radical nephrectomy and accounts for 90% to 95% of kidney neoplasms and 3% of all malignancies in adults. With the exception of hereditary syndromes with high tumor rates (see earlier), a positive family history incurs a two- to threefold increased risk of

kidney cancer, but such cases constitute only 2% of radical nephrectomies. Hematuria, a palpable mass, and flank pain compose the classic triad at presentation, but renal tumors are more often (approximately 72%) diagnosed incidentally during workup for other nonurologic problems. Occasionally, tumors are discovered owing to signs or symptoms of vena caval involvement such as dilated abdominal veins, (left) varicocele, lower extremity edema, or pulmonary embolism. Symptomatic tumors usually reflect more advanced disease and are more often associated with metastasis and a poor prognosis. Transitional cell cancers of the upper urothelial tract (ureters, renal pelvis) are also treated by radical nephrectomy with resection of the associated ureter, including a cuff of bladder tissue. Up to one-third of kidney cancer patients have metastases at diagnosis, but many are still candidates for surgery.

Radical nephrectomy involves renal artery and vein ligation with subsequent removal *en bloc* of the kidney, perinephric fat, Gerota fascia, proximal ureter, and often the adjacent adrenal gland. Lymph node dissection is then performed from the diaphragm to the aortic bifurcation. Most renal cancers stay within Gerota fascia and can be completely removed, but a disappointing 20% to 30% of patients with successful surgery still have their disease return. Although radical nephrectomy is standard for central and large tumors, the value of nephron-sparing partial nephrectomy for early-stage and small renal cell cancers is being evaluated. Although nonsurgical therapies are available, renal cell cancers are resistant to radiation and chemotherapy. Blood loss during radical nephrectomy is highly dependent on the location and extent of the tumor. Laparoscopic innovations have reduced bleeding for all types of nephrectomy surgeries.

### **Radical Nephrectomy with Inferior Vena Cava Tumor Thrombus**

Between 4% and 10% of patients with renal cell carcinoma have the so-called tumor thrombus extension beyond the kidney, either limited to the renal vein or extending into the IVC. Although often restricted to the vessel lumen, the thrombus may become adherent to the vessel wall,<sup>150</sup> and right atrial involvement is present in 1% of cases. Radical nephrectomy procedures involving resection of tumor thrombus are particularly challenging owing to their risk of sudden major bleeding and potential for acute hemodynamic instability (e.g., inferior vena cava clamping or tumor pulmonary embolism).

Renal tumors with IVC thrombus are classified by the extent of tumor thrombus within the IVC and right atrium (levels I to IV; Fig. 50-8) and require different procedures in addition to radical nephrectomy.<sup>151</sup> In general, thrombus extraction can occur with simple proximal and distal caval control alone for tumors that go no further than the infrahepatic IVC. As thrombus

extends into the intrahepatic IVC or higher, isolating the vessel to extract the thrombus becomes more challenging and ultimately can only be achieved safely using CPB with or without aortic cross-clamping and cardiac arrest. In addition to sternotomy incision, such procedures require standard heparin anticoagulation and employ an added circuit venous line filter to trap tumor fragments (Fig. 50-8). Other interventions used at some institutions in the treatment of renal tumor caval thrombus include venovenous bypass, inferior vena cava filter insertion, and even deep hypothermic circulatory arrest.

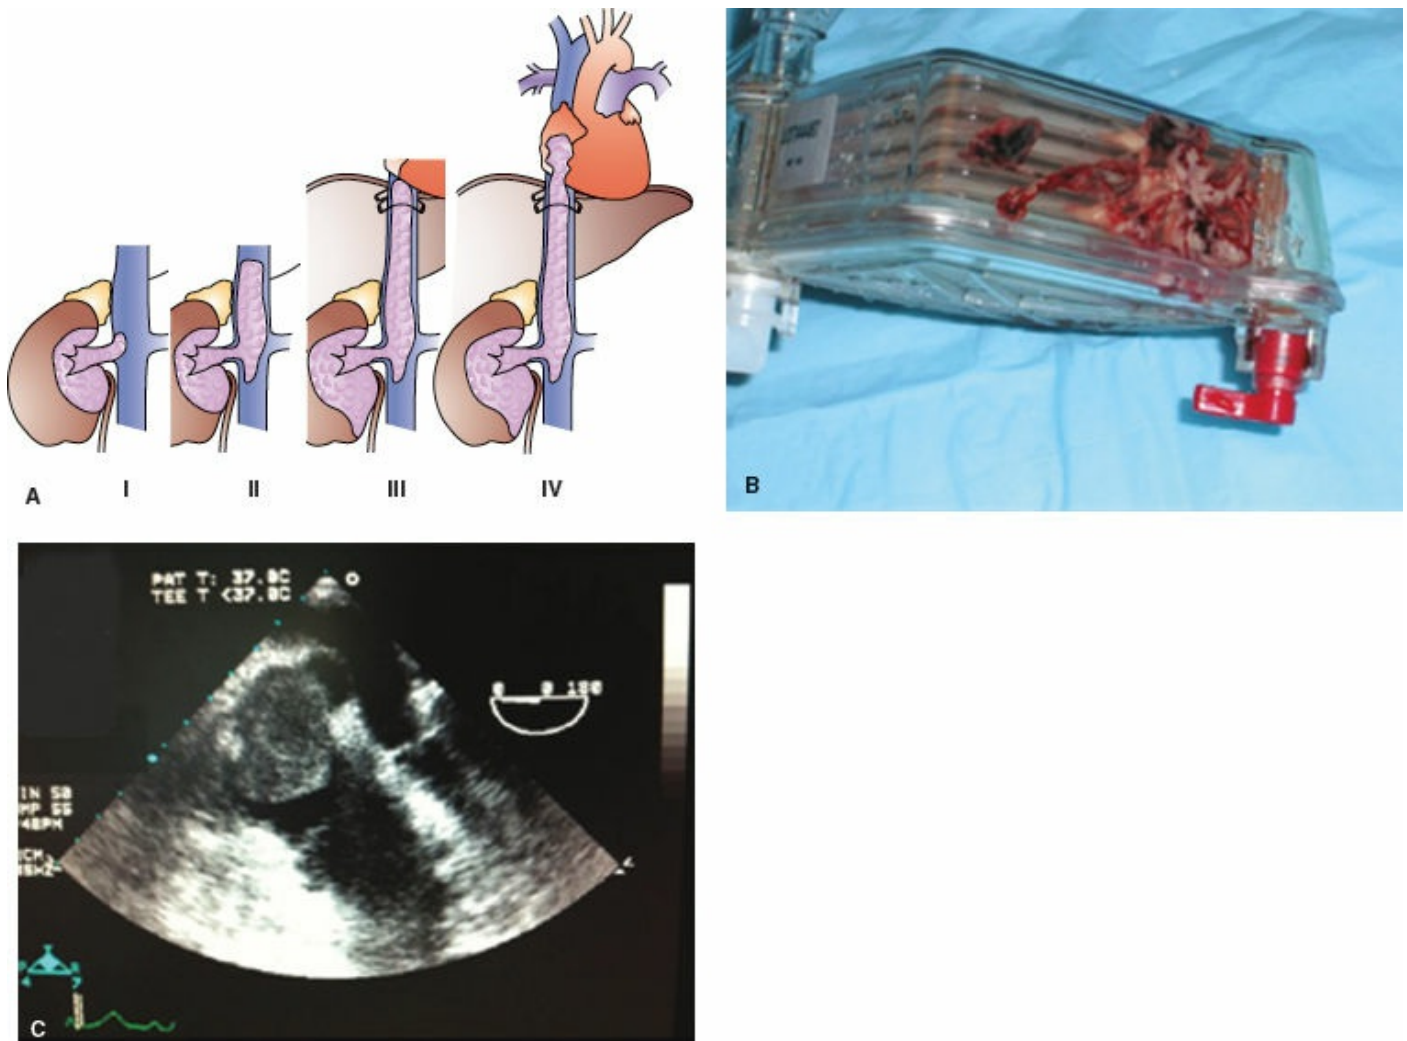

Appropriate considerations when monitoring these complex procedures include radial arterial catheterization, central venous or pulmonary artery catheter placement, and intraoperative transesophageal echocardiography (Fig. 50-8). In cases where supradiaphragmatic tumor thrombus is present, placement of a pulmonary artery catheter prior to thrombus resection is contraindicated owing to risk of embolization of tumor fragments. If the thrombus extends into the suprahepatic IVC, hepatic mobilization with the Pringle maneuver (clamping of the hepatoduodenal ligament to interrupt blood flow through the hepatic artery and portal vein) may be required, generally for less than 30 minutes.<sup>152</sup> Additional preparation includes all steps standard for procedures involving CPB (see Chapter 39), including large-bore peripheral intravenous access, vasoactive infusions, fluid, and blood products. Preoperative therapeutic embolization of the tumor is sometimes also used in cases of arterial thrombus or extensive parasitic vessel formation or when there is anticipated difficulty in isolating the renal artery. Despite the potential for significant blood loss, cell saver technology use is discouraged owing to the potential for returning tumor cells to the circulation.

### **Nephron-sparing Partial Nephrectomy**

Minimizing unnecessary loss of healthy tissue is a logical part of surgical planning for any kidney resection. Partial nephrectomy is often sufficient for benign tumors, but this procedure is also becoming an alternate to radical nephrectomy for some cancerous renal cell tumors, particularly when renal parenchyma must be preserved; examples include bilateral tumors, CKD, tumors in a single remaining kidney, or when the contralateral kidney is at risk for future disease or tumor. Even when the contralateral kidney is normal, studies are now demonstrating comparable long-term results with nephron-sparing partial nephrectomy procedures as with radical nephrectomy for patients with a single, localized small tumor (<4 cm) or even medium-sized (<7 cm) peripherally located tumors. Limitations of partial nephrectomy include a higher perioperative risk of bleeding and urine leak, and a local tumor recurrence rate of 1% to 6%.

## Laparoscopic and Robotic Nephrectomies

Laparoscopic and robotic techniques can be applied to retroperitoneal and transperitoneal approaches and all types of nephrectomies (i.e., radical, simple, or partial). Compared to open approaches, these minimally invasive strategies employ access through small airtight ports. Insufflation of carbon dioxide into the peritoneal cavity or retroperitoneal space is used to separate structures and enhance visibility. In recent years, laparoscopic techniques have surpassed open nephrectomies in popularity, particularly for simple and radical procedures. Laparoscopic approaches to radical nephrectomy are even being successfully employed in the treatment of locally invasive kidney cancer. Laparoscopic partial nephrectomy is technically more demanding than its open counterpart and currently involves temporary clamping of the renal hilum to optimize visibility during excision and minimize blood loss. The warm ischemic time related to clamping can cause AKI, particularly if the duration exceeds 30 minutes.<sup>153,154</sup>

**Figure 50-8** Radical nephrectomy with inferior vena cava thrombus removal for renal cell carcinoma is a major operative procedure. **A:** Surgical complexity is predicted by the extent of intravascular tumor thrombus, as classified by the most proximal level of tumor extension (levels I to IV). **B:** Evidence of thrombus emboli in the venous filter

following cardiopulmonary bypass highlights the friability of intravascular renal cell carcinoma thrombus. **C:** Intraoperative transesophageal echocardiography demonstrates right atrial extension of a renal cell tumor. (**A,** Adapted with permission from Nesbitt JC, Soltero ER, Dinney CP, et al. Surgical management of renal cell carcinoma with inferior vena cava tumor thrombus. *Ann Thorac Surg.* 1997;63:1592–1600.)

Some studies have reported comparisons of equivalent open and laparoscopic procedures. Laparoscopic radical nephrectomy for cancer involves smaller incisions, less blood loss, decreased postoperative analgesic requirement, shorter hospital stay and convalescent period, and similar long-term outcomes when compared with open radical nephrectomy.<sup>155,156</sup> Likewise, laparoscopic nephron-sparing partial nephrectomy results in less bleeding and a shorter hospital stay and for selected tumors has 5- and 10-year outcomes similar to those of open partial nephrectomy.<sup>157,158</sup> Laparoscopic donor nephrectomy has no adverse effects on the success of kidney transplant but is associated with less pain and analgesic requirement, faster hospital discharge, and better quality of life compared with open donor nephrectomy.<sup>159</sup> Institutional experience with laparoscopic and robotic assistance with nephrectomy procedures may influence anesthetic planning and the perceived need for invasive procedures (e.g., central venous cannulation).

Traditional open nephrectomy is associated with a significant incidence of chronic pain ranging from 5% to 26%.<sup>160,161</sup> The hope is that laparoscopic approaches will reduce the incidence of chronic pain syndromes. The perceived differences between laparoscopic and open nephrectomy procedures have influenced clinical practice, including anesthesia planning for postoperative pain management. Compared to open nephrectomy, the reduced pain and shorter recovery times have meant that epidural anesthesia is less likely to be selected for laparoscopic approaches, with postoperative pain control for these procedures provided by a multimodal strategy involving opiates and appropriate nonopioid adjuncts. NSAIDs are used rarely to avoid their potential nephrotoxic effects. Recent small studies have reported good success with continuous local anesthetic infusions via catheters placed in the rectus and retroperitoneal sheaths intraoperatively (across the intercostal, ilioinguinal, and iliohypogastric nerves). Benefits include reduction of the following: pain levels, opioid requirements, nausea, time to recovery and discharge, and cost.<sup>162,163</sup>

Robotic approaches to nephrectomy surgery are beginning to be employed but have very similar considerations to laparoscopic nephrectomy in terms of issues such as pneumoperitoneum. Notably, robotic nephrectomy has specific positioning requirements owing to the robotic equipment, and care must be

taken to assure that the robotic arms do not cause pressure injury to the patient. Depending on the experience of the surgical team, robotic procedures may also take more time. Notably, the role of robotic assistance is being similarly explored and developed for several other major urologic surgeries (e.g., partial nephrectomy, radical cystectomy, pyeloplasty, and radical cystectomy).<sup>164</sup>

## Physiology of Pneumoperitoneum

Despite potential surgical advantages of laparoscopic surgery, the consequences of pneumoperitoneum, most notably systemic CO<sub>2</sub> absorption and obstruction of venous return from the lower body, are important, particularly for patients with cardiopulmonary disease (see [Chapter 44](#)) ([Table 50-5](#)).<sup>165</sup> These include an average 30% decrease in cardiac output with the institution of pneumoperitoneum, which because of an associated increase in systemic vascular resistance (afterload), is often accompanied by little change or even an increase (up to 16%) in mean arterial blood pressure. Systemic vascular resistance and cardiac output usually return to near-normal values over the 10 minutes following institution of pneumoperitoneum. Preoperative fluid loading with additional preinduction colloid boluses before institution of pneumoperitoneum results in higher stroke volume and urine output compared to standard intraoperative fluid regimens, but studies are lacking regarding any evidence of improved outcome using this strategy.<sup>166</sup>

A strategy involving hydration and limiting insufflation pressures to below 12 mmHg is advocated. Presumably related to derangements of renal perfusion, pneumoperitoneum insufflation pressures of greater than 15 mmHg have been associated with postoperative AKI. Following laparoscopic donor nephrectomy, some donors develop oliguria despite hemodynamic stability and liberal fluid management strategies. The etiology of this is unclear, but it is usually self-limited. Urine output of more than 2 mL/kg/hr is reassuring, although there is no clear evidence that the diuretic effects of furosemide, mannitol, “renal dose” dopamine, fenoldopam, or ANP analogues are of any value in protecting the kidney.<sup>167</sup>

**Table 50-5** Physiology of CO<sub>2</sub> Pneumoperitoneum in the Trendelenburg Position

Organ System	Effect
Cardiovascular	↑ Systemic vascular resistance ↑ Mean arterial pressure ↑ Myocardial oxygen consumption ↓ Renal, portal, and splanchnic flow
Respiratory	↑ Ventilation–perfusion mismatch ↓ Functional residual capacity ↓ Vital capacity ↓ Compliance ↑ Peak airway pressure Pulmonary congestion and edema Hypercarbia, respiratory acidosis
Central nervous system	↑ Intracranial pressure ↑ Cerebral blood flow ↑ Intraocular pressure Catecholamine release
Endocrine	Activation of renin–angiotensin system
Others	Gastroesophageal regurgitation Venous air embolism Neuropraxia, especially brachial Tracheal tube displacement Facial and airway edema

Reprinted with permission from Irvine M, Patil V. Anaesthesia for robot-assisted laparoscopic surgery. *Contin Educ Anaesth Crit Care Pain*. 2009;9:125–129.

Other effects of pneumoperitoneum include restricted diaphragmatic excursion, acid–base abnormalities due to systemic absorption of CO<sub>2</sub>, neurohumoral responses, and the potential for venous gas embolism. Reductions in pulmonary compliance and functional residual capacity, combined with CO<sub>2</sub> absorption, often cause respiratory acidosis. Cephalad displacement of the abdominal contents, particularly in obese patients, can also add atelectasis and ventilation–perfusion mismatch. Cardiac valvular dysfunction has been reported during laparoscopic nephrectomy,<sup>168</sup> and cardiac ischemia can develop in at-risk patients with coronary artery disease. There is also an immediate increase in intracranial pressure with the institution of the pneumoperitoneum.

Hemodynamic instability or hypoxia that occurs with CO<sub>2</sub> insufflation owing to the abovementioned perturbations must be addressed, and a small number of patients will require conversion to an open surgical approach. However, despite the numerous disturbances, a majority of patients can be safely managed through episodes of pneumoperitoneum with appropriate circulatory support, thoughtful ventilator management, and good communication between surgeon and anesthesiologist that includes a willingness to adjust CO<sub>2</sub> insufflation pressures. Notably, adequate neuromuscular blockade plays a role in keeping insufflation pressures at the lowest level required to achieve optimal surgical exposure.

Offsetting advantages of laparoscopic approaches are risks also seen in settings other than nephrectomy, including trauma during trocar placement (~0.5%) and increased rates of postoperative deep venous thrombosis.

## Cystectomy and Other Major Bladder Surgeries

Cystectomy involves removal of all or part of the urinary bladder. Although radical cystectomy is standard for most muscle-invasive malignant disease, simple cystectomy is primarily for benign bladder disease. Of the estimated 69,250 cases of bladder cancer in 2011 in the United States, approximately 90% were expected to undergo a surgical procedure for their disease. Radical cystectomy combines bladder removal with resection of other pelvic organs and lymph nodes. Partial or simple cystectomy and transurethral resection of bladder tumor (TURBT) (see transurethral resection procedures section) are other procedures used in the treatment of benign and malignant bladder diseases.

As a result of removal of the entire bladder, simple and radical cystectomy procedures require a companion surgery to allow for future urine collection. The so-called diversion procedures involve redirecting the ureters, most commonly to a pouch fashioned from ileum (ileal conduit) that passively drains urine into a bag through a stoma on the patient's abdominal wall. Alternate options include the so-called continent diversion reconstructive procedures, which are becoming more popular. Because diversion surgeries can make future diagnosis of appendicitis difficult, some surgeons routinely also perform an appendectomy as part of urinary diversion procedures.

Supine or modified lithotomy positioning (Fig. 50-7) and midline incision with avoidance of the umbilicus are standard for open cystectomy surgery; however, a transverse abdominal incision is occasionally used. Much like nephrectomy, both retroperitoneal and transperitoneal approaches are feasible for cystectomy, and laparoscopic and robotic-assisted techniques are becoming popular for both cystectomy and diversion procedures.

### *Preoperative Considerations*

The most common patients presenting for cystectomy are those with bladder cancer. Approximately 90% have transitional cell tumors, and approximately 90% of these have already invaded muscle at diagnosis. Bladder tumors occasionally present with urinary retention but are generally diagnosed by hematuria (microscopic or macroscopic) with or without voiding symptoms such as urgency, frequency, and dysuria. Prior to cystectomy, patients have usually undergone one or several cystoscopies for tumor biopsy or resection, and many have already received radiation and chemotherapy.

Risk factors for bladder cancer and atherosclerosis overlap, and perioperative protocols for cardiac risk assessment and management are relevant to cystectomy surgery.<sup>137</sup> Smoking history is most important, doubling the risk of bladder cancer, and occupational exposures in the leather, dye, and rubber industry and drinking water with high arsenic levels also contribute. Men are about four times more likely than women to be diagnosed with bladder cancer, with white men twice as susceptible as African-American men. The average patient presenting with bladder cancer is 65 years old. Paraneoplastic syndromes similar to those seen with kidney cancer have been reported with bladder cancer but are relatively rare.

### *Intraoperative Considerations*

Anesthetic management for cystectomy is similar to that for nephrectomy surgery (see earlier), including preparation for the potential for major bleeding. Although patients could strictly undergo cystectomy surgery with epidural anesthesia alone, this is rarely chosen because of the extended duration of surgery. Particular attention should be paid to the approach to assessment of intravascular volume during cystectomy given the considerable potential for bleeding and hypovolemia and the absence of meaningful urine output data. Combining intraoperative epidural analgesia with a general anesthetic for cystectomy may reduce bleeding and improve postoperative analgesia without otherwise affecting complication rates.<sup>169</sup>

A trend in radical cystectomy has been toward the use of fast-track protocols (e.g., Enhanced Recovery After Surgery [ERAS]). Made popular by their use in colorectal surgeries, such protocols include a variety of evidence-based preoperative, intraoperative, and postoperative management strategies aimed at achieving early return of gastrointestinal function and good pain control, thereby minimizing the surgical stress response, reducing end-organ dysfunction, and improving overall recovery following major surgery. The use of such pathways has been reported to significantly reduce time to discharge and incidence of postoperative complications, with the best supporting evidence coming from colorectal surgery outcomes.

For radical cystectomy, the ERAS Society recommendations start with preoperative counseling, education, and optimization. Avoidance of oral mechanical bowel preparation is recommended. Rather than prolonged fasting, the patient can consume a light meal 6 hours prior to surgery, a clear carbohydrate drink for preoperative hydration and glucose and insulin optimization up until 2 hours before surgery. After arrival in the preoperative area, a multimodal analgesic regimen (often involving insertion of a thoracic epidural catheter for regional analgesia and a minimal approach to systemic opioid administration) is started, along with venous thromboembolism

prophylaxis using subcutaneous heparin injection. Intraoperatively, a minimally invasive surgical approach is employed whenever possible. End-organ function is optimized through a goal-directed fluid management strategy involving noninvasive cardiac output monitoring.<sup>170</sup> Postoperatively, return of gastrointestinal function is encouraged through early mobilization and oral diet and avoidance of nasogastric intubation.<sup>171</sup>

Notably, evidence of improved outcomes with implementation of ERAS protocols for cystectomy remains scant compared to that in colorectal surgery.<sup>172</sup> However, small studies point to improvements in return of bowel function and lower-readmission rates at 30 days,<sup>173</sup> as well as improved wound healing, decreased fever and thrombosis, lower analgesic requirement, improved gastrointestinal function, and decreased time in the intermediate care unit.<sup>174</sup>

## *Postoperative Considerations*

Simple cystectomy with diversion procedure involves a more limited dissection of pelvic structures relative to radical cystectomy and is generally associated with considerably less blood loss and lower complication rates.<sup>175</sup> Following radical cystectomy with diversion, some patients will require admission to an intensive care unit. Average blood loss ranges between 560 and 3,000 mL, and transfusion is common. Hospital lengths of stay can be long but vary considerably among centers. The mortality rate for radical cystectomy with diversion is approximately 1%, and perioperative complications are common (27.3%).<sup>176</sup> Early problems include acute pyelonephritis following ureteral catheter removal, ileus, injury to local structures such as the obturator nerve (adductor palsy and gait disturbance), and impaired lymph drainage (lymphocele, leg edema).

## *Specific Procedures*

### **Partial Cystectomy**

Nonmalignant indications for partial bladder resection include bladder endometriosis and benign tumors (e.g., lymphangioma). Whenever partial cystectomy will suffice, the effects of added surgery and poorer quality of life associated with a urinary diversion procedure can be eliminated; hence the current interest in methods to identify bladder cancer patients for whom partial cystectomy with pelvic lymph node dissection may be as good a treatment as radical cystectomy. Selective bladder-sparing protocols that use responsiveness of a tumor to chemotherapy and radiation therapy as a guide to surgical decision making appear to successfully identify about one-third of

the patients whose long-term outcome with partial cystectomy is equivalent to radical cystectomy, without the need for a diversion procedure.<sup>164</sup>

## Simple and Radical Cystectomy

Simple cystectomy is indicated for benign disease such as neurogenic bladder, refractory bladder pain syndrome (interstitial cystitis), bladder damage from radiation, and refractory incontinence.

Radical cystectomy involves resection of the bladder and related pelvic structures, including pelvic lymphadenectomy of obturator and iliac nodes. In the male, the bladder is removed *en bloc* with pelvic peritoneum, prostate and seminal vesicles, ureteric remnants, and a small piece of membranous urethra. In the female, the uterus, ovaries, fallopian tubes, vaginal vault, and urethra are removed. Alternate terminology to radical cystectomy for these major procedures include radical cystoprostatectomy in men and radical cystectomy with pelvic exenteration in women.

## Ileal Conduit and Other Diversion Procedures

The concept of ileal conduit surgery is relatively straightforward, involving creation of an ileal pouch that is attached to both ureters and the abdominal wall as a stoma. In contrast, continent diversion procedures are numerous and diverse in their approaches to urine collection and drainage. Continent urinary diversions can be categorized into (1) ureterosigmoidostomy, (2) continent cutaneous diversions, and (3) neobladder diversions to the native urethra.<sup>177</sup> Ureterosigmoidostomy is only occasionally used and involves tunneling the ureters to the sigmoid colon, with urine storage and elimination being through the rectum. Continent cutaneous reservoirs resemble ileal conduit surgery, but the stomal attachment to the abdominal wall is modified to produce a valve mechanism, with urine drainage achieved by intermittent catheter drainage. Many continent cutaneous variants exist that involve the use of different bowel segments as the source for the reservoir (e.g., ileum, ileocecum, ascending colon, sigmoid colon, or transverse colon). Finally, continent orthotopic diversions involve neobladder construction from terminal ileum, cecum, or sigmoid colon, which is attached to proximal urethra and its intact rhabdosphincter mechanism. Notably, all urinary diversion procedures involve extensive dissection and are considerably more challenging if the patient has received preoperative radiation therapy. Complications of urinary diversion surgery include bowel obstruction, urinary tract infection, deep venous thrombosis and pulmonary embolism, pneumonia, upper urinary tract damage, and skin breakdown around the stoma.

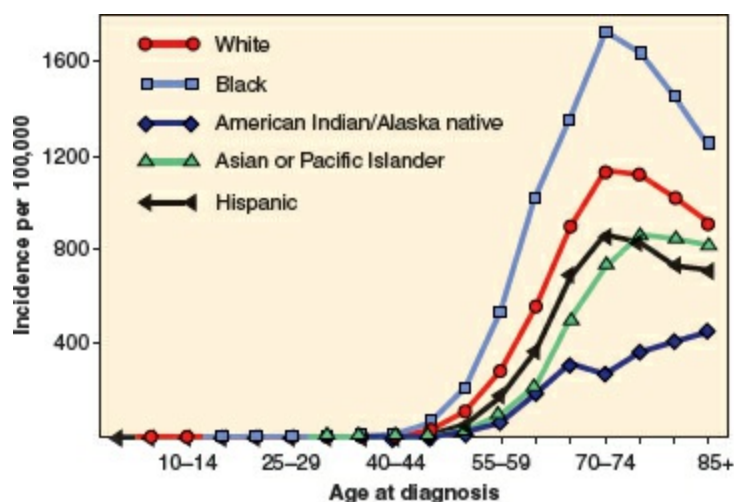

After recovery, patients with urinary diversions are vulnerable to

conditions that require subsequent surgeries; these include problems at the stoma site (e.g., stricture, hernia, prolapse, retraction; 5% to 10%), fistulae between urinary tract and bowel (3%), bowel obstruction, reservoir or other genitourinary stone diseases (5%), impotence, primary tumor recurrence, and even bowel cancer in the bladder pouch. In addition, post-radical cystectomy bladder cancer victims are subjected to frequent surveillance procedures owing to their high risk for future upper urinary tract urothelial malignancies (3%) and may require radical nephroureterectomy.

Anesthetic considerations for patients who present with existing diversion procedures include metabolic and electrolyte abnormalities such as hyperchloremic metabolic acidosis (common), hypokalemia, hypocalcemia and hypomagnesemia, and high rates of urinary tract infection and pyelonephritis. In addition, these individuals frequently suffer from chronic diarrhea and may have problems related to malabsorption (e.g., vitamin B12 deficiency).

## Prostatectomy

Almost all procedures involving complete resection of the prostate (i.e., prostatectomy) are for adenocarcinoma of the prostate, because nonmalignant surgical disease of the prostate is typically so amenable to TUR (see the next section). Although prostate cancer is a disease limited to men, it is the second most common cancer in most countries, with an incidence that increases significantly with age and is approximately 50% more common in African-American men than in Caucasian men (Fig. 50-9).<sup>178</sup>

**Figure 50-9** Crude incidence rates for prostate cancer, by race/ethnicity. (Adapted from [www.seer.cancer.gov](http://www.seer.cancer.gov).)

Current evidence-based opinion on the optimal management of prostate cancer is rapidly evolving, including the relative value of intervention (i.e.,

hormonal, cryo-, chemo-, and internal and external radiation therapy; highly focused ultrasound ablation; and surgery) compared to an expanded role for watchful waiting in low-risk groups, as identified by measures such as tumor aggressiveness (e.g., Gleason score) and biomarkers (e.g., prostate-specific antigen levels). A second related concept is also emerging—that prostate cancer may exist in clinically significant (approximately 15%) and insignificant forms.<sup>179</sup> In general, surgical approaches are likely in younger men, whereas elderly patients who may die from disorders other than the prostate cancer are being more frequently advised to pursue nonsurgical therapy.

Prostatectomy can be performed using retropubic or perineal approaches and is amenable to endoscopic techniques with or without robotic assistance. The retropubic approach requires the patient to be supine with the bed extended and in Trendelenburg position (Fig. 50-7). This allows access to the prostate gland and related lymph nodes from behind the pubic symphysis (and the best chance of sparing the neurovascular bundle), using either a vertical midline or Pfannenstiel (horizontal low suprapubic) incision. In contrast, the perineal approach requires the patient to be in exaggerated lithotomy and steep Trendelenburg position (Fig. 50-7), with an incision between the scrotum and the anal sphincter that provides adequate access to the prostate (but not lymph nodes).

### *Preoperative Considerations*

Beyond advanced age, relatively few factors predict likelihood of contracting prostate cancer. Family history more than doubles the chances of the disease, while African-American descent increases the risk by approximately 50% (Fig. 50-9). Otherwise, factors such as smoking, obesity, diet, history of vasectomy, prostatitis, or sexually transmitted diseases have little or no effect on prostate cancer risk. Owing to the advanced age of the population presenting for prostatectomy, an emphasis on comorbid disease in preoperative evaluation is particularly relevant. Paraneoplastic syndromes similar to those seen with kidney cancer are occasionally evident in prostate cancer patients.

### *Intraoperative Considerations*

Anesthetic management for open prostatectomy is similar to that for cystectomy surgery (see earlier), including attentiveness to the potential for major bleeding. Epidural catheter placement is usually in the low thoracic spinal region, guided in part by the chosen option for anesthesia, including spinal/epidural alone, general alone, or combined spinal/epidural and general anesthesia. A surgical block to at least the T10 level is required for procedures

performed using neuraxial block alone. In one study, patients experienced 33% less pain when preemptive epidural dosing occurred prior to incision.<sup>180</sup> Radical prostatectomy may take longer than the duration of a single-dose spinal anesthetic, so epidural or combined spinal–epidural is recommended. Notably, a neuraxial-alone strategy for perineal prostatectomy is likely to be poorly tolerated owing to the uncomfortable exaggerated lithotomy and head-down positioning requirements. Exaggerated lithotomy position for prostatectomy has also been associated in some studies with higher rates of neurologic injury (21% with transient sensory or motor deficit); patients appear to be at greater risk when surgery lasts longer than 180 minutes.<sup>181,182</sup> In addition, even with general anesthesia, some patients tolerate the exaggerated lithotomy–head-down position for perineal prostatectomy poorly owing to elevated ventilation pressures and impaired oxygenation.

As with cystectomy, the approach to intravascular volume assessment during prostatectomy must consider the potential for bleeding and hypovolemia and limited meaningful urine output data; the need for arterial and/or pressure central venous monitoring should be guided by patient comorbidities. Neuraxial anesthesia for prostatectomy has been associated with decreased blood loss in some studies.<sup>183</sup> However, any blood-sparing benefits of neuraxial anesthesia appear to be lost when it is combined with mechanical ventilation (and general anesthesia), possibly as a result of the effect of increased intrathoracic pressure on prostatic venous pressures.<sup>184</sup> Notably, breaching of the rich prostatic venous plexuses also creates the potential for acute hemodynamic instability from major venous air embolism, which has been reported during both retropubic and perineal prostatectomy approaches; suspicion of this complication warrants immediate steps to flood the surgical field and alter patient positioning to raise venous pressures above atmospheric, in addition to other standard resuscitation measures.<sup>185</sup>

### *Postoperative Considerations*

Simple prostatectomy requires a limited dissection relative to radical prostatectomy and is generally associated with less blood loss and lower complication rates. Nonetheless, most radical prostatectomy patients are not admitted to an intensive care unit. Average blood loss for radical prostatectomy is between 500 and 1500 mL,<sup>186</sup> and approximately 10% of patients will require a perioperative blood transfusion.<sup>187</sup> In addition to vascular injury, the most common serious intraoperative complication is bowel or ureteral injuries. The mortality rate for radical prostatectomy is less than 1%. Impaired lymph drainage (lymphocele, leg edema) is associated in some studies with increased rates of postoperative deep venous thrombosis and pulmonary embolism.<sup>187</sup>

Transversus abdominis plane local anesthetic blocks are used at some institutions for pain management to facilitate retropubic prostatectomy fast-track recovery protocols<sup>188</sup>; ultrasound guidance for these procedures can minimize procedure-related risk of adjacent structure injury (e.g., bowel).

## Specific Procedures

### Simple Prostatectomy

Simple open prostatectomy is occasionally required for resection of very large prostate glands affected by benign prostatic hypertrophy (BPH),<sup>189</sup> but, in the era of medical therapies such as  $\alpha$ -1 selective adrenergic receptor blockers and 5 $\alpha$ -reductase inhibitors, this is an infrequent procedure. Currently, retropubic prostatectomy is the most common approach in the United States.

### Radical Prostatectomy

Radical prostatectomy involves removal of the entire prostate gland, seminal vesicles, and generally the surrounding nerves and veins. The part of the urethra within the prostate gland's transition zone is also removed. Preservation of one or both cavernous nerves (part of the neurovascular bundle on each side of the prostate) can improve postsurgery quality of life (i.e., reduced urinary incontinence and erectile dysfunction) but limits the extent of possible resection. Notably, the incidence of positive margins with tumor resection during radical prostatectomy is significant (~30%). The value of more aggressive resection with sural nerve grafting to address erectile dysfunction remains unclear.<sup>190</sup> Controversial early data on the association of epidural anesthesia and analgesia with lower rates of cancer recurrence<sup>191</sup> have not been substantiated in more recent reports.

### Laparoscopic and Robotic Prostatectomy

Minimally invasive laparoscopic and robotic-assisted approaches to prostatectomy are gaining popularity (see [Chapter 44](#)). Although these techniques are characterized by less pain, shorter hospital stays, faster recovery, and improved patient satisfaction,<sup>192</sup> they also present added challenge for the anesthesiologist, including prolonged procedure duration, the risk of hypothermia, occult blood loss, and the physiologic stresses of pneumoperitoneum and exaggerated Trendelenburg with or without lithotomy positioning.

Laparoscopic and robotic prostatectomy procedures require general anesthesia with endotracheal intubation. Standard monitoring and adequate intravenous access must be established prior to patient positioning because

access after positioning is very difficult (Fig. 50-10). Pulse oximeter probe placement should avoid the earlobe to anticipate the potential for inaccurate readings in this location, presumably related to the venous engorgement with head-down positioning and pneumoperitoneum.<sup>193</sup> Intra-arterial and central venous monitoring are not routine but may be indicated based on patient comorbidities. As with all robotic surgeries, because of the fixed position of the robot arms, movements such as coughing can cause injury internally or at port sites, so care must be taken to maintain adequate depth of anesthesia and neuromuscular blockade. Exaggerated Trendelenburg positioning is required for the procedure, and some practitioners deliberately refrain from dosing epidural catheters to avoid cephalad spread of epidural drugs during the procedure.

Steep Trendelenburg positioning (30 to 45 degrees head-down) to facilitate pelvic access during laparoscopic and robotic prostatectomy increases the risk of several important complications (Fig. 50-7). To prevent sliding, patients must be well situated on the operating table (e.g., within a vacuum bean bag) then firmly secured (e.g., tape, safety belt). Arms should be placed on angled armboards *prior* to lowering the end table section during lithotomy positioning to minimize the risk of pinched or crushed fingers. The patient's arms are generally tucked at the side, and pressure points are carefully padded. Additional padding should distribute localized pressure from shoulder braces, which sometimes support a significant fraction of the patient's body weight (Fig. 50-10). Beyond brachial plexus protection with shoulder padding, attention should be paid to radial (at the humerus), ulnar (at the elbow), and lateral femoral cutaneous (by the lithotomy leg holders) nerves to minimize axonal injuries. Finally, because oral ulceration and even conjunctival burns have been attributed to lithotomy-related reflux of gastric contents, steps such as preoperative antacid therapy, stomach drainage by orogastric tube, and waterproof eye taping should all be considered.<sup>194</sup>

**Figure 50-10** Images from a robotic radical prostatectomy procedure highlight the significant difficulty in accessing patients after the robot is docked (**A**), the remote location of the surgeon (**B**), the utility of a carefully placed Mayo stand to protect the patient's face and endotracheal tube (**C**), and the value of shoulder support padding to avoid pressure injuries (**D**).

Lack of easy access to the patient is a concern during robotic prostatectomy, primarily caused by the sheer size of current robot arms ([Fig. 50-10](#)). Hence, positioning preparation must be thorough and completed prior to robot docking. A Mayo instrument standing directly above the patient's head can help prevent robotic arms from causing pressure-related facial injuries and/or endotracheal tube displacement ([Fig. 50-10](#)).<sup>195</sup> Operating

room staff must also be trained for robot emergencies, particularly timely removal of the device. Notably, although cardioversion and defibrillation are possible with the robot docked, cardiopulmonary resuscitation with chest compressions is nearly impossible.

The physiology of steep Trendelenburg positioning is well tolerated by healthy patients,<sup>196</sup> but this cannot be assumed for those with serious comorbidities. Adding to the stresses of head-down positioning during laparoscopic prostatectomy are the effects of CO<sub>2</sub> pneumoperitoneum (see nephrectomy section; [Table 50-5](#)). Although no formal guidelines exist, additional monitoring for patients with cardiac disease (e.g., compensated congestive heart failure) may be justified to assess responses to position-related intravascular volume shifts. Respiratory effects of robotic prostatectomy are numerous and often require considerable adjustments to mechanical ventilation parameters. Endotracheal tube cuff location should be just beyond the vocal cords to minimize the potential for developing a main stem intubation with the cephalad shift of the diaphragm and mediastinum from the combination of head-down positioning and pneumoperitoneum.<sup>193</sup> The related encroachment of abdominal contents onto the diaphragm also has significant effects on pulmonary function, particularly in obese patients, including reductions in functional residual capacity, vital capacity, and overall lung compliance, which translate into the need for higher peak airway pressures for equivalent tidal volumes. In addition, obese patients experience greater ventilation/perfusion mismatching. One study reported an average 8% lower tidal volumes, 22% higher respiratory rates, and 38% higher peak inspiratory pressures to maintain similar end-tidal carbon dioxide levels, but lower oxygen saturation during robotic compared to open retroperitoneal radical prostatectomy.<sup>197</sup> Interestingly, CO<sub>2</sub> insufflation for retroperitoneal laparoscopic procedures requires greater increases in minute ventilation to compensate for absorbed CO<sub>2</sub> than equivalent transperitoneal procedures.<sup>194</sup> Tolerance of mildly elevated CO<sub>2</sub> levels (permissive hypercarbia) during some phases of the surgery may be a good strategy in some patients, but is potentially ill advised for patients with CKD, in which even mild respiratory acidosis can be associated with significant hyperkalemia.<sup>198</sup> Transcranial Doppler<sup>199</sup> and cerebral oximetry<sup>196</sup> to monitor intracranial perfusion have been suggested for patients with cerebrovascular disease. Potential adverse effects on intraocular pressure of head-down positioning in at-risk patients (e.g., poorly controlled glaucoma) have not been rigorously studied. Despite all these physiologic perturbations, the need to convert from laparoscopic/robotic assisted to open techniques for major urologic procedures is remarkably infrequent.<sup>194</sup>

During robotic prostatectomy, one of the major surgical steps involves reanastomosis of the severed urethral ends after prostate gland resection. This

is often made more complicated by urine from the bladder neck's spilling directly into the operative field, obscuring the surgeon's view and impeding progress. Anticipation of this problem by the anesthesiologist can assist the surgeon through cautious fluid restriction, particularly prior to urethral anastomosis. A generally restrictive approach to fluid administration may also attenuate the development of mild facial, periorbital, and even occasionally laryngeal edema associated with prolonged steep lithotomy position.<sup>193,194</sup> However, edema accumulation is rarely sufficient to threaten airway patency after tracheal extubation.

## Transurethral Surveillance and Resection Procedures

Transurethral endoscopy is a commonly used, relatively noninvasive surgical tool in the armamentarium of the urologist that can play an important role in the management and treatment of urothelial cancers (e.g., cystoscopy/ureteroscopy surveillance, TURBT), urolithiasis (e.g., ureteroscopic stent placement, basket stone retrieval), and BPH (e.g., transurethral resection of the prostate [TURP]). Despite the benign and noninvasive appearance of transurethral tissue resection surgeries (TURBT, TURP), these procedures are occasionally associated with significant morbidity and even mortality.

Cystoscopy and TURBT procedures are used in the surveillance, staging, and management of transitional cell bladder cancers (see cystectomy section). For patients with superficial cancers that do not invade the bladder muscle, bladder biopsy and subsequent TURBT may be curative, but such patients require ongoing cystoscopy surveillance and often receive biologic therapies (e.g., *Bacillus Calmette–Guérin* vaccine) that reduce the recurrence rate of bladder cancer, presumably by boosting the immune response. Nonetheless, about 50% of patients with a resected bladder cancer will develop another bladder or ureteral cancer in the future.

TURP is a mainstay and even gold standard therapy to alleviate urine obstructive symptoms related to BPH. BPH describes the smooth muscle and epithelial cell proliferation within the transition zone of the prostate that histologically characterizes this disorder. The symptoms of BPH reflect the combination of bladder outlet obstruction (static) and increased smooth muscle tone (dynamic). Although TURP surgery with electrocautery has been for many decades central to the treatment of BPH, a proliferation of other options explains the steady decrease in the use of TURP for BPH treatment, partly owing to the significant side effects that can occur with this procedure (e.g., incontinence, impotence). Medical therapy for BPH is common, directed at both static and dynamic components of the disease ( $\alpha$ -1 adrenergic antagonists and  $\alpha$ -1A reductase inhibitors), and is part of the current more

conservative watchful waiting approach to surgical treatment of BPH. Numerous alternate procedures to TURP are now being used for BPH; in 2005, TURP represented only 39% of BPH procedures compared to 81% in 1999.<sup>200</sup> Description of these alternate procedures is beyond the scope of this text, but some of these include transurethral needle ablation, transurethral microwave thermal therapy, transurethral ablation prostatectomy, holmium laser ablation of the prostate, interstitial laser coagulation, high intensity focused ultrasound, and water intensity hyperthermia.

Positioning concerns for cystoscopy, TURBT, and TURP are the same as for other procedures in lithotomy position (Fig. 50-10) and in particular relate to adequate padding of pressure points and avoidance of peroneal nerve compression.

### *Preoperative Considerations*

Patients presenting for TURP are likely to be elderly and may have other serious comorbidities. Cardiovascular and pulmonary status should be carefully assessed to evaluate the patient's ability to tolerate the intravascular volume changes associated with the procedure. Patients on anticoagulant therapy may not be candidates for spinal anesthesia, depending on the indication for anticoagulation. The risk of stopping the anticoagulant perioperatively may or may not be worth the advantages of spinal anesthesia for a particular patient. Decisions about this should be made in conjunction with the surgeon, because the risk of postoperative bleeding following TURP will likely dictate an interval of normal coagulation or bridging treatment with short-acting anticoagulants such as heparin.

### *Intraoperative Considerations*

Choice of anesthetic technique for cystoscopy, TURBT, and TURP procedures should be tailored to the individual and can be performed safely with either general or regional anesthesia.<sup>201</sup> Neuraxial block allows the patient to remain awake and may hasten the diagnosis of bladder or prostatic capsule perforation and the TUR syndrome and may also decrease blood loss compared with general anesthesia.<sup>202,203</sup> For ambulatory surgery patients, care must be taken in the selection of spinal anesthetic medications so as to avoid prolonged anesthetic duration and delayed discharge from the facility. Combined spinal–epidural techniques or general anesthesia may have advantages if the length of surgery is unpredictable. Notably, the lower central venous pressure associated with regional anesthesia may actually increase the likelihood of significant irrigation fluid absorption.<sup>204</sup>

Hypothermia can complicate TURP procedures. Body temperature

decreases approximately 1°C per hour of surgery, and shivering occurs in 16% of patients who receive room-temperature irrigation fluids. Hypothermia does not develop if irrigation solutions are warmed to body temperature.<sup>205</sup>

Approximately 2.5% of patients require transfusion during TURP surgery. Average blood loss is 2 to 4 mL/min,<sup>206</sup> but individual bleeding rates can be difficult to assess owing to mixing with irrigating fluid. The patient's vital signs may be useful to guide transfusion,<sup>207</sup> but, with prolonged resections, serial assessments of hemoglobin level are advisable.

Surgical perforation of the prostatic capsule occurs in 2% of TURP procedures, usually resulting in extraperitoneal fluid extravasation. Awake patients with a neuraxial anesthetic may complain during surgery of new-onset pain localized to the lower abdomen and back.<sup>207,208</sup> Bladder perforation during TURBT more commonly results in extravasation of fluid intraperitoneally and may produce abdominal distension and complaints of abdominal and shoulder pain in awake patients.<sup>209</sup> Notably, evidence of perforation often only becomes clear postoperatively.

### *Postoperative Considerations*

Although abnormal bleeding after TURP occurs in fewer than 1% of resections,<sup>206</sup> 2% to 3% of patients will require transfusion perioperatively.<sup>210,211</sup> Blood loss following TURBT is usually less than 100 mL, although postoperative hemorrhage can rarely occur. Thromboplastin, a thrombogenic stimulant found in high concentrations in prostate cancer cells, can rarely trigger disseminated intravascular coagulation.<sup>207</sup> Another cause of post-TURP bleeding is release of prostatic tissue plasminogen activators. These factors convert plasminogen to plasmin, causing fibrinolysis. Treatment of these conditions is supportive and may include transfusion of coagulation factors and platelets.<sup>212</sup> Prophylactic administration of antifibrinolytics (e.g., tranexamic acid) demonstrated some success but has not gained widespread acceptance as standard practice.<sup>213</sup> Nevertheless, it may be considered in cases of refractory bleeding.

As outlined earlier, bladder, prostatic capsule, or urethral perforations are uncommon but serious complications that may manifest postoperatively with or without symptoms of TUR syndrome (see later). Fever related to TURP procedures may indicate bacteremia secondary to spread of bacteria through open prostatic venous sinuses, particularly with a history of infectious prostatitis.

The most common complications following TURP surgery are the need for urinary recatheterization (4%), prostatic capsule perforation (2%), and postoperative hemorrhage requiring transfusion (1%).<sup>214</sup> The 30-day mortality following TURP is 0.2%<sup>208,215-218</sup> and most commonly relates to

serious cardiac and respiratory complications.<sup>219</sup>

## **Specific Procedures**

### **Cystoscopy and Ureteroscopy**

Although surveillance cystoscopy is often performed under local anesthesia outside the operating room with minimal monitoring or sedation and without the involvement of anesthesia personnel, some cystoscopy and most ureteroscopy procedures, particularly for those patients with comorbidities, occur in the operating room setting. Cystoscopy and ureteroscopy are rarely associated with significant complications, and perioperative considerations should generally parallel those for the disease being screened for or managed (see related sections).

### **Transurethral Bladder Tumor Resection**

During any simple cystoscopy or ureteroscopy procedure, abnormal tissue may require one or more planned or unanticipated diagnostic biopsies or biopsy/resections. As outlined earlier (see cystectomy section), risk factors for bladder cancer and atherosclerosis overlap, and cardiac risk assessment is relevant to TURBT surgery.<sup>220</sup> A serious intraoperative complication of TURBT is bladder perforation by the rigid cystoscope during tissue resection, which occasionally occurs owing to unexpected patient movement. For this reason, muscle relaxation is preferred during general anesthesia, particularly in lateral wall resections, where the obturator nerve may be stimulated by electrocautery, producing a violent contraction of the ipsilateral thigh muscles. Neuraxial anesthesia to the T9 to T10 dermatomal level also provides adequate anesthesia for the procedure and prevents the obturator reflex. Regional anesthesia may facilitate detection of bladder perforation. Postoperative pain is usually minimal and responds well to nonopiate and opiate medications.

### **Transurethral Prostate Resection**

Standard procedure during TURP surgery involves inserting a resectoscope, a specialized endoscopy instrument with an electrode capable of both coagulating and cutting tissue, into the urethra, then the bladder; the tissue protruding into the prostatic urethra is then resected.<sup>221</sup> There has been much recent interest in the use of lasers rather than electrocautery to resect excess prostate tissue. A variety of different lasers have been utilized. Laser techniques have advantages over traditional electrocautery approaches, particularly related to traditional irrigation fluid restrictions. Laser resection

has no requirement for a nonconductive fluid, so 0.9% saline may be used, avoiding complications of absorption related to hypo-osmolality and solute toxicity (see TUR syndrome). Furthermore, the potential for systemic absorption may be reduced owing to the lower irrigation infusion rates and pressures necessary for laser procedures.<sup>222,223</sup> Lasers also have coagulative properties, resulting in less blood loss and lower rates of transfusion.

## Irrigating Solutions and Transurethral Resection Syndrome

Key to a surgeon's endoscopic view during transurethral procedures is a visually clear irrigating solution, infused with a pump or via gravity (and drained away) to flush out blood and resected tissue and keep space between structures. Safety characteristics of the irrigating solution are important because with tissue resection or urinary tract injury, significant amounts of the fluid may inadvertently enter the circulation, for example, during TURP through openings in the venous plexus or retroperitoneal rents in the prostatic capsule or consequent to perforation of the urinary bladder into the peritoneal space during TURBT. Other procedures where inadvertent perforation can cause the TUR syndrome include cystoscopy, ureteroscopy, percutaneous nephrolithotomy (PNL), and laser vaporization of the prostate.

**Table 50-6** Properties of Commonly Used Irrigating Solutions for Transurethral Resection Procedures

Solution	Osmolality (mOsm/L)	Advantages	Disadvantages
Distilled water	0	Improved visibility	Hemolysis Hemoglobinemia Hemoglobinuria Hyponatremia
Glycine (1.5%)	200	Less likelihood of TUR syndrome	Transient postoperative visual syndrome Hyperammonemia Hyperoxaluria
Sorbitol (3.3%)	165	Same as glycine	Hyperglycemia, possible lactic acidosis Osmotic diuresis
Mannitol (5%)	275	Isosmolar solution Not metabolized	Osmotic diuresis Possibility of acute intravascular volume expansion

**13** The spectrum of morbidities associated with irrigating solution absorption is termed the TUR syndrome. A variety of nonconductive *nonelectrolytic* solutions are in common use. The crystalloids have current-dispersing properties owing to their ionic characteristics that make them unsuitable for use with unipolar electrocautery. When absorbed in significant amounts, nonelectrolytic irrigation solutions combine electrolyte disturbances with hypervolemia. Notably, newer transurethral *bipolar* electrocautery and laser techniques now allow irrigation with isotonic crystalloid solutions (e.g.,

0.9% saline), but until these technologies totally replace unipolar electrocautery, nonconducting osmotically active irrigating solutions will continue to be used, each variant having its own concerns (Table 50-6).<sup>200</sup>

It is therefore important for anesthesiologists to be aware of solutions used for transurethral procedures at their own institutions, because TUR syndrome for each irrigating solution has its own profile (Table 50-6). Nonetheless, *TUR syndrome* historically describes a common cluster of symptoms related to hypervolemic water intoxication; the principal components are (1) excessive volume expansion (respiratory distress, congestive heart failure, pulmonary edema, hypertension, bradycardia, hypotension, etc.), (2) hyponatremia (mental confusion, nausea, etc.; Table 50-7), and (3) other problems specific to each of the irrigating solutions.<sup>224–226</sup> Notably, any future trend toward limiting irrigation to physiologic solutions (e.g., 0.9% saline) should eliminate all but the hypervolemic component of the TUR syndrome.

Of available irrigating solutions, distilled water is rarely utilized owing to its hypotonicity. Water intoxication with distilled water rapidly causes severe hyponatremia leading to hemolysis, hemoglobinemia, and renal failure. Sorbitol and glucose solutions cause hyperglycemia when they are absorbed. Glycine, an amino acid normally metabolized to ammonia, may cause a depressed mental status and even coma (due to hyperammonemia) that can last 24 to 48 hours postoperatively.<sup>227,228</sup> Also reported with glycine are blurred vision, minimally or nonreactive pupils, and transient blindness.<sup>229,230</sup> Because glycine has structural similarities to aminobutyric acid, these visual disturbances are thought to reflect neurotransmitter-mediated brainstem or cranial nerve inhibition rather than cerebral edema.<sup>230</sup>

Absorption of very large amounts of irrigant (>2 L) is usually required to manifest the TUR syndrome. The incidence of symptomatic TUR syndrome is highest during TURP procedures, where it may be as high as 1.4%.<sup>210</sup> Typically, intraoperative irrigation infusion rates of 300 mL/min are used during TURP procedures for optimal surgical visualization.<sup>219</sup> Some intravascular absorption is to be expected; rates of 20 mL/min are typical, but these can reach as high as 200 mL/min.<sup>231</sup> Factors that predict increased irrigation fluid absorption during a TURP procedure include the number and size of open venous sinuses (i.e., greater blood loss implies greater potential for irrigation absorption), surgical disruption of the prostatic capsule, longer duration of resection, higher hydrostatic pressure of the irrigating fluid, and lower venous pressure at the irrigant–blood interface.<sup>206</sup>

**Table 50-7** Signs and Symptoms of Acute Hyponatremia

Serum Na <sup>+</sup> (mEq/L)	CNS Changes	ECG Changes
120	Confusion Restlessness	Possible widening of QRS complex
115	Somnolence Nausea	Widened QRS complex Elevated ST segment
110	Seizures Coma	Ventricular tachycardia or fibrillation

CNS, central nervous system; ECG, electrocardiogram.

*Can J Anaesth.* 1991;38:90.

To minimize fluid absorption, procedural guidelines include limiting resection time to less than 1 hour and suspending the irrigating fluid bag no more than 30 cm above the operating table at the beginning and 15 cm above in the final stages of resection.<sup>206,232</sup> In addition, avoidance of hypotonic intravenous fluids and treatment of regional anesthesia-induced hypotension with judicious use of intravenous vasopressor agents rather than intravenous fluids should be considered.

Symptomatic TUR syndrome is much less common following TURBT (and usually related to symptoms of bladder perforation), but it is important to be aware of the possibility of its occurrence because it may present somewhat differently owing to the slower rate of fluid absorption.<sup>209</sup> Most notably, the time course of symptoms following bladder perforation during TURBT reflects the slower absorption from the abdominal cavity compared to direct prostatic venous plexus entry with TURP. For example, nadir serum sodium values are generally reached between 1 and 6 hours following TURP, whereas TUR syndrome following TURBT occurs between 2 and 9 hours postoperatively.<sup>209</sup>

Clinical manifestations of the TUR syndrome range from mild (restlessness, nausea, shortness of breath, dizziness) to severe (seizures, coma, hypertension, bradycardia, cardiovascular collapse). In the awake patient with a regional block, a classic triad of symptoms has been described that consists of an increase in both systolic and diastolic pressures associated with an increase in pulse pressure, bradycardia, and mental status changes.<sup>207,224</sup>

Early symptoms associated with TUR syndrome are mostly related to acute intravascular volume expansion independent of changes in serum osmolality and sodium.<sup>226</sup> Initial hypertension and bradycardia from acute volume overload may evolve into left heart failure, pulmonary edema, and even cardiovascular collapse.<sup>233</sup> With the continued absorption of hypotonic irrigation fluid, cerebral edema as a consequence of dilutional hyponatremia may develop. Rapid change, as opposed to a specific low-threshold serum sodium concentration, is responsible for most of the signs and symptoms of TUR syndrome (Table 50-7).<sup>224</sup>

When neurologic or cardiovascular complications of TURP procedures are recognized intraoperatively, prompt intervention is necessary (Table 50-8). First, the surgeon should be informed of the patient's status change so that the procedure can be completed or terminated as quickly as possible. The hallmark of patient treatment is to restore extracellular tonicity. Although the traditional recommended rate of serum sodium correction is 0.5 mEq/L/hr, this is for chronic hyponatremia, and no established rate for correction of acute hyponatremia exists. Symptomatic patients with serum sodium concentrations less than 120 mEq/L should have their extracellular tonicity corrected with hypertonic saline. Sodium chloride in a 3% solution should be infused at a rate no greater than 100 mL/hr. Serum electrolytes should be followed closely and the hypertonic saline discontinued when the patient is asymptomatic or serum sodium concentration exceeds 120 mEq/L. Treatment with hypertonic saline has been associated with development of demyelinating central nervous system lesions (central pontine myelinolysis) owing to rapid increases in plasma osmolality, and this approach should be reserved for patients with severe, life-threatening symptoms.<sup>234</sup> The demyelination is the result of excessive shrinkage of brain cells after rapid hydration with hyperosmolar solution, because the brain cells have extruded important osmoles to compensate for the chronic hypotonicity. Notably, reports of demyelination after correction of acute symptomatic hyponatremia are rare, and there are no reports of demyelination after treatment of acute TUR syndrome.<sup>226</sup>

**Table 50-8** Treatment of the Transurethral Resection Syndrome

Ensure oxygenation and circulatory support  
Notify surgeon and terminate procedure as soon as possible  
Consider insertion of invasive monitors if cardiovascular instability occurs  
Send blood to laboratory for evaluation of electrolytes, creatinine, glucose, and arterial blood gases  
Obtain 12-lead electrocardiogram  
Treat mild symptoms (with serum Na<sup>+</sup> concentration >120 mEq/L) with fluid restriction and loop diuretic (furosemide)  
Treat severe symptoms (if serum Na<sup>+</sup> <120 mEq/L) with 3% sodium chloride intravenously at a rate <100 mL/hr  
Discontinue 3% sodium chloride when serum Na<sup>+</sup> >120 mEq/L

## Therapies for Urolithiasis

Stone disease of the urinary tract, urolithiasis, can be subdivided on the basis of the location of the stone into nephrolithiasis (kidney), ureterolithiasis (ureter), or cystolithiasis (bladder). Nephrolithiasis is a common clinical problem, with an increasing incidence. The lifetime prevalence of

nephrolithiasis is 10% in men and 5% in women. Up to 50% of patients with an initial stone episode will have a recurrence within 5 years.<sup>235</sup>

The composition of kidney stones varies (Table 50-9). The most common type of stones contains calcium and is radio-opaque. Stones form when the concentration of stone-forming salts in the urine is elevated (e.g., oxalate) or when the level of stone inhibitors in the urine is low (e.g., citrate). This results in supersaturation of the urine with salts, allowing crystals to form and grow, particularly in situations where urine volume is low. This pathophysiology explains the principles of the medical management of kidney stones: increasing urine volume and maneuvers to restore urinary salt balance through dietary and medical treatment.<sup>236,237</sup>

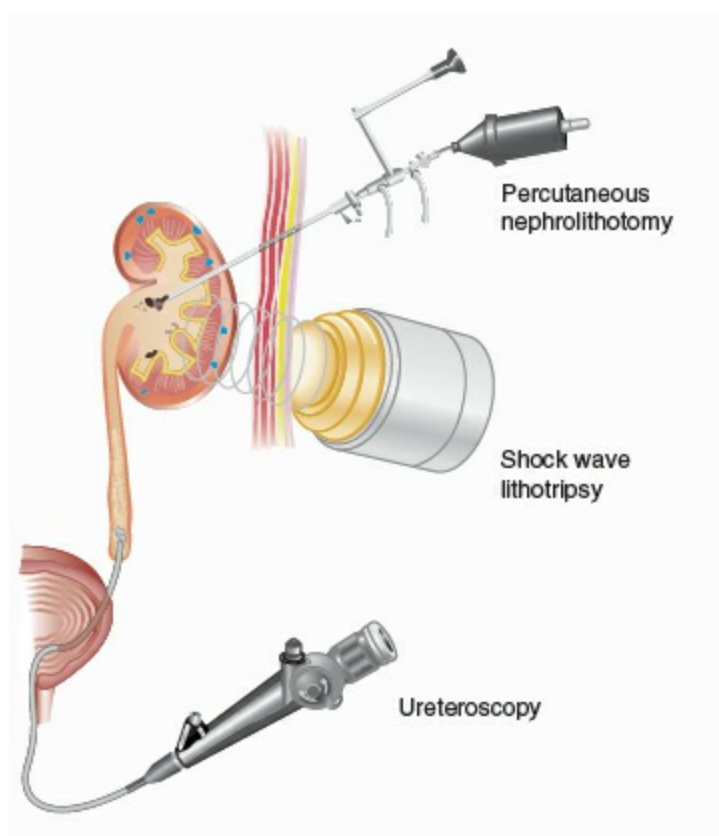

The preferred diagnostic modality for urolithiasis is helical noncontrast CT scan, which can identify radiopaque and radiolucent stones in the entire urinary system and determine whether hydronephrosis is present. Ultrasound imaging is also informative for stones in the kidney and proximal ureter but cannot show the distal ureter and may miss smaller stones. Compared to helical CT and ultrasonography, plain radiographs (kidney–ureter–bladder [KUB]) provide no additional information about obstruction or hydronephrosis and can miss stones in the kidney or ureter. Intravenous pyelography is rarely used because it offers no added information compared to other diagnostic modalities and exposes the patient to radiation and contrast-related renal injury.<sup>237</sup>

Patients with kidney stones typically present with intermittent or continuous moderate to severe colicky pain in the ipsilateral flank and upper abdomen. Testicular or labial pain is more typical with distal ureteric stones. Occasionally, patients present with painless urinary infection or hematuria. Conservative nonsurgical therapy for smaller stones consists of analgesics (e.g., NSAIDs and/or opiates) and aggressive fluid administration to promote urine flow and passage of the stone. The so-called medical expulsive therapy to promote ureter relaxation and the spontaneous passage of small ureteral stones involves treatment with calcium channel blockers (e.g., nifedipine),  $\alpha$ -blockers (e.g., tamsulosin), and sometimes corticosteroids.<sup>237,238</sup> The likelihood of stone passage without surgery relates to the size of the stone, its location, and the presence or absence of urinary system anatomic abnormalities such as strictures. If stones do not pass spontaneously or respond to medical expulsive therapy, various surgical options can be considered, as discussed earlier (Fig. 50-11).

**Table 50-9** Spectrum of Kidney Stones Types: Composition, Frequency, and Causes

Stone Composition	Frequency	Mechanism
Calcium oxalate or calcium phosphate	70%–80%	<p>Hypercalciuria</p> <ul style="list-style-type: none"> <li>• High sodium and protein diet</li> <li>• Hypercalcemia, e.g., hyperparathyroidism</li> <li>• Chronic metabolic acidosis</li> </ul> <p>Low urine output</p> <ul style="list-style-type: none"> <li>• Chronic dehydration</li> </ul> <p>Hyperuricosuria</p> <ul style="list-style-type: none"> <li>• High purine, high protein intake</li> <li>• Gout</li> </ul> <p>Hyperoxaluria</p> <ul style="list-style-type: none"> <li>• Low dietary calcium</li> <li>• High oxalate diet</li> <li>• Genetic</li> </ul> <p>Low urine citrate</p> <ul style="list-style-type: none"> <li>• Chronic metabolic acidosis</li> <li>• Renal tubular acidosis</li> <li>• Inflammatory bowel disease</li> </ul>
Uric acid	10%–15%	<p>Low urine pH</p> <p>Chronic metabolic acidosis</p> <p>Hyperuricosuria</p> <p>Obesity</p> <p>Lesch–Nyhan syndrome</p>
Magnesium ammonium phosphate (struvite)	10%–15%	Urinary infections (urea-splitting bacteria), e.g., <i>Proteus</i> , <i>Klebsiella</i> , <i>Staphylococcus</i> , <i>Pseudomonas</i> , <i>Providentia</i> , and <i>Corynebacterium urealyticum</i>
Cystine	<1%	Cystinuria—autosomal recessive
Others: indinavir	<1%	Antiretroviral drug for HIV
Triamterene		Potassium-sparing diuretic
Xanthine		Xanthine oxidase inhibitor therapy, e.g., allopurinol

kidneys and ureters. *Cleve Clin J Med.* 2009;76:592–598.)

## Preoperative Considerations

Anesthetic planning for urolithiasis surgery should include standard considerations. Typical calcium salt stone disease presents in the third to fifth decades of life<sup>237</sup> and is commonly associated with comorbidities such as obesity, hypertension, and hyperparathyroidism. Patients with renal failure or CKD should be assessed for the sequelae of these conditions, including platelet dysfunction, anemia, and electrolyte abnormalities. Bladder stones are often diagnosed in patients with poor voiding capacity, for example, paraplegic patients, and the associated perioperative concerns for these patients should be addressed. Although paraplegic patients with sensory deficits below T6 lack pain perception for cystoscopy procedures, they are at risk for *autonomic hyperreflexia* and require anesthesia to block the afferent stimulation that can provoke this reaction (e.g., bladder distension). This can be achieved with deeper levels of general anesthesia or regional anesthesia.<sup>239</sup> Patients with idiopathic hypercalciuria are often treated with thiazide diuretics, and serum potassium should be assessed preoperatively.<sup>237</sup>

Perioperative opioid analgesic dosing for urolithiasis procedures can be challenging. Patients with recurrent nephrolithiasis may be receiving chronic opioid therapy and demonstrate tolerance intra- and postoperatively. In contrast, when severe colic is alleviated by surgery for an opioid-naïve patient already treated with opiates, postoperative somnolence is quite common. Renal colic is often associated with nausea and vomiting, and preoperative aspiration prophylaxis should be considered.

Unless open surgery is planned, there is rarely a need for blood transfusion for stone surgery. Selection of appropriate monitors should be dictated by patient comorbidities, because significant blood loss or fluid shifts are unusual with these procedures. However, if difficulty achieving vascular access during a procedure is anticipated (e.g., percutaneous nephrolithotripsy), there should be a low threshold for establishing central access prior to the procedure. Antibiotic prophylaxis is important, particularly with infected stones or pyelonephritis. When lasers are required, appropriate eye protection should be provided for the perioperative team and patient.

## Intraoperative Considerations

Compared with other more invasive urologic procedures, stone surgeries generally do not involve large amounts of blood loss or fluid shifts, with the possible exception of percutaneous nephrolithotripsy (see later). Information about anesthetic choice and potential intraoperative issues is discussed in the

individual sections and in the sections on nephrectomy and transurethral surgery elsewhere in this chapter. Monitoring decisions and anesthetic choices should be made on the basis of patient comorbidity, and intraoperative care should focus on those as well.

## ***Postoperative Considerations***

Postoperative concerns for urolithiasis procedures are generally minor. Interestingly, patients with severe renal colic prior to less invasive surgeries (e.g., ureteroscopy) may have less or no pain postoperatively with relief of their urinary obstruction and stone retrieval. However, immediately following urinary tract instrumentation, many patients experience rather uncomfortable bladder and ureteral spasms. These spasms are typically more responsive to NSAIDs, oxybutynin, and belladonna and opium suppositories than to parenteral opioids.

Occasionally, open surgery is required for upper urinary tract stone removal, with postoperative concerns comparable to those for nephrectomy patients having similar incisions; these include pain, which may be sufficient to require epidural analgesia, and monitoring requirements to ensure that adequate resuscitation related to any blood loss has occurred.

Monitoring the adequacy of urine output and maintaining any urinary irrigation or drainage system (e.g., stents, three-way Foley catheters) to promote clearance of blood in the urinary system are important, because clots or stone fragments can cause acute urinary obstruction.

After extraction or lithotripsy of stones, particularly struvite stones or in the setting of pyelonephritis, patients may develop a pattern of rigors, hypotension, and fever, which can lead to shock. Urine culture results can be misleading in predicting which patients will develop sepsis because urine below the level of a stone may be clean, yet urine upstream of the stony obstruction may be infected. A sepsis picture can be noted during the procedure but is more likely to occur postoperatively. Indications of intravascular bacterial seeding from infected urine needs prompt attention with blood cultures, fluids and resuscitation, and institution of appropriate antibiotic therapy to prevent more serious sequelae of a sepsis syndrome. The potential acuity of this situation should not be underestimated, because even healthy ASA 1 to 2 patients can develop systemic inflammatory response syndrome and require aggressive resuscitation and intensive care.<sup>240</sup>

## ***Specific Procedures***

### **Shock Wave Lithotripsy**

Shock wave lithotripsy (SWL) is best suited for intranephric stones that are small-to-moderate in size but can be used for proximal ureteral stones as well. The principle of SWL is to use focused sound waves to break the stone into pieces small enough to pass through the ureters, bladder, and urethra during normal urination. This requires transmission of the sound wave beam via an interface with the patient's body. Early SWL was conducted via immersion in a water bath, which created this interface. In addition to the significant positioning maneuvers associated with this procedure, patients are prone to hypothermia during the procedure. Dysrhythmias can be a special problem because the transmission of the ultrasonic pulse is timed and triggered by the ECG. Significant respiratory and hemodynamic changes are associated with immersion and emergence from the water bath, which can be problematic particularly for patients with cardiopulmonary disease.<sup>241</sup> Modern dry SWL uses a smaller water-filled coupling device to provide an interface with the patient, which simplifies the procedure considerably. Newer SWL machines also have a more tightly focused sound beam and can deliver the required energy at pressures in each acoustic pulse that are less painful for the patient. These advances allow most procedures to be conducted in an outpatient setting, with topical local anesthesia and analgesia/sedation provided with combinations of NSAIDs and opiates. General anesthesia and/or deep sedation are rarely required.

Several factors affect the likelihood of success of SWL. Because increased distance from beam to stone reduces the effectiveness of SWL, this procedure is less successful in obese patients.

Extremely hard stones (such as cysteine and calcium oxalate) are more resistant to lithotripsy and may best be addressed with other treatment modalities.<sup>242</sup> Patients may require more than one treatment for complete stone comminution. As pulse counts increase, so does the risk of kidney injury and even subcapsular hematoma.<sup>236</sup> SWL is the least invasive and most commonly performed procedure for the management of stone disease; however, even for this approach, several relative and absolute contraindications exist (Table 50-10).

**Table 50-10** Contraindications to Shock Wave Lithotripsy

Absolute contraindications	Bleeding disorder or anticoagulation Pregnancy
Relative contraindications	Large calcified aortic or renal artery aneurysms Untreated urinary tract infection Obstruction distal to the renal calculi Pacemaker, ICD, or neurostimulation implant Morbid obesity

ICD, implantable cardioverter-defibrillator.

## Percutaneous Nephrolithotomy

PNL is useful for the management of larger intranephric stones, especially those resistant to SWL, staghorn calculi, and some proximal ureteral stones. PNL requires initial placement of a ureteral stent via cystoureteroscopy performed in the lithotomy position. This stent will prevent ureteral obstruction as fragments of stone pass through the ureter following PNL. Following stent placement, the patient is repositioned to an oblique prone position for percutaneous puncture of the renal pelvis under fluoroscopic guidance, which is followed by placement of a nephrostomy tube to facilitate placement of a nephroscope for stone extraction with forceps or other instruments. Large stones may require use of an ultrasound or laser probe, also placed via the nephrostomy, to fragment them to facilitate removal. The combination of fluoroscopy and direct vision of the renal pelvis and ureters with nephro- and ureteroscopy is used to ensure that complete removal of the stone(s) has been achieved. Large volumes of irrigation are used to cool the ultrasound probe and wash away the debris, making TUR syndrome an occasional complication of PNL. Because of the large irrigant volume, blood loss can be underappreciated, and unexplained hemodynamic instability during these procedures is often a manifestation of blood loss. Published rates of transfusion during or after PNL range from 5% to 14%.<sup>243</sup> Pneumothorax, though rare, is a possible complication of the procedure depending on the approach used for insertion of the nephroscope.

General anesthesia with endotracheal intubation allows for a secure airway for positioning into the prone position and is most commonly used in many centers; however, spinal anesthesia can also be used.<sup>244</sup> For certain patients, local infiltration with sedation may even suffice.<sup>245</sup>

## Ureteroscopy for Removal of Stones (URS)

URS is the procedure of choice for midureteral and distal ureteral stones that have failed conservative management. It is also indicated for treatment of

bilateral ureteral stones and can be considered in patients for whom cessation of anticoagulation is not advisable. Morbidly obese patients for whom SWL is not advised are also candidates for this procedure.<sup>236</sup> Although more invasive than SWL, URS generally achieves a higher stone-free rate and can be used to remove stones in all portions of the ureter. Newer technology has allowed smaller, more flexible ureteroscopes, and lasers are now incorporated to facilitate stone disintegration. Various basket and other retrieval devices can be inserted through the ureteroscope. The postoperative complications from ureteroscopic stone retrieval include perforation of the ureter (5%) and stricture formation (<2%) and rarely TUR syndrome.<sup>246</sup> The procedure can be performed using urethral local anesthesia with intravenous sedation and monitored anesthesia care, spinal anesthesia, or general anesthesia. The previous section addresses anesthetic concerns related to cystoscopy and URS.

### **Open and Laparoscopic Pyelolithotomy or Nephrectomy**

With the advent of the previously discussed modalities for the treatment of urolithiasis, the use of laparoscopic or open surgery for removal of stones has declined considerably, and they should not be considered first-line treatment for stone disease. Patients who have failed SWL or PNL or who require open surgery for other indications are candidates for open treatment of stone disease. This can be accomplished laparoscopically (retroperitoneal or transperitoneal) or open, depending on the capabilities of the surgeon. Compared with less-invasive approaches, both laparoscopic and open procedures result in more postoperative pain and longer hospital stays and recovery and are associated with higher complication rates.

### **Urogynecology and Pregnancy-related Urologic Procedures**

A variety of urogynecologic procedures that treat pelvic floor prolapse are directed at symptomatic improvement of stress incontinence. These procedures are relatively noninvasive, often accomplished using a transvaginal approach with the patient in the lithotomy position, and frequently performed as outpatient procedures with same-day discharge home. Anesthesia can be accomplished with local infiltration accompanied by heavy sedation and monitored anesthetic care, neuraxial anesthesia using spinal or combined spinal/epidural local anesthetic injection, or general anesthesia. Local preferences may dictate anesthetic choice, as suggested by reports from some centers regarding the selection of spinal anesthesia that describe on the one hand improved patient and surgeon satisfaction<sup>247</sup> and on the other a fourfold higher urinary retention rate<sup>248</sup> and 1 hour longer postanesthesia care unit stay.

Renal colic is the most common nonobstetric cause of abdominal pain requiring hospitalization in pregnant women.<sup>236</sup> Medical management of these patients must consider the fetal gestational age in decisions about appropriate analgesics (e.g., NSAIDs in the third trimester may cause premature closure of the fetal ductus arteriosus and adverse renal effects). Diagnostic tests preferably avoid ionizing radiation and favor the use of ultrasound whenever possible. Interventions in pregnant patients with symptomatic nephrolithiasis have traditionally been limited to ureteral stents to relieve pain and prevent obstruction, with definitive therapy delayed post partum; however, the need for repeated stent exchanges is common. More recent data support the safety and efficacy of URS for stone removal during pregnancy. SWL is contraindicated in pregnancy.<sup>249,250</sup>

Surgical urologic issues related to the obstetric patient are uncommon, with the exception of inadvertent injury to the ureter or bladder during cesarean section, which, if recognized, should be repaired intraoperatively.<sup>251</sup> Ureteral stenting is also occasionally required to enable ureter identification during a cesarean/hysterectomy procedure for placenta accreta or percreta.<sup>252</sup>

### *Impotence Surgery and Medication*

The impotence drugs sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra) all inhibit cyclic GMP-specific phosphodiesterase type 5 (PDE5) in vascular smooth muscle (Fig. 50-12). Blocking PDE5 impairs cyclic GMP breakdown, the mediator of nitric oxide effects that produce erectile responses to sexual stimulation through penile arterial vasodilation and corpus cavernosum smooth muscle relaxation. These agents have effects on other vessels and can be a useful treatment for pulmonary artery hypertension (trade names; sildenafil—Revatio, tadalafil—Adcirca).

Rational perioperative management of PDE5 inhibitor agents is important. Notably, although impotence therapies should be discontinued before surgery to minimize the risk of hypotension, pulmonary hypertension therapies must continue throughout the perioperative period. Although inhaled nitric oxide therapy can safely be used with PDE5 inhibitors, because its effects are limited to the pulmonary vasculature, whenever these agents are combined with systemic nitric oxide donors such as nitroglycerin or sodium nitroprusside exaggerated hypotensive responses are likely because of their dramatic potentiation of the peripheral vasodilator effects of nitric oxide.

**Figure 50-12** Nitric oxide–mediated vascular smooth muscle relaxation, including the inhibiting effects of sildenafil on cyclic GMP-specific phosphodiesterase type 5 (PDE5). (From [www.wiley.com/college/boyer/0470003790/cutting\\_edge/viagra/viagra.htm](http://www.wiley.com/college/boyer/0470003790/cutting_edge/viagra/viagra.htm). Reproduced with permission of John Wiley & Sons, Inc.)

Erectile dysfunction refractory to medical therapies can be treated by penile prosthesis implantation. Most prostheses are inflatable, with a secondary fluid reservoir and/or pump either behind the abdominal wall or inside the scrotum. Semirigid prostheses that do not involve pumps or reservoirs are also available, but these are less commonly used. Although penile implant procedures are relatively noninvasive, many recipients are elderly with multiple comorbidities, including vascular disease and diabetes. Traditionally, implantation has been performed under general or neuraxial anesthesia, but regional block (combined proximal dorsal nerve block and crural block) with sedation and monitored anesthesia care is also suitable if an abdominal incision is not required.<sup>253</sup>

## *Pediatric Surgical Urologic Disorders*

The anesthesiologist caring for a pediatric patient undergoing a urologic procedure must first and foremost have a strong grasp of concepts of pediatric anesthesiology. General anesthesia is typical for these procedures, although a caudal block may provide good postoperative pain control (see [Chapter 43](#)).

### *Nephrectomy and Adrenalectomy*

Many adult urologic procedures are also performed in children, although frequently for different indications. Nephrectomy, for example, is used to treat Wilms tumor and nonfunctioning kidney due to obstructive uropathy, stone disease, vesicoureteral reflux, or multicystic dysplastic kidney. Pediatric nephrectomy is amenable to open or laparoscopic approaches with general anesthesia.<sup>254</sup>

Adrenalectomy for neuroblastoma (28%), pheochromocytoma (21%), or adenoma (14%) can most often be achieved laparoscopically, although conversion to an open procedure, most often necessary owing to tumor adherence to surrounding organs, is more common than in adults (10%).<sup>255</sup>

As with adults, the preoperative workup and preparation of patients with pheochromocytoma should be thorough. Because inherited syndromes such as neurofibromatosis, von Hippel–Lindau disease, tuberous sclerosis, Sturge–Weber syndrome, and multiple endocrine neoplasia are commonly associated with pediatric pheochromocytoma, other related characteristics of these conditions should also be considered in preoperative preparation.<sup>256</sup> As with adult pheochromocytoma, preoperative therapy with  $\alpha$ -1 adrenergic blocking agents (e.g., phenoxybenzamine) is recommended (see [Chapter 46](#)).<sup>257</sup>

### *Reconstructive Urologic Procedures*

A number of urologic procedures related to congenital urologic deformities are performed almost exclusively on children. Many of these procedures are reconstructive in nature, intended to functionally repair a defect present at birth.

Bladder exstrophy, where part of the urinary bladder remains outside the body through a defect in the abdominal wall, occurs in 1 per 10,000 to 50,000 live births with a 2:1 male:female ratio.<sup>258</sup> Associated abnormalities are frequently present in the pelvic bones and external genitalia. Repair requires one or more of the following three procedures in a staged fashion: primary closure of the abdominal wall and osteotomy, usually occurring before 4 months of age; epispadias repair between 8 and 24 months of age; and bladder neck reconstruction at 40 to 60 months.<sup>259</sup>

Repair of ureteropelvic junction obstruction and ureterovesical reimplantation to treat vesicoureteral reflux requires general anesthesia and may be performed open or laparoscopically. Reconstruction of the lower urinary tract is more frequently achieved using an open approach, although laparoscopy is beginning to gain favor.

Posterior urethral valves (PUVs) are persistent embryonic membranes that cause bladder outlet obstruction and can lead to incomplete emptying, bladder hypertrophy, and even renal insufficiency or failure. PUVs occur exclusively in males, with an incidence of 1 to 2 per 10,000 male births, and may be diagnosed before or after birth by ultrasound. Although temporary treatment involves catheterization and antibiotics to prevent infection, definitive surgical repair is required, usually in the early postnatal period. Nonetheless, approximately one-third of the patients with PUV develop ESRD and require dialysis and/or renal transplantation.<sup>260</sup>

Undescended testis (cryptorchidism) affects 2% to 4% of male newborns. Cryptorchidism that persists at 1 year of age (1%) requires surgical repair (orchiopexy), normally as an outpatient procedure under general anesthesia.<sup>261</sup>

Hypospadias, an abnormal location of the urethral meatus on the ventral aspect of the penis resulting from incomplete embryologic development, occurs in 0.3% to 0.8% of male infants. Surgical repair is most commonly performed around 6 months of age as an outpatient procedure under general anesthesia, often supplemented with caudal analgesia. More complex repairs may require a second staged procedure around 12 months.

Circumcision of newborns is usually accomplished under ring block or local anesthetic infiltration without the presence of an anesthesiologist, although in older children general anesthesia with or without neuraxial anesthesia may be more appropriate.

## Urologic Surgical Emergencies

Urologic emergencies are relatively rare, but three urologic emergency surgeries are worthy of mention. *Testicular torsion* requires emergency attention owing to the high risk, if otherwise untreated, for infarction or gangrene, which would require orchiectomy. In contrast, patients with *Fournier gangrene* or *sepsis* associated with nephrolithiasis are noteworthy because emergent definitive surgical therapy is the most effective way to reverse their infectious process and improve their prognosis. These latter patients are generally very seriously ill, and often the anesthesiologist provides ongoing resuscitation and applies critical care principles while delivering anesthetic care.

### Testicular Torsion

Testicular torsion has a bimodal incidence, in the neonatal period and during early pubertal to teenage years. Testicular torsion affects approximately 1 in 4,000 young men, and 65% of cases occur in teenagers. When the spermatic cord twists, venous outflow from a testicle is obstructed, and eventually this compromises arterial flow, leading to ischemia and infarction.<sup>262</sup> Patients with testicular torsion present with acute scrotal pain and tenderness, most cases not involving a history of trauma. A predisposing anatomic bell-clapper deformity, which allows the testes to rotate freely in the tunica vaginalis, is the most common cause of this problem. Other risk factors include testicular tumors, a history of cryptorchidism, and an increase in testicular volume (e.g., puberty). Common misdiagnoses include epididymitis/orchitis, incarcerated hernia, and varicocele.<sup>262</sup> Absence of the cremasteric reflex is usually present on physical examination, and Doppler ultrasonography demonstrates decreased or absent blood flow. Equivocal physical examination findings dictate surgical exploration.

Apart from the considerable pain that torsion causes, the most important priority is the viability of the testicle. Testicular torsion requires immediate intervention, because viability decreases significantly with the duration of testicular ischemia. Success in saving the testicle relates to the timing from symptom onset to detorsion, with success rates of 90%, 50%, and 10% with delays of 6, 12, and greater than 24 hours, respectively.<sup>263</sup>

Anesthesia for testicular torsion surgery must respect its emergent nature, including the likelihood that the patient has not fasted. Regional or general anesthesia is appropriate, but spinal anesthesia is relatively contraindicated

owing to the high risk of postdural puncture headache in the young population where the problem is most often manifested.

## ***Fournier Gangrene***

Fournier gangrene is a form of necrotizing fasciitis affecting the genitalia. It presents most commonly in older men, and frequently associated comorbidities include diabetes mellitus, morbid obesity, and immune suppression.<sup>264</sup> Minor genital trauma is often the inciting event, but rapid widespread inflammation, infection, and ultimately polymicrobial sepsis characterize the condition. Fournier gangrene patients often present with already established septic shock warranting the emergent status for surgery, but fluid resuscitation and institution of broad-spectrum antibiotic therapy (commonly staphylococci, streptococci, enterobacteriaceae, and anaerobes) are also priorities.<sup>265</sup> Surgical management consists of incision, drainage, and debridement of affected tissue. Hyperbaric oxygen therapy is also employed at some centers<sup>266,267</sup> but does not replace emergent surgical debridement. Morbidity and mortality are significant, with advanced age and presence of septic shock at presentation portending the highest risk.<sup>268</sup>

Anesthetic planning must incorporate assessment of the degree of sepsis and hemodynamic status of the patient. General anesthesia with endotracheal intubation and positive-pressure ventilation is standard. Intra-arterial and central venous access are often indicated to facilitate resuscitation of the patient. Transfusion may be necessary because the extensive tissue resection can involve significant blood loss. Patients often require postoperative intensive care admission to manage the sequelae of sepsis and often undergo repeated procedures for additional debridement, wound care, and eventually wound closure.<sup>265</sup>

## ***Emergency Treatment of Nephrolithiasis***

Most patients who require surgical or interventional treatment of nephrolithiasis can be managed electively, but patients with infection associated with urinary tract obstruction, AKI, bilateral obstructing stones, intractable pain or vomiting, or obstruction in a solitary (native or transplanted) kidney should be managed urgently to avoid sepsis and preserve renal function.<sup>242</sup> Procedures indicated for these conditions to alleviate obstruction include cystoscopy with stent insertion, percutaneous nephrostomy, and, very rarely, open pyelolithotomy or nephrectomy for definitive treatment related to stones unsuccessfully treated by less-invasive interventions. Identification of patients who have infected urine and obstruction is important because they are at high risk of developing sepsis,

which can manifest preoperatively, intraoperatively, or postoperatively. As with any infection, the principles of drainage and institution of appropriate antibiotic therapy are paramount, and in the presence of complete urinary obstruction, antibiotic therapy alone is insufficient treatment. If the urinary tract can be decompressed with a stent or nephrostomy, definitive management can be postponed until the patient has responded to antibiotic therapy.<sup>236</sup> Patients with nephrolithiasis complicated by urinary tract infection are at higher risk for infection with antibiotic-resistant pathogens, which requires targeted antibiotic therapy.<sup>269</sup>

Another category of patients requiring urgent surgery are patients with declining renal function in the setting of urinary obstruction (e.g., ureteral obstruction from renal papillary necrosis, blood clots, or urethral obstruction due to blood clots or stricture).<sup>235</sup> Other situations (e.g., obstructed solitary or transplanted kidney, hemorrhage, and blood clots) may dictate urgent, rather than elective, surgery to relieve the urinary obstruction and preserve renal function, though in the absence of infection this group of patients may not be as acutely ill.

Anesthetic considerations for emergent nephrolithiasis surgery are similar to those for equivalent elective procedures (see earlier). Additional considerations include the potential need for more invasive monitoring, for example, direct arterial blood pressure monitoring in the setting of sepsis. Similarly, hemodynamically unstable septic patients often have ongoing needs for fluid resuscitation and pharmacologic support of the circulation and, in the setting of deteriorating renal function, may require alterations from standard anesthetic agent selections. Because evidence of sepsis may not manifest until the postoperative period, raised awareness for such concerns should continue into the postanesthetic recovery period.

- Venous Thromboembolism and Thromboprophylaxis

## KEY POINTS

- 1 Optimal anesthetic management for orthopedic surgery requires expertise in regional anesthesia and analgesia techniques.
- 2 Regional anesthesia can provide physiologic benefits and facilitate recovery compared to general anesthesia.
- 3 General anesthesia is appropriate for surgeries not amenable to and/or patients with contraindications to regional techniques.
- 4 Orthopedic surgery patients may have limited mobility and may require special attention to avoid positioning-related injury.
- 5 Patients presenting for spine surgery should be evaluated carefully for potential airway challenges and/or impaired respiratory function.
- 6 Major spine surgery frequently involves significant bleeding, and blood conservation techniques should be considered.
- 7 Intraoperative monitoring of spinal cord function should be used for surgeries where the cord is at risk of injury.
- 8 Catastrophic venous air embolism during spine surgery may present as unexplained hypotension with high end-tidal nitrogen and low end-tidal carbon dioxide.
- 9 Nerve injury may result from surgical trauma and/or nerve blockade in the setting of pre-existing neurologic deficits.
- 10 In the sitting position, for every 20 cm of difference in height of the head from the heart, there is a 15-mmHg difference in mean arterial pressure.
- 11 Ephedrine, atropine, and glycopyrrolate should be available for management of hypotensive bradycardic events occurring during surgery in the beach chair position.
- 12 Interscalene blocks cause hemidiaphragmatic paresis and can cause respiratory compromise in patients with reduced pulmonary function.
- 13 Venous thromboembolism is a common complication of lower extremity orthopedic surgery performed with inadequate thromboprophylaxis.
- 14 The American Society of Regional Anesthesia has released guidelines for safe use of regional anesthesia in the setting of antithrombotic or thrombolytic therapy.

## Introduction to Orthopedic Anesthesia

**1** Perioperative management of the patient undergoing orthopedic surgery involves knowledge of orthopedic surgical techniques and associated complications, including nerve injury. Expertise in regional anesthetic techniques for both surgical anesthesia and postoperative analgesia is of paramount importance. Appropriate patient positioning produces optimal surgical conditions while avoiding complications related to stretch, pressure,

and hemodynamic changes. Orthopedic procedures can be associated with major blood loss; therefore, one must be familiar with tourniquet use, controlled intraoperative hypotension, blood salvage techniques, use of antifibrinolytics, fluid resuscitation (see [Chapter 16](#)), transfusions, and related complications (see [Chapter 17](#)).

Orthopedic surgical patients benefit greatly from early mobilization and rehabilitation, both of which can be expedited by specific anesthetic techniques and proactive postoperative analgesia. A multimodal approach, often utilizing neuraxial and/or peripheral nerve blocks, can enhance recovery and improve functional outcomes. Patients undergoing major orthopedic surgery are at high risk for venous thromboembolism. Knowledge of current pharmacologic and mechanical methods of thromboprophylaxis is required, and regional techniques must be managed so as to minimize associated bleeding risk.

## Preoperative Assessment

All patients should undergo medical and laboratory testing appropriate to their medical history and planned procedure (see [Chapter 23](#)). Preoperative assessment of the orthopedic patient must include special attention to potential airway difficulties, considerations relating to mobility and intraoperative positioning, and medication history related to opioid dependence and anticoagulation status. Cardiopulmonary symptoms and exercise tolerance may be difficult to assess in this population because of limitations in mobility. As a result, pharmacologic functional cardiovascular testing and formal pulmonary function testing may be warranted in patients with concerning risk factors. Overall, patients undergoing orthopedic procedures are considered at intermediate risk for perioperative cardiac complications.

Patients with rheumatoid arthritis (RA) often require orthopedic surgery and merit special attention. RA can affect the pulmonary, cardiac, and musculoskeletal systems. Airway management can be challenging in these patients. Involvement of the cervical spine and temporomandibular joints results in limited neck range of motion and mouth opening. Atlantoaxial instability, with subluxation of the odontoid process, can lead to spinal cord injury during neck extension. Patients with RA on chronic steroid therapy may require perioperative steroid replacement.

All medications should be reviewed during a preoperative visit with detailed instructions as to which medications to hold and which to continue until surgery. Patients taking opioids for greater than 4 weeks often develop tolerance and opioid-induced hyperalgesia.<sup>1</sup> Although abrupt cessation of opioids is not advised, weaning of chronic opioids under the direction of a

pain management specialist prior to elective surgery may be beneficial. Antihypertensives without a significant rebound effect may be held on the day of surgery if there is concern for excessive intraoperative hypotension or renal injury related to angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. A plan for management of anticoagulants including heparins, warfarin, factor Xa inhibitors, and antiplatelet agents must be agreed upon by the medical and surgical teams and communicated clearly to the patient.<sup>2</sup> Anesthetic techniques must take into account the specifics of each patient's anticoagulation status and plan.

Preoperative evaluation should include a standard focused physical examination (see [Chapter 23](#)). Orthopedic patients may have coexisting disease or trauma requiring special attention to distorted airway anatomy or limited neck mobility. Proposed sites of needle placement for regional anesthesia and line placement should be assessed for evidence of infection and anatomic abnormalities. A brief neurologic examination with documentation of pre-existing deficits is crucial. Potential positioning difficulties related to body habitus, joint pain or instability, fractures, and/or fusions should be considered. Ideally, preoperative education regarding the surgical procedure, anesthetic/analgesic options, and postoperative rehabilitation plan should be provided.

## Selection of Anesthetic Technique

Many orthopedic surgical procedures, because of their localized **2** peripheral sites, lend themselves to regional anesthetic techniques. Neural structures may be blocked at the peripheral nerve, plexus, or neuraxial level (see [Chapters 35](#) and [36](#)). Regional anesthetics offer several advantages over general anesthetics including enhanced rehabilitation, accelerated hospital discharge, improved analgesia, decreased nausea and vomiting, less respiratory and cardiac depression, improved perfusion, reduced blood loss, and decreased risk of infection and thromboembolism. It is important to communicate potential benefits and encourage regional anesthesia when appropriate.

The optimal regional technique and local anesthetic depend on factors **3** including surgery duration, indication for postoperative sympathectomy, and degree and duration of postoperative sensory/motor block needed for active and passive physical therapy. General anesthesia is appropriate for orthopedic surgery at sites not amenable to regional and in patients with contraindications to regional techniques owing to factors such as anticoagulation status, infection at the needle insertion site, pre-existing nerve injury or disease, and patient refusal. Of note, a contraindication to one regional technique may not preclude the use of another. For example,

coagulopathy may prevent the use of neuraxial or deep plexus blocks, but a superficial peripheral nerve block may be appropriate. In contrast, a neuraxial block is likely to be safer in a patient with peripheral neuropathy.

## Anesthesia for Spine Surgery

### *Preoperative Assessment*

Preoperative evaluation for spine surgery should assess involvement of the respiratory, cardiovascular, and neurologic systems. Difficult airways are common in patients presenting for surgery involving the upper thoracic or cervical spine; therefore, airway evaluation should focus on restricted neck movement, cervical spine stability, and exacerbation of symptoms with movement or position. Both clinical and radiographic assessment of cervical spine stability should be discussed with the surgeon prior to neck manipulation. The decision to secure the airway awake, asleep, or with advance airway devices should be made prior to surgery and the patient counseled accordingly. Awake tracheal intubation is preferred when assessing for neurologic function prior to use of a traction device. 4

Patients presenting for spine surgery often have impaired respiratory function. Scoliosis can cause restrictive lung disease, neuromuscular diseases can be associated with recurrent chest infections, and patients with spinal cord injury may already be ventilator dependent. Physical exam and history should focus on functional impairment. Chest radiograph, arterial blood gas, and pulmonary function tests may be indicated in patients with restrictive pulmonary disease. A preoperative vital capacity less than 30% to 35% of predicted is associated with prolonged postoperative ventilation after scoliosis surgery.<sup>3</sup> Optimization of pulmonary function targets treatment of reversible causes with the use of preoperative physical therapy, antibiotics, and bronchodilators as indicated. 5 

Cardiac dysfunction is often associated with spine pathology and may be a primary manifestation of the disease as seen in muscular dystrophies. Rarely, scoliosis can cause cor pulmonale secondary to chronic hypoxemia and pulmonary hypertension. An electrocardiogram (ECG) and echocardiogram should be obtained to assess left ventricular function and pulmonary arterial pressures. Dobutamine stress echocardiography may be necessary to assess cardiac function in patients with limited exercise tolerance or mobility.

Neurologic deficits of spine patients generally relate to the underlying disease and should be discussed in detail with the patient and surgeon and documented. With cervical spine surgery, extra care must be taken to avoid injury during tracheal intubation and positioning. Neuromuscular diseases increase risk of aspiration during airway manipulation. In patients with spinal

cord injury, spinal shock and autonomic dysreflexia are of particular concern.

## **Positioning for Spine Surgery**

Positioning for spine surgery depends on the level and approach of the procedure. Patients may be transitioned between supine, lateral, and prone positions intraoperatively. Overall goals of positioning are to (1) pad as needed to protect peripheral nerves, bony prominences, and the eyes, (2) avoid displacement of unstable fractures during surgery, and (3) ensure low venous pressures and thereby minimize blood loss at the surgical site. Low venous pressures can be facilitated by maintaining a free abdomen and reverse Trendelenburg position.

The posterior approach to spine surgery requires prone positioning (Fig. 51-1). Pressure on the abdomen causes inferior vena cava compression, increasing bleeding from valveless epidural veins, reducing cardiac output, and increasing the risk of lower limb thrombosis.<sup>4</sup> Therefore, adequate foam padding should be placed under the chest (below the axillae) and the anterior superior iliac spines. The arms should not be abducted to more than 90 degrees and should be positioned with slight internal rotation to reduce the risk of brachial plexus stretching. With the elbow flexed in the prone position, the ulnar nerve is at particular risk of pressure-related injury and should be protected. The eyes should be taped closed; appropriate positioning with a ProneView (Mizuho OSI, Union City, CA) or Mayfield fixator will avoid pressure on the eyes/orbits while maintaining a neutral neck position.

The anterior approach to the thoracolumbar spine is achieved in the lateral position. For scoliosis surgery, the convexity of the curve is usually uppermost, and removal of one or more ribs may be necessary for surgical exposure. Placement of a double-lumen endotracheal tube to collapse the lung on the operative side may be required for surgery above T8.

For cervical spine surgery, anterior approaches require the supine position and posterior approaches require prone positioning (Fig. 51-1). The patient may be positioned with the head 180 degrees away from the anesthetic machine to allow surgical access. Therefore, extensions may be needed for breathing circuits and intravascular lines, and it may be necessary to place venous access in the patient's foot. Endotracheal tubes must be carefully secured without disruption of the surgical field. The head may be supported on a padded head ring or the "horseshoe" of a Mayfield attachment. If neck traction is required, it is generally achieved by placing pins and weights onto the outer skull. Reverse Trendelenburg minimizes venous bleeding and provides countertraction. Venous pooling in the lower limbs and carotid artery retraction can cause swift and significant hemodynamic changes; therefore, an arterial line is advisable. Because the arms will typically be

tucked at the sides, the arterial line should be placed prior to positioning.

**Figure 51-1** Positioning for spine surgery. **A:** Supine positioning for anterior approach. The neck is maintained in a neutral-flexed position and the head is supported with a round foam pillow or other supportive device. The shoulders are taped in caudal traction to aid exposure. In-line traction is applied via Gardner-Wells tongs. **B:** Prone positioning for posterior approach. The head and neck are neutral with the face supported on a head frame (ProneView) to avoid any direct pressure to the eyes. The shoulders are abducted to less than 90 degrees. The forearms are placed on padded supports at the level of the mattress to minimize direct pressure on the ulnar nerve at the elbow. The pelvis and chest are supported to minimize intra-abdominal pressure.

### **Blood Conservation**

The frequency of transfusion in adult spine surgery ranges from 50% to 81%.<sup>5</sup> Most of the blood loss during spinal instrumentation and fusion occurs with decortication and is proportional to the number of vertebral levels involved.<sup>6</sup>

Patients may become coagulopathic perioperatively owing to fibrinolysis or dilution of coagulation factors and/or platelets. The detailed mechanisms of coagulopathy and the role of factor testing during spine surgery are poorly defined. However, it appears that a significant deviation from baseline of either the prothrombin time or activated partial thromboplastin time is predictive of bleeding and may be used to guide transfusion therapy.<sup>7</sup> A rare cause of bleeding during spine surgery is trauma to the aorta, vena cava, or iliac vessels. Unexplained rapidly evolving hypotension with signs of hypovolemia should alert the anesthesiologist to this possibility.

Measures to decrease blood loss and transfusion requirements during major spine surgery include preoperative autologous donation, proper positioning, the use of intraoperative blood salvage, and the administration of

antifibrinolytics such as tranexamic acid (TXA) (see [Chapter 17](#)).<sup>5,8</sup> Recent data indicate that TXA not only reduces surgical bleeding and transfusion requirements but also does so without increased incidence of pulmonary embolism (PE), deep venous thrombosis (DVT), or myocardial infarction.<sup>9,10</sup>

## Spinal Cord Monitoring

**7** Intraoperative monitoring (IOM) of spinal cord function is now considered mandatory for all surgeries in which the cord is at risk of injury. Risk is incurred when corrective forces are applied to the spine, osteotomies are made, or the spinal canal is surgically invaded. Data suggest that IOM may reduce the incidence of motor deficits or paraplegia after scoliosis surgery from 3% to 7%<sup>11,12</sup> to 0.5%.<sup>13</sup> There are three main methods of IOM: the wake-up test, somatosensory evoked potential (SSEP) monitoring, and motor evoked potential (MEP) recording.

The wake-up test involves intraoperative awakening of the patient after completion of spinal instrumentation in order to assess motor function of upper and lower extremities. If there is satisfactory movement of the hands but not the feet, then distraction on the rod is released one notch and the wake-up test repeated. Surgical anesthesia can be achieved with a volatile anesthetic, nitrous oxide, and opioids, with or without propofol. Opioids are important for analgesia and tolerance of the endotracheal tube while the patient is awake. Although recall of the event occurs in only 0% to 20% of patients and is rarely viewed as unpleasant,<sup>14</sup> it is important to describe the wake-up test prior to surgery to minimize anxiety should the patient have recall.

The wake-up test has a number of disadvantages, including the risk that an uncooperative patient could move, dislodge the endotracheal tube, or even fall from the table. Additionally, the wake-up test assesses function only at the time it is performed and has the potential to provide false reassurance after instrumentation but prior to an unexpected neurologic injury. Thus, the wake-up test is most suitable if other monitoring techniques are not available or equivocal or if they fail.

SSEPs assess the dorsal column pathways of proprioception and vibration that are supplied by the posterior spinal artery. SSEPs are altered by neural injury, volatile anesthetics, hypercarbia, hypoxia, hypotension, and hypothermia.<sup>15,16</sup> Motor pathways are supplied by the anterior spinal artery and are monitored by MEPs. MEPs are considered technically more difficult to use, in part because they are impeded by use of muscle relaxants. If both SSEP and MEP are to be monitored during spine surgery, a suitable anesthetic regimen would include an ultrashort-acting opioid infusion with a low-dose inhaled anesthetic or total intravenous anesthesia with monitoring of the

electroencephalogram or bispectral index to minimize the potential for intraoperative awareness (see [Chapter 37](#)).

Postoperative paraplegia has occurred despite preservation of intraoperative SSEPs; however, MEPs in combination with SSEPs may increase the early detection of spinal cord ischemia.<sup>14,17</sup> Acute alterations in signal amplitude or latency can signify spinal cord compromise and may be the result of direct trauma, ischemia, compression, or hematoma. If changes occur, it is recommended that surgery be discontinued, blood pressure returned to normal or 20% above normal, and volatile agents decreased or discontinued. Arterial blood gases can help rule out a metabolic derangement. If the signal does not return to normal, the surgeon should release distraction on the cord. A wake-up test can be performed at this time to definitely exclude neurologic deficits.

## **Spinal Cord Injury**

Patients with a suspected spinal cord injury should be examined immediately to assess for signs of respiratory insufficiency, airway obstruction, rib fractures, and chest wall or facial trauma. Spinal cord function above the level of the injury should be determined. If the muscles controlled by the C5 nerve roots (deltoid, biceps, brachialis, and brachioradialis) are flaccid, partial diaphragmatic paralysis should also be expected.

Patients requiring spine stabilization surgery may present with spinal shock, which occurs immediately after the injury and lasts up to 3 weeks. Injuries at or above T5 are associated with hypotension due to a physiologic sympathectomy and loss of tone from the splanchnic vascular beds. Lesions above the cardiac accelerator fibers (T1 to T4) cause bradycardia. Hypotension due to spinal injury is poorly responsive to intravenous fluids and vasopressors, and excessive fluid administration may contribute to the development of pulmonary edema.

With complete cord transection above T5, following recovery from spinal shock, 85% of patients go on to exhibit autonomic hyperreflexia. The syndrome can also occur with injuries at lower levels and is characterized by severe paroxysmal hypertension with bradycardia from the baroreceptor reflex, dysrhythmias, and cutaneous vasoconstriction below and vasodilation above the level of the injury. Episodes are typically precipitated by distention of the bladder or rectum but can be induced by any noxious stimulus including surgery. Treatment involves removal of the stimulus, deepening of anesthesia, and administration of direct-acting vasodilators. Untreated, the hypertensive crisis may progress to seizures, intracranial hemorrhage, or myocardial infarction.

Ventilatory impairment increases with higher levels of spinal injury. A

high cervical lesion that includes the diaphragmatic segments (C3 to C5) results in respiratory failure and death without mechanical ventilation. Lesions between C5 and T7 cause significant alterations in respiratory function due to loss of abdominal and intercostal support. Flaccid thoracic muscles can lead to paradoxical respirations and a vital capacity reduction of 60%. Inability to cough and effectively clear secretions causes atelectasis and increased risk of infection.

Succinylcholine can be administered safely for the first 48 hours after spinal cord injury. After that time, a proliferation of acetylcholine receptors in the muscle can cause hypersensitivity to depolarizing muscle relaxants leading to marked hyperkalemia.<sup>18</sup> Maximal hyperkalemia risk from succinylcholine occurs between 4 weeks and 5 months after spinal injury. Serum potassium levels may rise as high as 14 mEq/L, causing ventricular fibrillation and cardiac arrest. Although succinylcholine should be avoided in all patients with spinal cord injury after 48 hours, nondepolarizing paralytic agents can be used.

Patients with spinal cord injury are poikilothermic owing to disruption of sympathetic pathways carrying temperature sensation and subsequent loss of vasoconstriction below the level of injury. Normothermia can be achieved by applying exogenous heat to the skin, increasing ambient air temperature, warming intravenous fluids, and humidifying gases.

## **Scoliosis**

Scoliosis involves a lateral and rotational deformity of the spine and occurs in up to 4% of the population. Most cases are idiopathic (70%), with a male to female ratio of 1:4. Surgery is considered when the Cobb angle, a measure of curvature, exceeds 50 degrees in the thoracic or 40 degrees in the lumbar spine. Surgery aims to halt progression of the condition and partially correct the deformity, preventing further respiratory and cardiovascular deterioration.

Scoliosis can cause chronic hypoxia, hypercapnia, and pulmonary vascular constriction resulting in irreversible pulmonary vascular changes, pulmonary hypertension, and eventually right ventricular hypertrophy and cor pulmonale. Thus, untreated idiopathic scoliosis can progress rapidly and is often fatal by the fourth or fifth decade of life. Scoliosis is also often associated with congenital heart conditions, including mitral valve prolapse, coarctation of the aorta, and cyanotic heart disease, suggesting a common embryonic insult or collagen defect.

Although the long-term effect of scoliosis repair is to halt the decline in respiratory function, pulmonary function acutely deteriorates for 7 to 10 days after surgery. Preoperative vital capacity is a reliable prognostic indicator of

respiratory reserve, and postoperative ventilator support is likely to be required for patients with a vital capacity less than 40% of predicted.

Anesthetic considerations for surgical correction of scoliosis by spinal fusion and instrumentation include management in the prone position, hypothermia during long procedures with extensive exposure, and replacement of blood and fluid losses.<sup>19</sup> Adequate hemodynamic monitoring and venous access are essential. An arterial line allows for close hemodynamic monitoring and assessment of blood gases, whereas a central venous catheter may be helpful in evaluating blood and fluid management and can be used to aspirate air in the case of venous air embolism. Patients with evidence of pulmonary hypertension or severe coexistent cardiovascular or pulmonary disease may require a pulmonary artery catheter.

### *Muscular Disorders*

Muscular dystrophy and cerebral palsy are important causes of scoliosis. Duchenne muscular dystrophy (DMD) has an incidence of 1:3,300 male births and is inherited as a sex-linked recessive condition affecting skeletal, cardiac, and smooth muscle. Patients with DMD lack a membrane cytoskeletal protein, dystrophin, and typically present between the ages of 2 and 6 years, with progressive weakness of proximal muscle groups. Up to one-third have intellectual impairment. DMD patients have a high incidence of cardiac abnormalities (50% to 70%). In the later stages of the disease, dilated cardiomyopathy may occur in association with mitral valve incompetence. Up to 50% of patients have cardiac conduction defects predisposing to dysrhythmias that can, in some cases, lead to cardiac arrest during spine surgery. Patients with DMD are sensitive to nondepolarizing neuromuscular blocking agents, and hyperkalemia may occur with use of succinylcholine. In general, the prognosis of scoliosis associated with neuromuscular disease is worse than that of idiopathic scoliosis, and these patients frequently require postoperative ventilatory support.

### *Degenerative Vertebral Column Disease*

Spinal stenosis, spondylosis, and spondylolisthesis are all forms of degenerative vertebral column disease, causing pain and/or progressive neurologic symptoms requiring surgical intervention.

A preoperative assessment of C-spine symptoms and the airway should be performed, as described earlier. Intraoperatively, the anterior incision approximates the border of the sternocleidomastoid muscle, near critical anatomic structures. Lateral retraction of the carotid artery may endanger

cerebral perfusion, particularly in the elderly patient. Retraction of the esophagus and trachea medially may cause pharyngeal laceration, laryngeal edema, and recurrent laryngeal nerve paralysis. Cerebrospinal fluid leaks and trauma to the vertebral artery have also been reported.

General anesthesia is preferred for nearly all thoracic and cervical procedures because of the high spinal level that would be required with a regional technique. General anesthesia ensures airway access, is associated with greater patient acceptance, and can be used for prolonged operations. For lower thoracic and lumbar spine surgery, either general or neuraxial anesthesia may be safely administered. A randomized trial in 2009 concluded that general anesthesia was associated with higher surgeon satisfaction and less nausea and vomiting.<sup>20</sup> Succinylcholine should be avoided if there are progressive neurologic deficits.

### *Postoperative Care of the Spine Patient*

Most patients can be extubated immediately after spine surgery if the procedure was uncomplicated and preoperative vital capacity values were acceptable. Postoperative ventilation may be required in patients with neuromuscular disorders, severe restrictive pulmonary dysfunction with a preoperative vital capacity of less than 35% of predicted, right ventricular failure, obesity, or sleep apnea. Patients with prolonged procedures, thoracic cavity invasion, or blood loss greater than 30 mL/kg<sup>-1</sup> may require postoperative ventilation.<sup>21</sup> In the event of significant blood loss requiring aggressive resuscitation, particularly in the prone position, facial and laryngeal edema may compromise an uncontrolled airway and extubation is not advisable. Residual opioid or muscle relaxant may lead to hypoventilation or apnea, especially in patients with neuromuscular disease. Neurologic status must also be monitored closely to determine appropriateness for extubation.

Postoperative mechanical ventilation may be maintained for a few hours, with the head of the bed elevated when possible, until hypothermia and metabolic derangements have been corrected and facial and airway edema have improved. Aggressive postoperative pulmonary therapy, including incentive spirometry, is necessary to avoid postextubation atelectasis and pneumonia. Careful monitoring of systemic pressures, urine output, and wound drainage is essential to ensure adequate resuscitation and absence of significant postoperative hemorrhage.

After spine surgery, analgesia is traditionally provided by systemic opioids. Adequate and safe opioid administration can often be accomplished using patient-controlled analgesia devices with or without background infusions. Side effects of opioids can include respiratory depression, sedation, and gastrointestinal ileus. These concerns are amplified after major spine

surgery when breathing may be compromised. Neurologic status must be followed closely and bowel dysmotility is common. Wound infiltration with local anesthetic and injection of intrathecal morphine have been associated with improved pain scores and decreased side effects in the early postoperative period.<sup>22</sup> Multimodal analgesia has become the gold standard for postoperative pain relief and can be useful after spine surgery. The addition of nonopioid analgesics, including nonsteroidal anti-inflammatories, corticosteroids, acetaminophen, or anticonvulsant pain medications, can reduce opioid use, improve analgesia, and decrease opioid-related side effects (Table 51-1). The surgical team should be consulted prior to use of nonsteroidal anti-inflammatory drugs because they may cause delayed bone healing after spine fusion.

### *Complications of Spine Surgery*

Venous air embolus (VAE) is a catastrophic event that is a particular risk 8 during laminectomy because of the large amount of exposed bone and location of the surgical site above the level of the heart. VAE presents as unexplained hypotension with an increase in the end-tidal nitrogen concentration or a precipitous fall in the end-tidal carbon dioxide concentration. Prompt diagnosis and treatment increase patient survival with VAE. Prevention and management measures include intravascular volume expansion, careful positioning, positive end-expiratory pressure, and jugular venous compression. Treatment includes flooding the surgical site with saline, controlling sites of air entry, repositioning the patient with the surgical site below the right atrium, aspiration of air from a multiorifice central venous catheter, cessation of inhaled nitrous oxide, and resuscitation with oxygen, intravenous fluids, and inotropic agents. Massive embolism may necessitate supine repositioning and cardiopulmonary resuscitation.

**Table 51-1** Multimodal Analgesia for Orthopedic Surgery

Drug Name	Mechanism of Action	Common Side Effects	Additional Considerations
<b>Paracetamol/Acetaminophen</b>			
Acetaminophen	COX inhibition (predominantly COX-2)	Hepatotoxicity	Avoid in liver disease and alcoholism
<b>NSAIDs</b>			
Ketorolac, meloxicam, ibuprofen	COX-1/2 inhibition	Nephrotoxicity Gastritis May impair bone healing	Avoid in renal impairment and/or inflammatory bowel disease
Celecoxib	Selective COX-2 inhibition	Nephrotoxicity Gastritis	Avoid in renal impairment and coronary artery disease Avoid in patients with sulfa allergy
<b>Anticonvulsants</b>			
Gabapentin, Pregabalin	Binds to voltage-gated Ca <sup>2+</sup> channels	Drowsiness, dizziness, peripheral edema	Adjust dose for renal impairment
<b>Nontraditional Opioids</b>			
Methadone	Opioid agonist, NMDA receptor antagonist, inhibits reuptake of NE	Drowsiness, sedation, constipation, dizziness, nausea/vomiting	Promotility bowel regimen required
Tramadol, Tapentadol	Weak $\mu$ -opioid agonist, inhibits reuptake of NE		Tramadol also blocks reuptake of 5-HT; opioid receptor binding affinity is 6000x lower than morphine.
<b>Miscellaneous</b>			
Ketamine	NMDA receptor antagonist	Tachycardia, dysphoria	Avoid with increased ICP, asthma; Transdermal patch or infusion
Lidocaine	Blocks Na <sup>+</sup> gated channels thereby blocking nerve conduction	Hepatic dysfunction	Transdermal patch or infusion
Dexmedetomidine	$\alpha$ -2 adenosine receptor agonist	Bradycardia Hypotension	Infusion only

COX, cyclooxygenase; NSAIDs, nonsteroidal anti-inflammatory drugs; NMDA, N-methyl-D-aspartate; NE, norepinephrine; ICP, intracranial pressure.

Vision loss is a rare, nonfatal yet catastrophic complication associated with spine surgery. A notable number of cases of unilateral and bilateral blindness have been reported after spine surgery.<sup>23–25</sup> The etiology of vision loss can be optic neuropathy, retinal artery occlusion, or cerebral ischemia. Most cases are associated with complex instrumented fusions,<sup>26</sup> significant sustained intraoperative hypotension, anemia, large intraoperative blood loss, and prolonged surgery.<sup>25</sup>

The American Society of Anesthesiologists (ASA) Postoperative Visual Loss Registry reported on 93 cases of visual loss after spine surgery submitted anonymously to the ASA Closed Claims Study. Ischemic optic neuropathy was the most common cause of visual loss and accounted for 83 of 93 cases.<sup>26</sup> Risk factors for ischemic optic neuropathy after spinal surgery include male sex, obesity, Wilson frame use, long anesthetic duration, large blood loss, and use of noncolloid fluids.<sup>27</sup>

## Upper Extremity Surgery

Orthopedic surgical procedures to the upper extremity are well suited to

regional anesthetic techniques. Peripheral nerve block adjuvants that prolong block duration can provide significant postoperative analgesia.<sup>28</sup> Continuous catheter techniques can also provide sustained analgesia and facilitate early limb mobilization.

The benefits of regional anesthesia for upper extremity surgery are well established. However, orthopedic patients may have concurrent cervical spine disease, and upper extremity surgical procedures may involve peripheral nerves with pre-existing deficits. Physicians must be cognizant of the risk of nerve injury resulting from the “second hit phenomenon” in the setting of surgical trauma and nerve blockade. The decision to perform regional anesthesia in a patient with pre-existing neurologic deficits or who is at risk for perioperative neurapraxia should be made on an individual basis after discussion with the patient and surgeon. Meticulous regional anesthetic technique with ultrasound guidance, appropriate use of local anesthetic solutions, careful patient positioning, and serial postoperative neurologic examinations may reduce the incidence of neurologic dysfunction.

Local anesthetic selection is based on the duration and degree of sensory or motor block required. The patient should be informed of the anticipated block duration prior to surgery and instructed to protect the extremity until block resolution. If there is a possibility of block resolution overnight, it is not unreasonable to recommend that patients commence oral pain medication at bedtime, even while numb, to minimize the risk of sudden and severe pain overnight. It should also be noted that supraclavicular and infraclavicular blocks can rarely be complicated by pneumothorax that may not manifest until 6 to 12 hours after surgery. Although these blocks are routinely performed safely for inpatient and ambulatory surgeries, each patient should be told to contact his or her surgeon immediately if any respiratory difficulties develop postoperatively.

### *Surgery to the Shoulder and Upper Arm*

Reconstructive shoulder surgery, including total shoulder arthroplasty (TSA) and rotator cuff repair, presents unique management and positioning considerations to the anesthesiologist. For example, a recent institutional review of 1,569 patients who underwent TSA between 1993 and 2007 revealed a 2.2% rate of perioperative nerve injury.<sup>29</sup> It is notable that although a significant percentage of TSA-associated nerve injuries occur at the level of the brachial plexus, this study found a lower rate of perioperative

5 nerve injury in patients who received interscalene blocks.<sup>30</sup> It is important to communicate both the risk of nerve injury after major shoulder surgery and the lack of evidence that brachial plexus nerve blocks contribute significantly to this risk.

Likewise, nerve injury can occur in association with trauma. For example, radial nerve palsy is identified in up to 17% of patients with humeral shaft fractures,<sup>30</sup> whereas axillary nerve and brachial plexus injury are often associated with proximal humerus fractures. This highlights the need for careful examination and documentation of deficits prior to use of a regional anesthetic and clear communication with patients regarding current evidence about associated risk and benefits.

## *Surgical Approach and Positioning*

Surgical procedures to the upper arm and shoulder are typically performed with the patient sitting in the “beach chair” or lateral decubitus position (see [Chapter 29](#)). In either position, the patient’s head, neck, and hips must be secured to prevent lateral movement during surgical manipulation, with frequent reassessment throughout the case. Excessive rotation or flexion of the head away from the operative side results in stretch injury to the brachial plexus. Care must be taken to avoid pressure on the eyes and ears. Access to the patient’s face and airway is often limited, so any airway devices and connections must be carefully secured. In spontaneously breathing patients with unsecured airways, good airflow must be maintained to minimize carbon dioxide rebreathing and pockets of oxygen that present a fire safety risk.

Depending on the surgery and surgeon preference, the lateral position **10** or the beach chair (sitting) position may be chosen. The lateral position has been associated with increased rates of neurapraxia from stretch injuries and is a challenging position from which to convert from an arthroscopic to an open procedure should this become necessary.<sup>31</sup> The beach chair position allows for easy conversion to open procedures but presents several hemodynamic challenges for the anesthesiologist. Blood pressure at the head will be lower than at the arm or leg, with every 20 cm of height difference equating to approximately 15-mmHg difference in mean arterial pressure ([Fig. 51-2](#)). Association between hypotension and cerebral desaturation has been reported, and there have been cases reports of strokes in the sitting position. However, The Anesthesia Patient Safety Foundation Beach Chair Study recently described decreased cerebral autoregulation and regional cerebral oxygenation in the sitting position with no associated increase in adverse neurologic outcomes or markers of neuronal injury.<sup>32</sup>

Up to 25% of patients undergoing surgery in the beach chair position **11** under general or regional anesthesia can experience hemodynamically significant hypotensive bradycardic events thought to be caused by ventricular underfilling and the Bezold–Jarisch reflex. Studies have found that intraoperative epinephrine and fentanyl use are associated with increased risk of hypotensive bradycardic events.<sup>33,34</sup> In contrast, preincision administration

of ondansetron or metoprolol may significantly decrease this risk.<sup>35,36</sup> Ephedrine, atropine, and glycopyrrolate have been used successfully to manage such events and should be immediately available when patients are undergoing surgery in the beach chair position.

**Figure 51-2** Positioning for upper extremity surgery: beach chair position. The patient is placed semi-recumbent with the head, neck, and torso supported in neutral position by a head harness and padding. Hips are flexed to 45 to 60 degrees and the knees to 30 degrees resting on a knee pillow. The chair is in 10 to 15 degrees of Trendelenburg. Pressure points are padded and the eyes are protected. The nonoperative arm is placed on an arm support. The major risk during surgery in the beach chair position is hypotension; for every 1-cm rise above the heart, there is a 0.75-mmHg drop in mean arterial pressure (MAP). Thus, a 20-cm rise in the head causes a 15-mmHg fall in cerebral MAP.

A tourniquet cannot be used during proximal upper extremity procedures, and significant blood loss may occur. Moreover, patients are at risk of sudden hemodynamic instability from embolic syndromes caused by fat, air, and/or cement. Arterial cannulation for continuous direct blood pressure measurement and monitoring of hemoglobin concentration should be considered—particularly during TSA and humeral fracture reduction/fixation.

### **Anesthetic Management**

Surgery to the shoulder and humerus may be performed under regional or general anesthesia. With careful positioning and appropriate sedation, interscalene or supraclavicular blockade alone can provide excellent surgical anesthesia ([Table 51-2](#)). However, a combination of regional and general anesthesia may be chosen because of limited access to the patient's airway, need for neuromuscular relaxation (i.e., during shoulder stabilization

procedures), or a surgical field extending outside of the block dermatomes. General anesthesia without a nerve block should be considered in patients with a pre-existing brachial plexopathy or significant cervical spine disease because of the risk of perioperative exacerbation of neurologic deficits.

**12** Historically, it was noted that interscalene blocks caused ipsilateral diaphragmatic paresis<sup>37</sup> in 100% of patients. With a functioning contralateral diaphragm, this leads to a 25% loss of pulmonary function. However, if the contralateral diaphragm is significantly impaired, complete respiratory failure will occur, and, therefore, bilateral interscalene blocks should be avoided. Recent studies have shown good analgesic efficacy of low-volume interscalene blocks in combination with general anesthesia for elective shoulder surgery with rates of hemidiaphragmatic paresis ranging from 13% to 93%.<sup>38,39</sup> In one study, rates of phrenic nerve blockade were 0% with ultrasound-guided supraclavicular blocks and 53% for those performed using a nerve stimulator.<sup>38</sup> Interscalene and superclavicular blocks should be used with caution in patients with severe pulmonary disease and should be performed using ultrasound guidance whenever possible. Care should also be taken when considering these blocks in obese patients and those with sleep apnea because they are also at increased risk of clinically significant reductions in pulmonary function.<sup>40</sup> Diaphragmatic paresis, when it occurs, is present for the duration of the block, so extra caution should be used when considering administration of adjuvants that will prolong these blocks.

### *Surgery to the Elbow, Wrist, and Hand*

In patients without contraindications, surgery in the areas of the distal humerus, elbow, forearm, wrist, and hand can be performed with supraclavicular, infraclavicular, or axillary nerve blocks (Table 51-2). Infraclavicular and supraclavicular approaches to the brachial plexus are the most reliable and provide consistent anesthesia to the four major peripheral nerves of the brachial plexus. The medial aspect of the upper arm, supplied by the intercostobrachial nerve, is generally spared by infraclavicular and axillary blocks and may be blocked by a subcutaneous injection of local anesthetic immediately distal to the axilla for the prevention of tourniquet pain.

Minor hand procedures such as carpal tunnel release, reduction of phalanx fractures, and superficial wound debridements without a tourniquet may require only local infiltration or peripheral blockade at the midhumeral, elbow, or wrist level. Intravenous regional anesthesia (Bier block) using a double tourniquet permits more extensive surgery and longer tourniquet times than distal peripheral block but does not provide postoperative analgesia.

## Postoperative Regional Analgesia

Peripheral nerve blocks are associated with earlier discharge and decreased risk of hospital admission following rotator cuff repair.<sup>41,42</sup> For TSA, peripheral nerve blocks improve pain management with no increase in complications or resource usage.<sup>43</sup> Indwelling perineural catheters may reduce hospital admission/readmission, decrease opioid-related side effects and sleep disturbance, and improve rehabilitation.<sup>44,45</sup> Brachial plexus catheters may be inserted using interscalene, infraclavicular, and axillary approaches. After surgery, catheters may be left indwelling for 4 to 7 days without adverse effects.

**Table 51-2** Regional Techniques for Upper Extremity Surgery

Block	Nerves Blocked	Applications	Comments
Interscalene	Entire brachial	Shoulder Humerus Partial coverage of lateral clavicle	May not cover inferior trunk/ulnar nerve High rate of phrenic nerve block; inadequate for hand/forearm surgery
Supraclavicular	Entire brachial	Shoulder Humerus Elbow Forearm Wrist Hand	Moderate rate of phrenic nerve block
Infraclavicular	Radial, ulnar, median, and axillary nerves	Distal humerus Elbow Forearm Wrist Hand	Musculocutaneous nerve may be spared Intercostobrachial nerve not blocked; supplementation of medial arm may be required
Axillary	Radial, ulnar, median	Elbow Forearm Wrist Hand	Musculocutaneous nerve can be blocked reliably at this level with ultrasound guidance

## Lower Extremity Surgery

Orthopedic surgeries involving the lower extremity are among the most commonly performed operations in the United States. Demand for total joint arthroplasty of the hip and knee is rising due to increased life expectancy and an increasing emphasis on improving quality of life. General anesthesia and/or regional anesthesia can be utilized for surgery to the lower extremities. However, there is evidence that regional anesthesia improves mortality and morbidity, particularly in older fragile patients.<sup>46</sup>

When compared to general anesthesia, neuraxial techniques for total hip arthroplasty (THA) and total knee arthroplasty (TKA) are associated with lower 30-day mortality, decreased incidence of thromboembolic events, less blood loss, and lower transfusion requirements, along with decreased length of stay (LOS), cost, and in-hospital complications.<sup>47</sup> Regional anesthesia also provides superior postoperative pain control for painful

procedures like TKA and foot reconstruction.

A major complication of orthopedic lower extremity surgery is perioperative DVT formation and venous thromboembolism. Knowledge of anticoagulant dose and timing is essential to prevent the rare yet devastating complication of an epidural hematoma as a result of neuraxial technique (Table 51-3) (see Venous Thromboembolism and Thromboprophylaxis).<sup>48</sup>

## ***Surgery to the Hip and Pelvis***

Primary partial or total hip arthroplasties are performed with increasing frequency, with almost 500,000 operations performed each year in the United States alone.<sup>49</sup> Including total hip revision and hip fracture surgery, there is significant associated anesthetic demand. The majority of hip fracture and arthroplasty patients are in the geriatric population and present with multiple comorbidities. Optimal perioperative conditions are essential for these patients.

### **Surgical Approach and Positioning**

The anterior surgical approach for hip arthroplasty is gaining favor because it is tissue sparing, allowing for a smaller incision and the potential for less pain, faster recovery, and improved mobility (Fig. 51-3).<sup>50</sup> However, most surgery to the hip and femur is performed using a posterior approach. For this approach, the patient is placed in the lateral decubitus position with the arms neutral and abducted/flexed less than 90 degrees, and an axillary roll is placed to prevent compression of the brachial plexus and axillary artery (Fig. 51-3). With general anesthesia, the airway should be accessed with the patient supine, prior to surgical positioning. A neuraxial anesthetic can be performed with the patient sitting or in the lateral position. The cervical spine and head must be kept neutral during positioning. Mild airway obstruction often improves in the lateral decubitus position; however, the airway should be secured prior to lateral positioning if there are any significant concerns.

**Table 51-3** Summary of ASRA Practice Advisory Guidelines for Neuraxial Anesthesia and Antithrombotics

Agent	American Society of Regional Anesthesia Guidelines for Neuraxial Anesthesia
Warfarin	Stop 4–5 days prior to neuraxial block, confirm normalization of INR prior to needle insertion. Catheters should be removed with INR <1.5. Removal with INR between 1.5 and 3.0 merits close neuromonitoring. Warfarin dose should be held for INR >3.0.
<b>Antiplatelets</b>	
ASA	No contraindications
Clopidogrel	Stop for 7 days prior to neuraxial block. If neuraxial considered between 5 and 7 days, restoration of platelet function should be confirmed.
Prasugrel	Stop for 7–10 days prior to neuraxial block. Wait 9 hours after neuraxial block or catheter removal before administration of drug.
Ticagrelor	Stop for 5–7 days prior to neuraxial block. Wait 10 hours after neuraxial block or catheter removal before administration of drug.
Ticlopidine	Stop for 14 days prior to neuraxial block.
<b>Heparins</b>	
LMWH	Preoperatively: Wait 10–12 hours after prophylactic dose, 24 hours after treatment dose. Postoperatively: Catheters should be removed at least 2 hours prior to initiation of twice-daily dosing regimens. For single daily dosing of LMWH, catheters can be maintained but should only be removed 10–12 hours after last dose.
Subcutaneous	10,000 units per day or less: no contraindication; >10,000 units per day, use extra caution. Check platelet count if >4 days on heparin.
Intravenous	Stop for 2–4 hours prior to catheter removal. Wait 1 hour after neuraxial block or catheter removal before administration of drug.
<b>Thrombin and Xa Inhibitors</b>	
Dabigatran	Stop for 5 days prior to neuraxial block. Wait 6 hours after neuraxial block or catheter removal before administration of drug
Apixaban	Stop for 3 days prior to neuraxial block. Wait 7 hours after neuraxial block or catheter removal before administration of drug.
Rivaroxaban	Stop for 3 days prior to neuraxial block. Wait 8 hours after neuraxial block or catheter removal before administration of drug.
Thrombolytics/fibrinolytics/ thrombin inhibitors	Neuraxial techniques contraindicated except in unusual circumstances.

INR, international normalized ratio; ASA, aspirin; LMWH, low-molecular-weight heparin.

**Figure 51-3** Positioning for hip surgery. **A:** The Mizuho OSI Hana trauma table utilized for anterior total hip arthroplasty. **B:** Patient positioned for anterior total hip arthroplasty

on Mizuho OSI Hana trauma table. A padded post is placed between the legs to allow for traction, dislocation, and rotation of the femoral head. **C:** Lateral positioning for hip arthroscopy. The surgical leg is placed in a boot for traction, dislocation, and rotation of the femoral head from the acetabulum. **D:** Lateral positioning for total hip arthroplasty. An inflatable axillary roll prevents pressure on the axillary artery and brachial plexus.

## Anesthesia Technique

General anesthesia is commonly used for hip and femur surgery as a result of institutional preference, perceived delays in surgical readiness, concern regarding lack of reliability, or prevention of urinary retention.<sup>51</sup> However, evidence supports the recommendation that neuraxial anesthesia should be utilized whenever possible for hip or femur surgery given the potential for improved mortality and morbidity.<sup>52</sup> Neuraxial anesthesia, when performed properly and with adherence to anticoagulation guidelines, is low risk. Epidural hematomas and neurologic complications are extremely rare (less than 0.04%).<sup>53–55</sup>

For hip fracture surgery, neuraxial techniques may decrease hospital LOS, but their overall mortality benefit is controversial.<sup>56</sup> Hip fracture patients are inherently fragile and difficult to optimize; however, surgery performed within 48 hours of admission will decrease inpatient mortality and development of pressure sores.<sup>57</sup> Therefore, surgery should be performed as soon as is safely possible.

Extra care should be taken when considering the impact of associated sympathectomy and hypotension in patients with major comorbidities, particularly severe aortic stenosis. Prior to epidural or spinal anesthesia, a fluid bolus will help avoid a precipitous drop in blood pressure. Slow and controlled dosing through an epidural catheter can also prevent rapid hypotension. Both hyperbaric and isobaric local anesthetics can be used for a spinal anesthetic.

A lumbar plexus block (LPB) or psoas compartment block is an anatomically deep block that provides a potent analgesic for hip surgery. The needle depth increases the risk of inadvertent intravascular injection; therefore, the LPB is avoided in anticoagulated patients. It should also be noted that performing an LPB can rarely result in inadvertent intrathecal injection. Femoral nerve block (FNB) is a useful alternative; however, quadriceps weakness may increase postoperative fall risk during rehabilitation.<sup>58</sup> For both LPB and FNB, continuous nerve catheters decrease postoperative opioid requirements.<sup>58,59</sup>

As THA surgical technique has evolved to include smaller implants, smaller incisions, and less cementing, recovery has become faster and less painful. As a result, some surgeons perform injections of a “cocktail” that may

contain a local anesthetic, epinephrine, a nonsteroidal anti-inflammatory, a corticosteroid, and/or an antibiotic into the periarticular space. Some surgeons will place an epicapsular catheter for postoperative pain management. Utilization of these techniques can avoid urinary retention associated with epidural opioids and weakness associated with peripheral nerve blocks. Although superior to placebo,<sup>60</sup> further studies are needed to establish noninferiority of this technique for pain control compared to percutaneous regional anesthesia techniques.

## **Blood Loss and Transfusion**

Deliberate hypotension using neuraxial anesthesia during hip surgery decreases blood loss and intraoperative transfusion needs when compared to general anesthesia.<sup>61,62</sup> This can be accomplished with either a lumbar spinal anesthetic utilizing a high dose of a short-acting local anesthetic such as mepivacaine, or a low thoracic epidural. In this setting, the inotropic effect of a low-dose epinephrine infusion prevents significant hypotension while maintaining cardiac output.<sup>63</sup> Maintaining normothermia improves intraoperative coagulation. Similar to spine surgery, TXA can be given intravenously or topically in the perioperative setting to decrease blood loss and transfusion requirements.<sup>64</sup>

## **Ambulatory Hip Surgery**

Hip arthroscopy is a common procedure to repair labral tears and to treat hip dysplasia and femoroacetabular impingement. Patients are placed in either the supine or lateral position (Fig. 51-3). Maximal relaxation is necessary while the leg is placed in traction to facilitate dislocation of the femoral head from the acetabulum for access to the hip joint. Relaxation can be achieved by spinal, epidural, or general anesthesia.

A potentially life-threatening complication of hip arthroscopy is extravasation of the arthroscopy fluid from the hip joint into the peritoneal cavity. In extreme cases, intra-abdominal fluid extravasation (IAFE) can cause abdominal compartment syndrome resulting in hemodynamic instability, cardiovascular collapse, and, in tragic cases, death.<sup>65</sup> Iliopsoas tenotomy with concomitant high pump pressures is a risk factor for IAFE. Treatment ranges from clinical observation to diuresis and, in severe cases, abdominal laparotomy.<sup>66</sup> IAFE should be considered in a hemodynamically unstable patient experiencing severe abdominal or pelvic pain postoperatively. Diagnosis can be made with bedside ultrasound utilizing the focused assessment with sonography in trauma exam.<sup>67</sup> Hip arthroscopy is a painful procedure, and an LPB can improve postoperative analgesia<sup>68</sup> but may prolong recovery.<sup>69</sup>

## ***Surgery to the Knee***

### **Total Knee Arthroplasty**

Nearly 700,000 TKAs are performed each year in the United States with a global projection of approximately 3.5 million in 2030.<sup>70</sup> Because TKA involves the cutting and cementing of two long bones, the femur and tibia, these procedures have a painful recovery with a high incidence of chronic pain following both primary and revision procedures.<sup>71</sup> It is important to create an appropriate postoperative analgesia plan to ensure mobility and range of motion.

### **Positioning and Anesthesia Technique**

Knee arthroplasties and arthroscopies are performed in the supine position to allow for easy access to and evaluation of the knee joint in extension and flexion. For TKA, neuraxial anesthesia should be used whenever possible, as described earlier. A thigh tourniquet will minimize bleeding and improve surgical visualization. Tourniquets should be used with caution in patients with active infections or thromboses in the lower extremity, because the exsanguination prior to tourniquet inflation may cause systemic spread of infection or PE. In patients with severe atherosclerosis, the tourniquet may not optimally compress the arteries. If a tourniquet is not applied, consider deliberate hypotension as described earlier for hip surgery.

### **Analgesia for Total Knee Arthroplasty**

The optimal analgesia for TKA is a complex and evolving topic ([Table 51-4](#)).<sup>72</sup> Regional anesthesia improves patient pain outcomes compared to traditional opioid regimens. Epidural catheters with a continuous infusion of dilute local anesthetic and low-dose opioid can provide excellent pain control, particularly when paired with patient-controlled epidural analgesia. Management of an epidural catheter for postoperative analgesia must account for pharmacologic venous thromboprophylaxis. Ultrasound-guided regional anesthesia has led to a significant increase in use of peripheral nerve blocks and catheters as components of postoperative analgesic regimens. A balanced multimodal analgesic regimen can include pharmacologic treatment with anti-inflammatories, acetaminophen, opioids, and medications that manage neuropathic components of pain, such as pregabalin. Such a multimodal approach has the potential to maximize analgesic efficacy while minimizing side effects.

**Table 51-4** Anesthetic Techniques and Nerve Blocks for Lower Extremity Surgery

Procedure	Anesthetic (*Optimal Anesthetic)	Nerve Block Options *(Preferred Blocks)
<ul style="list-style-type: none"> <li>• Partial or total hip arthroplasty</li> <li>• Hip fracture surgery</li> <li>• Hip arthroscopy</li> </ul>	<ul style="list-style-type: none"> <li>• *Neuraxial</li> <li>• General anesthesia</li> </ul>	<ul style="list-style-type: none"> <li>• *Lumbar plexus (psoas compartment) block</li> <li>• Femoral nerve block</li> <li>• Fascia iliaca block</li> </ul>
<ul style="list-style-type: none"> <li>• Partial or total knee arthroplasty</li> </ul>	<ul style="list-style-type: none"> <li>• *Neuraxial</li> <li>• General anesthesia</li> </ul>	<ul style="list-style-type: none"> <li>• *Femoral nerve block (FNB)</li> <li>• *Saphenous (adductor canal) block</li> <li>• Lumbar plexus (psoas compartment) block</li> <li>• Sciatic nerve block (in combination with FNB)</li> <li>• Selective tibial nerve block (in combination with FNB)</li> <li>• Obturator nerve block (in combination with FNB)</li> </ul>
<ul style="list-style-type: none"> <li>• Anterior cruciate ligament reconstruction</li> <li>• Bunionectomy</li> <li>• Hammer toe correction</li> <li>• Midfoot fusion</li> <li>• Ankle fracture</li> <li>• Achilles tendon repair</li> </ul>	<ul style="list-style-type: none"> <li>• Neuraxial</li> <li>• General anesthesia</li> <li>• Neuraxial</li> <li>• General anesthesia</li> <li>• Ankle block (surgery involving toes)</li> </ul>	<ul style="list-style-type: none"> <li>• *Saphenous (adductor canal) block</li> <li>• Femoral nerve block</li> <li>• *Popliteal fossa sciatic nerve block</li> <li>• Ankle block</li> <li>• Saphenous (adductor canal block) (in combination with popliteal fossa sciatic nerve block)</li> </ul>

The femoral, sciatic, and obturator nerves provide sensation to the knee joint. The most commonly utilized peripheral nerve blocks are the LBP, fascia iliaca (3-in-1 block), FNB, and adductor canal (or saphenous) nerve blocks (see [Chapter 36](#)). These blocks can be performed in combination with a sciatic nerve block and/or an obturator nerve block. Literature and clinical practice continue to evolve regarding which blocks or combination of blocks best facilitate rehabilitation and postoperative mobilization, thereby reducing time to hospital discharge, enhancing cost effectiveness, and reducing the risk for complications such as ambulation-related falls.<sup>73</sup>

The FNB is currently considered the peripheral nerve block of choice for TKA analgesia because it has a low complication profile and is easy to perform with either nerve stimulation or ultrasound guidance owing to well-defined anatomic landmarks. FNBs can be performed in a single shot or via catheter; both techniques are associated with reduced morphine consumption after TKA.<sup>74</sup> A major drawback to FNB is quadriceps weakness (up to 80%)<sup>75</sup> and associated fall risk; however, the correlation between FNB and postoperative falls is disputed.<sup>76</sup>

The saphenous nerve block (or adductor canal block) is gaining popularity as a means to avoid quadriceps weakness from an FNB while providing similar pain control and minimizing opioid consumption.<sup>77</sup> Performing the block requires ultrasound guidance and a low local anesthetic volume placed distally within the adductor canal to avoid motor blockade to the vastus medialis.

The sciatic nerve provides sensation to the posterior compartment of the knee and, in combination with an FNB, can reduce opioid consumption after TKA.<sup>73,78</sup> Sciatic nerve blockade causes a “foot drop” that can increase postoperative fall risk and delay diagnosis of common peroneal nerve palsy, a

complication seen with large valgus corrections of the knee.<sup>79</sup> A selective tibial nerve block is an alternative that provides similar analgesia without the corresponding foot drop.<sup>80</sup> Sole obturator nerve block is insufficient for TKA analgesia<sup>81</sup>; however, it may be beneficial in combination with FNB.<sup>82</sup>

Periarticular injections (local infiltration technique) with cocktails of medications (see Surgery to the Hip and Pelvis, Anesthesia Technique) performed by the surgeon can reduce LOS and improve resting pain scores<sup>83</sup>; however, its use with an FNB results in lower pain scores with ambulation and during continuous passive movement. Liposomal bupivacaine can be added to periarticular injections as a means to prolong the effect of the local anesthetic. The benefit of liposomal bupivacaine over standard local anesthetics is not conclusive, however, and both the safety profile<sup>84</sup> and cost<sup>85</sup> should be taken into consideration.

### **Ambulatory Knee Surgery**

Ambulatory knee surgery has increased because health-care costs have encouraged outpatient management of less complex cases. An optimal anesthetic has a rapid onset and fast offset with minimal side effects so as to prevent prolonged postanesthesia care unit stays or unexpected overnight admissions. Neuraxial anesthesia results in a lower rate of nausea and vomiting than general anesthesia. However, in a practice with rapid turnover time and/or limited postanesthesia care unit capacity, the need to wait for block resolution may not be practical. In such settings, the use of general anesthesia with multimodal anti-nausea prophylaxis may be appropriate.

In performing a spinal anesthetic in an ambulatory setting, a short-to-intermediate-acting local anesthetic should be utilized. Intrathecal lidocaine causes a high rate of transient neurologic symptoms (TNSs) and is rarely used. The reported incidence of TNS with 1.5% mepivacaine is approximately 6%<sup>86</sup>; however, in our practice the observed rates are much lower. This may be due to concomitant use of the anti-inflammatory ketorolac and dexamethasone for nausea prophylaxis. TNS is rare with 2% chloroprocaine<sup>87</sup> and 0.5% bupivacaine; however, bupivacaine may not be appropriate for ambulatory cases owing to its longer duration. Short-acting narcotics (e.g., fentanyl) can be added to spinal blocks to increase anesthetic potency, but the resulting pruritus may not be tolerated. Evidence has not demonstrated a clinically significant difference in patient outcome with respect to anesthetic technique for ambulatory knee surgery.<sup>88</sup>

Anterior cruciate ligament (ACL) reconstruction is a common ambulatory procedure performed with a cadaveric allograft or an autograft from the patellar tendon or hamstring. In younger and more active patients the autograft is preferred, but patellar tendon and hamstring grafts cause

significant postoperative pain. An epidural or spinal block can provide intraoperative anesthesia, in combination with an FNB or catheters for analgesia. However, recent data suggest that FNB is not superior to multimodal analgesia<sup>89</sup> and may prolong discharge. Additionally, quadriceps weakness can be a complication of ACL reconstructions owing to muscle atrophy and activation failure, and FNB may cloud the clinical picture.<sup>90</sup> An adductor canal block can provide similar analgesia to an FNB after ACL surgery without causing quadriceps weakness.<sup>91</sup>

## ***Surgery to the Foot and Ankle***

Innervation of the foot and ankle is provided by the femoral nerve (via the saphenous nerve) and the sciatic nerve (via the posterior tibial, sural, and deep and superficial peroneal nerves). Anesthesia for foot surgery can be performed with an ankle block or a sciatic nerve block in the popliteal fossa with a saphenous nerve block as needed for coverage of the medial foot and ankle (see [Chapter 36](#)). Some surgeons prefer ankle blocks in order to avoid the foot drop caused by a sciatic nerve block. A neuraxial or general anesthetic may be required to minimize patient movement and allow for thigh tourniquet inflation.

Surgery to the foot and ankle can cause severe postoperative pain, and regional anesthesia provides optimal postoperative analgesia, particularly in the outpatient setting. Long-acting local anesthetics such as bupivacaine and ropivacaine can provide up to 24 hours of analgesia, and the addition of adjuvants like preservative-free dexamethasone can consistently extend analgesia beyond 24 hours.<sup>28,92</sup> Local anesthetic infusion through an indwelling catheter is also common for major foot and ankle surgery and allows for prolonged analgesia with minimal opioid-related side effects, including in the outpatient setting.<sup>93</sup> Peripheral nerve catheters may be challenging for noncompliant patients or those with limited access to follow-up care. In the outpatient setting, care must be taken to prevent accidental trauma to an anesthetized extremity, and patients should be instructed on how to best protect the limb upon discharge.

## **Pediatric Orthopedic Anesthesia**

Pediatric patients present with a variety of orthopedic conditions, including congenital deformities, trauma, infections, and malignancies (see [Chapter 43](#)). Orthopedic procedures may be performed under regional, general, or a combination of anesthetic techniques depending on patient age, operative site, positioning, and surgical duration.

The Pediatric Regional Anesthesia Network database has established the

safety of regional anesthetic blocks and catheters in children.<sup>94,95</sup> Upper and lower extremity blocks may be performed with similar safety profiles in children who are awake as in those who are receiving sedation or general anesthesia.<sup>96,97</sup> The anatomic differences between the pediatric and adult spine and spinal cord must be appreciated, and caudal blocks should be considered for lower extremity surgery in very young children (see [Chapter 35](#)).

## Special Considerations in Orthopedics

### *Amputation*

Following amputation, many patients experience phantom limb pain, phantom limb sensations, and/or stump pain that can be chronic, debilitating, and difficult to manage. The incidence of persistent phantom limb pain is approximately 40% with upper extremity amputation<sup>98</sup> and up to 85% after lower limb amputation.<sup>99</sup> Prolonged outpatient local anesthetic administration (median 30 days) via perineural catheter may prevent phantom limb pain, with 84% of patients in one study reporting no pain at 12 months following lower limb amputation.<sup>100</sup> In contrast, a study of short-term (3 days) perioperative epidural and perineural analgesia found phantom limb pain rates of 38% and 50%, respectively, at 12 months.<sup>101</sup>

### *Microvascular Surgery*

Microvascular surgery is often required for restoration of blood flow following orthopedic trauma. Microvascular surgery can take many hours to perform, often requiring general anesthesia to maintain patient comfort and prevent movement. Mechanical ventilation can help avoid vasoconstriction caused by hyperoxia and hypocarbia as well as by hypercarbia-induced catecholamine release. Moreover, optimal anesthetic management for microvascular surgery utilizes regional techniques that provide sympathectomy (maximizing vasodilation) and diminish the stress response (minimizing vasospasm and thrombotic risk).<sup>102–104</sup> Maintenance of normothermia is essential to minimize vasoconstriction,<sup>104</sup> and volume replacement is recommended at a rate of should read 3.5 to 6 mL/kg per hour.<sup>105</sup> Permissive hemodilution to a hematocrit of 30% can be considered for optimization of blood viscosity, and oxygen-carrying capacity. Surgeons generally discourage vasopressors except in emergency situations, so their use must be discussed with the surgical team prior to initiation. However, rather than supporting adverse effects of vasopressor use, evidence suggests they may be beneficial for maintenance of flap flow.<sup>105,106</sup> Postoperative local

anesthetic neuraxial and/or perineural infusions are recommended to help maintain adequate perfusion postoperatively.<sup>107-111</sup> Antithrombotics, including unfractionated and low-molecular-weight heparins, are often used to prevent graft thrombosis and must be taken into consideration when managing catheter insertion and removal postoperatively.

### **Acute Compartment Syndrome**

Acute compartment syndrome (ACS) occurs when soft tissue pressures in a closed extremity compartment exceed capillary perfusion pressure, resulting in ischemic tissue damage. This complication is most commonly seen following tibial and forearm fractures.<sup>112</sup> ACS is often first heralded by symptoms of pain out of proportion to injury; therefore, the benefits of regional analgesic techniques must be weighed against the risk of delayed diagnosis of compartment syndrome. The severity of ACS-related pain is reported to “break through” the analgesic effects of low-dose neuraxial or perineural local anesthetic infusions.<sup>113-116</sup> However, dense blocks have been reported to mask episodes of ACS.<sup>117,118</sup> Thus, the use of regional analgesic techniques requires careful clinical monitoring for ACS, and the decision for their use should be made in collaboration with the surgical team.<sup>112</sup>

### **Tourniquets**

Tourniquets are often used to minimize blood loss and provide a bloodless operating field for extremity orthopedic surgery. The cuff should be large enough to comfortably encircle the limb, and the width should be more than half the limb diameter. Damage to underlying vessels, nerves, and muscles can be caused by excessively high tourniquet pressures and/or prolonged inflation times. In general, a cuff pressure 100 mmHg above a patient’s measured systolic pressure is adequate for the thigh and 50 mmHg above systolic pressure is adequate for the arm. The duration of safe tourniquet inflation is generally considered to be 2 hours<sup>119,120</sup>; however, a perfusion break followed by repeat exsanguination may be considered if longer total tourniquet times are required. Breakthrough bleeding during tourniquet inflation is often due to intramedullary blood flow in long bones or small arterial vessels between the two bones of a distal extremity and cannot be resolved by tourniquet overinflation.

Tourniquet pain can become significant over time and can be mitigated with opioids and/or hypnotics or definitively managed by tourniquet deflation. Transient systemic metabolic acidosis, increased arterial carbon dioxide levels, and a drop in systemic blood pressure can be expected with tourniquet deflation and are generally well tolerated in healthy patients.

Special care should be taken at the time of tourniquet deflation in patients with significant comorbidities who may be susceptible to such changes.

## Fat Embolus Syndrome/Bone Cement Implantation Syndrome

Fat embolus syndrome (FES) is associated with multiple traumatic injuries, surgery involving long-bone fractures, and bilateral arthroplasty.<sup>121–123</sup> The incidence of FES in isolated long-bone fractures is 3% to 4%, and the associated mortality rate is significant, ranging from 10% to 20%.<sup>2</sup> Early corticosteroid use in long-bone fracture patients may be beneficial in preventing the syndrome.<sup>124</sup> Symptoms of FES usually occur 12 to 40 hours after the injury and can range from mild dyspnea to frank coma; however, fulminant episodes can occur within hours of traumatic injury. Decreased arterial oxygen tension is the most consistent abnormal laboratory value. Major and minor clinical and laboratory criteria for FES diagnosis are listed in [Table 51-5](#), as classified by Gurd and Schonfeld.<sup>125,126</sup> Management of FES is largely supportive and may require early mechanical ventilation.

**Table 51-5** Criteria for Fat Embolism Syndrome<sup>125,126</sup>

Gurd's Criteria	Major	Minor	Laboratory
Requires 1 major and 4 minor/ laboratory signs	Petechiae (axillary/subconjunctival)	Tachycardia	Microglobulinemia (required for diagnosis)
	Hypoxemia	Fever	Thrombocytopenia
	Depressed consciousness	Retina: fat emboli	Anemia
	Pulmonary edema	Sputum: fat globules	Elevated erythrocyte sedimentation rate
		Urine: fat globules	
Schonfeld fat embolism index	Criteria	Points	
Requires 5 or more points	Petechial rash	5	
	Diffuse alveolar infiltrates	4	
	Hypoxemia	3	
	Confusion	1	
	Fever	1	
	Tachycardia	1	
	Tachypnea	1	

 Bone cement implantation syndrome (BCIS) is a poorly defined syndrome of hypoxemia, hypotension, and/or altered mental status observed in patients undergoing fracture repair or arthroplasty with cementation. The syndrome is defined as occurrence of these events in temporal proximity to cementation, prosthesis insertion, joint reduction, or tourniquet deflation, with its severity defined by degree of hypoxemia and hypotension.<sup>127</sup> Although BCIS has historically been attributed to circulation of methyl methacrylate cement monomers, it has since been shown that monomer levels are too low to account for the severity of observed signs and

symptoms. It is likely that the syndrome overlaps extensively with FES and results from embolization of fat and other debris that is exacerbated by high-pressure intramedullary expansion of cement. Such embolization can trigger a cascade of endothelial damage, histamine release, and complement activation that contributes to the severity of FES and BCIS.<sup>127</sup> Invasive monitoring with an arterial line is recommended when cemented implants are being placed. Central venous pressure and possibly pulmonary artery catheter placement should be considered in medically fragile patients in whom cementation cannot be avoided.

## Venous Thromboembolism and Thromboprophylaxis

**13** Without prophylaxis, DVT develops in 40% to 80% of orthopedic patients. A range of 1% to 28% show clinical or laboratory evidence of PE, and fatal PE occurs in 0.1% to 8% of patients.<sup>95</sup> In the absence of prophylaxis, several studies report a lower incidence of DVT and PE in patients undergoing hip or knee surgery under epidural<sup>46,128–131</sup> and spinal<sup>132–134</sup> anesthesia. With appropriate mechanical and/or pharmacologic thromboprophylaxis, significant decreases in rates of DVT and PE have also been noted.

Given the significant risk of thromboembolism following orthopedic surgery, the American College of Chest Physicians (ACCP) has issued guidelines recommending a minimum of 14 days of pharmacologic thromboprophylaxis and/or use of portable mechanical compression devices.<sup>135</sup> However, given concerns regarding perioperative bleeding risks, the American Academy of Orthopedic Surgeons does not support the ACCP recommended target international normalized ratio of 2.0 to 3.0 for warfarin use, with most orthopedic surgeons preferring a target of 1.5 to 2.0.<sup>136,137</sup>

Following introduction of a multimodal prophylaxis protocol for THA (consisting of preoperative discontinuation of procoagulant medication, autologous blood donation, hypotensive epidural anesthesia, intravenous administration of heparin during surgery, aspiration of intramedullary contents, pneumatic compression, knee-high elastic stockings, and early mobilization and chemoprophylaxis), one study found rates of symptomatic DVT and PE to be 2.5% and 0.6%, respectively.<sup>138</sup> Similarly, two recent institutional reviews comprising over 36,000 orthopedic surgery patients found that 1.1% to 1.3% of patients developed symptomatic PE.<sup>139,140</sup> The mortality rate in the larger of the two studies was 0.02%, and risk factors for symptomatic PE included elevated body mass index, elevated Charlson comorbidity index, knee arthroplasty, chronic obstructive pulmonary disease, anemia, depression, and presence of DVT.<sup>140</sup>

The 2010 American Society of Regional Anesthesia practice advisory **14** for the use of regional anesthesia in the setting of antithrombotic or

thrombolytic therapy provides essential guidelines for minimizing the risk of clinically significant hematomas in at-risk patients.<sup>48</sup> A summary of recommendations for neuraxial blockade in the setting of anticoagulants and draft updates from the fourth American Society of Regional Anesthesia Practice Advisory for Regional Anesthesia in the Patient Receiving Antithrombotic or Thrombolytic Therapy is presented in [Table 51-3](#).<sup>141</sup> It is generally recommended that the same guidelines be followed when deep plexus blocks are performed or peripheral nerve blocks are being placed near poorly compressible vessels.

# 52 Transplant Anesthesia

MARIE CSETE • GERARD MANECKE • DALIA BANKS

## Anesthetic Management of Organ Donors

Brain-dead Donors (Donation after Neurologic Death)

Donation after Cardiac Death (Donation after Circulatory Determination of Death)

Living Kidney Donors

Living Liver Donors

## Immunosuppressive Agents

Calcineurin Inhibitors

Corticosteroids

Polyclonal and Monoclonal Antibodies

Mammalian Target of Rapamycin Inhibitors

Purine Antagonists

Cell Therapies

## Corneal Transplantation

## Renal Transplantation

Preoperative Considerations

Intraoperative Procedures

## Liver Transplantation

Preoperative Considerations

Intraoperative Procedures

Pediatric Liver Transplantation

Acute Liver Failure

## Pancreas and Islet Transplantation

## Small Bowel and Multivisceral Transplantation

## Composite Tissue Allografts

## Lung Transplantation

Recipient Selection

Intraoperative Management

Primary Graft Dysfunction

Inhaled Nitric Oxide

## Heart-lung Transplant (Adult and Pediatric)

## Heart Transplantation

Left Ventricular Assist Devices

Recipient Selection

## Management of the Transplant Patient for Nontransplant Surgery

### KEY POINTS

- 1 Brain death is declared when the clinical picture is consistent with irreversible cessation of all brain functions.
- 2 Anesthesiologists have a significant role to play in organ procurement and should consult with local organ procurement personnel for protocols to optimize healthy graft retrieval.
- 3 Extended criteria organs, including donation after cardiac death (DCD), are used because of ongoing organ shortage; cold ischemia times should be minimized for extended criteria donor organs.
- 4 Living kidney and liver donors must be healthy and without significant cardiopulmonary, neurologic, or psychiatric disease, diabetes, obesity, or hypertension.
- 5 Immune suppression is associated with severe infections, increased risk of malignancy, and progressive vascular disease.
- 6 Renal transplant recipients are often anemic, with hyperdynamic cardiac indices.
- 7 For renal transplantation, the major anesthetic consideration is maintenance of renal blood flow. Typical hemodynamic goals during transplant are systolic pressure above 90 mmHg, mean systemic pressure above 60 mmHg, and central venous pressure above 10 mmHg.
- 8 Patients with end-stage liver disease have multiorgan dysfunction with secondary cardiac, pulmonary, renal, and neurologic complications.
- 9 Liver transplantation is traditionally described in three phases: dissection, anhepatic phase, and neohepatic phase, with graft reperfusion marking the start of the neohepatic phase.
- 10 Intraoperative management of lung transplant patients should focus on fluid and ventilatory strategies designed to minimize acute lung injury and primary graft dysfunction.
- 11 Left ventricular assist devices are increasingly common in patients presenting for heart transplantation.
- 12 Nonischemic cardiomyopathy has replaced ischemic cardiomyopathy as the most common indication for heart transplantation.
- 13 For all transplant recipients, antibiotic, antiviral, antifungal, immunosuppressive, and disease-specific drug regimens should be disrupted minimally in the perioperative period.

Transplantation begins with the donor, and an anesthesiologist's exquisite attention to the details of organ donor management affects the life of multiple organ recipients. Most anesthesiologists will have little experience managing donors, and high-quality literature in this area is lacking, so that experienced personnel from local organ procurement organizations should be consulted. The United Network of Organ Sharing (UNOS; [www.unos.org](http://www.unos.org)) was created by the 1984 National Organ Transplant Act to manage the organ procurement and transplant network for efficient and equitable distribution of donated organs. The system for organ placement received a technology upgrade in 2006 with the launch of DonorNet, an electronic resource for matching and distribution of organs around the United States. Speed of placement is important because brain-dead donors are unstable, and it is particularly important to transplant extended criteria donor (ECD) grafts with minimal cold ischemia times. In general, maximum cold ischemia times are ideally less than 6 hours for heart or lung grafts, 12 to 24 hours for livers, and up to 72 hours for kidneys. The UNOS website data contain center- and region-specific transplant databases, regularly updated. The Scientific Registry of Transplant Recipients ([www.ustransplant.org](http://www.ustransplant.org)) is also a source of transplant data for clinicians, patients, and researchers.

About 122,000 patients were on solid-organ transplant waiting lists in the United States as of March 2016. Transplantation starts with the donor, and donation has not kept pace with demand, as seen by transplant numbers in 2015. A total of 30,973 transplants in the United States from 15,064 donors were reported in 2015. The ongoing gap between need for and availability of donor organs continues to push practice changes to increase the donor pool and more equitably distribute organs, including use of grafts from "donation after cardiac death" (DCD) donors as well as paired kidney donations (kidney swaps), and new modifications to the Model for End-Stage Liver Disease (MELD) scoring.

## Anesthetic Management of Organ Donors

### *Brain-dead Donors (Donation after Neurologic Death)*

Brain-dead, heart-beating donors deserve expert intensive care unit (ICU) and anesthetic management because they contribute life to many transplant recipients.<sup>1</sup> Particular attention should be paid to communication because anesthesiologists may be interacting with unfamiliar personnel from organ procurement organizations and surgical procurement teams.

**1** Brain death is declared when the clinical picture is consistent with irreversible cessation of all brain functions.<sup>2</sup> Legal and medical brain death criteria differ from state to state, but all require cessation of both cerebral

and brainstem functions. Brain-dead donors are unresponsive to sensory stimuli and have no brainstem reflexes, including ventilatory drive with apnea testing, but may have complex motor activity. Physicians involved in the transplant recipient process should not be involved in declaration of brain death of a donor. Potentially reversible causes of coma must be ruled out (hypothermia, hypotension, drugs, toxins) before declaration of brain death. A flat electroencephalogram is consistent with brain death. Transcranial Doppler and traditional or isotope angiography are used to confirm the clinical examination and lack of circulation to the brain.<sup>3</sup> Brain-dead patients may have intact spinal reflexes, so they may require neuromuscular blockade during organ procurement. Hospitals should incorporate the most recent recommendations of the Quality Standards Subcommittee of the American Academy of Neurology for brain death assessment.<sup>1</sup>

Brain death is associated with hemodynamic instability, wide swings in hormone levels, systemic inflammation, and oxidant stress, all of which negatively impact donor organ function.<sup>4</sup> Just after brain death, adrenergic surges can cause ischemia and ischemia–reperfusion injuries. Studies of head trauma patients suggest that the onset of brain death is associated with a transient period of hypotension with increased cardiac index and tissue perfusion. During this period, vasoactive drugs administered to increase blood pressure can cause rapid circulatory deterioration.<sup>5</sup> This period precedes the autonomic storm associated with herniation of the brain and emphasizes the wide dynamic swings in blood chemistries and hemodynamics after brain death. Of note, bradycardia after brain herniation is often unresponsive to atropine. The timing of therapies to support hemodynamics is difficult because catecholamine storm is often followed quickly by pituitary failure. Once pituitary failure ensues, hormone therapy may help stabilize donors hemodynamically and thereby extend the donor pool.<sup>6</sup> Hormone therapy regimens include triiodothyronine (4- $\mu$ g intravenous [IV] bolus, then 3  $\mu$ g/hr, though its use is not well supported by meta-analyses) and desmopressin, 1 unit, then 0.5 to 4 units/hr to maintain systemic vascular resistance (SVR) at 800 to 1,200 dyne/s/cm<sup>5</sup> (and reduce the polyuria of diabetes insipidus). Low-dose vasopressin is also commonly used to treat diabetes insipidus. Methylprednisolone is often used, though variably applied, despite insufficient study on its benefits, but a prospective trial of hydrocortisone in 259 brain-dead subjects showed that its use was associated with significantly less vasopressor need.<sup>7</sup>

High doses of catecholamines should be avoided. Evidence suggests that use of vasopressin (1 to 2 units/hr) reduces pressor requirement,<sup>8</sup> protects lung function,<sup>9</sup> and increases the rate of successful organ procurement.<sup>10</sup> Terlipressin also can reduce norepinephrine requirements in brain-dead

donors.<sup>11</sup> Because there is little deep research on hormone replacement therapy, clinical practice varies widely. Insulin infusion to maintain blood glucose at 120 to 180 mg/dL is also recommended, and recent studies support glucose control for maintaining donor kidney graft quality.<sup>12</sup> Other medications that should be available for the donor operation are broad-spectrum antibiotics, mannitol and loop diuretics, and heparin (Table 52-1). Coagulopathies may require correction for active bleeding before and during organ recovery, but thromboprophylaxis is important because of the high incidence of pulmonary emboli found with organ retrieval.<sup>13</sup>

**Table 52-1** Anesthesiology Setup for Organ Procurement

<ul style="list-style-type: none"> <li>• <b>Equipment and supplies</b></li> <li>Ventilator as in intensive care unit</li> <li>Bronchoscope</li> <li>Warming blankets</li> <li>Blood warmers</li> <li>Ice</li> <li>• <b>Recheck items</b></li> <li>Declaration of death</li> <li>Cause of death</li> <li>Consent</li> <li>Blood type</li> <li>• <b>Fluids</b></li> <li>Lactated Ringer's</li> <li>Albumin</li> <li>• <b>Medications</b></li> <li>Pressors (vasopressin, norepinephrine, dobutamine, phenylephrine, ephedrine, dopamine)</li> <li>Antibiotics</li> <li>Neuromuscular blocker</li> <li>Heparin</li> <li>Corticosteroids (per procurement team)</li> <li>Povidone-iodine (per nasogastric tube if pancreas procured)</li> <li>N-acetylcysteine (per organ procurement organization)</li> <li>Insulin</li> <li>Mannitol, furosemide</li> <li>Prostaglandin E<sub>1</sub></li> </ul>
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Lung-protective ventilatory strategies, with tidal volumes of 6 to 8 mL/kg and positive end-expiratory pressure (PEEP) adjusted to allow minimal fraction of inspired oxygen (FiO<sub>2</sub>), are important in lung donors.<sup>14</sup> Pre-, post- and remote ischemic preconditioning in brain-dead and living donors has not been translated to clinical practice despite interesting preclinical studies.<sup>15</sup> In early trials ex vivo perfusion of beating donor hearts yielded similar results to traditional preservation methods.<sup>16</sup>

Donor heart history is very important in identifying heart donors, and electrocardiography and echocardiography are mandatory. The ideal heart donor is less than 50 years old and hemodynamically stable. Presence of major chest trauma, cardiac disease, active infection, prolonged cardiac

arrest, malignancy, human immunodeficiency virus (HIV) or hepatitis, or intracardiac injections moves the donor from ideal to marginal status. Overall health status of the donor prior to determination of brain death can facilitate a directed laboratory evaluation, which may include cardiac catheterization. For recipients with pulmonary hypertension, younger donors, short ischemic time, low donor inotrope requirement, and oversized organs are preferred. Human leukocyte antigen typing and ABO blood group compatibility are determined. The donor heart size should be within 20% to 30% of the recipient's heart size.

Anesthetic management during organ procurement is guided by the needs of the procurement teams, who may come from several centers and have discrepant requests, depending on the organs procured. UNOS has created a resource for managing organ donors in an effort to improve donor care and, therefore, the function of donated organs.<sup>1</sup> Transport of ventilated donors to the operating room (OR) often requires PEEP valves; if more complex ventilator settings are used in the ICU, they should be continued during transport and in the OR.

**2** The mainstay of donor management is maintenance of euvoledmia and perfusion; therefore, central venous pressure (CVP) monitoring is standard. CVP is maintained at 6 to 12 mmHg, and when pulmonary artery (PA) catheters are used to assess cardiac function, pulmonary capillary wedge pressure is maintained at lower than 12 mmHg. Surgeons procuring the lungs will want to keep the CVP low, and diuretics may be requested just prior to collection of the lungs. Surgeons procuring kidneys usually want high filling pressures. Efforts should be made to maintain serum sodium levels below 155 mmol/L; higher levels are associated with poor liver graft function.<sup>17</sup>

Donor oxygenation, perfusion, and normothermia are all important anesthetic goals, and the precise end points of therapy require coordination and communication with the various surgical teams. Generally, arterial PCO<sub>2</sub> is maintained at 30 to 35 mmHg.

Prior to lung removal, surgeons will perform bronchoscopy. Glucocorticoids may be requested, and prostaglandin E<sub>1</sub> may be requested to improve circulation of the lung preservation solution.

Donor lungs are more susceptible to injury in brain-dead patients before procurement than are other organs, likely from contusion, aspiration, or edema with fluid resuscitation. Consequently, many multiorgan donors do not meet the idealized strict criteria for lung donors (Table 52-2). Extended criteria are used for donor lungs because of ongoing shortages. For example, a review of UNOS data showed that lung donors less than 64 years old show no major differences from those less than 55 years old.<sup>19</sup> Another example of working outside the strict criteria is acceptance of some lungs from donors with a smoking history. Sputum Gram stains and cultures are routinely

obtained on all lung donors. Antibiotics for a donor with a positive Gram stain can lower the risk of posttransplant infection; however, organisms on bronchoalveolar lavage are associated with decreased survival.<sup>20</sup> One study suggested that evidence of aspiration seen on bronchoscopy, bilateral pulmonary infiltrates, or persistent purulent secretions are criteria for donor exclusion.<sup>21</sup> Ischemic times should still be less than 7 hours.<sup>22</sup> In addition to the usual immunologic criteria, donor–recipient compatibility is based on height and/or total lung capacity. DCD donors are still useful for lung transplantation, and ex vivo lung perfusion is emerging as a way to extend the lung donor pool.<sup>23</sup>

**Table 52-2** Ideal Deceased Lung Donor Characteristics

- Age <55 years
- ABO compatibility
- Clear chest radiograph
- Smoking history NONE; Tobacco history <20 pack years
- Ventilation <5 days
- PaO<sub>2</sub> >300 on FiO<sub>2</sub> 1, positive end-expiratory pressure 5 cm H<sub>2</sub>O
- Absence of chest trauma
- No evidence of aspiration or sepsis
- Negative sputum Gram stain
- Clear bronchoscopy

For heart retrieval, the surgeons perform a pericardiotomy, and the aortic root is cannulated for infusion of cardioplegia solutions. Following ligation of the great veins, the heart is compressed and exsanguinated, cardioplegia is given to induce cardiac arrest, and the aorta is cross clamped. After cardiectomy the donor heart is preserved in cold ice slush. For donors who provide both lungs and the heart to a single recipient, a combined cardiopulmonary surgical extraction is performed. Surgical techniques have been developed to allow three recipients from one thoracic donor: two single-lung transplants and a heart transplant.<sup>18</sup> The heart is removed first, leaving a small cuff of left atrium attached to the lungs. The harvesting team will ask for systemic heparinization just prior to exsanguination and excision. Cardioplegia is administered, the heart stops ejecting, and the heart is removed. The trachea is transected and the lungs are removed *en bloc* for later separation.

A shortage of available donors has led to increased use of marginal (extended criteria) donors and separate alternate transplant lists of recipients who consent to accept ECDs. Increased risk of primary graft dysfunction (PGD) is the main reason to avoid marginal donors. Marginal donors are typically used for patients who do not meet the standard recipient criteria, with advanced age a common reason for alternative listing. Common donor

factors that lead to marginal status are abnormal hepatitis screening tests, left ventricular (LV) dysfunction or coronary artery disease, advanced age, and DCD.

### *Donation after Cardiac Death (Donation after Circulatory Determination of Death)*

In 2007 US hospitals were mandated by The Joint Commission, in collaboration with organ procurement organizations, to develop DCD policies and protocols in response to organ donor shortages. DCD protocols have not been adopted uniformly. DCD donors accounted for 16.3% of donors in the United States in 2015 (per the Association of Organ Procurement Organizations). So DCD donors represent a fairly large portion of donors, but the number of organs used from DCD donors is less than from donation after brain death (DBD) donors, pointing to the need to optimize DCD protocols further. Pediatric DCD donors also provide quality organs for transplantation, and the American Academy of Pediatrics has endorsed their use.<sup>24</sup> Experience with DCD grafts suggests that DCD kidneys have an increased risk of delayed graft function, increasing costs, but long-term function is not reduced in DCD versus DBD grafts; DCD livers generally have worse survival than DBD livers.<sup>1</sup>

The protocols of planning for and managing DCD donors differ from center to center. Because any one center is unlikely to have considerable experience with these donors, an excellent quick reference was developed by UNOS, available at [https://www.unos.org/wp-content/uploads/unos/Critical\\_Pathway\\_DCD\\_Donor.pdf](https://www.unos.org/wp-content/uploads/unos/Critical_Pathway_DCD_Donor.pdf). DCD donors typically have severe brain damage considered not recoverable but may have brain electrical activity. Death is defined by cessation of circulation (arterial monitoring showing pulse pressure is zero, or Doppler monitoring showing no flow) and respiration after withdrawal of futile treatment measures. Timing of withdrawal of support is to maximize the function of organs from these donors. Optimally, end-of-life care is provided by the same medical team responsible for the care of the patient in the ICU. Informed consent is required for organ donation and for any preorgan recovery procedures, such as drug administration or vascular cannulation.

Suitable DCD donors are those in whom death is anticipated within 1 to 2 hours of withdrawal of life support. A plan for the donor's care should be in place if the patient does not die within the anticipated time frame, and ideally care should be transferred back to the team that knows the patient and family. Predicting death within an hour of withdrawal of support is not an exact science, so evaluation tools to help predict which patients will die within this time frame are useful (Table 52-3). For death to be declared,

circulation and respiration must be absent for a minimum of 2 minutes before the start of organ recovery. A scoring system for predicting death of pediatric DCD donors has also been developed and validated.<sup>25</sup>

Organ recovery started more than 5 minutes after respiratory and circulatory arrest may compromise donor organ quality, but this limit has been extended with reasonable transplant outcomes. The major goal of surgical management during procurement is to limit warm ischemia time (with rapid cooling techniques and minimal in situ dissection).<sup>26</sup>

No major differences in *intraoperative* events during the transplant procedure between DCD and DBD kidney grafts have been reported. A recent report suggests that withdrawal of support in the OR (after heparin administration) may lead to better function of the donor liver than withdrawal of support in the ICU.<sup>27</sup>

**Table 52-3** UNOS Consensus Committee Criteria for Prediction of DCD Death within 60 Minutes of Withdrawal of Life-sustaining Treatment

- Apnea
- Respiratory rate <8 or >30 breaths/min
- Dopamine  $\geq 15 \mu\text{g/kg/min}$
- Left or right ventricular assist device
- Venoarterial or venovenous extracorporeal membrane oxygenation
- Positive end-expiratory pressure  $\geq 10$  and  $\text{SaO}_2 \leq 92\%$
- $\text{FiO}_2 \geq 0.5$  and  $\text{SaO}_2 \leq 92\%$
- Norepinephrine or phenylephrine  $\geq 0.2 \mu\text{g/kg/min}$
- Pacemaker-unassisted heart rate <30
- IABP 1:1 or dobutamine or dopamine  $\geq 10 \mu\text{g/kg/min}$  and  $\text{CI} \leq 2.2 \text{ L/min/m}^2$
- IABP 1:1 and  $\text{CI} \leq 1.5 \text{ L/min/m}^2$

UNOS, United Network of Organ Sharing; DCD, donation after cardiac death;  $\text{SaO}_2$ , arterial oxygen saturation; IABP, intra-aortic balloon pump; CI, cardiac index.

## Living Kidney Donors

Safety and comfort are the primary considerations in the care of living donors. Living donors must be healthy and without significant **4** cardiopulmonary, neurologic, or psychiatric disease; diabetes; obesity; or hypertension. Renal function must be normal, with no history of renal stones or proteinuria. The vast majority of living kidney grafts are retrieved laparoscopically with only a small number of these robotically assisted.<sup>28</sup> A recent national study suggests that robotically assisted surgeries are still associated with increased complications over hand-assisted laparoscopic kidney retrieval.<sup>28</sup> An estimated 2.4% of kidney donors experience anesthetic/surgical complications of donation,<sup>28</sup> pointing to the need for enhanced recovery protocols including preoperative carbohydrate loading, an

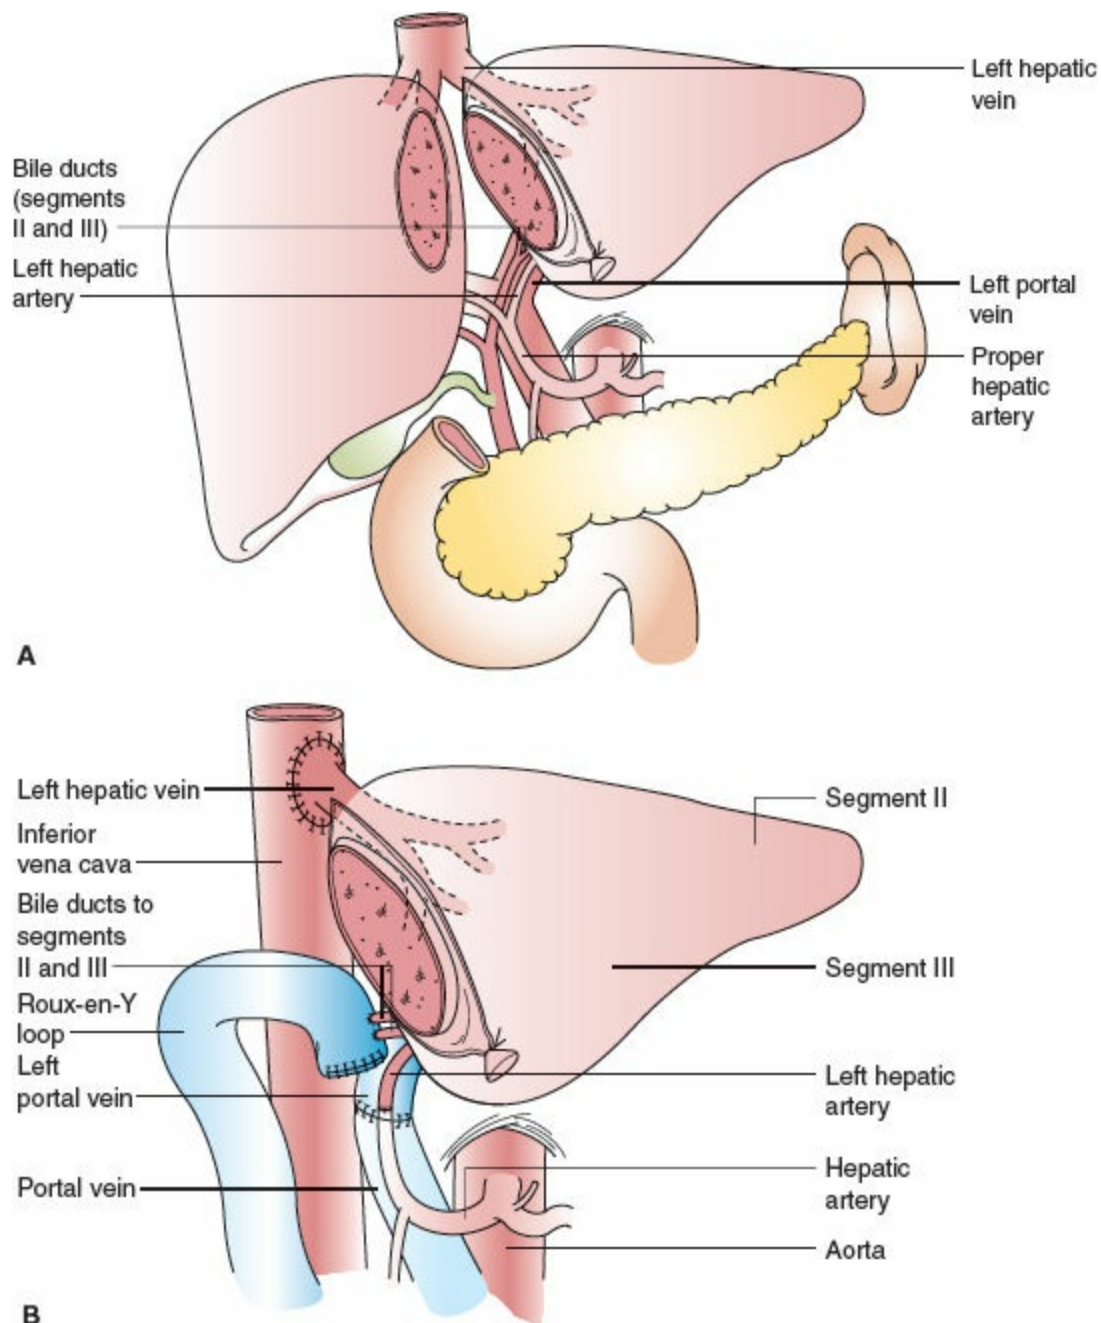

opioid-free anesthetic, and transversus abdominis blocks.<sup>29</sup> Both anesthetics and insufflation of the peritoneum with carbon dioxide (CO<sub>2</sub>), which are necessary for the laparoscopic procedure, decrease renal blood flow, so that a variety of fluid regimens have been suggested to blunt prerenal damage to the kidneys. Fluid loading overnight before surgery (versus fluid administration starting with surgery) is associated with better creatinine clearance acutely during the procedure,<sup>30</sup> and some suggest a colloid bolus just before pneumoperitoneum.<sup>31</sup> When a CVP end point is used for fluid goals, the CVP may not accurately reflect volume status with the patient in lateral decubitus position and with pneumoperitoneum.<sup>32</sup> Nitrous oxide is contraindicated for laparoscopic donor nephrectomy because distended bowel can get in the way of the surgeons.<sup>33</sup> For patient comfort, central venous lines (if used) are generally placed after induction of anesthesia.

Donor nephrectomy should be an uncomplicated procedure, and donor tracheas can be extubated in the OR. Deep venous thrombosis prophylaxis is warranted. For open nephrectomy, the patient is positioned in the lateral decubitus position with the bed flexed to expose and arch the flank. Donors are generally managed with general anesthesia, but epidural and combined epidural–spinal techniques (supplemented with intravenous propofol)<sup>34</sup> as well as general–epidural combined techniques are used. Postoperative pain following donor nephrectomy can be severe, and patient-controlled analgesia is often used. The pain can still be severe enough to limit respiratory effort and mobilization of the patient, however. Furthermore, a survey of 123 donors showed that one-third of them had chronic pain after the open procedure,<sup>35</sup> suggesting postoperative pain management is often not optimal. Early complications include pulmonary (atelectasis, pneumothorax, pneumonia), urinary tract infections, and wound problems; long-term complications include reduced renal function, hypertension, albuminuria, and psychiatric issues (anxiety, depression).<sup>36</sup> Some centers admit donors to a step-down or medical ICU for a day after surgery, but the total hospital stay is usually only 2 to 4 days. Bladder catheters are removed on postoperative day 1. Patients should be advised that full recovery (i.e., feeling normal) takes 4 to 6 weeks, especially after the open procedure. Fortunately, perioperative mortality is rare but cannot be denied as a possible outcome during preoperative patient discussions.

### *Living Liver Donors*

 Living liver donors have traditionally been employed in a stepwise manner to limit the chances of coercion, but increasingly living donors are being used for recipients with acute liver failure (ALF).<sup>37</sup> Left lobe liver donation (segments II and III) is usually done in the context of parent-to-child

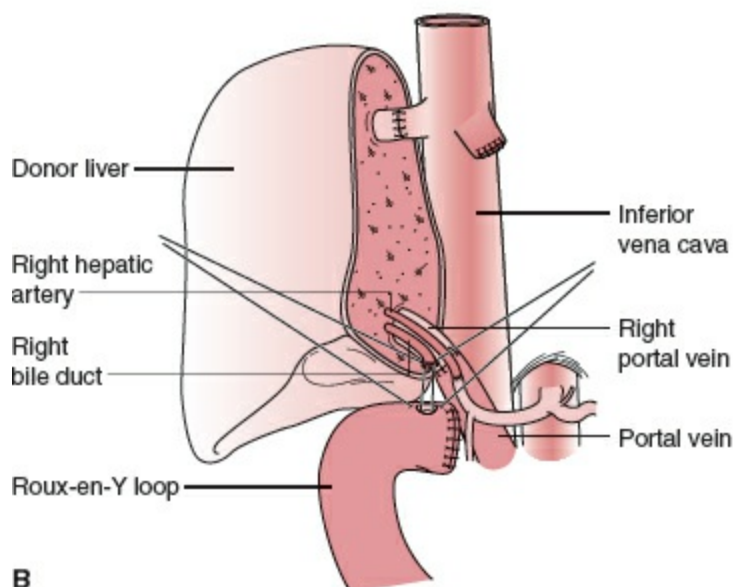

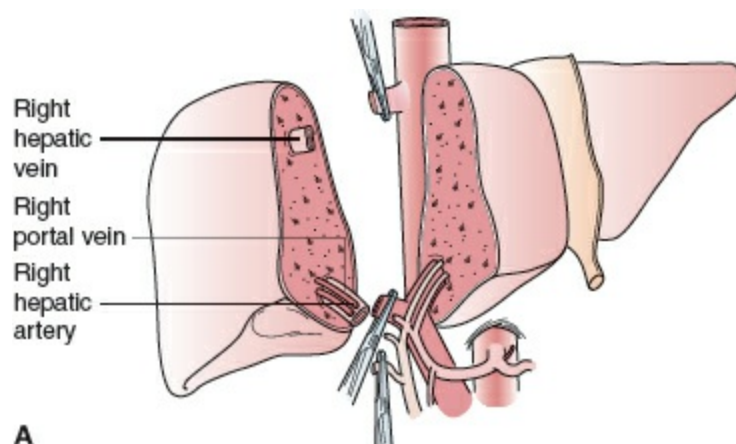

donation with recipients smaller than 15 kg. Although left lateral segmentectomy is a big operation, it is generally well tolerated (Fig. 52-1). Nonetheless, living left lobe donors must be healthy and without a history of or risk for thromboembolic disease. By comparison, donor right hepatectomy needed for adult-to-adult liver transplantation is a major procedure (Fig. 52-2) and carries significant risk. The residual liver volume of the donor must be greater than 35% of original volume to prevent “small for size” syndrome in the donor. Because risk for this syndrome is increased in older donors or in patients with cholestatic or hepatocellular disease, including steatosis,<sup>38</sup> adult-to-adult living donors should have no liver disease. Early death among live liver donors in the United States is estimated to be 1.7 per 1,000 donors<sup>39</sup> but is obviously devastating for both donor and recipient families. Serious complication rates are high for right liver donors (up to a third of donors depending on the center), including air embolism, atelectasis, pneumonia, respiratory depression, and biliary tract damage.<sup>40–42</sup> Nonetheless, experienced centers that report complication rates of 10% are developing enhanced recovery protocols for right liver donors.<sup>43</sup> Most centers do not perform living adult-to-adult liver transplants in very ill recipients.

**Figure 52-1** Left lateral segment (segments II and III) living donor transplantation. **A:** Donor operation. **B:** Recipient operation complete.

Large liver resections may require virtually complete hepatic venous exclusion (cross-clamping of the hepatic pedicle usually without cava clamping). Not unexpectedly, venous return falls significantly. Without the collaterals developed by patients with chronic liver disease, normal donors may experience significant hypotension when the hepatic pedicle is cross clamped. Blood pressure is maintained largely through reflex increases in endogenous vasopressin and norepinephrine levels.<sup>44</sup> For these reasons, volume loading is reasonable prior to clamping, but some centers try to reduce blood loss by maintaining low CVP, whereas CVP monitoring is not routine in other centers. Sufficiently powered studies to prove that the benefits of low CVP (reduced transfusion requirements) outweigh the risks

(renal compromise, air embolism) are unlikely to be performed, and institutional practices vary widely. If vasopressors are needed, vasopressin and norepinephrine are reasonable choices to enhance normal endogenous reflexes. Isovolemic hemodilution has been reported to reduce allogeneic red cell requirements in major hepatic resections.<sup>45</sup> At experienced centers, blood loss is usually less than 1 L, and transfusion requirements are usually not high. Blood salvage is useful, and some centers offer autologous donation programs for donors. Both can reduce the need for allogeneic blood transfusions. Transesophageal echocardiography (TEE), if expertise is available, is ideal and may obviate central line placement. Most donor tracheas can be extubated safely in the OR. Hypothermia is a preventable reason for not extubating in the OR. A wide variety of general anesthetics are used for liver donors, and epidural analgesia is useful for pain management,<sup>46</sup> though patient-controlled analgesia is preferred in some centers because of the potential for perioperative coagulopathy. Abdominal wall catheters placed by the surgeons may be useful for postoperative pain management.<sup>47</sup> Laparoscopic liver resection of left lobe (segments II and III) and right lobe is available in some centers, though concern has been raised about standardization for right lobe laparoscopic resections.<sup>48</sup>

**Figure 52-2** Right lobe (segments V to VIII) living donor transplantation. **A:** Donor operation. **B:** Recipient operation completed.

Hypophosphatemia (with excessive loss of phosphate in the urine) is common after hepatectomy<sup>49</sup> and should be treated with sodium phosphate infusions to maintain phosphate levels of 3.5 to 5.4 mg/dL, unless patients have significant renal compromise (creatinine clearance <50 mL/hr). Liver function tests including international normalized ratio (INR) are also abnormal in the postoperative period after liver resection and usually return to baseline levels within 3 months, although small changes in liver function tests can persist for up to a year after hepatectomy. Some living liver donors can experience chronic low platelet counts after hepatectomy.<sup>50</sup>

## Immunosuppressive Agents

Pharmacologic suppression of the immune response to allografts is associated with major side effects. Considerable variability in intestinal absorption, genetic and induced differences in metabolism of these drugs, changing dosage requirements with aging, and idiosyncratic complications all mandate individualization of immunosuppressive regimens. Immunosuppressed patients who are undertreated risk rejection; overimmunosuppression can be toxic, especially to the kidneys. All immunosuppression regimens carry **5** major risks, such as infection, malignancy, and progressive vascular disease. Immunosuppression regimens differ considerably from center to center, and anesthesiologists must communicate with the transplant team to obtain the schedule and dose of immunosuppressive agents for each patient, especially because immunosuppression drug options have expanded.<sup>51</sup> It is particularly important to review drug regimens with transplant coordinators when posttransplant patients are scheduled for surgery because the transplant team needs information about peak and trough drug levels that may not be accessible on the hospital record.

Immunosuppressed patients coming to the OR deserve special attention to sterile technique and maintenance of antibiotic, antifungal, and antiviral regimens during the perioperative period. Complications of chronic immunosuppression are summarized in [Table 52-4](#).

**Table 52-4** Complications of Chronic Immune Suppression

<b>Central Nervous System</b>
Lowered seizure threshold
<b>Cardiovascular</b>
Diabetes
Hypertension
Hyperlipidemia
Atherosclerosis
<b>Renal/Electrolyte</b>
Decreased glomerular filtration rate
Hyperkalemia
Hypomagnesemia
<b>Hematologic/Immune</b>
Increased risk of infections
Increased risk of malignancy
Pancytopenia
<b>Endocrine/Other</b>
Osteoporosis
Poor wound healing

### Calcineurin Inhibitors

The modern transplant era began with the introduction of the calcineurin inhibitor (CNI) cyclosporine into clinical practice. CNIs are still a mainstay of immunosuppression for solid-organ transplant recipients; tacrolimus is widely used. Inhibition of calcineurin, among other effects, modifies nuclear factor of activated T cells and frees nuclear factor- $\kappa$ B to translocate to the nucleus, where it enhances transcription of T-cell interleukin-2 (IL-2). Via these signal transduction pathways, CNI inhibits T-lymphocyte activation, differentiation, and cytokine production.<sup>52</sup>

Calcineurin is involved in diverse cellular processes, so its inhibition can cause many significant side effects. These include hypertension (often requiring therapy), hyperlipidemia, ischemic vascular disease (including in heart recipients), diabetes, and nephrotoxicity. Cyclosporine causes acute nephropathy, which is usually reversible with drug cessation. But chronic renal damage from cyclosporine is a more refractory problem. A variety of other drugs are used with CNI to reduce the amount of CNI required. Certain drugs, however, may cause renal dysfunction when coadministered with CNI, including amphotericin, cotrimoxazole, cimetidine, vancomycin, ranitidine, tobramycin, melphalan, gentamicin, and nonsteroidal anti-inflammatory drugs.<sup>53</sup>

Ischemic cardiac disease is the leading cause of death of kidney transplant recipients, in part because of underlying disease that preceded transplantation. But CNI can exacerbate risk factors for coronary artery disease. It is important to note that end-stage liver disease (ESLD) does not

confer protection from coronary artery disease, and liver transplant patients are also at risk for progression of ischemic cardiac disease after transplantation. Neurologic side effects also complicate CNI therapy, including tacrolimus-induced polyneuropathy<sup>54</sup> and encephalopathy.<sup>55</sup> When immunosuppression is interrupted by surgery or when multiple potentially interacting drugs are used, tacrolimus trough levels should be reassessed.

Tacrolimus is metabolized by cytochrome P450 3A4 and causes its upregulation. Cyclosporine may rarely prolong the action of pancuronium.<sup>56,57</sup> To switch from oral to intravenous dosing of cyclosporine, usually about one-third the oral dose is used. Usual dosage of tacrolimus is 0.15 to 0.3 mg/kg/day given in two doses. To switch from oral to intravenous tacrolimus, a starting dose of about one-tenth the oral dose can be used. Statin–cyclosporine interactions deserve vigilance because rhabdomyolysis has been reported in a few patients taking simvastatin and cyclosporine.<sup>58</sup>

### **Corticosteroids**

Corticosteroids disrupt expression of many cytokines in T cells, antigen-presenting cells, and macrophages. These drugs are used both for maintenance immunosuppression and in pulse dosing for acute rejection. Especially for growing children, corticosteroid-sparing regimens are increasingly popular. The well-known side effects are hypertension, diabetes, hyperlipidemia, weight gain (including cushingoid features), and gastrointestinal ulceration (see [Chapter 47](#)). Communication with the transplant service is important in determining timing and dose of steroid administration perioperatively in patients who are taking the drug chronically. Corticosteroids may be withheld during liver transplantation in recipients with hepatitis C because of concern that the drugs contribute to hepatitis C recurrence.<sup>59</sup>

### **Polyclonal and Monoclonal Antibodies**

Antithymocyte globulin (ATG), reviewed in Ippoliti et al.,<sup>60</sup> is purified rabbit immunoglobulin G taken from animals immunized with human thymocytes, so that previous exposure to rabbits is a risk factor for serum sickness with ATG exposure. Polyclonal immunoglobulin G antibodies can also be raised in horses. They suppress the immune system by depleting immune cells, mostly T cells, and interact with a wide variety of cell surface molecules involved in adhesion and cell trafficking and ischemia–reperfusion injury. ATG has a long history of use in treating acute rejection and induction of immunosuppression, particularly in sensitized transplant recipients and in steroid- and calcineurin-sparing regimens. Anesthesiologists should be aware that acute and severe

serum sickness is a rare side effect of ATG administration,<sup>61</sup> presenting as jaw pain, and is treated by stopping the drug, plasmapheresis, and corticosteroids.<sup>62</sup>

OKT3 monoclonal antibody is also directed against a component of the T-cell receptor complex and affects immunosuppression by blocking T-cell function. Acute administration of OKT3 in awake patients (especially first administration) may result in generalized weakness, fever, chills, and some hypotension. More severe hypotension, bronchospasm, and pulmonary edema have been reported. Formulations of OKT3 may require syringe filtering before administration. “Humanized” antibodies are antibodies engineered to contain human constant regions in the immunoglobulin protein, so that patients do not develop an antimouse immunologic response. Muromonab-CD3 is a humanized form of OKT3, usually used for acute rejection.<sup>63</sup>

IL-2 receptor (CD25) antagonists, such as basiliximab and daclizumab, are humanized antibodies directed against a portion of the IL-2 receptor expressed on activated T cells. About half of the heart transplant centers now use IL-2 receptor antagonists in their initial immunosuppression regimen to reduce the dose and cardiovascular side effects of CNIs. Gastrointestinal upset is the most commonly cited side effect of these drugs. However, basiliximab has been implicated in causing pulmonary edema in young renal transplant patients.<sup>64</sup> Generally these newer antibodies are associated with fewer side effects than other antibody therapies.<sup>65</sup>

Belatacept is directed against the CD80/CD86 ligands on antigen-presenting cells that activate T cells through the CD28 (costimulatory) pathway. It is approved for maintenance immunosuppression for kidney transplant recipients and is associated with fewer cardiovascular complications than CNI drugs.<sup>64</sup> Infusion reactions can include hypotension, but acute reactions are usually mild. New targets for immunosuppressive drugs include complement and B cells as well as drugs directed at molecules that exacerbate ischemia–reperfusion.<sup>66</sup> Coagulopathy has been reported as a side effect of alemtuzumab (Campath),<sup>67</sup> which recognizes CD52 on B cells. Rituximab is another anti-B-cell antibody that acts at CD20 and is used for humoral rejection.

### ***Mammalian Target of Rapamycin Inhibitors***

Mammalian target of rapamycin inhibitors are often used in combination with CNI to decrease the complications of dose-related side effects (calcineurin-sparing regimens) such as nephrotoxicity. Target of rapamycin is involved in complex signaling processes that promote synthesis of proteins, including several that regulate cellular proliferation. Thus, mammalian target of rapamycin inhibitors such as sirolimus (Rapamycin) are antiproliferative, used

both in immunosuppression and increasingly in cancer therapies. Similar to cyclosporine and tacrolimus, sirolimus is metabolized in liver via P450 CYP3A isoenzymes, but coadministration of sirolimus and a CNI does not increase CNI drug requirements. In fact, the combination may be synergistic.<sup>68</sup> Diltiazem raises the plasma concentration of sirolimus.<sup>69</sup>

## **Purine Antagonists**

Purine antagonists include mycophenolate mofetil and azathioprine. Azathioprine is hydrolyzed in blood to 6-mercaptopurine, a purine analogue and metabolite with the ability to incorporate into DNA during the S phase of the cell cycle. Because DNA synthesis is a necessary prerequisite to mitosis, azathioprine exerts an antiproliferative effect. Antiproliferative drugs rely on the fact that immune activation implies explosive proliferation of lymphocytes. Side effects occur because other proliferating cells (gastrointestinal tract, bone marrow) are also affected. Repression of bone marrow cell cycling can cause pancytopenia. Cardiac arrest and severe upper airway edema are rare complications.<sup>70</sup> The intravenous dose is about half the oral dose.

Mycophenolate mofetil is metabolized into a molecule that inhibits purine synthesis. It too can cause leukopenia and thrombocytopenia as side effects, as well as red cell aplasia<sup>71</sup>; it is considered teratogenic.<sup>72</sup> The usual oral dose is 1 to 1.5 g twice a day.

## **Cell Therapies**

Tolerance of organ grafts without pharmacologic immunosuppression, the Holy Grail of transplantation, is possible using combined bone marrow and solid-organ transplants with marrow and the solid organ derived from the same donor.<sup>73</sup>

Mesenchymal stem cells (MSCs) are anti-inflammatory stem cells, currently in multiple clinical trials as adjuncts to transplant immunosuppression. MSCs are multipotent cells easily derived from marrow or fat (and other sources), and can be used autologously or from allogeneic sources without risk of cytotoxic T cell rejection. Their first use in the context of organ transplantation was for the treatment of grade IV graft versus host disease in marrow transplant recipients.<sup>73</sup> MSCs have pleiotropic effects on the immune response, including antiproliferative T-cell function. The goal of MSC trials for solid-organ transplantation is to reduce the amount of pharmacologic immunosuppression needed, and clinical trials are ongoing for liver, renal, heart, lung and islet transplantation. No adverse acute reactions to MSC infusion or injection have been reported after thousands of

treatments.

## Corneal Transplantation

Corneas are the most common organs transplanted in the United States, with ~46,000 transplants per year. Corneal transplants can be performed under local anesthesia (often with IV sedation), topical anesthesia, or general anesthesia depending on the details of surgery. The use of laryngeal masks versus endotracheal intubation may reduce the potential for ocular hypertension from coughing postoperatively.<sup>74</sup> Recipients of cornea grafts are often elderly. A major anesthetic goal is maintaining low intraocular pressure (see [Chapter 49](#)). Patient positioning (head-up angle of the bed) on transfer from the OR should be directed by the surgeon. For patients undergoing endothelial keratoplasty, less invasive than full cornea replacement, positioning in the prone or Trendelenburg position may rarely be requested. Rejection of corneal allografts is the most common cause of graft loss in the first year after transplantation.

## Renal Transplantation

### *Preoperative Considerations*

Allocation of kidneys in the United States changed in December 2014 with use of the Kidney Donor Risk Index (KDRI), and for deceased donors, the Kidney Donor Profile Index (KDPI), intended to provide the best grafts to patients with longest predicted posttransplant survival. Replacing extended donor criteria that were more limited, KDRI factors in age, height, weight, ethnicity, history of hypertension, history of diabetes, cause of death, creatinine, hepatitis C status, and DCD status. This system was intended to particularly benefit patients who were on dialysis for long periods of time, blood type B recipients, and highly sensitized patients. Systematic analysis of the impact of this change has not yet been reported. A living donor KDPI was recently proposed to compare the quality of liver donor kidneys.<sup>75</sup>

The prevalence of end-stage renal disease (ESRD) is about 0.17% in the United States, where 17,1017 kidney transplants were performed in 2014. Of these 11,570 came from deceased donors and 5,537 came from living donors. The most common recipient age group was 50 to 64 years (6,645 patients), and 3,325 recipients were over 65 years. In 2014, 4,761 patients died while waiting for a kidney transplant, and another 3,668 became too sick to undergo transplantation (<http://optn.transplant.hrsa.gov>).

Diseases treated with renal transplants are shown in [Table 52-5](#). Many of these underlying diagnoses are also risk factors for coronary artery disease, so

preoperative evaluation is focused on cardiovascular function, but a comprehensive medical workup is essential.

About half the mortality of patients on dialysis is due to heart failure. Cardiovascular disease is the leading cause of death (and therefore graft loss) after renal transplantation.<sup>76</sup> Therefore, cardiovascular risk factor modification is imperative before and after transplantation, including hypertension and hyperlipidemia. Renal transplant recipients are often **6** anemic, with hyperdynamic cardiac indices. Patients above 50 years (with or without risk factors for coronary disease) are generally screened with dobutamine stress tests or myocardial scintigraphy. The interval at which these studies are repeated in patients listed for transplantation varies from center to center. Peripheral vascular disease should also be assessed. Pulmonary function tests (PFTs) should be reviewed by anesthesiologists prior to transplantation (see [Chapter 15](#)). PFTs are particularly important in type 1 diabetics, who often present with reduced lung volumes and diffusing capacity. The precise cause of abnormal PFTs in these patients is not known, but clinical studies suggest that long-term normoglycemia after kidney or pancreas transplantation is associated with improved pulmonary function.<sup>77</sup> Hypercoagulable states are common in patients with renal disease and deserve detailed evaluation so that they can be managed perioperatively.<sup>78</sup>

**Table 52-5** Diagnoses of Patients on Adult Renal Transplant Waiting List

Diagnosis	Patients on List (%)
Type 2 diabetes	29.1
Hypertension (and malignant hypertension)	21.7
Retransplant/failing transplant	6.8
Polycystic kidney disease	6.4
Focal glomerular sclerosis	5.1
Type 1 diabetes	3.7
IgA nephropathy	3.4
Systemic lupus erythematosus	2.6
Other/not reported	9.7

Data from [optn.transplant.hrsa.gov](http://optn.transplant.hrsa.gov).

All solid-organ transplant patients are screened for tumors (mammography, Papanicolaou test, colonoscopy, prostate-specific antigen) and infection (dental evaluation, viral serologies). Patients should have good control of their diabetes before transplantation and have an evaluation for psychiatric stability and social support. Severe heart, lung, or liver disease; most malignancies; and active or untreatable infections such as tuberculosis are exclusion criteria for renal transplantation.

Dialysis-dependent patients should be dialyzed before surgery. Cadaveric

grafts can be safely transplanted after 24 hours of cold ischemia time, and potentially after 36 hours, allowing scheduling of preoperative dialysis. With preoperative dialysis, severe hyperkalemia during surgery is unusual. ECDs are often used for kidney transplantation. Factors used in designation of ECD kidneys are age (>60 yr), creatinine value, stroke as cause of death, and hypertension. DCD donors are also an ECD category. ECDs affect the scheduling of transplantation because minimization of cold ischemia times is essential and delayed graft function may complicate the intraoperative course of DCD graft recipients,<sup>79</sup> but recently the UK Transplant Registry reported that long-term outcomes after DCD and DBD donor kidney transplants were similar.<sup>80</sup>

Kidney allocation protocols were changed in late 2014 with the goal of improving longevity matching between donor and recipient, and better access to patients who have been historically difficult to match (highly sensitized patients) or those on long-term dialysis. Initial indications suggest that these goals have been met but at the cost of increased cold ischemia times associated with higher rates of delayed graft function.<sup>81</sup> Kidney allocation is much more complicated than liver allocation; updated rules for kidney allocation can be found at [optn.transplant.hrsa.gov](http://optn.transplant.hrsa.gov).

### *Intraoperative Procedures*

Renal transplantation can be done using epidural or spinal anesthesia, and most renal transplantation is done under general anesthesia, though patients with epidurals reportedly have better postoperative pain relief.<sup>82</sup> Concerns over uremic platelet dysfunction and residual heparin from preoperative dialysis have limited the use of regional anesthesia for kidney transplantation. The patient's preoperative medication lists should be reviewed; antihypertensives are common in this population. Although recommendations vary and renal transplant patients have not been well studied, consideration should be given to maintaining  $\beta$ -blockers and withholding angiotensin II receptor blockers before transplantation.<sup>83</sup>

Rapid-sequence induction (preceded by oral sodium bicarbonate) is indicated in diabetic patients with gastroparesis. Esmolol may be useful for blunting the hemodynamic response to intubation.<sup>83</sup> Anemic, hyperdynamic patients may have higher dose requirements for induction agents such as propofol.<sup>84</sup> Rocuronium is useful for patients in whom rapid-sequence induction is indicated, but the duration of block is variable in patients with ESRD.<sup>85</sup> Similarly, plasma clearance of rapacuronium is reduced with renal failure, but titration of dose to neuromuscular blockade monitoring end points prevents delayed recovery.<sup>86</sup> Generally, the long-acting nondepolarizing muscle relaxants are avoided and shorter-acting agents such as cisatracurium (cleared

by Hoffman elimination) are used. Before incision, antibiotics are given. A central venous catheter (usually triple lumen) is often placed for CVP monitoring and drug administration in most centers, and a bladder catheter is placed.

Incision is usually in the lower right abdomen to facilitate placement of the graft in the iliac fossa. The recipient iliac artery and vein are used for graft vascularization, followed by connection of the ureter to the recipient bladder. If the kidney is too large for the iliac fossa, it can be positioned in the retroperitoneal space. Iliac vessels may be used for anastomoses, or the aorta and inferior vena cava may be required.

The major anesthetic consideration is maintenance of renal blood flow. No data are available to determine whether inhaled versus balanced intravenous techniques are better at preserving (graft) renal flow. Similarly, the choice of inhaled gas has not been shown to significantly affect posttransplant renal function. Isoflurane, sevoflurane, and desflurane are all used to manage renal transplant patients. Morphine effect is prolonged in the setting of ESRD, and high doses of meperidine can cause accumulation of its metabolite, normeperidine, in these patients. Similarly, remifentanyl metabolite accumulation occurs in ESRD, whereas fentanyl, alfentanil, and sufentanil pharmacokinetics are clinically normal, though heterogeneity in pharmacokinetics in this population warrants increased vigilance for postoperative respiratory depression.<sup>87</sup>

Hypertensive renal transplant patients often require antihypertensive drugs perioperatively. Calcium channel blockers have been best studied for renal protection of cyclosporine-treated hypertensive transplant patients. But after surgery, angiotensin-converting enzyme inhibitors, increasingly used, and  $\alpha$ -blockers may be as effective as calcium channel blockers.<sup>88</sup> Typical hemodynamic goals during transplant are systolic pressure greater than 90 mmHg, mean systemic pressure greater than 60 mmHg, and CVP greater than 10 mmHg. These goals are usually achievable without vasopressors, using isotonic fluids and adjustment of anesthetic doses. Hemodynamic management varies widely from center to center, so close communication between surgeon and anesthesiologist is imperative. Plasma Lyte is the crystalloid of choice for kidney transplantation, and it preserves acid-base balance and electrolytes when compared with Ringer's lactate or normal saline.<sup>89</sup>

Once the first anastomosis is started, diuresis is initiated (both mannitol and furosemide are often given). Heparin and verapamil should also be available in the OR. In some centers, anesthesiologists are asked to administer the first doses of immunosuppression. A kidney graft is defective in concentrating urine and reabsorbing sodium, so attention to electrolytes is important.

Glucose control is also important for patients undergoing transplantation.<sup>90</sup> A small, single-center prospective study of living kidney donor recipients identified glucose above 160 mg/dL as a risk factor for acute perioperative renal dysfunction, likely associated with more severe ischemia–reperfusion injury.<sup>90</sup> Tight glucose control after kidney transplant is associated with less rejection, and diabetics with poorly controlled glucose levels after transplantation have increased mortality.<sup>91</sup> For these reasons, tight blood glucose control (80 to 110 mg/dL) is a reasonable anesthetic management goal during renal transplantation. Dopamine does not reliably improve renal function in this setting. The selective DA1 agonist fenoldopam is used to preserve renal function during kidney transplantation in some centers and is a superior renal protectant compared to dopamine,<sup>92</sup> although not extensively studied.

Transfusion is rarely required in the OR, although renal transplant patients are often anemic coming to surgery (and may be receiving erythropoietin). Because of immunosuppression, if cytomegalovirus (CMV)-negative patients receiving a CMV-negative organ are transfused, CMV-negative blood is preferred. Leukocyte filters are also effective in preventing CMV transmission but are probably inferior to CMV-negative blood.<sup>93</sup> The entire surgery should take less than 3 hours.

Most surgical complications of renal transplantation are not recognized in the OR. The common postoperative complications are ureteral obstruction and fistulae, vascular thromboses, lymphoceles, wound complications,<sup>94</sup> and bleeding. Vascular complications can lead to early graft loss.<sup>95</sup>

Patient-controlled analgesia is a good choice for postoperative pain management, and despite prolonged action, morphine can be used safely if patients are well monitored. Nonsteroidal anti-inflammatory agents and cyclooxygenase-2 inhibitors are contraindicated. Pain can be severe, prompting some centers to explore combination blocks (ilioinguinal–iliohypogastric and intercostal nerve blocks)<sup>96</sup> or transversus abdominis plane blocks<sup>97</sup> for posttransplant pain control. Chronic pain after kidney transplantation is common,<sup>98</sup> suggesting that more attention should be given to early postoperative pain management.

In children, the most common causes of ESRD requiring transplantation are congenital (largely anatomic developmental) anomalies. Kidney size mismatch can complicate the surgery in small children. Adult donor kidneys may have to be placed in the retroperitoneum of small children. Although chronic peritoneal dialysis may help expand the abdominal volume,<sup>99</sup> attention to peak inspiratory pressures at closure is important, and increased pressures should be reported to the surgical team. Pediatric renal transplantation is associated with somewhat lower rates of success than adult transplantation, with vascular thromboses of the grafts more common in

younger children as well as problems with adherence to immunosuppressive regimens.

## Liver Transplantation

### Preoperative Considerations

In June of 2013 Share 35 was initiated for liver transplantation to get donor livers to the sickest patients (with MELD scores >35), resulting overall in sicker patients transplanted since that time. The program mandated extended regional sharing of livers and intestines to liver-intestine candidates. Though overall mortality after liver transplantation did not change with Share 35, some regions experienced poorer outcomes.<sup>100</sup> Hyponatremia in liver transplant recipients is associated with increased mortality on the waiting list, especially in less sick patients.<sup>101</sup> For this reason, MELD score itself was modified in January 2016 to include sodium, the first score change since its implementation in 2002.<sup>102</sup>

MELD is calculated as follows:

$$10 \times [(0.957 \times \ln(\text{creatinine})) + [(0.378 \times \ln(\text{bilirubin})) + 1.12 \times \ln(\text{INR})] + 6.43.$$

MELD-Na is  $\text{MELD} - \text{Na} - [0.025 \times \text{MELD} \times (140 - \text{Na})] + 140.$

Mathematical modeling suggests that this change will save about 60 lives per year.

Liver transplant programs vary considerably in the number of transplants performed; however, the number of transplants performed in a given center is only a percentage of patients evaluated for liver transplantation, for which anesthesiology expertise will be sought. The anesthesiologist's input into the workup of liver transplant recipients is essential for decisions regarding candidacy and optimal preparation of patients for transplantation. Patients with ESLD have multiorgan dysfunction with cardiac, pulmonary, and renal compromise because of their liver disease (Table 52-6). Furthermore, many liver transplant recipients are more than 60 years old. Common liver diagnoses leading to liver transplantation are shown in Table 52-7. With the availability of pharmacologic cures for hepatitis C, the number of these patients requiring transplantation is expected to fall, and these drugs open new opportunities for treating posttransplant recurrence of hepatitis C virus.

**Table 52-6** Multisystem Complications of End-stage Liver Disease

System	Consequence
<b>Central Nervous System</b>	
Encephalopathy (confusion to coma)	Fatigue Blood–brain barrier disruption and intracranial hypertension (acute liver failure)
<b>Pulmonary</b>	
Respiratory alkalosis Reduced diffusing capacity	Hypoxemia/hepatopulmonary syndrome
Pulmonary hypertension	Reduced right heart function
<b>Cardiovascular</b>	
Reduced systemic vascular resistance Diastolic dysfunction Prolonged QT interval Blunted responses to inotropes Blunted responses to vasopressors Diabetes	Hyperdynamic circulation
<b>Gastrointestinal</b>	
Gastrointestinal bleeding from varices Ascites Delayed gastric emptying	
<b>Hematologic</b>	
Decreased synthesis of clotting factors Hypersplenism (pancytopenia) Impaired fibrinolytic mechanisms	Risk of massive surgical bleeding
<b>Renal</b>	
Hepatorenal syndrome	Impaired renal excretion of drugs
Hyponatremia	
<b>Endocrine</b>	
Glucose intolerance Osteoporosis Nutritional/metabolic	Fracture susceptibility Muscle wasting and weakness
<b>Other</b>	
Poor skin integrity; pruritus Increased volume of distribution for drugs Decreased citrate metabolism	Calcium requirement with rapid fresh-frozen plasma infusion

**Table 52-7** Diagnoses Leading to Liver Transplantation in Adults

<b>Hepatocellular Disease</b>
Hepatitis C
Laennec cirrhosis (alcoholic)
Combined hepatitis C virus/Laennec cirrhosis
Autoimmune hepatitis
Cryptogenic (idiopathic) cirrhosis
Hepatitis B
Small hepatocellular carcinoma (usually with other hepatocellular diseases)
Nonalcoholic steatohepatitis
<b>Cholestatic Disease</b>
Primary biliary cirrhosis
Primary sclerosing cholangitis
<b>Acute Liver Failure</b>
Viral (unknown)
Acute hepatitis viruses (A, B, C)
Drug-induced liver failure
Wilson disease

Pediatric patients are prioritized for transplant using the pediatric (<12 years) ESLD score or pediatric end-stage liver disease (PELD) score, calculated as follows:

$$10 \times [(0.48 \times \text{Ln}(\text{serum bilirubin})) + [1.857 \times \text{Ln}(\text{INR})] - [0.687 \times \text{Ln}(\text{albumin})] = \text{Listing age factor} + \text{Growth.}$$

For pediatric patients, exception diagnoses are urea cycle disorders, organic acidemia, and hepatoblastoma.

Patients with ALF are given priority for donor livers, then the patients with the highest MELD/PELD score and compatible blood group are next.

All liver transplant patients are screened for infectious diseases including HIV, CMV, and Epstein–Barr virus. As for other solid-organ transplants, major infection and malignancy may exclude patients from consideration for transplantation. Several centers have had good experience transplanting HIV-positive patients (kidney or liver), though these patients have somewhat increased mortality compared to HIV-negative controls. Nonetheless in HIV-positive patients with high MELD, transplantation confers a survival benefit.<sup>103</sup>

Renal dysfunction is common in patients undergoing liver transplantation and should be the focus of anesthetic regimens for patients with chronic liver disease undergoing transplantation. Serum creatinine levels are not extremely useful in capturing renal function in patients with liver disease. Even a small increase in serum creatinine in these patients suggests significant renal dysfunction; hence, creatinine is emphasized in MELD scoring.

Difficult decisions about patient candidacy are common in evaluating liver transplant candidates. Several are discussed here to highlight the need for regular involvement of a transplant anesthesiologist in the candidacy evaluation process. Patients with ESLD generally have very low SVR, high

cardiac index, and increased mixed venous oxygen saturation. Liver disease is not protective against coronary artery disease. Because cardiovascular disease is the most common cause of 30-day mortality following liver transplantation,<sup>104</sup> a rigorous cardiac workup is warranted. Most patients are screened for cardiac disease using dobutamine stress echocardiography or myocardial stress scintigraphy, although the effectiveness of diagnosing coronary artery disease in these patients is not well established.<sup>105</sup> Patients with evidence of significant coronary lesions usually require cardiac catheterization to identify stenoses amenable to angioplasty preoperatively. These studies can be done safely even in patients with significant renal dysfunction.<sup>106</sup> Patients with severe coronary artery disease are generally not candidates for liver transplantation. Functional assessment of patients in addition to laboratory and imaging studies is important, and one study found that achieving a distance of less than 250 m on a 6-minute walk test is an independent predictor of death on the transplant waiting list.<sup>107</sup> A small retrospective study suggests that troponin I levels greater than 0.07 ng/mL may predict liver transplant patients at risk for cardiovascular complications.<sup>108</sup>

Every effort should be made to maximize therapy for coronary artery disease and other heart disease before transplantation. Patients with hypertrophic obstructive cardiomyopathy (HOCM) and LV outflow tract obstruction can be treated with alcohol ablation of the septum before surgery to improve cardiac function during transplantation.<sup>109</sup> HOCM patients can benefit particularly from TEE monitoring because PA capillary wedge pressure does not accurately reflect LV volume in this population. Patients with patent foramen ovals may be at risk for intraoperative stroke, and some centers work with cardiologists to close larger shunts noninvasively before surgery. Nonalcoholic steatohepatitis is increasingly an indication for liver transplantation and may be associated with increased major postoperative cardiac events.<sup>110</sup>

Portopulmonary hypertension (PPH) patients coming to transplantation are particularly challenging. Diagnosis of PPH is made in the setting of liver disease or a mean pulmonary artery (PA) pressure of 25 mmHg or higher, pulmonary vascular resistance (PVR) greater than 240 dyne/s/cm<sup>5</sup>, and PA occlusion pressure 12 mmHg or lower.<sup>111</sup> Echocardiography is also used to screen patients for PPH and intracardiac shunts. Systolic PA pressure estimates are made by capturing the maximum velocity of regurgitant flow across the tricuspid valve, and this velocity is used in the Bernoulli equation for the pressure gradient between the right ventricle and the right atrium ( $\Delta P = 4V^4$ ). If moderate-to-severe pulmonary hypertension (estimated systolic PA pressure > 50 mmHg) is suggested, right heart catheterization is needed for direct pressure measurements. Multiple case reports and small retrospective

reviews demonstrate that patients with PPH are at substantial risk of perioperative death. There is general agreement that a mean PA pressure greater than 50 mmHg is an absolute contraindication to liver transplantation. Patients with PA pressures between 35 and 50 mmHg and PVR greater than 250 dyne/s/cm<sup>-5</sup> are also likely at increased risk. Efforts to lower PA pressure before transplantation pay off and considerably reduce the risk of transplantation.<sup>111</sup> Epoprostenol is the usual first-line therapy for PPH and is effective in lowering PA pressures significantly in many patients, but it requires home IV delivery. Inhaled iloprost has been used in Europe for PPH patients with good results.<sup>112</sup> Sildenafil is also useful for treatment of PPH<sup>113</sup> and can be given via nasogastric tube during surgery. Controlling PA pressures is critical in patients with the most severe PPH, and patients have been successfully managed with the mixed endothelin antagonist bosentan<sup>114</sup> or the selective endothelin-A receptor antagonist ambrisentan<sup>115</sup> or imatinib.<sup>116</sup> Right heart dysfunction that does not reverse after treatment of primary pulmonary hypertension is considered a contraindication to liver transplantation.<sup>117</sup> Inhaled nitric oxide (iNO) can be extremely useful for managing PA pressures during liver transplantation.

PFTs are often abnormal in ESLD, with most patients showing reduced diffusion capacity for carbon monoxide. Hepatopulmonary syndrome (HPS, a widened alveolar–arterial gradient in room air owing to liver disease) can lead to severe hypoxemia. Contrast echocardiography is used to diagnose intrapulmonary vasodilation using agitated saline. The microbubbles act as a contrast, and, if intracardiac shunts are present, they appear within three heartbeats after injection in the left ventricle. The later appearance of bubbles suggests intrapulmonary shunting. Once a contraindication to transplantation, HPS is now an indication for transplantation because it is the only therapy that can reverse the underlying physiology.<sup>118</sup> If HPS is severe and completely unresponsive to oxygen, transplantation is risky because the immediate perioperative period may be complicated by frank graft hypoxia and failure. Fortunately, most patients with HPS have some element of physiologic ventilation–perfusion mismatch, are oxygen responsive, and, with this “room to move,” can be safely transplanted.

Some patients with refractory ascites and normal renal function can have relief from ascites with terlipressin treatment.<sup>119</sup> The FDA approved terlipressin in 2013 (orphan status) for treatment of ascites.

Recently, a large number of new drugs for the treatment of hepatitis C have entered the market,<sup>120</sup> including protease inhibitors, viral polymerase inhibitors, viral replication complex inhibitors, new interferon formulations, and new ribavirin formulations. Drug–drug interactions with the new anti-hepatitis C virus drugs are just being reported. Telaprevir inhibits CYP3A and induces a significant reduction in oral clearance of midazolam (and limits its

oxidation) in liver microsomes.<sup>121</sup> Protease inhibitors used to treat HIV can interact with midazolam to cause prolonged sedation.<sup>122</sup>

## *Intraoperative Procedures*

Uncomplicated liver transplants can take as few as 2 to 3 hours, and the trachea can be extubated at the end of the case, but predicting easy versus difficult cases is not an exact science. Consequently, intensive preparation for surgery is important. Rapid-sequence induction of general anesthesia is indicated because patients with ESLD often have gastroparesis<sup>123</sup> in addition to increased intra-abdominal pressure from ascites. For anticipated difficult cases, many centers place two arterial catheters; one can be in the femoral artery (left femoral if a kidney transplant is planned). PA catheters are still used in many centers to follow PVR, and TEE is increasingly used for monitoring volume status, particularly for patients with cardiac disease undergoing transplantation (see [Chapter 27](#)).<sup>124</sup> Major hemorrhagic complications of TEE use during liver transplantation in patients with esophageal varices are rare, but fear of these complications has limited TEE use in some centers.<sup>125</sup> For difficult cases, two large-bore (9 French) catheters are placed for rapid intravenous infusions. In many centers, anesthesiologists are capable of placing percutaneous lines specifically for use in venovenous bypass (VVB) if necessary, but most U.S. centers rarely use VVB with cava-sparing surgical techniques. Bladder catheters and nasogastric tubes are placed in all patients. A rapid infusion system with the ability to deliver at least 500 mL/min of warmed blood is primed and is in the room. Before surgical incision, blood product availability is confirmed. Normothermia, essential for optimal hemostasis, is maintained with fluid warmers and convective air blankets over the legs and over the upper body.

Liver transplantation is traditionally described in three phases: **9** dissection, anhepatic phase, and neohepatic phase, with reperfusion of the graft marking the start of the neohepatic phase. The major issues during the first phase of transplantation are coagulation management and renal protection, so the major anesthetic goals of this phase are correction of coagulopathies and maintenance of intravascular volume for renal protection. Some centers advocate low CVP management of liver transplant patients to reduce blood loss,<sup>126</sup> but this technique may not be tolerated by patients with higher MELD scores and marginal renal function. The incision in patients with massive ascites is a rapid paracentesis, and albumin infusion is warranted to prevent postparacentesis circulatory dysfunction, because cirrhotics often have very low albumin levels as well as poorly functioning albumin.<sup>127</sup>

## **Coagulation**

Although standard laboratory coagulation studies do not predict bleeding well, they are still the gold standard for coagulation management. Though many transplants can be done with minimal transfusions, predicting bleeding is an inexact science, and anesthesiologists should be prepared for massive transfusion in these cases. Fresh frozen plasma (FFP) is used to maintain an INR of 1.5 or less in patients with anticipated or ongoing bleeding. Point-of-care INR is extremely useful in patients with massive blood loss, providing information in seconds. In the authors' experience, point-of-care INR and clinical laboratory INR values may be different, but once the offset is known, the two INR values track well. Rapid infusion of FFP can quickly lead to ionized hypocalcemia because of the citrate load that is not metabolized by a diseased liver. Infusion of calcium chloride (CaCl<sub>2</sub>), adjusted to ionized Ca<sup>2+</sup> levels, is better at maintaining constant calcium (Ca<sup>2+</sup>) levels than are intermittent boluses. Use of calcium boluses will cause wide calcium swings and overuse of calcium. At this time, there is no sufficient U.S. experience with prothrombin complex concentrates<sup>128</sup> in liver transplant recipients to know the place for these factor concentrates. Platelet transfusion has traditionally been used to maintain platelet counts above 50,000/mm<sup>3</sup>; however, platelet transfusion has been associated with worse graft and patient survival.<sup>129,130</sup> Importantly, we find that maintaining fibrinogen above 150 mg/dL with cryoprecipitate is critical for hemostasis and obviates the need for platelet transfusions in almost all patients. Cell-saver blood may also be used to limit allogeneic transfusions, although it is generally not used in patients with hepatocellular carcinoma.

Many other factors contribute to poor hemostasis in liver transplant patients besides poor clotting factor synthesis, including renal failure, infection, endothelial dysfunction, and high portal pressures.<sup>131</sup> This complexity in the etiology of underlying bleeding problems is likely a factor in the unpredictability of bleeding during liver transplantation.

In addition to complex coagulopathies of ESLD, many patients with liver disease have a superimposed hypercoagulable state (see [Chapter 17](#)). For example, patients with autoimmune liver diseases may have antiphospholipid antibodies. Many authors have suggested that the coagulation status of cirrhotics is “balanced” when procoagulant abnormalities are balanced by anticoagulant abnormalities.<sup>132</sup> But experienced transplant anesthesiologists recognize that both coagulopathy and hypercoagulability can cause simultaneous and serious problems—two diseases rather than a balanced system. In general, prohemostatic factors are also elevated in patients with liver disease, including von Willebrand factor and factor VIII, and low values of ADAMTS-13, antithrombin, protein C, and plasminogen disrupt the normal balance of hemostatic factors.<sup>131</sup> So in addition to monitoring discrete parts of the coagulation profile to guide transfusion therapies, it is important to look

at a measure of whole-blood clotting to assess thrombotic potential. Most centers use thromboelastography (TEG) and increasingly thromboelastometry to help sort out complex coagulation disturbances and their evolution during liver transplantation, to help with interpretation of standard laboratory tests of coagulation, and to get a picture of overall clotting and fibrinolysis status. If TEG or thromboelastometry indicates normal or hypernormal whole clotting in the presence of high INR and low fibrinogen and platelets (and usually elevated D-dimers), this pattern is a caution that the patient may have a clinically significant hypercoagulable state. A formal hypercoagulability workup should be done as part of liver transplant evaluation. Under these circumstances, the authors' approach is to avoid pharmacologic procoagulant or antifibrinolytic drugs. For the majority of patients with coagulopathy dominated by synthetic dysfunction, thrombocytopenia, and hypofibrinogenemia, whole-blood clotting is delayed. If these patients have insufficient hemostasis, many centers supplement transfusion therapy with antifibrinolytic agents. Considerable center-dependent variation in use and dosing of antifibrinolytics makes generalizations difficult. In the authors' experience, -aminocaproic acid (EACA; 5-g load and 1 g/hr infusion) to support hemostasis during surgery is useful and safe<sup>133</sup> in most coagulopathic patients during liver transplantation, provided there is no evidence or history of hypercoagulability. Other centers use considerably less drug, less often. Fibrinolysis acutely worsens immediately after reperfusion to varying degrees, depending largely on the amount of tissue plasminogen activator released from the graft.<sup>134</sup> A (re)bolus of EACA is helpful to maintain hemostasis once this postreperfusion exacerbation of fibrinolysis is documented. Some centers use tranexamic acid instead of EACA, which is also a plasminogen inhibitor but has a longer half-life than EACA.

Activated factor VII can be used safely during liver transplantation but is usually reserved for rescue of refractory critical bleeding unresponsive to more standard management because of its expense and because the risk of thrombosis in liver disease patients is not known. Furthermore, its use may be associated with poor clinical outcomes.<sup>135</sup> When this drug is given, INR rapidly normalizes, although the amount of circulating clotting factors does not change, complicating interpretation of laboratory coagulation studies. NovoSeven administration is also useful for surgical hemostasis for placement of intracranial pressure (ICP) monitors in patients with ALF and for selected patients undergoing liver transplantation with difficult red cell crossmatches or in patients who refuse transfusion on religious grounds.

Pulmonary embolism is an unusual complication of liver transplantation, reflecting the complex coagulation imbalance of ESLD and liver transplantation. If diagnosed promptly, low-dose tissue plasminogen activator (0.5 to 4 mg) delivery into the CVP port of a pulmonary artery catheter

(PAC) can lyse the clot quickly.<sup>136</sup>

Perioperative renal dysfunction is a major challenge in liver transplantation and can be exacerbated by hypovolemia and anesthetic-induced impairment of renal blood flow. Unsurprisingly a literature review showed that preoperative renal dysfunction and severity of liver disease as well as intraoperative hemodynamic instability and graft quality are associated with post-liver transplant renal dysfunction.<sup>137</sup> Creatinine levels can significantly underestimate the degree of renal dysfunction, especially in ESLD patients with significant muscle wasting.<sup>138</sup> Hepatorenal syndrome (HRS) is a functional renal disorder associated with liver disease, categorized as type 1 (acute severe decompensation), which is often fatal, and type 2 (chronic moderate renal failure with creatinine more than 1.5 and glomerular filtration rate less than 40 mL/min). Recently HRS type 1 was recategorized as a specific type of acute kidney injury, incorporating the idea that treatment should be based on relative changes in serum creatinine ( $>0.3$  mg/dL over 48 hours) rather than an absolute threshold number for serum creatinine.<sup>139</sup> HRS in general is the diagnosis if the patient has ascites, is not in shock, has not been exposed to nephrotoxic drugs, has no parenchymal renal disease, has a creatinine level more than 1.5 mg/dL, and does not improve after 2 days of diuretic withdrawal and albumin therapy (1 g/kg/day up to 100 g/day).<sup>140</sup> HRS-acute kidney injury prevention best practices include SBP prophylaxis, intravenous albumin administration if SBP is present, and antibiotic prophylaxis for gastrointestinal bleeding.<sup>139</sup> In addition, large-volume ( $>5$  L) drainage of ascites with incision is paracentesis and should be accompanied by albumin therapy to prevent renal decompensation, with recommended albumin doses of 6 to 8 g/L of ascites drained. Importantly, higher doses of albumin are associated with better survival in type 1 HRS.<sup>141</sup> Terlipressin and norepinephrine may be useful for HRS because they relieve splanchnic vasodilatation, though the data about these therapies are sparse.<sup>142</sup> The  $\alpha_1$ -agonist midodrine in combination with octreotide is useful for improving renal function in some patients.<sup>143</sup> No prospective trials have been done to support use of one vasopressor over another during transplantation, and intraoperative pharmacologic renal support is largely guided by the hepatology literature. Dopamine is not useful for preserving renal function during liver transplantation. The most important consideration for patients with HRS is to ensure adequate volume replacement before instituting diuresis in the OR.

The *anhepatic phase* begins when the liver is functionally excluded from the circulation. Historically, the vena cava was clamped above (suprahepatic anastomosis) and below (infrahepatic anastomosis) the liver, and the portal vein and hepatic artery were clamped. With complete cava cross-clamping, venous return falls by 50% to 60%, often resulting in hypotension. VVB may

be used to increase venous return and therefore blood pressure, to increase renal and gut perfusion pressures, and to decompress portal pressures for a better surgical field. VVB is rarely used in centers where surgeons use cava-sparing techniques, and hemodynamics during the anhepatic period can be managed with volume loading and vasopressors as needed. VVB carries potential complications, including arm lymphedema, air embolism, and vascular injury, and its benefit is limited when anhepatic times are short. Surgical techniques that preserve caval flow (e.g., piggyback technique) are standard in most U.S. centers and make intraoperative management significantly easier, but anesthesiologists should be familiar with managing both surgical situations.

*Reperfusion* of the graft is the most treacherous time of the liver transplant. Communication between the surgical and anesthesia teams is essential in precise preparation for reperfusion. Caval clamps are removed first, and the integrity of the caval anastomoses are ensured. Caval reperfusion is usually hemodynamically well tolerated. However, portal vein reperfusion often results in hemodynamic instability. The original descriptions of reperfusion syndrome emphasized (often severe) hypotension and bradycardia with portal reperfusion.<sup>144</sup> Now, with flushing techniques that precede reperfusion and changes in preservation solution, bradycardia is less common. Typically, reperfusion is associated with hypotension (further drop of already low SVR), which may or may not require treatment. The authors' preparation for reperfusion is to give sodium bicarbonate just before unclamping (25 to 50 mEq) to meet the acid load from the graft. For particularly prolonged acidosis, tris(hydroxymethyl)aminomethane infusion is useful.<sup>145</sup> Importantly, administration of 500 to 1,000 mg of CaCl<sub>2</sub> *precisely at the time of portal reperfusion* can counteract the effects of high potassium on the heart. If, despite these preparations, T waves on electrocardiogram (ECG) become elevated, the same treatment is repeated. Some anesthesiologists prefer to treat ECG changes only after they are diagnosed, but because the acid and potassium of reperfusion can be anticipated, the authors' practice is to counteract these prophylactically. Lidocaine, atropine, and norepinephrine are available at the time of reperfusion in case of ventricular dysrhythmias, bradyarrhythmias, and severe hypotension. Hepatic artery unclamping is usually hemodynamically uncomplicated.

Microemboli and right ventricular (RV) dysfunction are common at reperfusion, and intracardiac thromboemboli are not rare.<sup>146</sup> Intracardiac emboli and biventricular dysfunction are associated with adverse postoperative cardiac events.<sup>146</sup> Methylene blue is used by some to counteract the vasoplegic state of reperfusion, but its effects on outcome are unknown.<sup>147</sup> On the other hand, a study in which iNO was given during the entire transplant suggested significant acute benefits (decreased hepatocyte

apoptosis) and earlier graft recovery, including faster coagulation factor synthesis.<sup>148</sup> Attempts to precondition the reperfused graft were analyzed in a well-designed trial, which showed no difference with propofol versus sevoflurane.<sup>149</sup>

In the *neohepatic phase*, calcium is not required after reperfusion; therefore one early indication of graft metabolic function is the lack of a calcium requirement, even when FFP is infused rapidly. Usually within 30 minutes, the base deficit improves with graft metabolism of citrate and lactate. Within the first hour, the CO decreases (after an acute increase after portal reperfusion) as SVR increases with graft metabolism of vasoactive substances unleashed at reperfusion. In addition, the graft appearance should be noted. It should have a smooth edge and no evidence of engorgement. Bile is made in the first half-hour after reperfusion in a well-functioning graft. Often, renal function improves after reperfusion, probably because of graft metabolism of renal vasoconstrictors. ECD grafts are often slow to function metabolically in the OR. (For these and other classes of ECD livers, cold ischemia times should be limited, which can significantly affect the OR schedule.) Fibrinolysis after reperfusion may require antifibrinolytic agents. Thromboelastometry may be more sensitive than thromboelastography in detecting fibrinolysis,<sup>150</sup> but decision to add or increase antifibrinolytics after reperfusion should be made by assessing surgical hemostasis as well as point-of-care tests.

During the neohepatic period, biliary anastomoses are completed and sources of surgical bleeding are corrected. Drains are placed and the abdomen is closed. Fast-tracking protocols for liver transplant patients are common in experienced centers.<sup>151</sup>

## **Pediatric Liver Transplantation**

Indications for pediatric liver transplantation differ considerably from those of adults, with biliary atresia (44%) and inborn errors of metabolism (34%) being the most common indications.<sup>152</sup> PPH is rare in children, but biliary atresia is associated with cardiac defects and situs inversus.<sup>153</sup> Children younger than 1 year of age with inherited liver disease are often very small for age. In small children, a radial artery catheter and at least one large (18-g) peripheral intravenous line are placed after induction of anesthesia. Surgeons may place tunneled central lines before incision, which are useful for intraoperative transfusions, postoperative administration of drugs, and CVP monitoring. Children with previous Kasai operations for biliary atresia may have massive bleeding during dissection because of adhesions. Small children receiving large grafts may have respiratory compromise with abdominal closure. Because hepatic artery thrombosis (HAT) is a more common complication in children than adults, some centers choose to have

the INR at the end of surgery in the 1.8 to 2 range; postoperative aspirin and alprostadil are often used to prevent HAT. If flow is inadequate (by poor Doppler signals) in the artery after anastomosis, intraoperative reanastomosis or a new anastomosis may be required acutely. Aortic cross-clamping may be required for these anastomoses. Biliary complications are also common in pediatric transplant recipients, especially those receiving adult left lateral segment grafts, with HAT a significant contributor to biliary complications. Use of split livers (one liver for two patients) puts a strain on transplant teams but is important for extending the donor pool.<sup>154</sup>

## **Acute Liver Failure**

Anesthetic considerations for adults and children with ALF are focused on protection of the brain (see [Chapter 37](#)), so that in many ways management is opposite that of chronic liver failure, in which the kidneys are the most fragile organ requiring protection during liver transplantation. Patients with a diagnosis of ALF should be managed in the ICU, because they can have a rapidly progressive course of elevated ICP, leading to herniation and death. Because ALF is much less common than chronic liver disease, a single center gets little experience with ALF, so it is important to develop a detailed multidisciplinary protocol for managing these patients. ICP monitoring is useful in managing these patients but risks intracranial bleeding; nonetheless its use is advocated by the U.S. Acute Liver Failure Study Group in nonacetaminophen-induced ALF.<sup>155</sup> Some centers have gained expertise in transcranial Doppler monitoring in place of invasive ICP monitoring<sup>156</sup> thereby avoiding the risk of ICP monitoring in coagulopathic patients. In the authors' experience, bispectral index monitoring, especially in patients without ICP monitors, can help detect acute disruption of cerebral blood flow, such as with vascular clamping.

Anesthetic management of these patients starts in the ICU, with intubation as needed for airway protection in the setting of encephalopathy or for initiation of therapeutic hypothermia. Mild hypothermia (core temperature 34° to 35°C) is used in some centers for ALF, though recent retrospective analysis suggests no benefit.<sup>157</sup> The head is positioned midline and the head of the bed raised. Mild hyperventilation is also commonly used to manage ICP but is best used as a rescue therapy. Mannitol is used for osmotherapy to an end point of 310 to 315 mOsm/L. Hypertonic saline is also useful for lowering ICP in some patients, with a target serum Na of 145 to 155 mEq/L.<sup>158</sup> Liver-assist devices used to bridge patients with ALF to transplantation have not generally shown benefit, but cell-based assist devices are in active clinical trial.

Importantly, vasodilating anesthetics, including all inhaled agents, should

be avoided, especially without ICP monitoring. In the authors' experience, pentothal is a good maintenance anesthetic, and acute rises in ICP can be managed with etomidate. With decreased availability of barbiturates, propofol is commonly used. Patients may come to the OR on *N*-acetylcysteine, a glutathione donor. When antihypertensive therapy is required, labetalol does not cause significant cerebral vasodilation in these patients.<sup>159</sup> Acute cerebral vasodilatation often accompanies reperfusion. Management of intracranial hypertension and cerebral edema is based on very small studies of patients with ALF and on adaptations of studies directed at control of intracranial hypertension in other settings (see [Chapter 37](#)).

## Pancreas and Islet Transplantation

The majority of pancreas transplants (about 75%) are done as simultaneous pancreas and kidney transplants from a single deceased donor. Pancreata grafted in these procedures have historically had better long-term survival than grafts done after kidney transplantation or independent pancreas grafts. Independent pancreas grafts are usually performed for patients with type 1 diabetes, who have frequent metabolic complications (hypoglycemia) but preserved renal function. With proper donor selection and aggressive attention to targeted antibiotic coverage, better graft survival rates after isolated pancreas transplant have recently been reported.<sup>160</sup> Nonetheless, pancreas transplantation is becoming less frequent, and islet transplantation has increased,<sup>161</sup> likely because pancreas transplants are associated with higher rates of surgical and postoperative complications. Optimal immunosuppression for islet transplantation, to ward off both allo- and autoimmunity, remains a significant problem. Encapsulation of islets to create a barrier to immune cells has also been a surprisingly hard problem.<sup>162</sup>

The preoperative assessment of pancreas/islet transplant recipients focuses on the end-organ complications of type 1 diabetes (see [Chapter 47](#)). Monitoring will depend on cardiac status, but generally patients do not require PA catheters and have been evaluated for cardiac disease as part of the transplant workup. Nonetheless, cardiovascular disease is present in many patients undergoing pancreas transplantation, although they tend to be younger than liver transplant recipients.

The major difference between pancreas transplantation and other procedures is that strict attention to control of blood glucose is indicated to protect newly transplanted  $\beta$  cells from hyperglycemic damage. No formula for controlling blood glucose has emerged as a standard of intraoperative management. In general, if adult patients arrive with glucose above 250 mg/dL, 10 units of insulin can be given intravenously, followed by an infusion of insulin. The infusion starting rate varies, depending on the initial

blood glucose level. Once blood glucose levels are controlled ( $<150$  mg/dL), intravenous 5% dextrose (about 100 mL/hr) should also be infused as the insulin infusion is continued. The most important issue is to check the response to insulin frequently and adjust infusions as necessary. Little literature exists for a patient with an implanted insulin pump, though more than 400,000 have been implanted in the United States.<sup>163</sup> One center developed a protocol for patients undergoing surgery with insulin pumps, emphasizing preadmission contact with an endocrinologist and documentation of pump status from preoperative to postoperative settings.<sup>163</sup> A reasonable recommendation is to continue to use the pump at basal rates in these patients as long as its operation is reviewed and blood glucose levels are monitored regularly during surgery.

Islet transplants were revived by the Edmonton protocol, published in 2000.<sup>164</sup> The major changes introduced included a glucocorticoid-free immunosuppression regimen and immediate transplantation of islets after isolation. Since that time, islets have been cultured after isolation in many centers, which makes surgical scheduling easier. Islets are generally infused into the portal circulation; acute portal hypertension may result from the infusion. This surgery should not be complicated by significant blood loss.

## **Small Bowel and Multivisceral Transplantation**

Indications for intestinal transplantation include impending liver failure in patients with intestinal failure (or short-gut syndromes requiring total parenteral nutrition [TPN]), frequent severe dehydration in patients with intestinal failure, and severe complications of central lines for TPN (sepsis, thrombosis of central veins). Patients who develop liver failure from TPN for intestinal failure are candidates for combined liver–intestine transplantation, and the presence of a liver in the graft may have a protective effect on the bowel graft.<sup>165</sup> In these cases, liver failure should be irreversible, and biopsy findings are often required to corroborate this conclusion in patients without overt ESLD. In general, intestinal transplantation is usually performed only in patients with life-threatening complications of intestinal failure, mostly in children, but increasingly in adult recipients.

A major hurdle for these transplants is line placement adequate for transfusion of blood products and fluids, need for which may be substantial during these long cases. Anesthesiologists should review angiographic studies to determine venous patency before attempting central line placement. Ultrasound devices are helpful in identifying the known patent vessels for cannulation, but surgical cutdowns for venous access may be necessary, including transhepatic or intraoperative renal vein catheterization. Superior vena cava or inferior vena cava obstruction may require preoperative

intervention (surgical and/or lytic) for adequate vascular access for surgery.<sup>166</sup> Antibiotic regimens should be continued during the surgery. Nitrous oxide, as in liver transplantation, should be avoided.

Common complications of intestinal failure include dehydration and electrolyte abnormalities, gastric acid hypersecretion, pancreatic insufficiency, bone disease, and TPN-induced liver failure.<sup>167</sup> Because electrolyte abnormalities are common, they should be monitored continuously during surgery and appropriate replacement instituted. Because enteral feeding will not be possible until weeks after surgery, TPN should be continued in the perioperative period.

Like reperfusion of liver grafts, intestinal graft reperfusion is associated with an acute release of acid and potassium from the graft and a postreperfusion syndrome. Anticipatory bicarbonate and CaCl<sub>2</sub> administration is useful to counteract the effects of acid and potassium on the heart. After reperfusion, coagulopathy may worsen and is usually managed by reassessment of INR and fibrinogen and platelet counts and correction with blood products. Epidural anesthesia is useful for pain management in both intestine donors and recipients.<sup>168</sup>

## Composite Tissue Allografts

Upper extremity and face transplants are extremely complex procedures performed only in a few centers. More than 85 patients have received hand or arm transplants, with the longest survivor 11 years posttransplant. More than 20 patients have received face transplants ([hopkinsmedicine.org](http://hopkinsmedicine.org)). For face donors, surgeons prefer to procure the face first, before other organs are procured. The graft recovery is complex, with isolation of motor and sensory nerves as well as venous and arterial vessels. Multiple surgeons are involved in both graft recovery and implantation. Recipient nose and mouth deformities will certainly require individualized airway care. Protocols for these patients are just being developed, but the choice of anesthetic and fluid management is directed at preventing microvasculature constriction and postoperative edema.

Anesthesiologists should be involved in perioperative protocol development for these new procedures from the initial planning stages of a program, especially because well-planned regional nerve blocks can be very useful for upper extremity transplants and other anesthesia-specific concerns can be addressed in advance.<sup>169</sup> Limb transplant recipients may be heparinized.<sup>169</sup> Bilateral limb allografts expose the recipient to two reperfusion events. The common feature of these grafts is that they contain multiple organs (blood vessels, nerves, muscle, skin). Multiple anastomoses imply a very long surgical procedure. Composite tissue recipients require

intense immunosuppression, in part because the skin is highly antigenic, and some immunosuppressants that are unfamiliar to anesthesiologists may be administered intraoperatively. In addition to complex triple-drug immunosuppression, increasingly donor marrow infusions are used in an effort to induce tolerance to the allograft.<sup>170</sup> Preparation for massive blood loss in these cases is essential.

Face grafting also may require massive transfusion, and blood loss may be difficult to quantify because of bleeding into the drapes; the surgery can be very prolonged. Common complications include postoperative renal dysfunction, acute respiratory distress syndrome, and jugular thrombosis. These cases are immunologically extremely complex.<sup>171</sup>

## Lung Transplantation

Lung transplantation is accepted therapy for end-stage pulmonary and pulmonary vascular disease, based on documented improvement in longevity and quality of life.<sup>172</sup> The Department of Health and Human Services Organ Procurement and Transplantation Network reports more than 31,000 lung transplant procedures in the United States since 1988, and the 2015 Registry of the International Society for Heart and Lung Transplantation reports 51,400 lung transplants worldwide since 1989.<sup>173</sup> With median waiting time between 500 and 1,000 days, however, many patients die awaiting transplant because of the shortage of suitable organs. Over the past 20 years there has been a slow but steady improvement in overall outcome in lung transplantation. Data compiled from January 1990 to June 2013 reveal a median survival of 5.7 years and a 54% survival rate at 5 years. It has now become clear that long-term survival after bilateral lung transplantation is better than after single-lung transplantation (median 7.1 versus 4.5 years). The most common indications for lung transplantation are chronic obstructive pulmonary disease (32%), interstitial lung disease (24%), cystic fibrosis (CF) (16%), and  $\alpha_1$ -antitrypsin deficiency (5%).<sup>173</sup>

Surgical options for lung transplantation are single-lung transplant, *en bloc* double, sequential double, and heart–lung transplantation. The International Society for Heart and Lung Transplantation registry for 2015 indicates a continued increase in double-lung transplants over the past two decades, with a relatively stable number of single-lung transplants, a trend likely related to reports of improved outcome after double-lung transplantation.<sup>173</sup> There has been a continued trend toward avoiding the use of cardiopulmonary bypass (CPB) in single and sequential double-lung transplantation, although CPB should always be available and is often used for patients with pulmonary hypertension. Double-lung transplantation is most commonly used in patients with pulmonary vascular disease and CF, although its use is increasing in

chronic obstructive pulmonary disease and interstitial lung disease. Single-lung transplantation for emphysema has favor because of good short-term outcomes, with the added advantage of leaving a donor lung for another recipient. Lung transplant centers vary in applying single- or double-lung transplant to different diagnoses as well as in the application of CPB, and the procedure indications are still debated.<sup>174</sup> Double-lung transplantation, however, is indicated if a single-lung transplantation would allow a continuing pathologic process to jeopardize either the native or transplanted lung. For example, the presence of pulmonary infection, as in CF, in the native lung would likely spread to the transplanted lung. In pulmonary hypertension, remaining pulmonary vascular disease in the native lung would result in progressive pulmonary hypertension and thus hypertensive vasculopathy in a transplanted lung. Finally, a severely emphysematous lung, with its high compliance, would be at risk for air trapping and barotrauma when coexisting with a transplanted lung with normal compliance.

### *Recipient Selection*

International Guidelines for the Selection of Lung Transplant Candidates were updated in 2006 by consensus agreement of several thoracic societies (summarized in [Table 52-8](#)).<sup>175</sup> In general, patients should be considered for lung transplantation if they exhibit poor pulmonary function despite maximal medical therapy. Contraindications to lung transplantation are based on their impact on long-term survival. Patients with severe cardiac disease can be considered for heart–lung transplantation but are not candidates for isolated lung transplant. A Lung Allocation System, developed by the United Network for Organ Sharing, is used, with candidates given a lung allocation score to determine their wait-list status. This system weighs net benefit of transplant and clinical urgency.<sup>176</sup>

**Table 52-8 Lung Recipient Selection Guidelines**

<b>General Indications</b>
End-stage lung disease
Failed maximal medical treatment of lung disease
Age within limits for planned transplant
Life expectancy <2–3 yr
Ability to walk and undergo rehabilitation
Sound nutritional status (70%–130% of ideal body weight)
Stable psychosocial profile
No significant comorbid disease
<b>Disease-specific Indications</b>
<b>Chronic Obstructive Pulmonary Disease</b>
FEV <sub>1</sub> <25 % of predicted value after bronchodilators and/ or PaCO <sub>2</sub> = 55 mmHg and/or pulmonary hypertension (especially with cor pulmonale)
Chronic O <sub>2</sub> therapy
<b>Cystic Fibrosis</b>
FEV <sub>1</sub> <30% predicted
Hypoxemia, hypercapnia, or rapidly declining lung function
Weight loss and hemoptysis
Frequent exacerbations, especially young females
Absence of antibiotic-resistant organisms
<b>Idiopathic Pulmonary Fibrosis</b>
Vital capacity <60%–65% of predicted
Resting hypoxemia
Progression of disease despite therapy (steroids)
<b>Pulmonary Hypertension</b>
NYHA functional status Class III or IV, despite prostacyclin therapy
Mean right atrial pressure <15 mmHg
Mean pulmonary artery pressure <55 mmHg
Cardiac index <2 L/min/m <sup>2</sup>
<b>Eisenmenger Syndrome</b>
NYHA class III or IV, despite optimal therapy
<b>Pediatric</b>
NYHA class III or IV
Disease unresponsive to maximal therapy
Cor pulmonale, cyanosis, low cardiac output

FEV<sub>1</sub>, forced expiratory volume in 1 second; NYHA, New York Heart Association.

As for other transplants, patients are screened for malignancy (mammography, Papanicolaou test, and colonoscopy). PFT, left and right heart catheterization, and transthoracic echocardiography are used to evaluate potential recipients. Lung transplantation is not advocated for acute disease processes, such as acute respiratory distress syndrome. Specific age limits were recommended in the past; however, current guidelines list age more than 65 years as a relative contraindication only. CF is associated with complex pulmonary infections and colonization with microbial flora that can negatively affect transplant outcomes. However, with the exception of patients colonized with *Burkholderia cepacia*, most CF patients can be successfully transplanted despite chronic bacterial infections.<sup>177</sup>

Medical evaluation prior to listing a patient for transplantation requires

many specialties. If the patient has been on the waiting list for an extended period, it is important to review recent laboratory and functional data; disease progression may have resulted in change in status since the original workup. It is critical to confirm ABO compatibility of donor and recipient prior to surgery. Lung transplant candidates have poor pulmonary status and are frequently receiving multiple therapies including oxygen, inhaled bronchodilators, steroids, and pulmonary vasodilators. These medications should be continued in the perioperative period. Although *ex vivo* lung perfusion is now used in many centers,<sup>178,179</sup> the transplant must still be done as soon as a lung becomes available. Because these procedures are done on an urgent or emergent basis, the patient often presents with a full stomach.

Although lung transplant patients are understandably anxious, they also have minimal pulmonary reserve, and sedation must be given carefully under monitored conditions. After determining oxygen saturation, slow incremental dosing of a short-acting benzodiazepine (0.25- to 1.0-mg of midazolam) may be used for anxiolysis. Premedication with narcotics such as fentanyl must be administered with extreme caution, if at all, because of their ventilatory depressant effect. Use of metoclopramide, histamine-2 antagonists, and a nonparticulate antacid are usually warranted because of “full stomach” status. Many patients are unable to rest in a supine or in Trendelenburg position for central venous catheterization. Placement of large-bore peripheral intravenous and arterial access is usually adequate for initiation of the anesthetic, with central access achieved after induction. Placement of a PAC is often warranted for monitoring cardiac output and PVR, with a catheter capable of continuous cardiac output and mixed venous oxygenation saturation ( $MvO_2$ ) preferable. Thoracic epidural catheters are placed preoperatively at some centers, especially in patients who are believed unlikely to require CPB with its associated anticoagulation. Another option is to place the epidural in the early postoperative period, after coagulopathies are corrected. The epidural can be placed using light sedation during weaning from mechanical ventilation, allowing better neurologic monitoring and pain control prior to tracheal extubation. Other options for postoperative pain relief include postoperative paravertebral blocks, and intercostal nerve blocks performed intraoperatively. Multimodal analgesic techniques, including dexmedetomidine infusion, intravenous acetaminophen, and nonsteroidal anti-inflammatory agents, are now standard components of enhanced recovery after surgery programs.<sup>180</sup> These will likely be useful after lung transplantation as well.

## ***Intraoperative Management***

### **Single-lung Transplantation**

Lung transplant recipients are often chronically intravascularly volume depleted, and chronic pulmonary hypertension is common. These factors predispose the patients to hypotension and decreased cardiac output on anesthetic induction. Restriction of anesthetic doses because of this concern increases the risk of awareness in this patient population. Monitoring with processed electroencephalography may thus be useful; anesthetic management guided by bispectral index monitoring has been associated with a reduction of the incidence of intraoperative awareness in this population.<sup>181</sup> Because fluid restriction is beneficial for postoperative management,<sup>182</sup> small fluid boluses, particularly with colloid, and judicious induction with etomidate, benzodiazepine, and narcotics is prudent. A balanced technique combining narcotic and inhalation anesthetics or benzodiazepines is usually an effective approach to maintenance of the anesthetic. Possible plans for early extubation should be discussed with the surgeon, and minimizing narcotics while providing multimodal pain relief should be utilized if early extubation is planned. Muscle relaxation can be maintained with rocuronium or vecuronium and is associated with minimal hemodynamic side effects. Nitrous oxide is rarely used because it may exacerbate bullous emphysematous disease, pulmonary hypertension, or intraoperative hypoxemia.

Lung isolation, preferably with a double-lumen endobronchial tube, is necessary for single and bilateral sequential lung transplantation. The double-lumen tube, compared to bronchial blockade techniques, allows better suctioning of secretions, improved deflation of the operative lung during dissection, and application of continuous positive airway pressure to the operative lung if indicated. A bronchial blocker is more easily dislodged with surgical manipulation, may not provide isolation of the right upper lobe, and requires repositioning midsurgery in the case of a bilateral sequential procedure. A left-sided endobronchial tube is preferred, because a right-sided tube may be difficult to position relative to the right upper lobe bronchus.

Fluid restriction and lung ventilation strategies designed to protect **10** the lung allograft are indicated, because these patients are at increased risk for acute lung injury and pulmonary edema. This implies use of small tidal volumes (6 mL/kg) and oxygenation techniques using PEEP and lowest acceptable FiO<sub>2</sub> settings.<sup>182</sup> Fluid restriction may decrease lung water in the newly transplanted lung, and there are data showing that elevated CVP is associated with increased mortality after lung transplantation.<sup>183</sup> Intermittent fluid boluses while keeping CVP less than 7 cm of H<sub>2</sub>O and use of vasoactive drugs to maintain hemodynamics are recommended. Cardiac output monitoring using PAC, or minimally invasive techniques such as esophageal Doppler or pulse contour analysis, are useful for guiding fluid restriction while assuring adequate cardiac output. Lung recipients are susceptible to

pulmonary hypertension and RV dysfunction or failure during single-lung ventilation. Optimizing oxygenation and ventilation does not always improve RV function, and vasodilator and/or inotropic support may be required. iNO is an option for improving respiratory and right heart function.

During single-lung ventilation, hypoxemia is common. Strategies to improve oxygenation and ventilation are discussed in detail in [Chapter 38](#). They include application of PEEP to the dependent lung and CPAP to the nondependent lung and PA clamping of the nonventilated lung by the surgeon. Anesthesia machines with pressure-controlled ventilation and other advanced options have diminished the need for ICU ventilators during the operative procedure. CPB is indicated during lung transplantation if adequate oxygenation cannot be maintained despite ventilatory and pharmacologic maneuvers and PA clamping. Other indications for CPB include inability to provide adequate ventilation, or RV failure.

Single-lung transplantation can be performed via lateral thoracotomy. If the surgeon is concerned about possible need for CPB, then the patient must be positioned to allow rapid access to either the aorta and right atrium or the femoral artery and vein. This can be accomplished via either anterior thoracotomy with partial sternotomy or lateral thoracotomy with decreased angulation of the hips to allow access to the femoral vessels. Determination of operative side is based on preoperative ventilation–perfusion studies and prior thoracic surgeries. The lung with poorer function is typically the one replaced.

After pneumonectomy, the surgeon will size the donor vascular tissue to the recipient vessels and sequentially anastomose the atrial/pulmonary vein patch, bronchus, and PA. The lung is kept cold with ice in the surgical field until reperfusion. Circulation is restored to the donor lung, suture lines are checked for hemostasis, and then ventilation is begun. Systemic hypotension can occur during reperfusion but is usually not as significant as that with liver graft reperfusion. The anesthesiologist is often asked to assess the bronchial anastomosis using fiberoptic bronchoscopy and to perform bronchopulmonary toilet on the transplanted lung if necessary (removal of blood, secretions). TEE is useful to assess pulmonary venous drainage of the transplanted lung (see earlier). Along with *ex vivo* perfusion, Perfadex, a low–molecular-weight dextran solution, improves early graft function and is used widely for preservation during procurement.<sup>184</sup> There can nonetheless be reperfusion injury to the lung presenting as pulmonary edema. PEEP and lung protective strategies are particularly useful in this scenario.

Intraoperative TEE has become a valuable tool in the assessment of lung transplant patients. A comprehensive TEE examination should be performed after induction of anesthesia with attention focused on biventricular function, presence of valvular regurgitation, patent foramen ovale or atrial septal

defect, and pulse wave Doppler flow patterns in the pulmonary veins. Significant RV dysfunction, valvular regurgitation, or intra-atrial shunt may lead to the decision to utilize CPB. TEE can be helpful in monitoring RV function during initial clamping of the PA; acute deterioration of RV function is an indication for the institution of CPB. After reperfusion, another TEE examination should be performed. Pulmonary vein anastomotic obstruction can be diagnosed with careful Doppler examination of the pulmonary venous inflow (see [Chapter 27](#)). Because this condition leads to acute graft failure, rapid diagnosis and treatment in the OR is essential.

At the completion of the procedure, the patient should be evaluated for exchange of the double-lumen endotracheal tube to a large (8-mm internal diameter or larger) single-lumen tube. The large diameter facilitates postoperative bronchopulmonary toilet and diagnostic bronchoscopy, as needed. Significant oropharyngeal edema, high PEEP requirement, or need for differential lung ventilation justifies leaving the double-lumen tube in place postoperatively to allow improvement in clinical status prior to endotracheal tube exchange.

## **Double-lung Transplantation**

Bilateral lung transplant is performed in the supine position, using a “clamshell” incision. The arms can be suspended on a padded bar above the patient or tucked at the sides. If the arms are suspended, care must be taken to avoid stretching the brachial plexi. These cases can also be performed via midline sternotomy. *En bloc* double-lung transplantation requires CPB, and a single-lumen endotracheal tube is sufficient. Bilateral sequential transplantation requires lung isolation, preferably via a double-lumen endotracheal tube. Bilateral sequential transplantation is now the preferred procedure because a tracheal anastomosis is unnecessary, and there is less surgical bleeding. Most centers electively institute CPB for this procedure if preoperative pulmonary hypertension is present and urgent CPB if difficulties in oxygenation, ventilation, or RV function develop. Serial implantation implies longer ischemic time for the second lung, but this has not been shown to adversely affect outcome. In some institutions, sequential bilateral transplantation with CPB is performed using a double-lumen endobronchial tube, allowing immediate ventilation and oxygenation of the first transplanted lung while the second is being transplanted. In most institutions, the bronchial circulation is not re-established, so a transplanted lung on CPB does not receive oxygenated bronchial blood flow. Thus, ventilation of a newly transplanted lung with 50% oxygen, even during CPB, is advisable. The clamshell incision is extensive and can cause significant postoperative pain. Thoracic epidural may be very useful for managing postoperative pain.

## Pediatric Lung Transplantation

The Registry of the International Society for Heart and Lung Transplantation Pediatric Report was last published in 2015.<sup>185</sup> Pediatric lung transplantation has increased over the past 15 years, with adolescents undergoing the majority of the procedures. One hundred and twenty-four pediatric lung transplants were reported worldwide in 2013, compared to only 73 in 1999. The most common diagnoses are CF, congenital heart disease, and idiopathic pulmonary hypertension. Overall survival is similar for pediatric and adult populations. There now appear to be age-related survival differences, with infants doing better than adolescents, but overall, survival is improving. An evaluation in 2007 of patients with CF listed for and/or receiving lung transplantation showed that only 1% of the patients showed a survival benefit from surgery.<sup>186</sup> However, a more recent study was more promising, with 5-year survival after transplant of 67%. Regardless of mortality outcome, quality of life still appears improved by lung transplantation in patients with CF. Efforts to quantify quality of life are ongoing.<sup>174</sup> The role of lung transplantation in treatment of CF deserves further study to determine optimal age, pretransplant diagnosis, status, and firm indications. Most pediatric patients receive double-lung transplantation with CPB, with a single-lumen endotracheal tube. The clamshell incision is used. Central and arterial access is necessary for perioperative monitoring.

### *Primary Graft Dysfunction (PGD)*

The most common causes of acute transplanted lung failure are acute graft rejection, inadequate pulmonary venous drainage, and PGD. The etiology of PGD, a major cause of posttransplant morbidity and mortality, is multifactorial and complex.<sup>187,188</sup> PGD, defined as allograft dysfunction within 72 hours of transplantation, is graded on a scale of 0 to 3. Grade 3 is defined as  $\text{PaO}_2/\text{FiO}_2$  less than 200 with radiographic infiltrates consistent with pulmonary edema. Grade 3 PGD is associated with statistically decreased 30-day mortality.<sup>187</sup> Grades 1 and 2 are also associated with infiltrates, but are less severe, with  $\text{PaO}_2/\text{FiO}_2$  ratios greater than 300 and between 200 and 300, respectively. Grade 0 is essentially a normal lung, in which the  $\text{PaO}_2/\text{FiO}_2$  ratio is greater than 300 and there are no pulmonary infiltrates. Possible contributing factors for PGD include prolonged organ ischemia time with ischemia/reperfusion injury, advanced donor age, recipient pulmonary hypertension, and the use of CPB. Specific anesthetic management factors have not emerged as a risk factor for PGD. To date there are no specific data to support a link between transfusion and PGD, although an association has been suspected. However, data are limited on transfusion during lung

transplantation, in contradistinction to the data available on transfusion requirements during liver transplantation. Patients undergoing double-lung transplants or procedures with CPB or those with Eisenmenger syndrome or CF reportedly have increased transfusion requirements during lung transplantation. Further study is needed to determine whether transfusion negatively affects lung transplant outcomes. The transplant literature does not show a correlation between fluid management in the OR and outcome, although management of pulmonary transplant patients as if they have acute lung injury with a protective strategy as described earlier is recommended. Severe, life-threatening PGD has been successfully managed with extracorporeal membrane oxygenation (ECMO).<sup>189</sup>

### *Inhaled Nitric Oxide (iNO)*

iNO therapy may be used to decrease PVR and improve oxygenation (see [Chapter 38](#)). iNO has an extremely short duration of action in vivo, rapidly inactivated by reacting with heme, resulting in methemoglobin. Because iNO is preferentially delivered to ventilated areas, vascular relaxation in these areas leads to improved blood flow and hence improvements in ventilation-perfusion matching and oxygenation. Rapid inactivation of iNO in the pulmonary vasculature prevents its systemic distribution and avoids systemic vasodilatation and hypotension.

Some anesthesiologists use iNO routinely for lung transplantation,<sup>190</sup> whereas others believe its potential adverse side effects should lead to restriction of its use.<sup>191</sup> Proponents argue that use of iNO in the recipient, and possibly even the donor, takes advantage of immunomodulatory and antimicrobial activities of NO that reduce recipient lung injury.<sup>192</sup> Opponents argue that iNO use should be limited to the population at risk for needing CPB during lung transplantation and to patients with reperfusion injury. They cite risks of methemoglobinemia, NO-metabolite—related lung injury, and decreased sensitivity of exhaled NO monitoring as a diagnostic tool for acute lung rejection. Some have suggested a prophylactic role for iNO, but the decision to use iNO should be based on specific clinical circumstances.<sup>193</sup> A randomized clinical trial of 30 patients undergoing double-lung transplant at an institution with high usage of CPB showed no benefit of prophylactic iNO in prevention of pulmonary edema.<sup>194</sup>

NO may mediate other clinically beneficial effects. NO activates guanylate cyclase in platelets to attenuate platelet aggregation and adhesion.<sup>195</sup> iNO can decrease PVR, improve oxygenation, decrease inflammatory response to surgery or trauma, impede microbial growth, and have a hemodynamic effect limited only to the pulmonary system. Its use in successful management of lung transplant patients is well documented.<sup>196</sup>

## Heart–lung Transplant (Adult and Pediatric)

Heart–lung transplantation is the least common intrathoracic transplant procedure, with less than 40 per year currently being reported worldwide.<sup>173</sup> Bilateral sequential lung transplant has largely replaced heart–lung transplantation, and improved pharmacologic management of pulmonary hypertension and RV failure obviates the need for the heart–lung procedure. Because indications for lung transplantation have evolved to replace heart–lung transplant for diagnoses such as primary pulmonary hypertension and CF, congenital heart disease and idiopathic pulmonary hypertension are now the most common indications for heart–lung transplantation.<sup>173</sup> Pediatric heart–lung transplantation is now very infrequent, with only 11 performed in 2013.<sup>185</sup> Anesthetic management of heart–lung transplant patients is similar to that of isolated heart or lung transplant patients. Because a tracheal anastomosis is performed, a single-lumen endotracheal tube is sufficient. The endotracheal tube is either removed or withdrawn above the suture line during CPB to facilitate the tracheal anastomosis. Inotropes may be needed for RV dysfunction immediately after bypass. Pulmonary reperfusion injury can also occur, requiring management of acute lung injury as described for lung transplantation.

## Heart Transplantation

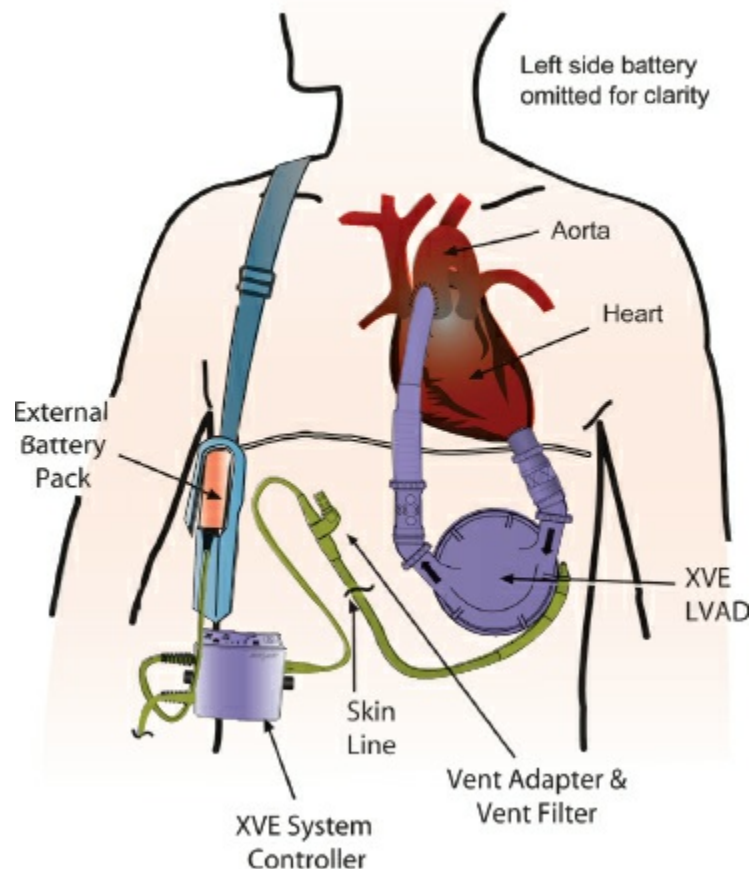

Since Christian Barnard performed the first successful heart transplant in South Africa in 1967,<sup>197</sup> the procedure has become accepted practice for treatment of heart failure recalcitrant to medical therapy. Over 50,000 individuals have received heart transplants in the United States since 1988.<sup>198</sup> Unfortunately, more than 8,000 patients died while waiting for a donor during that time. Currently, more than 2,600 patients await heart transplants. Overall 1-year survival has improved from 74% in the early 1980s to 86% currently. The 5-year survival for primary transplantation is currently 72%. As our population ages and the use of cardiac transplantation and mechanical assist devices expands, increasing numbers of patients will present for transplantation, management of previous transplantation, or mechanical assist devices. In this section, anesthetic considerations for patients undergoing heart transplantation, as well as those with left ventricular assist devices (LVADs), are discussed.

### *Left Ventricular Assist Devices*

Survival rates for patients with congestive heart failure (CHF) remain **11** poor, despite improvements in medical therapy. One-year survival has

been reported to be approximately 63%, with 5-year survival as low as 20%.<sup>199</sup> Patients with end-stage heart failure who have mechanical cardiac support experience better survival and quality of life than those receiving medical management alone.<sup>200</sup> Anesthesiologists often see heart failure patients for both initial device placement and perioperative management of LVADs. LVADs assist the heart by withdrawing blood from the failing left ventricle (inflow cannula in the left ventricle or left atrium) and pumping it into the aorta or femoral artery (outflow cannula) (Fig. 52-3). LVADs vary in significant ways, and it is important to understand the specifics of the LVAD being used. Variations include flow pattern (pulsatile or nonpulsatile), requirement for anticoagulation (none, aspirin, warfarin), filling pattern, power source (battery or alternating current), potential for electromagnetic interference, and impact of dysrhythmias and defibrillation on the device. Acetone-containing products and Betadine should be avoided near these devices because they can damage the cannula or drive lines.

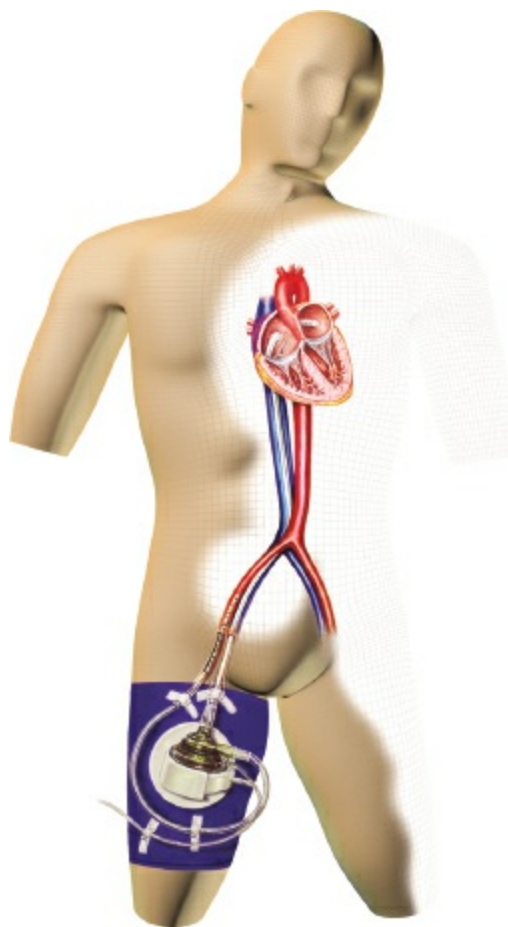

LVAD pump flow is affected by intravascular volume and afterload. Failure to maintain adequate preload or afterload will result in decreased LVAD flow and hypotension because of low functional cardiac output (LVAD flow plus native heart cardiac output). An individual familiar with the device should be present to assist with management and troubleshooting if the clinician does not have sufficient experience. Patients presenting for initial device placement are in various stages of decompensated heart failure and require advanced monitoring, often with an arterial line and either PA or central venous catheter. TEE is indicated to evaluate for valve pathologies and intracardiac shunts, which may complicate LVAD placement. TEE examination is repeated after device placement to confirm proper cannula placement and flow. These patients will likely need inotropic support until institution of CPB and device placement. Many clinicians advocate standard placement of TEE with central venous access. These facilitate perioperative management of volume status, assessment of forward flow, and administration of vasoactive medications.

**Figure 52-3** Implanted HeartMate XVE, an intracorporeal left ventricular assist device. An inflow cannula is in the left ventricle, and an outflow cannula is in the aorta. The prosthetic left ventricle (pump) propels blood from the left ventricle to the aorta, offloading some or all of the demand on the left ventricle. The cannulas and pump are within the patient, and the controller, drive line, and battery pack are external. (Courtesy of Thoratec Corp, Pleasanton, CA.)

LVADs are placed for rescue therapy, bridge to transplantation, and destination therapy. Most patients will show significant hemodynamic improvement with an LVAD, but some patients require support of the right ventricle via a right ventricular assist device or biventricular assist device. The TandemHeart (Cardiac Assist Inc., Pittsburgh, PA) is a percutaneous ventricular assist device usually placed in a cardiac catheterization laboratory. The indications are short-term hemodynamic support for patients in cardiogenic shock or temporary support of a patient undergoing high-risk percutaneous intervention. The left-sided cannula is advanced from the femoral vein into the left atrium by puncturing the interatrial septum (Fig. 52-4). The Abiomed options (Abiomed, Inc., Danvers, MA) are commonly used for postcardiotomy failure via direct cannulation. The chest is left open, and the cannulas can be left in place for up to 2 weeks. The Thoratec device (Thoratec Corporation, Pleasanton, CA) is an implanted device that can be used for long-term biventricular support. The HeartMate devices (Thoratec)

are currently approved as therapy for patients with intractable heart failure who are not candidates for transplantation (destination therapy).

**Figure 52-4** TandemHeart percutaneous ventricular assist device. Cannulas are placed percutaneously into the femoral vein and femoral artery, and the drive mechanism and power supply are external. The femoral venous line is placed across the atrial septum so as to drain the left atrium. Minimally invasive placement is a significant advantage of this system. (Courtesy TandemLife, Inc.)

The most common conditions leading to transplantation are ischemic and idiopathic cardiomyopathies. Less common diagnoses include valvular heart disease, retransplant, and congenital heart disease.<sup>198</sup> Because of the limited availability of donor organs, technologies that can extend the life of patients awaiting donors have been developed. For transplants performed in 2009 to 2013, 40% of recipients were receiving intravenous inotropic support and 49% were receiving mechanical circulatory support.<sup>198</sup> In addition, **12** cardiac resynchronization therapy (CRT) has been shown to reduce morbidity and mortality in patients with LV systolic dysfunction, prolonged QRS duration, and New York Heart Association Class III or IV heart failure despite optimal pharmacologic therapy.<sup>201</sup> Many patients presenting for heart transplantation have had a CRT device placed as part of their management, frequently with implantable cardioverter–defibrillator capability as well.

Totally implantable artificial hearts are not currently in clinical use; however, their development is an active area of research.

## **Recipient Selection**

Pharmacologic options for management of CHF include angiotensin-converting enzyme inhibitors,  $\beta$ -blockers, diuretics, and digoxin. CRT can also improve symptoms, exercise tolerance, and quality of life in properly selected patients,<sup>202</sup> as well as survival.<sup>203,204</sup> More than 5 million Americans have CHF, with the incidence increasing with age. Of these, only about 3,000 per year are listed for heart transplantation.

Consensus guidelines for selection of patients for heart transplantation were published in 2006 and updated in 2016.<sup>205,206</sup> Patients referred for transplant evaluation should have Class III or IV heart failure despite optimal medical therapy. Surgical correction of coronary artery disease or valvular heart disease should be considered prior to listing, and patients with severe mitral regurgitation and low ejection fraction should be considered for mitral valve repair instead of transplantation. Although most candidates have severe LV systolic dysfunction, transplantation is occasionally indicated for refractory angina, unmanageable dysrhythmias, or diastolic heart failure.

Prognosis in patients with CHF has been linked to functional capacity. Functional capacity can be assessed using exercise testing, and oxygen uptake ( $\text{VO}_2$ ) during maximal exercise is a useful method to determine functional capacity.<sup>207</sup> In patients on a stable medical regimen, maximal  $\text{VO}_2$  less than 10 mL/kg/min is associated with a poor prognosis. Patients with  $\text{VO}_2$  more than 10 mL/kg/min have a better 1-year prognosis with medical therapy than transplantation.

Severe, irreversible pulmonary hypertension is a contraindication to transplant because of subsequent RV failure in the transplanted heart. Right heart catheterization is performed to determine transpulmonary gradient (the difference between mean PA pressure and pulmonary capillary wedge pressure) and pulmonary arteriolar resistance. Transpulmonary gradient above 12 mmHg indicates significant pathology. Pulmonary arteriolar resistance (the ratio of transpulmonary gradient to cardiac output, expressed as Wood units) greater than 2.5 also indicates a high risk of perioperative RV failure. Patients with elevated transpulmonary gradient or pulmonary arteriolar resistance require a trial with nitroprusside, prostacyclin, dobutamine, or milrinone in an attempt to decrease pulmonary resistance. Patients unresponsive to these therapies are often considered too high a risk for transplantation and may be candidates for LVAD or biventricular assist device insertion as definitive, destination therapy.

Contraindications to cardiac transplantation include some significant

noncardiac diseases.<sup>206</sup> Because immunosuppressive agents have renal and hepatic side effects, the presence of intrinsic renal or hepatic disease increases perioperative risk of organ dysfunction or failure. Some patients with multiorgan disease can be considered for combined heart–kidney or heart–liver transplantation. Patients with forced expiratory volume in 1 second (FEV<sub>1</sub>) less than 50% predicted despite optimal management of CHF are at increased risk for ventilatory failure and respiratory infections posttransplant. The presence of significant atherosclerosis is a contraindication because of the increased perioperative risk of atheroembolic complications.

### *Preanesthetic Considerations*

Donor heart function worsens with donor cold ischemia times above 6 hours. For this reason, timing of transplantation depends on when the donor surgery can be done, frequently during night hours. Preoperative evaluation and preparation of the patient must be expeditious. Close communication between the donor and recipient teams facilitates optimal use of donor organs while minimizing ischemia times. Ideally, the recipient heart is excised as soon as the donor heart arrives at the recipient hospital. Induction of anesthesia and surgical incision of the recipient begin when the donor team has evaluated the donor and made the final determination that the organ is acceptable. Timing decisions are based on distance and time necessary to transport the donor organ, as well as time it will take to prepare the recipient. History of prior sternotomy or difficult airway can increase recipient preparation time.

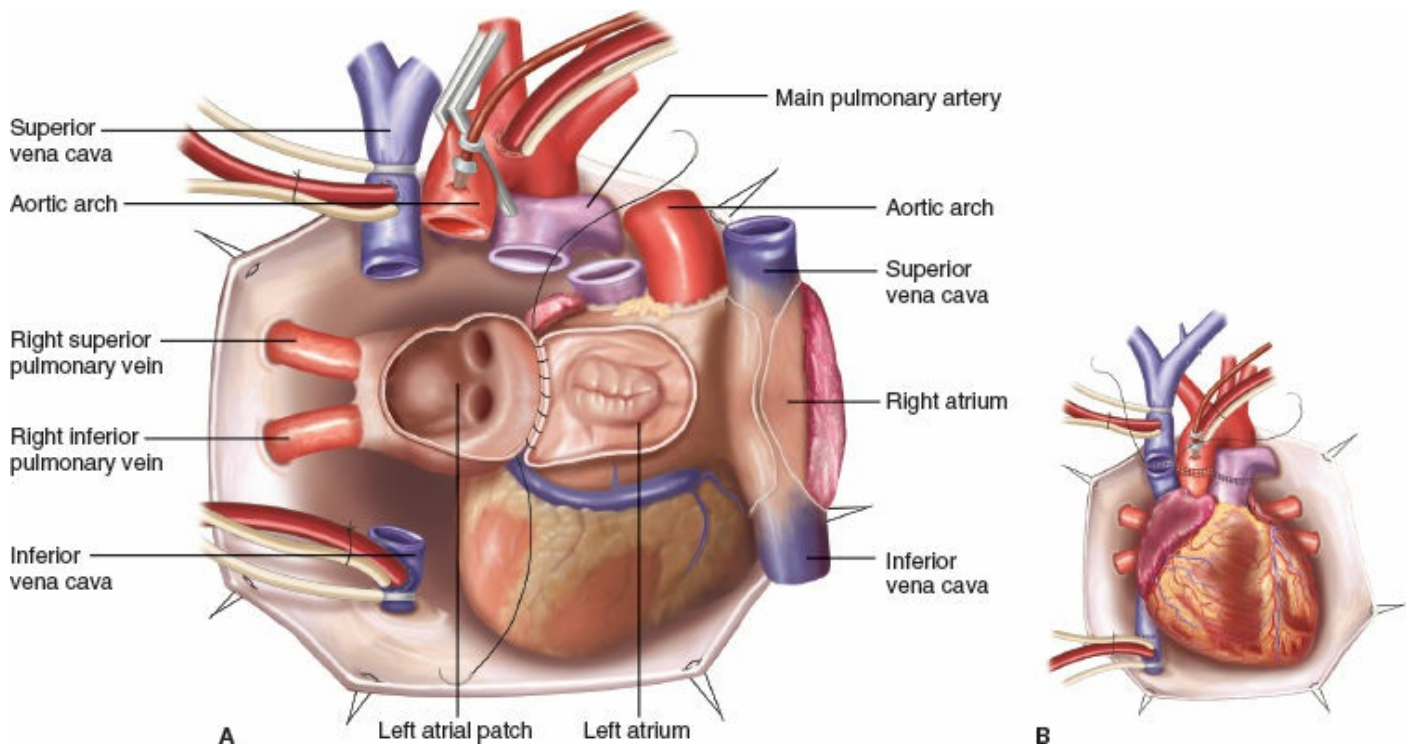

When evaluating the recipient, a few issues need special attention: nothing by mouth status, level of cardiovascular support (inotropic infusions, chronic medications for heart failure, presence of LVAD), and presence of hemodynamic monitoring lines or antiarrhythmic devices, such as pacemaker, CRT device, or defibrillator. Antiarrhythmic devices need to be interrogated and reprogrammed to a mode that will not be affected by electrocautery interference. Because of the emergent nature of these cases, it is common that the patient has recently eaten, and rapid-sequence induction may be necessary. Patients are frequently taking angiotensin-converting enzyme inhibitors that could increase the risk of intraoperative hypotension, or anticoagulants such as clopidogrel, aspirin, Coumadin, or rivaraxaban that can increase risk of bleeding. Vasopressin infusions can be beneficial for treatment of angiotensin-converting enzyme inhibitor–induced hypotension, and plasma should be ordered if the INR is elevated. Coagulation function testing with TEG and platelet mapping may be useful in managing coagulation status. If cardiac status has deteriorated recently, the patient may be receiving infusions of inotropes, such as dobutamine or milrinone. On occasion, patients are receiving chronic dobutamine or milrinone therapy as outpatients. If

patients have had multiple central lines, ultrasound evaluation of the central vessels may be helpful to determine vessel patency. Recent chest radiographs and laboratory studies must be reviewed to assess pulmonary, hepatic, and renal compromise associated with CHF.

Many anesthetic management issues related to the heart transplant patient are similar to those for open-heart surgeries (see [Chapter 39](#)). The notable differences are strictest attention to sterility and immunosuppression, poorer hemodynamic status of transplant candidates, and issues related to early donor heart function and denervation. The surgical team will request antibiotics specific to donor and recipient infection patterns, and immunosuppressive medications are often given prior to incision.

Placement of a PAC is favored by many centers. Invasive arterial pressure monitoring should be used during anesthetic induction. Large-bore intravenous access, central or peripheral, is necessary for administration of resuscitation medications and volume during induction. Inotropes should be readily available prior to induction. Dobutamine, epinephrine, milrinone, norepinephrine, dopamine, vasopressin, and phenylephrine have all been used effectively in the perioperative management of heart transplant patients.

Presence of an LVAD or prior sternotomy increases the length and the risks associated with the procedure. Where possible, old medical records should be reviewed to determine if the patient had prior aprotinin exposure. EACA or tranexamic acid can be used as an antifibrinolytic agent to decrease perioperative bleeding. Packed red blood cells should be immediately available prior to incision, particularly in repeat sternotomy. CMV status of the donor and recipient is needed to determine whether CMV-negative packed red blood cells should be ordered. Availability of plasma, platelets, and cryoprecipitate should be confirmed at the start of the procedure.

**Figure 52-5** Anatomy of bicaval orthotopic heart transplant. **A:** A recipient left atrial patch including the four pulmonary veins remains in the recipient. Anastomoses are performed at the superior and inferior venae cavae, aorta, pulmonary artery, and left atrium. **B:** The completed transplantation. (Modified from Lima B, Gonzalez-Stawinski GV. Heart transplants: bicaval versus biatrial techniques. In: Grover FL, Mack MJ, eds. *Master Techniques in Surgery: Cardiac Surgery*. Philadelphia, PA: Wolters Kluwer; 2016:409–418.)

### Intraoperative Management

Anesthetic induction in patients with poor ventricular function can be complicated by hemodynamic instability. Instituting or increasing inotrope infusions can be beneficial in these cases. Choice of anesthetic technique should be focused on minimizing cardiovascular instability and complications. High-dose narcotic techniques have been used for induction and management of cardiac transplant patients for many years with good results.<sup>208</sup> Balanced anesthetic techniques, using lower doses of narcotics, and inhalation anesthetics, can be used,<sup>209</sup> and early extubation using ultra fast-track protocols has been successful.<sup>210</sup> Neuromuscular blockade with a nondepolarizing agent is recommended. Hypotension may not respond to ephedrine or phenylephrine, and other inotropes and vasopressors such as epinephrine and vasopressin should be instituted rapidly in such cases.

A comprehensive TEE examination should be performed after induction of anesthesia and after weaning from CPB. The native heart can be monitored prior to CPB for changes in ventricular function or an increase in valvular regurgitation. Early diagnosis of deterioration can facilitate rapid therapy and hemodynamic stability. The risk of intracardiac thrombus is increased in the

recipient heart. The left atrium and ventricle should be carefully examined. Surgical manipulation of the heart is minimized prior to aortic cross-clamping if thrombus is noted.

Median sternotomy is performed for orthotopic heart transplantation. After initiation of CPB, the recipient heart is excised, except for the left atrial tissue encompassing the pulmonary veins. In the classic biatrial approach, the atria are transected at the grooves, and there are right and left atrial anastomoses, along with PA and aortic anastomoses. The bicaval approach (Fig. 52-5), in which anastomoses are created in the superior and inferior vena cavae rather than the right atrium, is gaining popularity because it preserves tricuspid valve function and normal conduction in the right atrium.<sup>211</sup> A meta-analysis revealed benefits of the bicaval technique, so this technique is now performed frequently.<sup>212</sup>

Heparin dosing is similar to that for other CPB procedures. Cannulation of the aorta is performed high along the ascending aorta, near the aortic arch. The superior and inferior venae cavae are cannulated individually. By encircling the cavae with tourniquets, all blood flow is directed through the cannula in to the bypass circuit, and the surgical field is bloodless. Prior to resection of the native heart, the PAC should be withdrawn from the surgical field. The catheter can be readvanced after removal of the superior cava cannula. Maintenance of CPB and weaning from CPB are associated with the same issues as for other cardiac surgical procedures. Ischemic time for the donor heart starts with aortic cross-clamping during the harvest and ends with removal of the cross-clamp from the recipient aorta. Air should be evacuated prior to weaning from CPB.

Prior to weaning from CPB, the heart is reevaluated with TEE, with attention to ventricular and valvular function. Intracardiac shunts should be ruled out. Because the donor heart is denervated, normal physiologic feedback controlling inotropy and chronotropy are lost. Isoproterenol is used frequently for its direct effects on cardiac  $\beta$ -receptors to increase graft heart rate. Use of temporary epicardial pacing is sometimes needed until isoproterenol has had adequate time to reach maximal effect. (Vasoactive drug effects in heart transplant recipients are reviewed in Table 52-9.) Residual atrial tissue, in the case of biatrial technique, may continue to have electrical activity, seen clinically as two P waves on ECG (one from native atrial tissue, one from donor). The native P wave has no physiologic effects on the donor heart.

**Table 52-9** Effect of Denervation on Cardiac Pharmacology

Substance	Effect on Recipient	Mechanism
Digitalis	Normal increase of contractility, minimal effect on atrioventricular node	Direct myocardial effect, denervation
Atropine	None	Denervation
Adrenaline	Increased contractility Increased chronotropy	Denervation hypersensitivity
Noradrenaline	Increased contractility Increased chronotropy	Denervation No neuronal uptake
Isoproterenol	Normal increase in contractility, normal increase in chronotropy	
Quinidine	No vagolytic effect	Denervation
Verapamil	Atrioventricular block	Direct effect
Nifedipine	No reflex tachycardia	Denervation
Hydralazine	No reflex tachycardia	Denervation
$\beta$ -Blocker	Increased antagonist effect	Denervation

Reprinted with permission from Deng MC. Cardiac transplantation. *Heart*. 2002;287:177.

Inotrope selection for weaning from CPB is similar to other cardiac surgical procedures (see [Chapter 39](#)). Special consideration should be given to recipients with preoperative pulmonary hypertension, donor hearts with long ischemic times, or donor hearts that are deemed marginal. The risk of donor right heart failure is increased in these cases. The donor right heart is not accustomed to high pulmonary resistance and may fail acutely. Therapy for graft right heart failure is similar to therapy for right heart failure in other cardiac cases. The goal is to improve contractility and decrease PVR. If intravenous agents do not facilitate weaning from CPB, iNO and inhaled prostacyclin (iloprost) have been shown to be beneficial in this population.<sup>213–216</sup>

### **Pediatric Heart Transplantation**

UNOS reports over 5,000 pediatric heart transplants performed since 1988; 60% are performed in children less than 1 year or over 11 years old. The pretransplant diagnosis was congenital heart disease or idiopathic/viral cardiomyopathy in 75% of these patients, with retransplantation an increasing indication. The annual volume of pediatric cardiac transplantations reported to the International Society of Heart and Lung Transplantation is increasing, with a record 577 reported in 2013.<sup>217</sup> ECMO is used as a bridge to transplant at some centers, although it is acknowledged to be only a short-term option.<sup>218</sup> Even though ECMO is the therapeutic choice for circulatory support in most pediatric cardiac patients, some pediatric patients (mostly adolescents) benefit from placement of a ventricular assist device.<sup>219</sup>

Preoperative evaluation focuses on cardiopulmonary status and the particulars of the cardiac physiology in congenital heart disease patients (see [Chapter 39](#)). Palliative procedures may have been performed prior to transplant, and reoperation increases surgical risk. Central venous catheters

and intra-arterial catheters are placed routinely, usually after induction. After an inhalation induction, anesthetic management frequently involves high-dose narcotics and intermittent benzodiazepines.

Marginal donors are, not surprisingly, also being used for pediatric heart grafts, including size mismatches, high donor inotrope requirement, prolonged ischemic time, and ABO mismatch.<sup>220</sup> Although ABO-incompatible transplantation is contraindicated in the adult population, it is more successful in infant recipients.<sup>221,222</sup> Hyperacute rejection does not occur because of the immaturity of the immune system and absence of antibodies to various antigens, including blood group antigens. For ABO mismatched grafts, recipient isohemagglutinin titers are obtained pretransplantation, then plasma exchange is performed during CPB. Four-year follow-up data show similar morbidity and mortality compared with ABO-compatible recipients. Furthermore, waiting list survival is improved because of expansion of the donor pool.

## Management of the Transplant Patient for Nontransplant Surgery

As the population of transplant recipients increases, the incidence of elective or emergent nontransplant surgery becomes more commonplace. These patients cannot always return to the transplant center for surgery, so anesthesiologists outside transplant centers will encounter these patients. For solid-organ recipients, evaluation of patients is centered on the function of the grafted organ. In renal and liver transplant patients, the level of renal dysfunction will often determine the choice of drugs such as antibiotics, particularly neuromuscular blockers, and dose modification of drugs is dependent on renal excretion. [Table 52-4](#) lists medications that can cause renal dysfunction when administered to a patient receiving immunosuppressive agents. A major consideration for renal transplant recipients is maintenance of renal perfusion with adequate volume replacement. Thus, CVP monitoring is useful for preventing prerenal damage to transplanted kidneys, but CVP lines must be placed using strict aseptic technique. It is important to note that signs of infection may be masked in transplant patients. Failing, rejecting, or reinfected liver grafts are often accompanied by deterioration of renal function. Protection of the kidneys is a central part of anesthesia plans, and CVP or TEE is useful to guide fluid replacement, especially in cases where large fluid shifts are anticipated.

**13** For all transplant recipients, antibiotic, antiviral, antifungal, and immune suppression regimens should be disrupted as little as possible in the perioperative period. The types of infection to which transplant recipients are susceptible change over time, with donor-derived and hospital-acquired

infections predominating in the first posttransplant month.<sup>223</sup> Infections acquired by transplant patients in months 2 to 6 versus later after transplantation are also distinct, and these patterns should guide surgical prophylaxis and perioperative diagnostic procedures. Infectious disease specialists are important consultants for preoperative transplant patients.

Complications of immune suppression are reviewed in [Table 52-4](#). Significant intraoperative fluid shifts can cause an acute decrease in cyclosporine or tacrolimus blood levels. In these cases, consideration should be given to repeat testing of drug levels during the day of surgery. Nonsteroidal anti-inflammatory medications should be avoided for a number of reasons. First, many patients have underlying renal dysfunction related to immunosuppressive agents. Second, the risk of gastrointestinal hemorrhage is increased in patients already at risk for gastritis from chronic steroids.

Patients who present for surgery with signs of acute rejection or infection may benefit from delay of surgery to optimize their status. Both rejection and infection in the face of surgery are associated with increased risk of morbidity and mortality. Regional and general anesthetic techniques have been used successfully in posttransplant patients. In addition to the standard American Society of Anesthesiology monitors, invasive monitors should be used if warranted based on surgical procedure and general health status of the patient. Invasive monitoring is not indicated solely on the basis of prior transplantation. Nasal intubation should be avoided because of the potential risk for infection presented by nasal flora.

Virtually all liver diseases can recur in grafted livers, including autoimmune diseases, fatty liver, and hepatitis C. The degree of liver dysfunction from recurrent disease should be evaluated by hepatologists and by using standard laboratory tests.

For lung transplant recipients with a tracheal anastomosis, denervation has occurred below the level of the suture line, and the cough reflex is diminished or absent. These patients are at increased risk of retained secretions and pneumonia and have an increased airway hyperreactivity and bronchospasm. Because most lung transplants are now being done with bronchial instead of tracheal anastomoses, the risk of tracheal suture line stenosis or disruption with manipulation is markedly diminished. Advantages of regional anesthetic techniques in lung transplant patients include minimization of airway manipulation and decreased infectious risk. Comparison of preoperative PFT, arterial blood gas, and chest x-ray results with prior studies can help diagnose acute infection or rejection. Significant decreases in forced expiratory volume in 1 second, vital capacity, and total lung capacity and an obstructive pattern may indicate acute rejection. Arterial blood gas in the presence of rejection will show an increased alveolar—arterial gradient from stable baseline gases, along with perihilar infiltration on chest x-ray. However, rejection and

infection can be difficult to distinguish clinically. If the patient is suspected of having an active pulmonary process, consultation with Pulmonary Medicine for a possible diagnostic bronchoscopy should be considered prior to surgery.

Transplanted hearts are denervated, affecting perioperative management significantly. The transplanted heart cannot respond to indirect acting agents, such as ephedrine and even dopamine, or to peripheral attempts to induce hemodynamic changes, such as carotid massage, Valsalva maneuver, or laryngoscopy.  $\beta$ -Receptor effects of epinephrine and norepinephrine are exaggerated in heart transplant recipients (versus  $\alpha$  effects). Isoproterenol is the mainstay of chronotropic therapy in these patients. ECG analysis may show two P waves, one from the native atrium and one from the implanted atrium. The native P wave will not conduct to the implanted heart, and these nonconducted P waves should not be confused with complete heart block. Isoproterenol should be available as an inotrope and a chronotrope. Dobutamine can also be helpful; norepinephrine and epinephrine should be reserved for refractory cardiogenic shock. Because the denervated heart does not reflexively compensate for hemodynamic changes induced by regional anesthetics, general anesthesia is usually preferred.

Preoperative evaluation of heart transplant recipients should focus on cardiac functional status. Significant rejection will present with symptoms of heart failure. All heart transplant patients should be evaluated with ECG and transthoracic echocardiography prior to surgery. New findings should be discussed with the cardiology consultant to determine need for stress testing or myocardial biopsy. Invasive monitors should be placed only when warranted by the clinical status and surgical procedure. Use of TEE, CVP, or minimally invasive cardiac output monitoring such as esophageal Doppler or arterial pulse wave cardiac output can be helpful in managing fluids and inotropic support.

# 53 Trauma and Burns

LEVON M. CAPAN • SANFORD M. MILLER • COREY SCHER

## Initial Evaluation and Resuscitation

- Airway Evaluation and Intervention
- Management of Breathing Abnormalities
- Management of Shock

## Early Management of Specific Injuries

- Head Injury
- Spine and Spinal Cord Injury
- Neck Injury
- Chest Injury
- Abdominal and Pelvic Injuries
- Extremity Injuries
- Burns

## Operative Management

- Monitoring
- Anesthetic and Adjunct Drugs
- Management of Intraoperative Complications

## Early Postoperative Considerations

- Ventilatory Support
- Acute Kidney Injury
- Abdominal Compartment Syndrome
- Thromboembolism

## KEY POINTS

- 1 Airway management is tailored to the type of injury, the nature and degree of airway compromise, and the patient's hemodynamic and oxygenation status.
- 2 Generally diagnosis of suspected cervical spine injury is reliably done for most patients by thin cut multidetector computed tomography scanning.
- 3 Generally it is reasonable to allow some relaxation of the manual inline stabilization of the cervical spine to improve the glottic view when visualization of the larynx is restricted.
- 4 A linear correlation exists between the rib score and development of pneumonia, acute respiratory failure, and need for tracheostomy.
- 5 A systolic blood pressure of 110 mmHg is accepted as a prehospital triage

threshold for delivery to a Level I trauma center for trauma patients older than 65 years; systolic blood pressure of 90 mmHg remains a triage threshold for young patients.

- 6 The method of resuscitation of the hemorrhaging patient has changed since the Iraq and Afghanistan wars. The concept of damage control resuscitation has replaced the classic crystalloid resuscitation.
- 7 Damage control resuscitation consists of brief permissive hypotension; rapid control of any bleeding source; minimal crystalloid infusion; early administration of plasma and other blood products in a balanced ratio (preferably 1:1:1) of packed red blood cells, plasma, and platelets by activation of the massive transfusion protocol; early administration of tranexamic acid; and, if indicated, damage control surgery to control bleeding and sources of contamination. Definitive surgery is deferred until after normalization of the patient's physiologic condition.
- 8 Management strategies in the diagnosis and treatment of blunt aortic injuries have gone through major changes in the past 10 years with substantially improved early outcomes. In the area of diagnosis, computed tomography angiography replaced aortography, and, in the area of treatment, endovascular stenting practically replaced open repair, although in grade 3 or 4 blunt aortic injuries, open repair in the form of mostly "clamp and saw" technique is done.
- 9 Clinically, burn injury is manifested in two phases: burn shock, which is characterized by continued plasma loss from the intravascular space into burned, and often into intact, tissues for about the first day or two after injury, and the subsequent hypermetabolic or hyperdynamic phase, which may last for months.
- 10 In burn-injured patients, intravascular volume should be restored with utmost care to prevent excessive edema formation in both damaged and intact tissues which results from the generalized increase in capillary permeability caused by the injury. Edema from overaggressive resuscitation has many deleterious and potentially life-threatening effects.
- 11 Of the many resuscitation formulas available, the Parkland (Baxter) and modified Brooke formulas are tailored to the clinical condition of the patient and are accepted in most centers. Parkland formula uses crystalloid whereas Brooke formula uses combination of crystalloid and colloid during the first 24 hours. The addition of glucose is not necessary except in children, especially those weighing less than 20 kg. Albumin 5% may be administered after the first day following injury at a rate of 0.3, 0.4, or 0.5 mL/kg/24 hours for burns of 30% to 50%, 50% to 70%, or 70% to 100% of total body surface area, respectively. These formulas are guidelines only, and none can be expected to provide adequate

restoration of intravascular volume in all burn victims, especially small children and patients with inhalation injuries.

- 12 Traditionally, monitoring of fluid therapy for burn injury is limited to hourly urine output, heart rate, systemic blood pressure, and base deficit. Indeed, there is some evidence to suggest that hourly monitoring of urine output as an end point of resuscitation compared to sophisticated hemodynamic monitoring provides similar outcomes in terms of mortality, organ function, length of hospital or intensive care stay, duration of mechanical ventilation, and burn-related complications such as pulmonary edema, compartment syndromes, or infection.
- 13 The transthoracic echocardiography (TTE) technique most commonly used in the trauma setting involves obtaining images through the subcostal long axis, subcostal inferior vena cava, parasternal long axis, parasternal short axis, and apical four-chamber windows. Placement of a phased-array, low-frequency (5 to 2 MHz) probe in these locations provides ideal views that are sufficient to inform the clinician of an underlying hemodynamic problem. TTE can be used in the emergency department, operating room, or intensive care unit and provides rapid information about the etiology of hypotension or other hemodynamic complications.
- 14 Unrecognized hypoperfusion may lead to splanchnic ischemia with resulting acidosis in the intestinal wall, permitting the passage of luminal microorganisms into the circulation and release of inflammatory mediators, causing sepsis and multiorgan failure. Base deficit and blood lactate level are considered acceptable markers of organ hypoperfusion in the *apparently* resuscitated patient and may be used intraoperatively to set the optimal end points of resuscitation.
- 15 Although trauma center laboratories cannot provide results of the standard coagulation tests rapidly, at least international normalized ratio can be monitored with a point-of-care device and provide some information. Thromboelastography and rotation transmission electron microscopy are point-of-care devices that provide a relatively rapid, comprehensive, and quantitative graphic evaluation of clotting function.
- 16 Anesthetic and adjunct drugs for general anesthesia need to be tailored to five major clinical conditions: airway compromise, hypovolemia, head or open eye injuries, cardiac injury, and burns. The varying contribution of these conditions to the clinical picture of a given patient necessitates priority-oriented planning.
- 17 Reducing or eliminating anesthesia to avoid abolishing the hemodynamic balance in hypovolemic patients is a natural and often utilized practice, especially when permissive hypotension, as part of damage control resuscitation, to limit bleeding is employed. This approach provides high

pressure and low flow to the organs. Another concept, aggressive titrated administration of anesthetics and blood products to produce a high-flow and low-pressure hemodynamic state with vasodilation to improve organ flow and oxygenation and to reduce fibrinolytic activity and inflammation, has been proposed recently. Further research will determine the validity of these approaches.

- 18 Component transfusion therapy, used universally in civilian trauma, is inferior to the whole blood transfusion practiced by the military. During the preparation of platelets and fresh frozen plasma, 100 mL of nonhemostatic anticoagulants is put in each bag. This additional fluid lowers factor levels by 20%. Similarly 100 mL of solution is added to packed red blood cells for storage injury protection in addition to 100 mL of anticoagulant. During massive transfusion protocol, each blood product administered dilutes out the other two blood product components. Fresh frozen plasma will decrease the hematocrit and platelet count. Likewise, packed red blood cells lower coagulation factors and platelet counts. Thus a 1:1:1 ratio cannot be compared with whole blood in its hemostatic ability.
- 19 Death is a much greater threat during emergency trauma surgery than it is in any other operative procedure. Approximately 0.7% of patients admitted for acute trauma die in the OR, accounting for approximately 8% of postinjury deaths. Uncontrollable bleeding is the cause of approximately 80% of intraoperative mortality; brain herniation and air embolism are the most common causes of death in the remaining patients.
- 20 Recent advances in the management of acute trauma and critical care, such as limiting crystalloid infusion, hemostatic resuscitation, damage control, and open abdomen strategies, have substantially decreased the incidence of postinjury abdominal compartment syndrome.

Injury is responsible for 9% of the total annual mortality (more than 5 million people) in the world.<sup>1</sup> Traffic accidents alone killed 1.24 million people in 2010; almost half of the victims were pedestrians (22%), cyclists (5%), and motorcyclists (23%).<sup>2</sup> The death rate was higher in low- (18.3/100,000) and middle-income (20.1/100,000) countries than in high-income (8.7/100,000) countries. Homicide alone resulted in 475,000 deaths (6.7/100,000) in 2012, and violence, encompassing homicides, suicides, and war-related injuries, is estimated to kill about 1.5 million people every year in the world, of whom the vast majority reside in low- and middle-income countries.<sup>3</sup>

According to the National Trauma Institute, more than 192,000 people died as a result of trauma in the United States in 2014.<sup>4</sup> The National Safety Council<sup>5</sup> reported that intentional injuries (suicide, homicide, and assault)

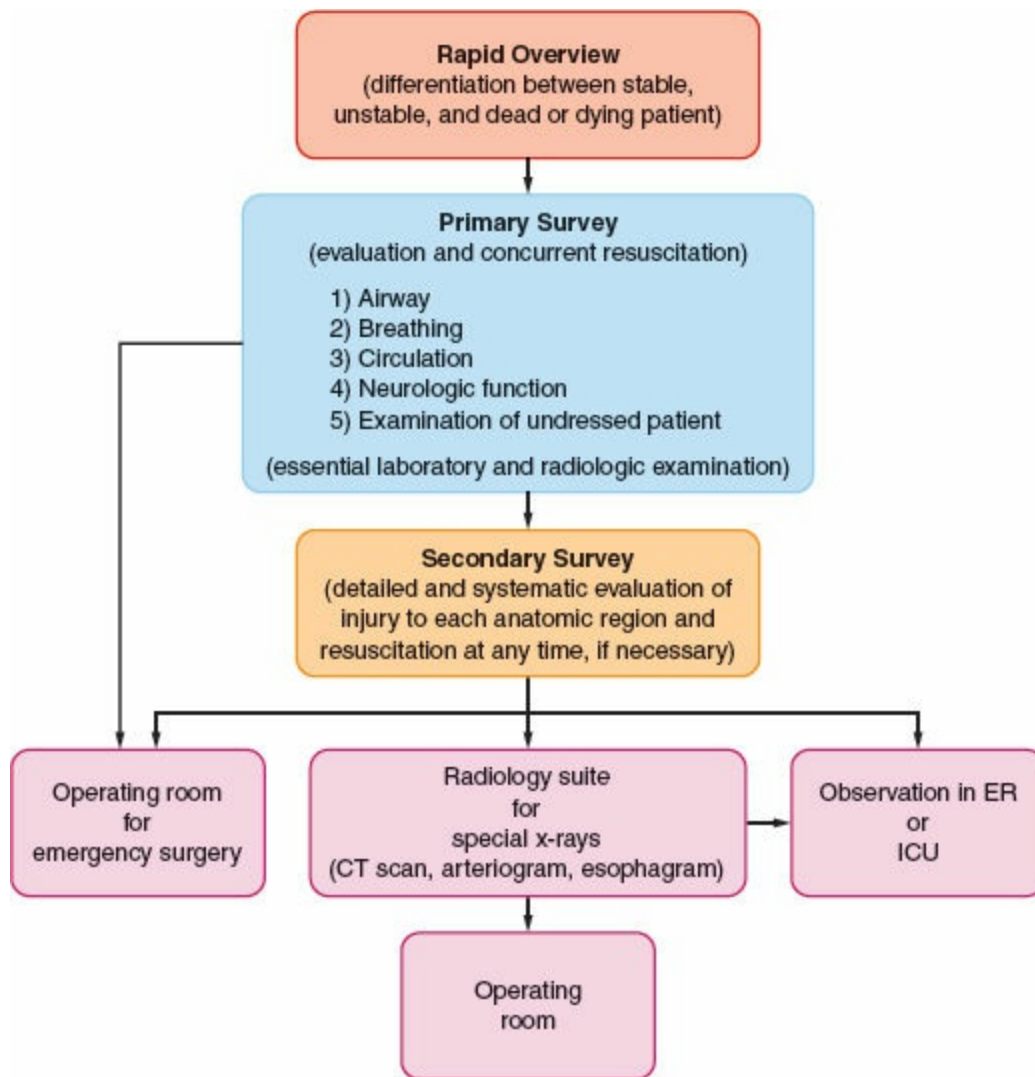

claimed 56,253 lives, unintentional (motor vehicle accidents, falls, drowning, poisoning, etc.) mortality claimed 126,438 lives, and additional undetermined injuries caused 4,773 deaths in 2011. Trauma especially afflicts young people; as of 2013 it was the leading cause of death for those aged between 1 and 46 years, and the third most common cause of death after cardiovascular diseases and cancer.<sup>4</sup> Unintentional injuries were the fifth, suicides the tenth, and assault the fifteenth leading causes of death overall.<sup>5</sup> Injuries account for 30% of life-years lost in the US, severely affecting productivity.<sup>4</sup> It has been estimated that worldwide for every trauma death there are dozens of cases of morbidity<sup>1</sup>; injury-related emergency department (ED) visits and hospital admissions reached 41 million and 2.3 million, respectively, in the US in 2014.<sup>4</sup> As such, the annual cost of trauma is estimated to be between \$585 and \$830 billion in the US. This includes the direct costs of fatal and nonfatal injuries, employer costs, vehicle damage, and fire losses.<sup>4,5</sup> As an interesting phenomenon, between 2000 and 2010 trauma deaths in the US increased out of proportion to population increase; population increased by 9.7%, whereas trauma-related deaths increased by 23%.<sup>6</sup> This has been attributed to the aging of the US baby boomer population, who, because of their age and pre-existing conditions, are more likely to die than younger patients. This trend may be more pronounced in the future with the increasing number of aging baby boomers.<sup>6</sup> Thus it is likely that the percentage of older trauma victims with pre-existing conditions coming to the operating room (OR) for surgery may increase.

Approximately 75% of hospital deaths from high-energy trauma such as motor vehicle accidents, falls, and gunshot or stab wounds occur within 48 hours after admission, most commonly from central nervous system (CNS), thoracic, abdominal, retroperitoneal, or vascular injuries.<sup>7</sup> CNS injury and hemorrhage are the most common causes of early trauma mortality.<sup>8</sup> Nearly one-third of these patients die within the first 4 hours after admission, representing the majority of OR trauma deaths. Of the hospital deaths, 5% to 10% occur between the third and seventh day of admission, usually from CNS injuries, and the rest in subsequent weeks, most commonly as a result of multiorgan failure.<sup>7</sup> Pulmonary thromboembolism and infectious complications may also contribute to mortality during this phase.<sup>7</sup> Interestingly, injuries caused by low-energy impacts, mainly from falls, usually in the elderly, also produce significant mortality from head injury and complications of skeletal injuries. Of these deaths, 20% occur within 48 hours, 32% after 3 to 7 days, and 48% after 7 days. Pre-existing conditions such as congestive heart failure, cirrhosis, warfarin intake, and/or  $\beta$ -blocker usage increase the mortality rate in trauma patients.<sup>9</sup>

## Initial Evaluation and Resuscitation

Major trauma presents with a wide variety of clinical conditions in terms of the type and intensity of injury to individual organ systems, the combination of multiple injured locations, and the resulting physiologic disturbances. The  strategy of initial management can be defined as a continuous, priority-driven process of patient assessment, resuscitation, and reassessment. After information has been obtained from paramedics about the mechanism of injury, possible injuries, vital signs at the field and during transport, prehospital treatment, and, if available, pre-existing medical disease(s), the general approach to evaluation of the acute trauma victim has three sequential components: rapid overview, primary survey, and secondary survey. Based on the findings of this evaluation, the patient is directed to an appropriate care unit for further management (Fig. 53-1). Resuscitation is initiated, if needed, at any time during this continuum. *Rapid overview* takes only a few seconds and is used to determine whether the patient is stable, unstable, dying, or dead. The *primary survey* involves rapid evaluation of functions that are crucial to survival. The ABCs of airway patency, breathing, and circulation are assessed. Then a brief neurologic examination is performed, and the patient is examined for any external injuries that might have been overlooked. A rapid limited transthoracic echocardiogram with parasternal long and short axis, apical, and subxiphoid views may give useful information about myocardial contractility, intravascular volume, and the presence of pericardial effusion at this point.<sup>10</sup>

**Figure 53-1** Clinical sequence for initial management of the major trauma patient. CT, computed tomography; ER, emergency room; ICU, intensive care unit.

The *secondary survey* involves a more elaborate systematic examination of the entire body to identify additional injuries. Radiography (focused assessment with sonography [FAST], computed tomography [CT], angiography, interventional radiologic procedures, magnetic resonance imaging [MRI]) and other diagnostic procedures may also be performed if the stability of the patient permits. With installation of multidetector CT scans (MDCT) in most Level 1 trauma centers, especially those in proximity to the ED, total body imaging is accomplished rapidly, helping substantially to direct subsequent surgical, interventional radiologic, or conservative management. In fact it has been emphasized that imaging by MDCT is most helpful in the unstable multiply injured patient.<sup>11</sup> Within this general framework the anesthesiologist, aside from managing the airway, contributes as part of the team for evaluation and resuscitation, while gathering information needed for possible future anesthetic management.

Injuries may be missed during initial evaluation and even during emergency surgery, resulting in significant pain, complications, residual disability, delay of treatment, or death.<sup>12</sup> Reported missed diagnoses include

cervical spine, thoracoabdominal, pelvic, nerve, and external soft tissue injuries and extremity fractures. Some of these injuries may present during administration of anesthesia, such as spinal cord damage in a patient with unrecognized cervical spine injury, massive intraoperative bleeding from an unrecognized thoracoabdominal injury during extremity surgery, or sudden intraoperative hypoxemia in a patient with unrecognized pneumothorax.

A *tertiary survey* within the first 24 hours after admission (which may include a period of anesthesia) can potentially diagnose the majority of clinically significant injuries missed during initial evaluation by the care team's repeating the primary and secondary examinations and reviewing the results of radiologic and laboratory testing.<sup>12</sup>

## **Airway Evaluation and Intervention**

**2** Airway evaluation involves the diagnosis of any trauma to the airway or surrounding tissues, recognition and anticipation of the respiratory consequences of these injuries, and prediction of the potential for exacerbation of these or other injuries by any contemplated airway management maneuvers. Airway evaluation should be made for mask ventilation, tracheal intubation, and placement of a surgical airway. In obese patients with excessive pretracheal tissues, the cricothyroid membrane may be difficult to identify. Use of ultrasound can help to locate the trachea in these circumstances.<sup>13</sup> Although nontraumatic causes of airway difficulty, such as pre-existing factors, may be present, only the management of trauma-related problems is discussed in this section. Generally, the American Society of Anesthesiologists's (ASA) difficult airway algorithm can be applied with certain modifications to various trauma airway management scenarios. For instance, cancellation of airway management when difficulty arises may not be an option. Likewise, awake rather than anesthetized intubation or a surgical airway from the outset may be the preferred technique in some situations. The ASA's difficult airway algorithm as modified for various **1** trauma conditions is available.<sup>14</sup> Airway management is tailored to the type of injury, the nature and degree of airway compromise, and the patient's hemodynamic and oxygenation status. Each of these conditions may present with great diversity, rendering trauma intubation difficult. Simultaneously performed resuscitation, time and environmental pressure, and possibly suboptimal equipment and assistance are additional factors increasing the difficulty. Continuous communication with members of the trauma team and obtaining information may help reduce the extent of the difficulty.

### **Airway Obstruction**

Airway obstruction is probably the most frequent cause of asphyxia after trauma and may result from posteriorly displaced or lacerated pharyngeal soft tissues; cervical or mediastinal hematoma; bleeding, secretions, or foreign bodies within the airway; and/or displaced bone or cartilage fragments. Bleeding into the cervical region may produce airway obstruction not only because of compression by the hematoma but also from venous congestion and upper airway edema as a result of compression of neck veins. Signs of upper and lower airway obstruction include dyspnea, cyanosis, hoarseness, stridor, dysphonia, subcutaneous emphysema, and hemoptysis. Cervical deformity, edema, crepitation, tracheal tug and/or deviation, or jugular venous distention may be present before these symptoms appear and may help indicate that specialized techniques are required to secure the airway.

The initial steps in airway management are chin lift, jaw thrust, clearance of the oropharynx, placement of an oropharyngeal or nasopharyngeal airway, and, in inadequately breathing patients, ventilation with a self-inflating bag. Immobilization of the cervical spine and administration of oxygen should be applied simultaneously. Blind passage of a nasopharyngeal airway or a nasogastric or nasotracheal tube should be avoided if a basilar skull fracture is suspected because the airway may enter the anterior cranial fossa. A supraglottic airway may permit ventilation with a self-inflating bag, although these devices do not provide protection against aspiration of gastric contents. They may be used as temporary measures and can serve as a bridge for a brief period to re-establish the airway patency or to facilitate intubation aided by a flexible fiberoptic bronchoscope (FOB). If they do not provide adequate ventilation, the trachea must be secured immediately using direct laryngoscopy, video laryngoscopy, or cricothyroidotomy, depending on the results of airway assessment.

Maxillofacial, neck, and chest injuries, as well as cervicofacial burns, are some of the difficult trauma-related reasons for tracheal intubation. Airway assessment should include a rapid examination of the anterior neck for feasibility of access to the cricothyroid membrane. Tracheostomy is not desirable during initial management because it takes longer to perform than a cricothyroidotomy and requires neck extension, which may cause or exacerbate cord trauma in patients with cervical spine injuries. Conversion to a tracheostomy should be considered later to prevent laryngeal damage if a cricothyroidotomy will be in place for more than 2 to 3 days. Possible contraindications to cricothyroidotomy include age younger than 12 years and suspected laryngeal trauma. Permanent laryngeal damage may result in the former, and uncorrectable airway obstruction may occur in the latter situation.

## **Full Stomach**

A full stomach is a background condition in acute trauma: The urgency of securing the airway often does not permit adequate time for pharmacologic measures to reduce gastric volume and acidity. Thus, rather than relying on these agents, the emphasis should be placed on selection of a safe technique for securing the airway when necessary: rapid-sequence induction with cricoid pressure for those patients without serious airway problems, and awake intubation with sedation and topical anesthesia, if possible, for those with anticipated serious airway difficulties.

In agitated and uncooperative patients, topical anesthesia of the airway may be impossible, whereas administration of sedative agents may result in apnea or airway obstruction, with an increased risk of aspiration of gastric contents and inadequate conditions for tracheal intubation. After locating the cricothyroid membrane and denitrogenating the lungs, a rapid-sequence induction may be used to allow securing of the airway with direct or video laryngoscopy or, if necessary, immediate cricothyroidotomy. Personnel and material necessary to perform translaryngeal ventilation or cricothyroidotomy must be in place before induction of general anesthesia.

### **Head, Open Eye, and Contained Major Vessel Injuries**

The principles of tracheal intubation are similar for these injuries. Apart from the need to ensure adequate oxygenation and ventilation, these patients require deep anesthesia and profound muscle relaxation before airway manipulation. This helps prevent hypertension, coughing, and bucking, and thereby minimizes intracranial, intraocular, or intravascular pressure elevation, which can result in herniation of the brain, extrusion of eye contents, or dislodgment of a hemostatic clot from an injured vessel, respectively. The preferred anesthetic sequence to achieve this goal in patients who are not hemodynamically compromised includes preoxygenation and opioid loading, followed by relatively large doses of an intravenous anesthetic and muscle relaxant. Hemodynamic responses to this sequence should be carefully monitored and promptly corrected. Systemic hypotension, intracranial pressure (ICP) elevation, and decreased cerebral perfusion pressure (CPP; CPP equals mean arterial pressure minus ICP) may occur whether cerebral autoregulation is present or absent in patients with head injuries and if untreated can produce secondary ischemic insults. Ketamine, once thought to be contraindicated in patients with head and open eye injuries because it may potentially increase both intracranial and intraocular pressures (IOPs), is shown to be advantageous in this setting because it maintains the systemic blood pressure and does not cause an appreciable increase in ICP and IOP.<sup>15,16</sup> By increasing systemic blood pressure it can, however, cause dislodgment of a hemostatic plug, initiating bleeding in

vascular injuries. Any muscle relaxant, including succinylcholine, may be used as long as the fasciculation produced by this agent is inhibited by prior administration of an adequate dose of a nondepolarizing muscle relaxant. Alternatively, rocuronium can provide intubating conditions within 60 seconds with a dose of 1.2 to 1.5 mg/kg; neuromuscular blockade produced by this dose lasts approximately 2 hours. Of course, neither muscle relaxants nor intravenous anesthetics are indicated when initial assessment suggests a difficult airway. As in any other trauma patient, hypotension, depending on its severity, dictates either reduced or no intravenous anesthetic administration. Tracheal intubation should be performed expeditiously, especially in head-injured patients, to prevent a decline in O<sub>2</sub> saturation, which may adversely influence outcome. Comparison of video laryngoscopy with direct laryngoscopy (Macintosh blade) in trauma patients showed longer intubation times with the video laryngoscope, resulting in a decline in O<sub>2</sub> saturation to 80% or less in more patients.<sup>17</sup> Although this finding should not discourage the use of a video laryngoscope in trauma patients, it should remind the clinician of the potential for the problem and that precautions such as applying appropriate preoxygenation are needed before attempting laryngoscopy and intubation.

## **Cervical Spine Injury**

Overall, 2% to 4% of blunt trauma patients have cervical spine (C-spine) injuries, of which 7% to 15% are unstable.<sup>18</sup> The most common causes include high-speed motor vehicle accidents, falls, diving accidents, and gunshot wounds. Head injuries, especially those with a low Glasgow coma score (GCS) and focal neurologic deficits, are likely to be associated with C-spine injuries. Approximately 2% to 10% of head trauma victims have C-spine injuries, whereas 25% to 50% of patients with C-spine injuries have an associated head injury.<sup>18</sup> The incidence of assault-related injuries depends on the mechanism, being highest after gunshot wounds (1.35%), lowest after stab wounds (0.12%), and intermediate after blunt trauma (0.4%) to the cervicothoracic region.

### *Initial Evaluation*

Accurate and timely evaluation is important because 2% to 10% of blunt trauma-induced C-spine injury patients develop new or worsening neurologic deficits after admission, partly attributable to delayed diagnosis and improper C-spine protection and/or manipulation.<sup>18</sup> Often there is no time to evaluate the injury, and emergency airway management may have to be performed without ruling out C-spine injury while the patients are in a rigid collar and neck-stabilizing devices. Clearance of the neck at the earliest possible time

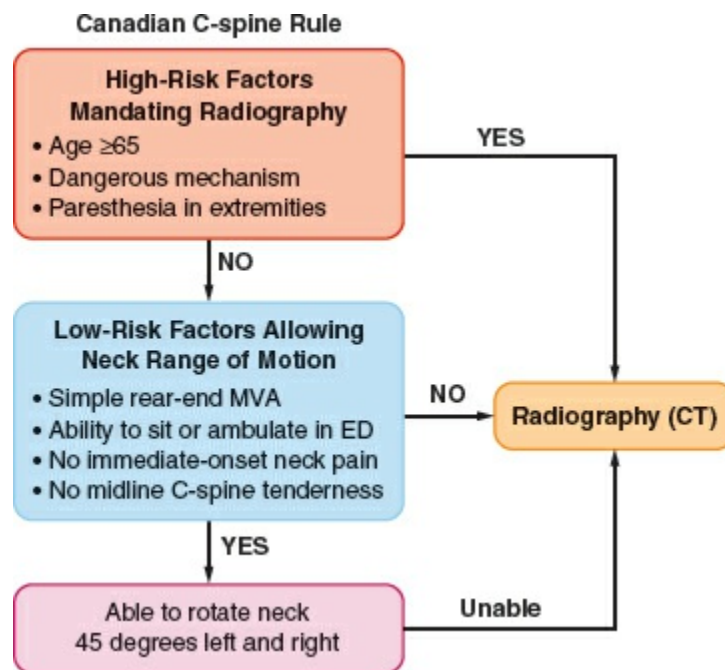

after airway management should be performed to minimize the complications associated with the collar, such as pressure ulceration, ICP elevation in head-injured patients, compromised central venous access, and airway management challenges if reintubation is needed.

In the conscious patient with a suspected injury, diagnosis is relatively easy. According to the American National Emergency X-radiography Utilization Study (NEXUS), a clinical evaluation revealing no posterior midline neck tenderness and focal neurologic deficit, in an injured patient with a normal level of alertness, and no evidence of intoxication, and painful distracting injury indicates a low probability of a C-spine injury. There is thus no need for radiographic evaluation.<sup>19</sup> Recently, however, it has been shown that a significant number of major-trauma patients cleared by these criteria had clinically important unstable C-spine injuries requiring treatment. Therefore, routine CT in addition to clinical evaluation is recommended to rule out C-spine injury in major trauma victims.<sup>20</sup> Probably the reason for the lower reliability of the NEXUS criteria is the difficulty of evaluating distracting injuries.

The Canadian C-spine rule for radiography after trauma is another tool designed to identify low-risk patients.<sup>18</sup> With this diagnostic tool, proper answers to the following three questions eliminate the possibility of injury and the need for radiographic studies: Is there any high-risk factor mandating radiography? Are there low-risk factors that permit safe evaluation of the range of motion of the neck? Can the patient rotate the neck laterally for 45 degrees in each direction without pain (Fig. 53-2)? Comparison of these two sets of criteria showed that the Canadian rule is more reliable than NEXUS in diagnosing C-spine injury in responsive patients.<sup>21</sup> Generally patients without neck pain, tenderness, or upper extremity paresthesia are considered free of C-spine injury, especially in the absence of distracting pain from other anatomic locations. Absence of clinical findings is also shown to rule out C-spine injury in pre-elementary schoolchildren, eliminating the need for diagnostic studies and thus radiation exposure.<sup>22</sup> Children with persistent midline neck pain with no other clinical findings and negative initial imaging findings have also been shown to have very little possibility of an unstable C-spine.<sup>23</sup>

Currently in modern trauma centers radiographic evaluation of the C-spine is performed using thin-cut CT images with sagittal and coronal reconstruction. There is, however, a subset of patients with normal CT scans who are either comatose or obtunded or are awake but have neck pain. Given the fact that CT is not sensitive in diagnosing soft tissue and ligamentous injury, ruling out ligamentous C-spine injury in these patients is difficult, and the diagnostic strategy is somewhat controversial. Dynamic fluoroscopy to obtain flexion/extension series has limited value because it is extremely low

yield, relatively dangerous, and cost ineffective.<sup>24</sup> It requires repeat examinations, it is difficult to identify specific ligamentous injury, and often the lower cervical spine cannot be visualized. In many trauma centers it is no longer performed.

**Figure 53-2** Canadian cervical spine rule designed to diagnose cervical spine injury in conscious patients and identify patients who require further radiographic (computed tomography [CT]) evaluation. MVA, motor vehicle accident; ED, emergency department. (Adapted from Stiell IG, Wells GA, Vandemheen K, et al. The Canadian C-Spine Rule for radiography in alert and stable trauma patients. *JAMA*. 2001;286:1841–1848; and Stiell IG, Clement CM, McKnight RD, et al. The Canadian C-spine rule versus the NEXUS low-risk criteria in patients with trauma. *N Engl J Med*. 2003;349:2510.)

MRI is a reliable tool; a normal examination can conclusively exclude C-spine injury.<sup>25</sup> It is thus the gold standard for ruling C-spine injury in or out. However, it is so sensitive that it can detect subtle injuries that are clinically insignificant. It cannot be performed in multiple-trauma patients who have metallic skeletal fixators. It is expensive and requires patient transport. MRI **2** may be useful in evaluating spinal cord-injured children without radiologic (CT) abnormalities. In this subgroup of patients, MRI can demonstrate the underlying pathology in some, but not all, patients.<sup>26</sup> A more recently proposed approach, which is practiced in many countries and in many, but not all, trauma centers in the US, is to rely on the MDCT study performed with less than 3-mm cuts. The diagnostic capability of this method is excellent, with the possibility of missing one unstable C-spine injury in about 5,000 patients not cleared by clinical examination.<sup>27–29</sup> Some clinicians advocate obtaining an MRI after CT as a definitive diagnostic measure to rule out C-spine injury, but the necessity for this strategy has not yet been

shown.<sup>30</sup> In brain-injured children with suspected C-spine injury, this approach did not offer any yield.<sup>31</sup>

Interestingly, published series describe very few instances of neurologic deficits related to airway management in C-spine-injured patients. Recently, Hindman et al.<sup>32</sup> reviewed the closed claims data for perioperative cervical cord, nerve root, and spine injury between 1970 and 2007, which showed that overall airway management-related neurologic damage represented 11% of 48 claims. Nine patients in the series had unstable spines preoperatively and developed neurologic deficits. In two of these patients the injury was attributed to airway management following direct laryngoscopy and intubation without C-spine precautions. McLeod and Calder<sup>33</sup> reviewed nine allegedly intubation-related cervical spinal cord injuries. Of these, three patients in two reports developed increased neurologic deficit after laryngoscopy and intubation without stabilization of the neck. It is likely that two of these patients are the same patients described by Hindman et al.<sup>32</sup> Thus, it is possible that airway management-related cervical cord injury in C-spine-injured patients can occur, but, if it does, it is rare.

### *Airway Management*

Almost all airway maneuvers, including jaw thrust, chin lift, head tilt, and oral airway placement, result in some degree of C-spine movement.<sup>18</sup> To secure the airway with direct laryngoscopy, manual inline stabilization (MILS) of the neck is the standard of care for these patients in the acute stage. A hard cervical collar alone, which is routinely placed, does not provide absolute protection, especially against rotational movements of the neck. MILS is best accomplished by having two operators in addition to the physician who is actually managing the airway. The first operator stabilizes and aligns the head in neutral position without applying cephalad traction. The second operator stabilizes both shoulders by holding them against the table or stretcher. The anterior portion of the hard collar, which limits mouth opening, may be removed after immobilization.

In the presence of MILS, the glottic view may be suboptimal during direct laryngoscopy in 10% to 15% of patients because of limitation of neck extension. Airway management may be further compromised in some patients because of enlargement of the prevertebral space by a hematoma from the vertebral fracture. Consequently, greater anterior pressure needs to be applied to the tongue by the laryngoscope blade in order to visualize the larynx. This increased anterior pressure is transmitted to the spine and can increase the movement of an unstable vertebral segment. Thus, the greater the restriction of the glottic view during direct laryngoscopy, the greater the pressure on the tongue, the spine, and the unstable segment with potential displacement of the unstable fragment. Santoni et al.<sup>34</sup> demonstrated that

during various phases of direct laryngoscopy and intubation, the pressures exerted on the tongue and indirectly to the spine were greater with MILS than without MILS. This finding confirmed the results of a videofluoroscopic study by Lennarson et al.,<sup>35</sup> who demonstrated significant anteroposterior displacement when MILS was applied to cadavers with destabilized C-spines.

Although convincing, these data should not eliminate the current standard practice of applying MILS during airway management of these patients. Currently, there is no scientifically rigorous clinical trial to show conclusively that airway management without MILS is associated with a favorable spinal cord outcome. Based on the available data, it is, however, reasonable to allow some relaxation of the MILS to improve the glottic view when visualization of the larynx is restricted.<sup>36</sup>

Other measures such as videolaryngoscopy, use of a gum elastic bougie, translaryngeal (retrograde) intubation, and cricothyroidotomy can be used to secure the airway in the acute phase of cervical spine immobilization. Neck motion with modern videolaryngoscopes does not seem to be different from that produced by the Macintosh blade, although they do provide better glottic views. Cricoid pressure may optimize the view during laryngoscopy, but it should be applied with great care because it may produce undue motion of the unstable spine if excessive force is used. Supraglottic intubation of airways to facilitate intubation with or without the aid of FOB can be used, but neck movement with these devices appears to be comparable to that produced by conventional laryngoscopes. Flexible fiberoptic laryngoscopy, use of a lightwand, and possibly translaryngeal-guided intubation (see Maxillofacial Injuries) cause almost no neck movement, but blood or secretions in the airway, a long preparation time, and difficulty in their use in comatose, uncooperative, or anesthetized patients reduce their utility during initial management. Nasotracheal intubation carries the risks of epistaxis, failure of intubation, and possibility of entry of the endotracheal tube into the cranial vault or the orbit if there is damage to the cranial base or the maxillofacial complex. Absence of the usual signs of cranial base fracture (battle sign, raccoon eyes, or bleeding from the ear or the nose) cannot be relied on to exclude the possibility of its occurrence because with rapid prehospital transport, these signs may not be immediately apparent.

In the subacute phase of C-spine injury when time constraints, full stomach, and patient cooperation issues do not exist, the use of FOB in the awake sedated patient with appropriate topical anesthesia is preferred. Advantages of this technique are minimal movement of the neck, positioning of the patient awake, maintenance of protective reflexes, and ability to assess the neurologic status after intubation.

## **Direct Airway Injuries**

Direct airway damage can occur anywhere between the nasopharynx and the bronchi. Sometimes more than one site may be involved, resulting in persistent airway dysfunction after one of the problems is corrected.<sup>37</sup> Head, face, and neck injuries are more common in military personnel in combat than in the civilian population; effective torso protection by body armor in combat leaves these regions unprotected.<sup>38</sup>

### *Maxillofacial Injuries*

The mechanism of maxillofacial injuries can be divided into high-impact (motor vehicle accident, industrial explosion, free fall) and low-impact (altercation) trauma. Airway management is often challenging in patients with high-impact maxillofacial injuries. In addition to soft tissue edema of the pharynx and peripharyngeal hematoma, blood or debris in the oropharynx may be responsible for partial or complete airway obstruction in the acute stage of these injuries. Occasionally, teeth or foreign bodies in the pharynx may be aspirated into the airway, causing some degree of obstruction, which may occur or be recognized only during attempts at tracheal intubation. Another problem is the dynamic nature of soft tissue injuries in this region. A hematoma or edema of the face, tongue, or neck may expand during the first several hours after injury and ultimately occlude the airway. Serious airway compromise may develop within a few hours in up to 50% of patients with major penetrating facial injuries or multiple trauma, caused by progressive inflammation or edema resulting from liberal administration of fluids.

The face, head, and neck are vulnerable to missile and explosion injuries.<sup>38</sup> Although rare, massive hemorrhage, most frequently from the internal maxillary artery or its branches, and less frequently from the facial, external carotid, or sphenopalatine arteries and other small branches, may be life threatening, requiring anterior, posterior, or anteroposterior packing, intermaxillary fixation, and, when these measures are ineffective, angioembolization.<sup>39,40</sup> Tracheal intubation or a surgical airway is necessary as an initial measure to avert airway compromise in these circumstances.

Fracture-induced encroachment on the airway or limitation of mandibular movement, pain, and trismus may limit mouth opening. Fentanyl in titrated doses of up to 2 to 4 µg/kg over a period of 10 to 20 minutes may produce an improvement in the patient's ability to open the mouth if mechanical limitation is not present.

The selection of an airway management technique in the presence of a maxillofacial fracture is based on the patient's presenting condition. Most patients with isolated facial injuries do not require emergency tracheal intubation. Surgery may be delayed for as long as a week with no adverse effect on the repair. Patients who present with existing or impending airway compromise may be intubated using direct laryngoscopy; the decision about

the use of anesthetics and muscle relaxants is based on the results of airway evaluation. When there is bleeding into the oropharynx, a flexible fiberoptic laryngoscope may be useless because of obstruction of the view. A retrograde technique, using a wire or epidural catheter passed through a 14-gauge catheter introduced into the trachea through the cricothyroid membrane, may be used if the patient can open his or her mouth. A surgical airway is indicated when there is airway compromise, when direct laryngoscopy has failed or is considered impossible, when the jaws will be wired, or when a tracheostomy will be performed anyway after definitive repair of the fracture.<sup>41</sup> Tracheostomy may be indicated as an emergency procedure in the ED within a few minutes of arrival, as a delayed procedure in the OR for airway control within 12 hours of arrival, or as an elective procedure during definitive surgery in the OR more than 12 hours following admission to the hospital.<sup>38</sup> Comminuted mandibular, midfacial bilateral Le Fort III, and panfacial fractures are likely to be managed with tracheostomy for definitive surgery.<sup>41</sup> To avoid the possible complications of tracheostomy, submental or submandibular intubation, which involves externalizing the proximal end of a flexible armored orotracheal tube through a small submental incision, has been performed. Thus, the trachea remains surgically intact and the endotracheal tube is not in the mouth, permitting comfortable surgical exposure and ability to apply intermaxillary fixation.<sup>42</sup> Nasogastric or nasotracheal intubation should be avoided when a basilar skull or maxillary fracture is suspected because of the possibility that the tube may enter the cranium or the orbit. Hemorrhagic shock and life-threatening cranial, laryngotracheal, thoracic, and cervical spine injuries may accompany major facial fractures, and airway management must be tailored accordingly. The likelihood of cranial injury increases in midface fractures involving the frontal sinus, as well as the orbitozygomatic and orbitoethmoid complexes.

### *Cervical Airway Injuries*

Injury to the cervical air passages can result from blunt or penetrating trauma. The incidence of patients with blunt or penetrating laryngotracheal injuries admitted to major trauma centers is 0.34% and 4%, respectively.<sup>43</sup> Similar to maxillofacial injuries, wartime laryngotracheal trauma is more severe and more frequent (5% to 6%) than peacetime injuries (0.91%).<sup>44</sup> Although the pharynx and esophagus are close to the cervical air passages, their involvement in peacetime trauma is less likely than airway injuries (0.08% after blunt and 0.9% after penetrating trauma).<sup>43</sup> Clinical signs such as air escape, hemoptysis, and coughing are present in almost all patients with penetrating injuries, facilitating the diagnosis. In contrast, major blunt laryngotracheal damage may be missed, either because the patient is asymptomatic or unresponsive or because suggestive signs and symptoms are

missed in the initial evaluation. The typical presentation includes hoarseness, muffled voice, dyspnea, stridor, dysphagia, odynophagia, cervical pain and tenderness, ecchymosis, subcutaneous emphysema, and flattening of the thyroid cartilage protuberance (Adam’s apple). Whether the trauma is blunt or penetrating, attempts at blind tracheal intubation may produce further trauma to the larynx and complete airway obstruction if the endotracheal tube enters a false passage or disrupts the continuity of an already tenuous airway.<sup>45</sup> Thus, whenever possible, intubation of the trachea should be performed using an FOB, or the airway should be secured surgically. A CT scan of the neck provides valuable information and should be performed before any airway intervention in all stable patients without respiratory and hemodynamic compromise. Originally, the severity of laryngeal injury was classified based on endoscopic findings. With modern equipment, information similar to that provided by FOB can be obtained with CT scanning. A classification of laryngeal injuries is depicted in [Table 53-1](#).<sup>46,47</sup>

**Table 53-1** Classification of Laryngeal Injuries

Grade	Laryngeal Findings	Airway
1	No fractures Minor lacerations Minimal edema	Minimal airway symptoms
2	Undisplaced fractures Mucosal damage without cartilage exposure	Mild airway compromise
3	Displaced fractures Vocal fold immobility	Significant airway compromise
4	Multiple fractures with instability	Significant airway compromise
5	Laryngotracheal separation	Catastrophic airway obstruction

Data from Schaefer SD. Primary management of laryngeal trauma. *Ann Otol Rhinol Laryngol.* 1982;91:399; and Fuhman GM, Stieg FH III, Buerk CA, et al. Blunt laryngeal trauma: classification and management protocol. *J Trauma.* 1990;30:87.

The strategy for tracheal intubation depends on the clinical presentation.<sup>45</sup> The tracheas of some patients with penetrating airway injuries, especially stab wounds, may be intubated through the airway defect without the need for anesthetics or optical equipment. The presence of cartilaginous fractures or mucosal abnormalities necessitates awake intubation with an FOB or awake tracheostomy.<sup>37</sup> Laryngeal damage precludes cricothyroidotomy. Tracheostomy should be performed with extreme caution because up to 70% of patients with blunt laryngeal injuries may have an associated cervical spine injury.<sup>45</sup> Uncooperative or confused patients may not tolerate awake airway manipulation. It may be best to transport these patients to the OR, induce anesthesia with ketamine or inhalational agents, and intubate the trachea

without muscle relaxants.<sup>45</sup> Episodes of airway obstruction during spontaneous breathing under an inhalational anesthetic can be managed by positioning the patient upright in addition to the usual maneuvers.

Complete transection of the trachea is rare, but when it occurs it is life threatening. The distal segment of the trachea retracts into the chest, causing airway obstruction either spontaneously or during airway manipulation. Surgery involves pulling up the distal end and performing an end-to-end anastomosis to the proximal segment or suturing it to the skin as a permanent tracheostomy. In extreme situations, such as complete or near-complete transection of the larynx and trachea, femorofemoral bypass or percutaneous cardiopulmonary support may be considered if time permits.<sup>48</sup>

Following repair, immediate or early extubation of the trachea is safe in patients with isolated cervical tracheal injuries. In patients who require prolonged airway control because of tracheal or extratracheal injuries, immediate tracheostomy and prolonged intubation are the two choices available. The former is associated with increased surgical site infection and the latter with pneumonia.<sup>49</sup> Thus every attempt should be made to aim for early extubation, and, if it is not possible, the risks and benefits of tracheostomy and prolonged intubation should be considered before final selection.

### *Thoracic Airway Injuries*

Whereas penetrating trauma can cause damage to any segment of the intrathoracic airway, blunt injury usually involves the posterior membranous portion of the trachea and the main stem bronchi, usually within approximately 3 cm of the carina. A significant number of these injuries result from iatrogenic causes such as tracheal intubation.<sup>50</sup> Pneumothorax, pneumomediastinum, pneumopericardium, subcutaneous emphysema, and a continuous air leak from the chest tube are the usual signs of this injury. They occur frequently but are not specific for thoracic airway damage. In intubated patients without the suspicion of a tracheal injury, difficulty in obtaining a seal around the endotracheal tube or the presence on a chest radiograph of a large radiolucent area in the trachea corresponding to the cuff suggests a perforated airway. Other radiographic findings include a radiolucent line along the prevertebral fascia due to air tracking up from the mediastinum, peribronchial air or sudden obstruction along an air-filled bronchus, and the “dropped lung” sign when complete intrapleural bronchial transection causes the apex of the collapsed lung to descend to the level of the hilum. Occasionally, simultaneous esophageal injury with a tracheoesophageal fistula may be present.<sup>51</sup>

Airway management is similar to that for cervical airway injury. Anesthetics, and especially muscle relaxants, may produce irreversible

obstruction, presumably because of relaxation of peritracheal or peribronchial structures that maintain airway patency in the awake patient. However, airway loss may also occur during attempts at awake intubation, often as a result of further distortion of the airway by the endotracheal tube, patient agitation, or rebleeding into the airway. After intubation of the trachea, the adequacy of airway intervention is evaluated mainly by auscultation and capnography. Pulmonary contusion, atelectasis, diaphragmatic rupture with thoracic migration of the abdominal contents, and pneumothorax may complicate the interpretation of chest auscultation. Likewise, carbon dioxide (CO<sub>2</sub>) elimination may be decreased or absent in shock and cardiac arrest.

The outcome after surgical repair of these injuries is often suboptimal and complicated by stump leak and empyema, suture line stenosis, or the need for tracheostomy or pneumonectomy. The recent trend is selective conservative management with an endotracheal tube placed using bronchoscopic guidance distal to the tracheal injury.<sup>52</sup> Patients with lesions larger than 4 cm, cartilaginous rather than membranous injuries, concomitant esophageal trauma, progressive subcutaneous emphysema, severe dyspnea requiring intubation and ventilation, difficulty with mechanical ventilation, pneumothorax with an air leak through the chest drains, and mediastinitis are still managed surgically. Those without these problems may be treated nonoperatively with a reasonable outcome.<sup>50,52</sup> Following repair, early tracheal extubation should be the goal; it is likely that (as in cervical tracheal injuries) tracheostomy or prolonged intubation may be associated with infectious complications.<sup>49</sup>

### ***Management of Breathing Abnormalities***

Of the several causes that may alter respiration after trauma, tension pneumothorax, flail chest, and open pneumothorax are immediate threats to the patient's life and therefore require rapid diagnosis and treatment. Hemothorax, closed pneumothorax, pulmonary contusion, diaphragmatic rupture with herniation of abdominal contents into the thorax, and atelectasis from a mucous plug, aspiration, or chest wall splinting can also interfere with breathing and pulmonary gas exchange and deteriorate into life-threatening complications.

Although cyanosis, tachypnea, hypotension, neck vein distention, tracheal deviation, and diminished breath sounds on the affected side are the classic signs of tension pneumothorax, neck vein distention may be absent in hypovolemic patients and tracheal deviation may be difficult to appreciate. Inability to position most trauma patients upright and the likelihood of inadequate imaging decrease the diagnostic value of chest radiographs.<sup>53</sup> In the supine position the deep sulcus sign, which results from the tendency of

pleural air to track in the lateral and caudal regions, is usually diagnostic of tension pneumothorax.<sup>54</sup> The definitive diagnosis is made by CT scanning.<sup>55</sup> However, in hypoxemic and hypotensive patients, immediate insertion of a 14-gauge angiocatheter through the fourth or fifth intercostal space in the midaxillary line or, at times, through the second intercostal space at the midclavicular line is essential. There is no time for radiologic confirmation in this setting.

A flail chest results from fractures at two or more sites of at least three adjacent ribs, or rib fractures associated with costochondral separation or sternal fracture. An underlying pulmonary contusion with increased elastic recoil of the lung and increased work of breathing is the main cause of respiratory insufficiency or failure and resulting hypoxemia.<sup>56</sup> It often develops over a 3- to 6-hour period, causing gradual worsening seen in the chest radiograph and deterioration of arterial blood gases (ABGs).<sup>56</sup> Coexisting hemopneumothorax, paradoxical chest wall movement, and/or pain-induced splinting may contribute to the gas exchange abnormalities. Repeat evaluation by physical examination, chest radiography, and ABG determinations is essential for early recognition of these complications. The fraction of lung volume contused, as determined by chest radiography or CT, may be predictive of the subsequent development of acute respiratory distress syndrome (ARDS). The likelihood increases abruptly once the contusion volume exceeds 20% of total lung volume.<sup>57</sup> There are other predictive signs of pulmonary complications after rib fractures. In the recently proposed *rib score* system, one point is assigned for each of the following types of rib fractures: six or more rib fractures, bilateral fractures, flail chest, three or more severely (bicortically) displaced fractures, first rib fracture, and at least one fracture in each of the anterior, lateral, and posterior regions of the ribs.

**4** A linear correlation exists between the rib score and development of pneumonia, acute respiratory failure and need for tracheostomy.<sup>58</sup> Vital capacity (VC) may be another predictive parameter. Patients with a VC greater than 50% of a nomogram-based normal VC had little likelihood of pulmonary complications, whereas the probability increased 2.5 times in those with VC below 30%.<sup>59</sup> Without significant gas-exchange abnormalities, chest wall instability alone is not an indication for respiratory support. There is evidence that liberal use of tracheal intubation and mechanical ventilation in the presence of a flail chest or pulmonary contusion increases the rate of pulmonary complications and mortality and prolongs the hospital stay.<sup>56,60</sup> Effective pain relief by itself can improve respiratory function and often avoids the need for mechanical ventilation. For this purpose, continuous epidural analgesia with local anesthetics and opioids, preferably directed to thoracic segments, and, if epidural access is not possible, thoracic paravertebral block with local anesthetics provide better pain relief and

ventilatory function than parenteral opioids, reducing morbidity and mortality in elderly patients with chest wall trauma.<sup>56</sup> Other therapeutic measures include supplemental oxygen, continuous positive airway pressure of 10 to 15 cm water (H<sub>2</sub>O) by face mask, airway humidification, chest physiotherapy, incentive spirometry, bronchodilators, airway suctioning (using FOB, if necessary), and nutritional support.<sup>56</sup> Overzealous infusion of fluids and transfusion of blood products may result in deterioration of oxygenation by worsening the underlying pulmonary injury.<sup>56</sup>

Severe pulmonary contusion, respiratory insufficiency or failure despite adequate analgesia, clinical evidence of severe shock, associated severe head injury or injury requiring surgery, airway obstruction, and significant pre-existing chronic pulmonary disease are indications for tracheal intubation and mechanical ventilation. The outcome in these patients may be dependent on the pattern of ventilation. Unless the clinical evidence suggests imminent cerebral herniation, hyperventilation must be avoided in head-injured patients because it increases cerebral vasoconstriction, thus decreasing perfusion, with accumulation of cerebral lactic acid immediately after its institution.<sup>61</sup> In hypovolemic patients, hyperventilation may interfere with venous return and cardiac output, leading to hypotension, further decrease in organ perfusion, and even cardiac arrest. Ventilation with low tidal volumes (6 to 8 mL/kg) and moderate positive end-expiratory pressure (PEEP), producing low inspiratory alveolar or plateau pressures, appears to be the best pattern to prevent hemodynamic deterioration and decrease the likelihood of ARDS.<sup>62</sup> In intubated, spontaneously breathing patients, airway pressure release ventilation, in which spontaneous breathing is superimposed on mechanical ventilation by an intermittent brief decrease of continuous positive airway pressure, provides improved ventilation/perfusion ( $V/Q$ ) matching and systemic blood pressure, lower sedation requirements, greater oxygen (O<sub>2</sub>) delivery, shorter periods of intubation, and a decreased incidence of ventilator-associated pneumonia, which occurs in up to 30% of ventilated patients with pulmonary contusion.<sup>60,63,64</sup> Severe unilateral pulmonary contusion unresponsive to these measures may be treated by differential lung ventilation via a double-lumen endobronchial tube. In bilateral severe contusions with life-threatening hypoxemia, high-frequency jet ventilation may enhance oxygenation and cardiac function, which may be compromised by concomitant myocardial contusion or ischemia.<sup>65</sup>

Systemic air embolism occurs mainly after penetrating lung trauma and blast injuries or, less frequently, after blunt thoracic trauma that produces lacerations of both distal air passages and pulmonary veins.<sup>66</sup> Positive-pressure ventilation after tracheal intubation may then result in entrainment of air into the systemic circulation. Hemoptysis, circulatory instability, and CNS dysfunction immediately after starting artificial ventilation, as well as

detection of air in blood from the radial artery, establishes the diagnosis. Air bubbles may also be seen in the coronary arteries during thoracotomy. Surgical management involves immediate thoracotomy and clamping of the hilum of the lacerated lung. Respiratory maneuvers that minimize or prevent air entry into the systemic circulation include isolating and collapsing the lacerated lung by means of a double-lumen tube or ventilating with the lowest possible tidal volumes via a single-lumen tube.<sup>66</sup> Transesophageal echocardiography (TEE) of the left side of the heart may permit visualization of air bubbles and their disappearance with therapeutic maneuvers.

## Management of Shock

Hemorrhage is the most common cause of traumatic hypotension and shock and is, after head injury, the second most common cause of mortality after trauma. Other causes of hypotension are abnormal pump function (myocardial contusion, pericardial tamponade, pre-existing cardiac disease, or coronary artery or cardiac valve injury), pneumothorax or hemothorax, and spinal cord injury. Anaphylaxis occurs rarely in the acute stage, and sepsis, except in unrecognized bowel injury, is a cause of hypotension only several days after trauma.

**Figure 53-3** Relationship between emergency department systolic blood pressure, base deficit, and overall mortality rate of trauma patients; head injury patients are not included. Note that mortality and base deficit decrease as systolic blood pressure increases, stabilizing at 110 mmHg rather than at the generally accepted 90 mmHg. (Adapted from Eastridge BJ, Salinas J, Wade CE, et al. Hypotension begins at 110 mm Hg: redefining “hypotension” with data. *J Trauma*. 2007;63:291.)

In bleeding patients the primary goal is the urgent surgical control of the source. Certain types of bleeding, however, may be temporarily controlled with nonsurgical measures, such as finger compression of open neck injuries and tourniquet control of external bleeding from extremities. Tourniquets should be removed as soon as urgent surgical control is achieved to avoid pressure-induced nerve damage, skin necrosis, or limb ischemia.

Evaluation of the severity of hemorrhagic shock in the initial phase is

based on the mechanism and anatomic pattern of injury, prehospital and ED hemodynamic data, and the response to fluid resuscitation. Free falls from heights over 6 meters, high-energy deceleration impact, and high-velocity gunshot wounds are very likely to produce major damage and bleeding. Noncompressible thoracoabdominal and pelvic injuries also are likely to be associated with major bleeding. Immediate evaluation of these anatomic sites clinically and with radiographs of the chest and pelvis, FAST, CT, or, rarely, diagnostic peritoneal lavage is necessary. Patients with significant intra-abdominal fluid recognized with these tests and hemodynamic instability require immediate surgical intervention. Those who are suspected to have occult abdominal bleeding based on a high-risk mechanism of injury but who are hemodynamically stable must undergo further evaluation with CT. The modern multislice CT devices available in most trauma centers can provide early whole-body scanning within a few minutes.<sup>11,67</sup>

Clinical assessment using hemodynamic data is based on a few relatively insensitive and nonspecific clinical signs. For example, tachycardia, which is traditionally used as an index of hypovolemia, may be absent in up to 30% of hypotensive trauma patients because of activated Bezold–Jarisch reflex, increased vagal tone, chronic cocaine use, or other reasons.<sup>68</sup> Inability of the patient to elevate the heart rate in the face of hypoperfusion is considered a predictor of increased mortality independent of severity of injury, systemic blood pressure, or presence of a head injury.<sup>68</sup> In contrast, by increasing catecholamine output, tissue injury and associated pain may result in maintenance of tachycardia and normal systemic blood pressure in the presence or absence of hypovolemia without necessarily increasing the cardiac index or tissue oxygen delivery. In fact, in this situation an increase in intestinal vascular resistance and a decrease in splanchnic blood flow may occur and, if prolonged, may allow entry of intestinal microorganisms into the circulation and increase the likelihood of subsequent sepsis and organ failure.<sup>69,70</sup> Thus, equating a normal heart rate and systemic blood pressure with normovolemia during initial resuscitation may lead to loss of valuable time for treating underlying occult hypovolemia or hypoperfusion. This is especially true in the elderly trauma population (age >65), in whom significant tissue hypoperfusion in the presence of normal blood pressure is more likely than in younger patients.<sup>71</sup> Traditionally, the normal systolic blood pressure (SBP) is defined as 90 mmHg. Recent findings suggest that trauma patients with ED SBP at this level or lower have higher mortality, higher blood lactate levels, and greater base deficits than civilian trauma patients with an SBP of 110 mmHg or injured soldiers with an SBP of 100 mmHg (Fig. 53-3).<sup>72,73</sup> Thus, the optimal SBP in the trauma patient appears to be 100 to 110 mmHg. Based on these findings, an SBP of 110 mmHg is accepted as a prehospital triage criterion for admission to a Level I

trauma center for trauma patients over 65 years old<sup>74</sup>; 90 mmHg remains as a level for younger patients. Although traditional vital signs are relatively unreliable for recognizing life-threatening shock, heart rate, systemic blood pressure, pulse pressure, respiratory rate, urine output, and mental status are still used as early clinical indicators of the severity of hemorrhagic shock (Table 53-2).<sup>69,75</sup>

Efforts directed to early identification of uncontrolled hemorrhage led to several clinical diagnostic tools. Because of the immediate activation of transcapillary refill after hemorrhage, there is a decline in hematocrit (Hct) even in the absence of administration of fluids in both adults and children. Thus a low Hct on admission should elicit the suspicion of significant bleeding.<sup>76,77</sup> However, decision making based on a single Hct value may lead to erroneous management decisions. On the other hand, serial Hct measurements and consideration of the type and amount of fluid received may be useful in deciding the timing and amount of transfusion.<sup>78</sup> Among many scoring systems the most practical is the Assessment of Blood Consumption (ABC) score, which asks four yes/no questions: penetrating mechanism of injury, SBP of 90 mmHg or less, heart rate of 120/min or greater, and a positive FAST finding.<sup>79</sup> Shock index (SI), a value derived by dividing the heart rate by the SBP, appears to be another accurate indicator of early hemorrhagic shock and a predictor of mortality. In normal individuals, SI varies between 0.58 and 0.64 (mean 0.61), increasing from 0.70 to 0.80 (mean 0.75) after a moderate degree of blood loss. In the elderly, it has been demonstrated that age times SI identifies early shock and predicts mortality better than SI itself.<sup>80</sup> Additional predictive measures of major bleeding include blood lactate level greater than 2 mmol/L, low tissue O<sub>2</sub> saturation, and pulse oximeter-derived photoplethysmography analysis. Hypoperfusion of abdominal organs can also be detected by CT: Free peritoneal fluid, small bowel enhancement, and flattened inferior vena cava (IVC) and renal veins suggest hypoperfusion.<sup>81</sup>

**Table 53-2** Advanced Trauma Life Support Classification of Hemorrhagic Shock<sup>a</sup>

	Class I	Class II	Class III	Class IV
Blood loss (mL)	≤750	750–1,500	1,500–2,000	≥2,000
Blood loss (% blood volume)	≤15	15–30	30–40	≥40
Pulse rate (per min)	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14–20	20–30	30–40	>35
Urine output (mL/h)	≥30	20–30	5–15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused, lethargic
Fluid replacement (3:1 rule)	Crystalloid <sup>b</sup>	Crystalloid	Crystalloid + blood	Crystalloid + blood

<sup>a</sup>For a 70-kg male patient, based on initial presentation.

<sup>b</sup>The 3:1 rule is based on empiric observation that most patients require 300 mL of balanced electrolyte solution for each 100-mL blood loss. Without other clinical and monitoring parameters, this guideline may result in excessive or inadequate fluid resuscitation.

Adapted from American College of Surgeons, Committee on Trauma. Shock. In: *Advanced Trauma Life Support Student Course Manual*. 8th ed. Chicago, IL: American College of Surgeons; 2008:55–71.

One of the reasons scoring systems have been introduced for assessing the severity of hemorrhage is to determine the need for initiating the massive transfusion protocol (MTP). The ABC score represents the initially described basic form of these scoring systems. In this system, SBP lower or less than 90 mmHg, heart rate above 120 bpm, positive FAST, and presence of penetrating trauma each are given 1 point. In the US two more detailed scoring systems have been designed: the Cincinnati Individual Transfusion Trigger and the massive transfusion score, which has been recently revised.<sup>82</sup> In both these scoring systems additional parameters such as base deficit, international normalized ratio (INR), hemoglobin, and temperature are added to the simple ABC system to strengthen the predictive power for initiating MTP. Each criterion is given one point, and a minimum score of 1 or 2 suggests activation of the MTP. A sum of one point, although this may initiate MTP, may lead to some unnecessary activations. On the other hand, considering a sum of two points as indication for initiating MTP may result in omission of some patients who actually need activation of MTP. It has been realized that relying only on these scoring systems without using the clinical gestalt is likely to lead to under- or over use of MTP. Thus these scoring systems, preferably the revised massive transfusion score, should be relied upon only in conjunction with clinical judgment. Although the scoring systems are generally used for initial assessment in the ED, they also can be helpful in judging whether the MTP should be continued or stopped later during the process of management.<sup>83</sup> The method of resuscitation of the hemorrhaging patient has changed over the past several years since the Iraq and Afghanistan wars. The concept of damage control resuscitation has replaced the classic crystalloid resuscitation, which served to replenish depleted interstitial fluid and also to estimate the severity of intravascular volume depletion during the initial period. The response to initial fluid resuscitation with lactated Ringer's (LR) or normal saline solution of about 2

L, or 20 mL/kg in children, over a period of 15 to 30 minutes allowed estimation of the severity of hemorrhage.<sup>64</sup> Transient or no blood pressure response to this maneuver suggested major hemorrhage and dictated administration of blood products.

*Damage control resuscitation* is diametrically opposed to this principle. The severity of hemorrhage is estimated using the combination of clinical, laboratory, ultrasonographic, and radiologic diagnostic measures described earlier. After a major hemorrhage is identified, several components of the process are initiated. These consist of brief permissive hypotension; rapid control of any bleeding source; minimal crystalloid infusion; early administration of plasma and other blood products in a balanced ratio (preferably 1:1:1) of packed red blood cells (PRBCs), plasma, and platelets by activation of the MTP; and tranexamic acid. If indicated, damage control surgery may be required to control bleeding and sources of contamination. Definitive surgery is deferred until after normalization of the patient's physiologic condition. The purpose of damage control resuscitation is to prevent the pulmonary edema, ARDS, coagulopathy, multiple organ failure (MOF), and abdominal compartment syndrome attributed to administration of large volumes of resuscitative crystalloids. In addition, administration of large volumes of LR solution and normal saline are associated with elevated blood lactate levels and increasing base deficit, respectively.<sup>84</sup> An ever-increasing number of reports in the trauma literature indicate the deleterious effects of crystalloid resuscitation. Thus the amount of crystalloid administered during damage control resuscitation is limited to a carrier solution for blood products in most instances. Neil et al.<sup>85</sup> found that a cumulative crystalloid to PRBC ratio greater than 1.5:1 (liters to units) during the first 24 hours after admission was an independent cause of ARDS and abdominal compartment syndrome. Using ratios of less than 0.75:1 and more than 0.75:1 in two groups of trauma patients, another study found no statistical differences in oxygenation, ARDS and mortality between the low- and high-ratio groups, although fewer people in the low-ratio group died.<sup>86</sup> Thus, it is obvious that the crystalloid volume should be kept low during initial resuscitation.

Because management of the trauma patient is a continuum from the prehospital phase to the ED and then to the OR, the anesthesiologist should check the type and amount of resuscitation fluids administered before surgery and adjust the volume of crystalloids accordingly. The deleterious effects of crystalloid fluids are attributed to their effect on the glycocalyx and syndecan-1, a network of soluble plasma components on the endothelium stabilizing membrane integrity. Massive hemorrhage alters the integrity of the endothelial glycocalyx; damage to the cell membrane is thought to be the primary mechanism of shock in these patients. Although plasma is able to reconstitute syndecan-1, the main component of glycocalyx, crystalloids cause

further destruction, worsening the endothelial dysfunction.<sup>87</sup>

Overinfusing fluids before control of the hemorrhage may lead to further bleeding by increasing arterial and venous pressures, displacing a hemostatic plug, diluting clotting factors and platelets, reducing body temperature, and decreasing blood viscosity.<sup>88,89</sup> Bickell et al.<sup>90</sup> showed that delaying fluid resuscitation until surgical control of bleeding in victims of penetrating trauma improved survival to hospital discharge and decreased the length of hospital stay. Although many experimental studies have confirmed the findings of Bickell et al.,<sup>90</sup> it has also become clear that withholding fluids completely can result in as much harm as vigorous resuscitation.<sup>91</sup> Feasibility of the time-sensitive permissive hypotension described by Bickell et al.<sup>90</sup> has been studied in a prospective randomized study comparing low-volume versus standard-volume (2L) crystalloid administration to hypotensive trauma patients during the prehospital phase.<sup>92</sup> Mortality was lower in patients who received low-volume crystalloids despite maintenance of hypotension.<sup>92</sup> Although controversial, this concept emphasizes the fact that fluid administration in excess of that needed to achieve normovolemia prior to control of hemorrhage may be deleterious. Permissive hypotension is also contraindicated in traumatic brain and spinal cord injuries and in elderly patients with chronic systemic hypertension in which adequate perfusion is crucial,<sup>89</sup> it emphasizes the fact that fluid administration in excess of that needed to achieve normovolemia prior to control of hemorrhage may be deleterious.<sup>88</sup> Early use of vasopressors to maintain hemodynamic stability also may be associated with deleterious effects. However, judicious use of these drugs along with carefully titrated fluids may offer some advantages.

Some of the proven markers of organ perfusion can be used during early management to set the goals of resuscitation. Of these, the base deficit and blood lactate level are the most useful and practical tools during all phases of shock, including the earliest. The base deficit reflects the severity of shock, the oxygen debt, changes in O<sub>2</sub> delivery, the adequacy of fluid resuscitation, and the likelihood of MOF and survival with reasonable accuracy in *previously healthy* adult and pediatric trauma patients.<sup>89</sup> Base deficit is considered a better prognostic marker than the arterial pH. A base deficit between -2 and -5 mmol/L suggests mild shock, between -6 and -9 mmol/L indicates moderate shock, and more than 10 m/mol is a sign of severe shock.<sup>89</sup> An admission base deficit below -5 to -8 mmol/L correlates with increased mortality. Thus, normalization of the base deficit is one of the end points of resuscitation. Elevation of the blood lactate level is less specific than base deficit as a marker of tissue hypoxia because it can be generated in well-oxygenated tissues by increased epinephrine-induced skeletal muscle glycolysis, accelerated pyruvate oxidation, decreased hepatic clearance of lactate, and early mitochondrial dysfunction. All these conditions may be

present in the trauma patient. Thus, blood lactate and base deficit may not closely correlate with each other. Nevertheless, in most trauma victims an elevated lactate level correlates with other signs of hypoperfusion, rendering it an important marker of dysoxia and an end point of resuscitation. The normal plasma lactate concentration is 0.5 to 1.5 mmol/L; levels over 5 mmol/L indicate significant lactic acidosis. The half-life of lactate is approximately 15 to 30 minutes in healthy individuals; thus, the level decreases rather rapidly after correction of the cause. Failure to clear lactate within 24 hours after reversal of circulatory shock is a predictor of increased mortality.<sup>89,93</sup>

The usefulness of hemoglobin (Hgb) or Hct as a PRBC transfusion threshold remains unclear, although the recommended target Hgb concentration in all phases of management is 7 to 9 g/dL, including in brain-injured patients in whom tissue oxygenation is most relevant.<sup>89</sup> Several studies demonstrated that increasing the Hgb level to 9 or 10 g/dL from lower levels with PRBCs of less than 19 days' storage increased brain oxygenation in 75% of head injured patients. However, data from other sources showed either increased morbidity and mortality with PRBC transfusion or improved neurologic outcome when the Hct was kept below 30 (Hgb < 10 g/dL) for longer periods.<sup>97</sup> Transfusion of PRBCs has been shown to be an independent risk factor for mortality, lung injury, increased infection rate, renal failure, and intensive care unit (ICU) and hospital length of stay in trauma patients, especially when the transfused red cells are older than 14 days; this finding was independent of the severity of shock.<sup>98,99</sup> Nevertheless, this concern should not preclude timely and adequate administration of blood products.

Normally, type-specific crossmatched blood can be available in most centers in about 30 minutes, including transport time. Type-specific uncrossmatched blood can be available in even less time for patients with severe hemorrhage. However, if the situation dictates immediate transfusion, type O Rh-positive PRBCs and AB-negative fresh frozen plasma (FFP) are satisfactory in most situations. Controversy exists about the use of uncrossmatched type O PRBCs because of concern about the development of alloantibodies and allergic reactions. Dutton et al.,<sup>100</sup> reviewing their experience in 161 patients receiving 581 units of universal donor blood, demonstrated that only 1 of the 10 Rh-negative males receiving type O Rh-positive blood developed alloantibodies. All four females in the series received type O Rh-negative blood without apparent problem.

Most trauma patients are hypercoagulable when admitted to the ED and do not develop coagulopathy when administration of hemostatic agents is delayed. However, in the estimated 10% to 15% of patients with severe trauma and shock who enter the hospital in a hypocoagulable state<sup>101</sup> or

rapidly develop hypocoagulation, resuscitative fluids and PRBCs may further worsen the coagulopathy and facilitate the vicious cycle. A computer simulation study by Hirshberg et al.<sup>102</sup> clearly demonstrated that with crystalloid resuscitation techniques, most major trauma patients are coagulopathic when they arrive at the OR. In their study, the prothrombin time (PT) increased to below hemostatic levels after replacement of 1 blood volume, fibrinogen function would become inadequate at replacement of 1.25 blood volumes, and platelets would become inadequate with replacement of 1.75 blood volumes. Experience gained in the Iraq and Afghanistan wars attests to the accuracy of the findings of Hirshberg et al.<sup>102</sup> Holcomb et al.<sup>103</sup> strongly recommend starting liquid plasma replacement along with fluids and PRBCs as soon as the patient arrives in the ED and continuing it throughout surgery. In a recent multicenter randomized clinical trial, Holcomb et al.<sup>104</sup> compared the effect of 2:1:1 with 1:1:1 ratios of PRBCs, FFP, and platelet resuscitation on mortality and continuation of hemorrhage during the initial 24-hour period after trauma and could not demonstrate a statistical difference in mortality, although patients treated with a 1:1:1 ratio had significantly decreased bleeding.

Liquid plasma differs from FFP in that it is never frozen and can be used up to 28 days after collection, but at a cost of containing a much lower level of hemostatic factors. Not all trauma center blood banks carry liquid plasma. Instead most centers keep thawed plasma stored in liquid form available to be used until FFP or PF 24 is thawed, which takes about 30 to 45 minutes. PF 24 is plasma frozen within 24 hours of collection, whereas FFP is frozen within 8 hours. It contains about 60% of the factors found in FFP except fibrinogen, which, because of its long half-life of 12 hours, is not affected. One unit of FFP contains approximately 7% of the coagulation factor activity of a 70-kg man. Available plasma preparations and their characteristics are shown in [Table 53-3](#). Military data demonstrate that the death rate was 65% when the plasma to PRBC ratio was 1:8, 34% at 1:2.5, and 19% at 1:1.4.<sup>105</sup>

**Table 53-3** Available Plasma Preparations and Their Features

	Collection to Freezing Interval (h)	Collection to Thawing Interval (h)	Factor Activity (%)	Time Taken to Thaw (min)	Comments
Fresh frozen plasma (FFP)	≤8	0–24	~100	45	Blood bank receives it frozen from the blood center
Plasma frozen 24 (PF24)	≤24	0–48	~60	45	All factors except fibrinogen are depleted
Liquid plasma	Never frozen	Never thawed	<30	—	Only few blood centers have it. It is good for 28 days.
Thawed plasma	8–24	0–48	20–30 Depending on the interval used after thawing	45	This product is kept thawed from 1 to 5 days and if not used discarded. It is released as the first group of plasma to be used until thawing of FFP or PF24 is completed

Currently many trauma centers use hemostatic resuscitation by activating MTPs during initial resuscitation of major traumatic hemorrhage in the ED and OR. These involve administering a relatively limited quantity of crystalloid solutions and volume replacement with FFP or PF 24 and PRBCs. In addition, platelets and cryoprecipitate are given regularly. One such protocol, used in Grady Memorial Hospital in Atlanta, Georgia, is shown in [Table 53-4](#).<sup>106</sup>

Elderly (age >65 years) patients appear to tolerate MTP as well as their younger counterparts. Murray et al.<sup>107</sup> compared MTP in old (age >65 years) and young patients and found no difference in survival to discharge. For children the term *massive hemorrhage* is relatively new and is considered if transfusion volume exceeds 40 mL/kg.<sup>108</sup> A comparable definition is the administration of 50% of blood volume over 24 hours.<sup>109</sup> The adult definitions and treatments do not apply to the pediatric population because of the differences in size, physiology, nature of injury, and demographics. The circulating blood volume in the infant is 90 mL/kg and in children over 3 months, it is 70 mL/kg. Children have a greater hemodynamic reserve than adults, and vital signs deteriorate only if a significant quantity (about 35% to 40%) of blood is lost. A narrow pulse pressure is the most constant vital sign for early volume loss.<sup>110</sup> The high metabolic rate increases oxygen extraction, underscoring the importance of an adequate hemoglobin concentration. Above all, the procoagulant hemostatic proteins including the vitamin K-dependent factors are at subnormal levels until 6 months of age.<sup>110</sup> Neonatal platelet counts and function are normal, but fibrinogen is dysfunctional in the fetal form until 6 months to a year after birth. Plasmin generation and fibrinolysis are markedly reduced in infants. The PT and partial thromboplastin time (PTT) are mildly prolonged in infants and should not be used as a transfusion trigger. Thromboelastography, which looks at clot stability, is a better measure of coagulation status.

**Table 53-4** Massive Transfusion Protocol Used in Grady Memorial Hospital in Atlanta

Package	PRBCs	Plasma	Platelets	Cryoprecipitate
<b>Initiation</b>	<b>6 units (UD/TS)</b>	<b>6 U (UD)</b>		
1 (0.5 hr)	6 units (UD/TS)	6 U (UD)	1 apheresis <sup>a</sup>	
2 (1 hr)	6 units (UD/TS)	6 U (TS)		10 U
3 (1.5 hr)	6 units (UD/TS)	6 U (TS)	1 apheresis <sup>a</sup>	
4 (2 hr)	6 units (UD/TS)	6 U (TS)		10 U
5 (2.5 hr)	6 units (UD/TS)	6 U (TS)	1 apheresis <sup>a</sup>	
6 (3 hr)	6 units (UD/TS)	6 U (TS)		10 U

UD, universal donor; TS, type specific.

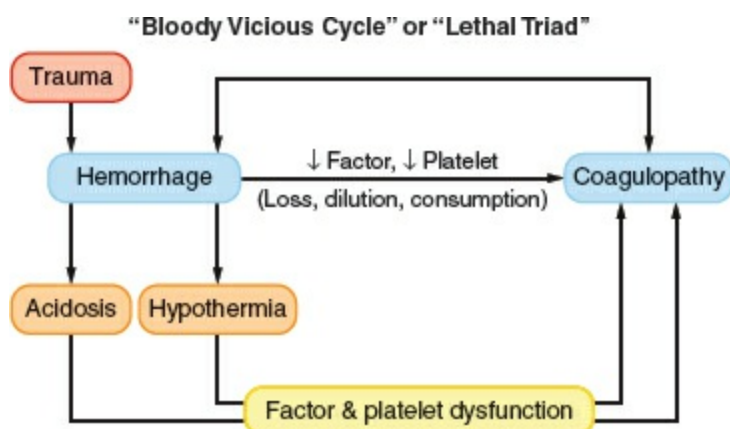

<sup>a</sup>One apheresis unit of platelet is equal to 8 to 10 standard units.

Reprinted with permission from Dente CJ, Shaz BH, Nicholas JM, et al. Early predictors of massive transfusion in patients sustaining torso gunshot wounds in a civilian level 1 trauma center. *J Trauma*. 2010;68:298.

The 1:1:1 ratio that is often applied to adults translates to 20 mL/kg of PRBCs, 20 mL/kg of FFP, and 10 mL/kg of platelets in children.<sup>111</sup> This ratio has not been tested rigorously in pediatrics and serves as a guideline pending prospective investigation. Tranexamic acid and other procoagulants are given according to the comfort and experience of the clinician. This drug and many other procoagulants have also not been tested in pediatric trauma. In pediatric patients currently the actual trigger for activating the MTP is a high injury severity score. The decision to activate MTP is made by an experienced pediatric trauma surgeon or anesthesiologist. Bleeding into the retroperitoneal space and in the brain is more common in pediatric patients than in adults and should not be missed in the initial evaluation of the pediatric trauma patient. Although intracranial bleeding, if not accompanied by another injury, is not likely to cause hypotension in adults, it can cause significant hypotension in the pediatric age group. The basic principles of administering blood components to promote both hemostatic and hemodynamic resuscitation in children are similar to the adult patient. Studies emphasize that a proper ratio of blood components (1:1:1) leads to better survival; presently evidence-based support for this is lacking in the pediatric population. There are several scoring systems that predict outcome for the massively transfused pediatric patient. The child who presents on admission with a base deficit above 6 or INR over 1.8 is predicted to have the highest mortality.<sup>110</sup>

One of the principal goals during early management of the hemorrhaging trauma victim is to avoid the development of the so-called vicious cycle or lethal triad, consisting of acidosis, hypothermia, and dilutional coagulopathy (Fig. 53-4). Both acidosis and hypothermia are major factors in the induction of coagulopathy. Resuscitation with crystalloids and PRBCs, which have no hemostatic activity, further adds to this effect by diluting platelets, already reduced in number and dysfunctional, and coagulation factors. Bleeding and intravascular coagulation further augment coagulopathy via loss or consumption of damaged or depleted platelets and coagulation factors.

Augmented coagulopathy further increases the blood loss, necessitating additional fluid replacement and thus maintaining the vicious cycle, which ultimately results in MOF and death. More recent findings suggest that coagulopathy of the trauma patient has two components: acute traumatic coagulopathy (ATC) and resuscitation-associated coagulopathy (RAC). The former develops shortly after trauma and is caused by hyperfibrinolysis and severe tissue injury that releases tissue factor, which in turn activates the coagulation pathways. This type of coagulopathy appears to be independent of hypothermia or dilution of factors by crystalloids. The latter is caused by hypothermia, fluids, and possibly other resuscitation-related factors. In most severe trauma patients coagulopathy is caused by a combination of ATC and RAC. In fact patients presenting with ATC will require more intense resuscitation and likely develop hypothermia and dilutional coagulopathy. However, it appears that the presence of ATC has greater effect on the development of MOF and death than the components of the vicious cycle. Coagulopathy itself in one study was an independent predictor of MOF and mortality independent of shock, injury severity, and the vicious triad.<sup>112</sup> Thus initiating resuscitation with a high ratio of hemostatic fluids and PRBCs early enough, preferably in the prehospital phase, may improve outcome in this setting.

**Figure 53-4** Schematic representation of bloody vicious cycle or lethal triad. Trauma-induced hemorrhage causes acidosis, hypothermia, and coagulopathy. Acidosis and hypothermia produce factor and platelet dysfunction, enhancing coagulopathy, which in turn causes increased bleeding. The cycle continues until death ensues, unless effective treatment by timely control of bleeding and correction of acidosis, hypothermia, and coagulopathy is instituted.

Rapid establishment of venous access with large-bore cannulae placed in peripheral veins that drain both above and below the diaphragm is essential for adequate fluid resuscitation in the patient who is severely injured. When vascular collapse and extremity injury impair access to arm or leg vessels, percutaneous cannulation of the internal jugular, subclavian, or femoral veins

can be performed. Ultrasound guidance may facilitate cannulation of the internal jugular vein and prevent needle entry and infusion of fluids into the pleural space in patients with a large hemothorax. Ultrasound may also be used for infraclavicular access to the axillary vein, the cephalic or basilic veins at the midarm level, or the femoral vein. If necessary, a cutdown to a saphenous or arm vein can be rapidly performed in older children and adults. In children less than 5 years of age, intraosseous cannulation has a high success rate and a low incidence of complications. Infusion rates comparable with those obtained with intravenous lines are possible in small children, although a pressure infusion device may be necessary to achieve adequate flow.

Patients who arrive in the ED in cardiac arrest require advanced cardiac life support. However, the success rate of external cardiac massage in hypovolemic trauma victims is likely to be low.<sup>113</sup> ED thoracotomy not only permits performance of open cardiac massage but also aids resuscitation efforts by allowing drainage of pericardial blood, control of cardiac and great vessel bleeding, and application of a cross-clamp to the aorta. A small Foley catheter introduced into the right atrium or, in desperate situations, a large-bore catheter or introducer inserted in the descending aorta can be used for rapid administration of fluids. Not all patients who arrive in the ED in cardiac arrest benefit from ED thoracotomy. Countless reports attempted to identify predictors of survival to avoid fruitless ED thoracotomies and thereby decrease the risk of provider contamination with possibly infected patient blood. Some of the survival predictors include injury mechanism, anatomic injury location, extent of physiologic derangement, presenting signs of life, and presence of cardiac rhythm or vital signs. More recently, after review of available evidence-based studies, the survival rate with or without intact neurologic function after ED thoracotomy in different types of injuries in the presence and absence of signs of life has been reported.<sup>114</sup> Patients arriving with penetrating thoracic injury and signs of life have the greatest likelihood to survive (21.3%), and 11.7% have and a neurologically intact survival. In contrast patients arriving with pulseless blunt injury without signs of life have the least likelihood to survive (0.7%) and to have neurologically intact survival (0.1%). Signs of life include pupillary response, spontaneous ventilation, presence of carotid pulse, measurable or palpable blood pressure, extremity movement, and cardiac electrical activity. The highest survival with or without intact neurologic function occurred after penetrating thoracic trauma presented with signs of life. Those without signs of life on arrival had a lower rate of survival, but an ED thoracotomy could still be justified. Patients presenting pulseless after penetrating extrathoracic injury had more favorable outcome if they had some signs of life than those who did not. Those patients who had blunt injury with or without signs of life had a very

poor survival rate, precluding ED thoracotomy.

## Early Management of Specific Injuries

### Head Injury

Approximately 40% of deaths from trauma are caused by head injury, and indeed even a moderate brain injury may increase the mortality rate of patients with other injuries. In nonsurvivors, progression of the damaged area beyond the directly injured region (secondary brain injury) can be demonstrated at autopsy.<sup>115</sup> The major factor in secondary injury is tissue hypoxia, which results in lactic acidosis; free radical generation; prostaglandin synthesis and release of excitatory amino acids (primarily glutamate); lipid peroxidation and breakdown of cell membranes; entry of large quantities of sodium, calcium, and water into the cells; and leakage of fluid from the blood vessels into the extracellular space.<sup>116,117</sup> This process results in brain edema and both regional and global disturbances of the cerebral circulation. Thus, of all the possible secondary insults to the injured brain, decreased oxygen delivery as a result of hypotension and hypoxia has the greatest detrimental impact (Table 53-5).<sup>118,119</sup>

**Table 53-5** Effects on Outcome of Secondary Insults on the Brain Occurring from Time of Injury Through Resuscitation<sup>a</sup>

Secondary Insults	No. of Patients	Total Patients (%)	6-Month Outcome (%)		
			Good/Moderate	Severe/Vegetative	Dead
Total cases	717	100	43.0	20.2	36.8
Neither	308	43.0	63.9	10.2	26.9
Hypoxia	161	22.4	50.3	21.7	28.0
Hypotension	62	11.4	32.9	17.1	50.0
Both	166	23.2	20.5	22.3	57.2

<sup>a</sup>Data from hospital emergency departments enrolled in Traumatic Coma Data Bank.

Reprinted with permission from Prough DS, Lang J. Therapy of patients with head injuries: key parameters for management. *J Trauma*. 1997;42(Suppl):10S.

Brain injury by itself does not cause hypotension in adults except as a preterminal event and in pediatric patients. However, more than half of the patients with severe head trauma have other injuries that render approximately 15% of them hypotensive. Approximately 30% are hypoxic on admission as a result of central respiratory depression or associated chest injuries. Furthermore, exposure to these insults is likely to occur during any phase of the continuum of hospital care: in the emergency room, the radiology unit, the OR, the postanesthesia care unit, the ICU, or elsewhere. The most common early complications of head trauma are intracranial hypertension, brain herniation, seizures, neurogenic pulmonary edema,

cardiac dysrhythmias, bradycardia, systemic hypertension, and coagulopathy.

## Diagnosis

Mental impairment after trauma may have any of several etiologies. However, the possibility of hypoxia and shock must always be considered first. If consciousness remains depressed despite ventilation and fluid replacement, a head injury is assumed to be present and the patient is managed accordingly. As noted, hypotension is the most important cause of death in the head-injured patient. Chesnut<sup>119</sup> demonstrated that a single episode of SBP less than 90 mmHg is associated with a 50% increase in mortality, and subsequent episodes or lower pressures increase mortality even further.<sup>120</sup> Therefore, every effort should be made to support the blood pressure with fluids and vasopressors (preferably phenylephrine, which does not constrict cerebral vessels) and ensure adequate oxygenation *before* the unconscious patient is evaluated. A baseline neurologic examination should be performed after initial resuscitation but before any sedative or muscle relaxant agents are administered, and this should be repeated at frequent intervals because the patient's condition may change rapidly. Anesthetic and adjunct drugs may render an adequate neurologic examination impossible; thus, long-acting muscle relaxants, opioids, sedatives, or hypnotics should be given selectively.<sup>118,121</sup>

Consciousness can be initially assessed within a few seconds using the AVPU system (*a*lert; *r*esponds to verbal stimuli; *r*esponds to *p*ain; *u*nresponsive) (Table 53-6). More precise information is provided by the GCS, which provides a standard means of evaluating the patient's neurologic status. In this test, the sum of the scores obtained for eye opening, verbal response, and motor activity correlates with the state of consciousness, the severity of the head injury, and the prognosis.<sup>121</sup> Assessment of motor function should be performed on the extremity that responds best. The limb affected by neurologic injury is examined, but the result is not considered in the GCS.

**Table 53-6** Two-Level Initial Evaluation of Consciousness

<b>Level 1. AVPU System</b>	
A = <u>A</u> lert	
V = Responds to <u>v</u> erbal stimuli	
P = Responds to <u>p</u> ainful stimuli	
U = Unresponsive	
<b>Level 2. Glasgow Coma Scale (GCS)</b>	
Eye opening (E)	
Spontaneous, already open and blinking	4
To speech	3
To pain	2
None	1
Verbal response (V)	
Oriented	5
Answers but confused	4
Inappropriate but recognizable words	3
Incomprehensible sounds	2
None	1
Best motor response (M)	
Obeys verbal commands	6
Localizes painful stimulus	5
Withdraws from painful stimulus	4
Decorticate posturing (upper extremity flexion)	3
Decerebrate posturing (upper extremity extension)	2
No movement	1
GCS $\leq 8$ = deep coma, severe head trauma, poor outcome	
GCS 9–12 = conscious patient with moderate injury	
GCS $>12$ = mild injury	

Dilatation and sluggish response of the pupil are signs of compression of the oculomotor nerve by the medial portion of the temporal lobe (uncus). A maximally dilated and unresponsive “blown” pupil suggests uncal herniation under the falx cerebri. The presence of similar findings in ocular injuries makes interpretation of pupillary findings difficult when eye and head injuries coexist. However, the pupillary reaction to light is usually more sluggish in the head-injured patient.

CT scanning is used for the diagnosis of most acute head injuries. Positive CT findings after acute head injury include midline shift, distortion of the ventricles and cisterns, effacement of the sulci in the uninjured hemisphere, and presence of a hematoma at any location in the cranial vault. Subdural hematomas usually have a concave border, whereas epidural hematomas present with a convex outline classically termed a *lenticular* configuration. Patients in severe coma (GCS  $<8$ ) have a 40% likelihood of an intracranial hematoma. Those with higher GCS scores are less likely to have had intracranial bleeding although it is evident that the significant incidence of this complication even in these patients necessitates a CT study, preferably

with contrast enhancement. Other benefits of CT scanning include detection of intracranial air and depressed skull fractures.

## Management

The primary objective of the early management of brain trauma is to prevent or alleviate the secondary injury process that may follow any complication that decreases the oxygen supply to the brain, including systemic hypotension, hypoxemia, anemia, raised ICP, acidosis, and possibly hyperglycemia (serum glucose >200 mg/dL). These insults cause exacerbation of trauma-induced cerebral ischemia and metabolic derangements, worsening the outcome.<sup>122,123</sup> *The most important therapeutic maneuvers in these patients are aimed at normalizing ICP, CPP, and oxygen delivery.* The Brain Trauma Foundation and the American Association of Neurological Surgeons have published evidence-based guidelines for the treatment of head-injured patients.<sup>118</sup> Primary therapy includes normalization of the systemic blood pressure (mean blood pressure >80 mmHg) and maintaining the PaO<sub>2</sub> over 95, the ICP below 20 to 25 mmHg, and the CPP at 50 to 70 mmHg. Maintaining the CPP at levels above 70 mmHg, the former standard, is no longer advised because it may be associated with an increased incidence of ARDS.<sup>118</sup> The patient is kept at 30-degree head elevation, sedation and paralysis are employed as necessary, and cerebrospinal fluid is drained through a ventriculostomy catheter if available. Rapid and adequate restoration of the intravascular volume with isotonic crystalloid and, if necessary, with colloid solutions should be aimed at maintaining the CPP between 50 and 70 mmHg while attempting to minimize further brain swelling. LR solution, which is slightly hypotonic (Na<sup>+</sup> 130 mEq/L, osmolality ~255 mOsm/L), may promote swelling in uninjured areas of the brain if it is given in large quantities. Edema tends to occur in injured brain regions regardless of the type of solution administered because of increased permeability of the blood–brain barrier. To minimize edema formation, it is wise to monitor serum osmolality and to replace LR solution with isotonic normal saline. If serum osmolality cannot be measured, this change can be made empirically after 3 L of LR solution.

Much of the focus has been on in-hospital management of patients with brain trauma, but there is increasing interest in the impact of prehospital care on the outcome in these patients. Multiple studies have demonstrated an association between prehospital endotracheal intubation and mortality of patients with severe brain trauma.<sup>124,125</sup> In a large multicenter retrospective study, Davis et al.<sup>126</sup> found that patients with GCS no higher than 8, in whom endotracheal intubation was attempted at the accident site, had a higher mortality than those who were not intubated until arrival at the emergency

room (adjusted odds ratio of 2.91;  $p < 0.01$ ). The authors speculated that this may result from physiologic insults during intubation (elevated ICP, oxygen desaturation, or inadvertent postintubation hyperventilation and cerebral hypoperfusion with ischemia) and concluded that there may be no benefit to prehospital endotracheal intubation.

Normalization of the ICP has been shown to reduce mortality.<sup>127</sup> Effective reduction in ICP can be provided, or at least aided, by administration of mannitol, an important part of the management of severe head injury. It is administered in boluses of 0.25 to 0.5 g/kg and repeated every 4 to 6 hours as needed to control the ICP.<sup>118</sup> Higher doses, up to 2 g/kg, are recommended by some authors.<sup>128</sup> In addition to its osmotic diuretic effect, this agent may improve cerebral blood flow (CBF) and O<sub>2</sub> delivery by reducing the Hct and thus the blood viscosity immediately after administration.<sup>118</sup> There is a risk of hypovolemia and resultant hypotension when therapeutic doses of mannitol are used. If the ICP elevation persists, additional doses of mannitol should be given cautiously. Acute mannitol toxicity, manifested by hyponatremia, high serum osmolality, and a gap between calculated and measured serum osmolality over 10 mOsm/L, may result when the drug is given in large doses (2 to 3 g/kg) or to patients with renal failure. Mannitol should be used with great care in the presence of hypotension, sepsis, nephrotoxic drugs, or pre-existing renal disease, because these may also precipitate renal failure.<sup>118</sup> Further, the effects of mannitol result from its activity in regions of the brain where the blood–brain barrier is intact. It may exacerbate edema in injured areas in which it may easily enter the tissues.

The addition of relatively small volumes of hypertonic saline in concentrations between 3% (6 to 8 mL/kg) and 7.5% (4 mL/kg) followed by infusion of LR may be beneficial in multiple-trauma patients with head injury.<sup>129</sup> In addition, hypertonic saline (15% solution), in bolus doses of 0.42 mL/kg, is as efficacious as mannitol for initial therapy of elevated ICP in this patient population.<sup>128</sup> Like mannitol, hypertonic saline draws fluid from the intracellular space, and thus in addition to restoring the blood volume, it reduces brain edema and prevents elevation of the ICP.<sup>130</sup> On the other hand, hypertonic saline may, also like mannitol, increase edema in the injured region of the brain.<sup>131</sup> However, administration of hypertonic saline cannot be maintained for long periods. It may cause hypernatremia, hyperosmolality, or hyperchloremic acidosis, probably from renal bicarbonate loss secondary to increased levels of chloride (Cl<sup>-</sup>). Serum concentrations of sodium (Na<sup>+</sup>) and Cl<sup>-</sup> and the patient's acid–base status should be followed, and the administration of hypertonic saline should be discontinued if plasma Na<sup>+</sup> reaches 160 mEq/L.

There have been several studies comparing hypertonic saline and mannitol for brain relaxation during craniotomy.<sup>132</sup> Although saline seems to be

somewhat more effective in reducing brain swelling, the studies were all underpowered, and the clinical relevance of their results is questionable. Resuscitation with albumin 5% or 25% provides a sustained improvement in vital signs, but the increase in colloid osmotic pressure produced by these solutions may be associated with an increased risk of mortality.<sup>133</sup>

Hyponatremia in these patients results from intravascular volume expansion rather than sodium loss; thus treatment with saline solutions is not appropriate. Because of a synergistic action between mannitol and loop diuretics in improving the ICP, addition of furosemide may be a safer and more effective treatment than increasing the dose of mannitol when intracranial hypertension persists. Until about 1995, hyperventilation to a PaCO<sub>2</sub> of 25 to 30 mmHg was a mainstay of the therapy of head injury. However, brain ischemia, which is probably the most threatening consequence of head injury, is likely to occur during the first 6 hours after trauma even when the CPP is maintained above the generally recommended 50 to 70 mmHg.<sup>134</sup> Coles<sup>134</sup> has demonstrated by positron emission tomography scanning that a significant increase in the region of critical hypoperfusion may result from hyperventilation in these patients. This hypoperfusion seems to be caused largely by increased cerebral vascular resistance, which may be enhanced by hyperventilation. However, some degree of hyperventilation may be necessary for short periods of time in patients who have severe injuries and elevated ICP that does not respond to normal ventilation and diuretics, although this should not be used during the first 24 hours following injury.<sup>118</sup> Its use after the initial phase should be based on monitoring of the ICP. It should be noted that hyperventilation in the severely brain-injured patient may also be associated with acute lung injury.<sup>135</sup>

If the ICP remains elevated despite all of these measures, pentobarbital (3 to 10 mg/kg given over 0.5 to 2.5 hours, followed by a maintenance infusion of 0.5 to 3.0 mg/kg/hr, aimed at a serum concentration between 2.5 and 4.0 mg/dL) may be required. High-dose barbiturates are of no value in the routine therapy of head injury and should be used only for refractory ICP elevation. Of course, immediate surgical decompression, especially of epidural hematomas, is an important factor in reducing morbidity and mortality.

Over the past several years there has been much debate regarding optimal blood glucose level in critically ill patients. Brain-injured patients are unique members of this group because brain metabolism is altered by the injury and is heavily dependent on glucose. Hypoglycemia (<40 g/dL) may cause metabolic crisis, whereas hyperglycemia (>200 g/dL) can cause detrimental effects through excitotoxicity, oxidative stress, and inflammatory cytokine release. However, tight insulin control therapy (80 to 110 mg/dL) has been

associated with episodes of hypoglycemia. As a result, the current recommendations are to maintain glucose levels of 110 to 180 mg/dL.<sup>136</sup>

Nearly 75% of severely brain-injured patients who die expire within the first 3 days following the initial trauma. Many of the survivors will later succumb to nonneurologic organ dysfunction involving pulmonary failure and cardiac impairment, which may be related to sympathetic hyperactivity.  $\beta$ -Blocker therapy has been proposed as a treatment that may be beneficial in these patients.<sup>137</sup> The optimal agent, the dose level, the timing, and the duration of treatment, however, remain to be determined.

If the patient is hemodynamically stable, a CT scan is performed. The strictest attention should be paid to ensure adequate oxygenation, ventilation, blood pressure, and ICP control during the procedure. If the patient is hemodynamically unstable or requires emergency surgery for associated injuries and has a history suggesting a head injury, even though a significant intracranial hematoma is unlikely on clinical grounds, intraoperative ICP monitoring is indicated to permit rapid detection of ICP elevation. Both intracranial hematomas and hemorrhage in other regions have a high surgical priority. In the multiple trauma victim, prioritization between the two is based on the severity of each injury. Because there is no time to obtain a CT scan of the head in patients with both profuse hemorrhage and brain herniation, the patient is brought directly to the OR for simultaneous control of the bleeding site and evacuation of the intracranial hematoma. The site of the craniotomy can be determined by a ventriculogram or an ultrasound examination with a pencil-tip probe; both tests may be performed under local anesthesia through a frontal burr hole.

### *Anesthetic Management*

Intraoperative management is a continuation of the pre-existing intensive care.<sup>138</sup> Thus in addition to providing anesthesia, it is necessary to maintain the blood pressure, oxygenation, and CPP. It should be noted that there have been no studies comparing intravenous to inhalation techniques. It seems reasonable to assume that preserving the vital signs is more important than the specific means employed to accomplish this. Beyond the standard ASA monitors, an arterial line will permit beat-to-beat monitoring of the blood pressure, along with following blood gas levels and blood glucose. An ICP monitor will generally be placed by the neurosurgeons. Vital signs, PaO<sub>2</sub>, and PaCO<sub>2</sub> should be maintained at the same levels as they are before the patient reaches the OR. Preoperative fluid management is also continued during surgery. Blood should be administered carefully, because overtransfusion may increase blood viscosity and thus decrease CBF.

It may be possible to improve the outlook for brain-injured patients, as outlined here:

1. The earlier definitive treatment is initiated, the better the outcome is likely to be. Rudehill et al.<sup>139</sup> have demonstrated improvement in outcomes in a large series of patients when care was initiated by anesthesiologists at the accident scene. On the other hand, Haltmeier et al.<sup>140</sup> found no difference between the outcomes for traumatic brain injury patients treated onsite by anesthesiologists in Bern or paramedics in US.
2. Meanwhile, the wide variety of types and severities of injury and of responses to treatment—both among different patients and in the same patient at different times—imply that therapeutic interventions must be individualized.<sup>141,142</sup> These aims may be met, at least partly, by carefully structured intensive care.<sup>143,144</sup> Therapeutic goals should be set explicitly and reviewed, and altered if necessary, at every change of shift.

For instance, the traumatic brain injury pathway guideline of Bellevue Hospital Center, New York, generally follows the recommendations of the Brain Trauma Foundation guidelines, with adjustments depending on GCS and ICP.

Indeed, early intervention and controlled management may explain much of the improvement in outcomes that has been obtained over the past 20 years, including the results obtained by Patel et al.<sup>145</sup> and Palmer et al.<sup>143</sup> using strict protocol-driven therapies (in the latter case, the 1995 Brain Trauma Foundation guidelines) (Table 53-7).

## *Spine and Spinal Cord Injury*

### **Initial Evaluation**

The objective in the evaluation of spinal trauma is to diagnose instability of the spine and the extent of neurologic involvement. Not stabilizing the spine in the first hours after a major accident until a definitive diagnosis is established carries the risk of converting a neurologically intact patient into a paraplegic or quadriplegic. During transport to the hospital, the patient should be immobilized with a hard collar, a spine board, and tape. After admission, patients should not be left on a rigid spine board for longer than 1 hour, especially when they are paralyzed, because of the risk of decubitus ulcers.

**Table 53-7** 6-Month Outcomes for Patients with Brain Injury In Various Studies

Name of Study	No. of Patients	Year Published	6-Month Outcome (%)			Comments
			Good/ Moderate	Severe/ Vegetative	Dead	
Three-country Jeanett and Teasdale <sup>146</sup>	700	1977	38	11	51	Various treatments, some untreated
Miller et al. <sup>147</sup>	158	1981	47	12	40	Vent, surgery, ICP monitoring, hyperventilation, and Rx
Traumatic Coma Data Bank (TCDB) <sup>148</sup>	717	1997	43	20	37	Total patients, standard therapy
TCDB <sup>148</sup>	308	1997	54	19	27	Patients without hypotension or hypoxia
Palmer et al. <sup>143</sup>	56	2000	70	14	16	1995 BTF Guidelines
Rudehill et al. <sup>139</sup>	1,508	2002	69	11	20	Standard protocol, early management
Patel et al. <sup>149</sup>	129	2002	63	13	20	NCCU Protocol

Results of various treatment protocols for brain injuries. The three-country study surveyed patients who had received a wide variety of treatment; some were untreated. Miller et al.<sup>147</sup> relied on hyperventilation and, when necessary, barbiturates. The TCDB patients were treated similarly; note the difference in outcome of the patients who did not experience hypotension or hypoxia. The final three studies are described in the text. ICP, intracranial pressure; BTF, Brain Trauma Foundation; Rx, other treatment; NCCU, neurosurgical critical care unit.

In the conscious patient, the diagnosis is relatively easy: a history of a motor vehicle, industrial, or athletic accident; an act of violence; a fall; penetrating trauma resulting in a neurologic deficit below a specific spinal level; or pain and tenderness over the involved vertebrae strongly suggest a spine injury. It should be noted, however, that spinal pain is not always localized to the level of injury.<sup>150</sup> Obviously, these symptoms are difficult to elicit in the comatose patient. In these circumstances, flaccid areflexia, loss of rectal sphincter tone, paradoxical respiration, and bradycardia in a hypovolemic patient suggest the diagnosis. In cervical spine trauma, an ability to flex but not to extend the elbow and response to painful stimuli above but not below the clavicle also indicate neurologic injury. Current guidelines consider absence of neck pain or paresthesia and a negative physical examination—lack of tenderness with palpation and during voluntary flexion and extension of the neck—in a neurologically intact, conscious patient as adequate indications for ruling out a cervical spine injury without further radiologic studies. Alcohol intoxication and distracting associated injuries do not seem to alter these criteria as long as the patient is alert, conscious, and able to concentrate. A large meta-analysis of obtunded trauma patients demonstrated that modern multislice helical CT imaging is sufficient to detect unstable cervical spine injuries. However, this approach may still miss some patients at risk for subsequent cervical cord insult.<sup>151</sup>

Depending on the degree of deficit, spinal cord injuries are categorized as *complete* or *incomplete*. Intact sensory perception over the sacral distribution and voluntary contraction of the anus (sacral sparing) are present in incomplete, but not in complete, injuries. There is practically no possibility of significant neurologic recovery in complete injury, whereas functional restoration may occur in up to 50% of patients after incomplete injuries. In

some patients the development of *spinal shock*, which is manifested by absolute flaccidity and loss of reflexes, precludes distinguishing between complete and incomplete injuries during the initial phase of treatment. Therefore, even in the absence of sacral sparing, the possibility of neurologic recovery dictates that all possible efforts be made at this time to prevent further damage and to preserve cord function. A similar principle applies to the evaluation of the level of injury. After the first few days, spinal cord edema subsides, and the final injury level is commonly a few segments lower than on initial presentation. Thus, early therapeutic efforts should not be abandoned even in the patient with a high-level injury, which carries a grim functional prognosis.

Spinal shock is probably caused by direct trauma to the spinal cord and usually subsides within days to weeks. The term is frequently used as a misnomer for *neurogenic shock*, which is defined as hypotension and bradycardia caused by the loss of vasomotor tone and sympathetic innervation of the heart as a result of functional depression of the descending sympathetic pathways of the spinal cord. It is usually present after high thoracic and cervical spine injuries and improves within 3 to 5 days.<sup>152</sup>

## **Initial Management**

The spinal cord, a microcosm of the brain, is also vulnerable to a secondary injury process that may be a product of hypotension, hypoxia, and probably other physiologic complications.<sup>153</sup> Prompt recognition and aggressive treatment of these insults, which may also result from associated trauma, may minimize exacerbation of spinal cord lesions and improve the long-term outlook of these patients.<sup>122,154</sup>

### *Immobilization and Intubation*

Maintenance of immobilization of the injured spine is of paramount importance. If a cervical spine fracture is suspected, immobilization or MILS of the neck is necessary before the patient is moved. If the patient has a thoracic or lumbar injury, a careful logrolling maneuver should be used.<sup>153,155</sup>

About one-third of paraplegic patients require airway management, mostly within the first 24 hours after injury. Signs of respiratory distress or fatigue, or a rising respiratory rate or PaCO<sub>2</sub>, are major indications for ventilatory assistance. Severe bradycardia or dysrhythmias may result from unopposed vagal activity during tracheal intubation or suctioning: The patient must be preoxygenated, and atropine (0.4 to 0.6 mg) should be given before any instrumentation. If bradycardia develops during airway management, treatment includes additional atropine, glycopyrrolate, isoproterenol, or, if necessary, cardiac pacing.

The techniques of intubation in spine-injured patients are discussed in the Airway Management section.

## Respiratory Complications

Respiratory complications are common in all phases of the care of spinal cord–injured patients and are the most frequent cause of death in the acute stage.<sup>156,157</sup> In the initial period, these problems may be augmented by associated brain, neck, chest, or abdominal injury; alcohol intoxication; or the effects of self-administered or iatrogenic drugs. Injuries at C5 or lower are usually associated with normal tidal volumes because the function of the diaphragm is intact, whereas patients with injuries at C4 or above may require permanent ventilatory assistance. Nevertheless, accessory respiratory muscle paresis may cause a significant loss of expiratory reserve even when the injury involves the lower spinal segments.<sup>158,159</sup> Pulmonary edema is another significant cause of respiratory dysfunction. A severe catecholamine surge follows acute trauma to the spinal cord.<sup>160</sup> Although the resultant severe hypertension lasts for only a few minutes, its effects persist. It may produce both pulmonary capillary damage, as a result of shifting of a large portion of the blood volume into the pulmonary circulation, and left ventricular dysfunction. Overzealous fluid therapy to treat the patient's initial hypotension may lead to acute pulmonary edema when the sympathetic activity returns approximately 3 to 5 days after the injury.

Paradoxic respiration in the quadriplegic patient results from partial chest wall collapse during inspiration. It may produce limitation of the tidal volume and an increased risk of hypoventilation.<sup>159</sup> The situation is aggravated when the patient is in an upright position. The diaphragm cannot maintain its normal domed shape, the only way in which it can contract efficiently, because the weight of the thoracic contents is not opposed by the normal tone of the abdominal muscles. Thus, in contrast to other diseases that produce respiratory insufficiency, the supine position improves respiration in persons with quadriplegia (Fig. 53-5).<sup>159</sup> It should be noted that disordered breathing (probably mostly from obstructive sleep apnea) is common while the patient is asleep and may exacerbate the problems caused by other complications.<sup>161</sup>

**Figure 53-5** Effect of semi-Fowler's position on ventilation in quadriplegic patients. Adapted with permission from Winslow C, Rozovsky J: Effect of spinal cord injury on respiratory system. *Am J Phys Med Rehab.* 2003;82:803–14.

Other causes of inadequate respiration in the early phase of spinal cord injury are aspiration of gastric contents, atelectasis, pneumonia, and bronchoconstriction. Management includes careful observation of the patient's breathing and preparation to ventilate the lungs and intubate the trachea at the first sign of respiratory depression.<sup>159</sup>

## Hemodynamic Management

Hemodynamic management of quadriplegic patients includes a complete assessment, with insertion of a central venous or pulmonary artery catheter (PAC) if necessary, as early as possible after injury. In as many as 25% of patients with cervical spinal cord injuries, left ventricular dysfunction may contribute to the hypotension.<sup>162</sup> There is evidence to support the maintenance of mean arterial pressure above 85 mmHg.<sup>163</sup> Decreased preload can be treated with fluid infusion using cardiac function curves as a guide. In general, volume may be safely replaced to a central venous or pulmonary capillary wedge pressure (PCWP) of 18 mmHg.<sup>162</sup> This avoids, or at least limits, the severity of the pulmonary edema described previously. Hypotension, despite adequate fluid infusion, acidosis, or low mixed venous  $PO_2$ , requires treatment with inotropes such as dopamine.

A review by Dhall et al.<sup>164</sup> indicates that these patients frequently experience deep vein thrombosis (DVT), which may adversely affect both hemodynamic and pulmonary function. The authors recommend the initiation of low-molecular-weight or low-dose unfractionated heparin therapy, combined with a rotating bed, compression stockings, or electrical stimulation, within 72 hours of the injury. This therapy should be held on the day of any surgical procedure.

## Anesthetic Considerations

Any anesthetic technique compatible with the patient's general condition is satisfactory for the spinal cord–injured patient. Hypotension is very common during anesthesia in quadriplegics. Placement of a TEE or a central venous catheter or PAC may facilitate management of the patient's volume and blood pressure status.

## Neck Injury

Both penetrating and blunt trauma may injure the major structures in the neck: vessels, respiratory and digestive tracts, and nervous system. Hemorrhage, asphyxia, mediastinitis, paralysis, stroke, or death may result if these injuries are not promptly recognized and treated.

Penetrating neck injuries usually present with obvious clinical manifestations; blunt cervical trauma may be more subtle. Airway compromise or obstruction, brisk bleeding from the wound site, an expanding pulsatile hematoma, and shock with or without external bleeding are obvious signs of cervical vascular injury and dictate immediate airway management and vascular control. Decreased or absent upper extremity or distal carotid pulses, as well as carotid bruit or thrill, are pathognomonic for cervical arterial injury. Hemothorax, pneumothorax, and signs of air embolism are also suggestive of cervical vascular injury. Respiratory distress, cyanosis, or stridor is an obvious sign of airway injury and requires immediate tracheal intubation. Other signs that strongly suggest airway injury are dysphonia, hoarseness, cough, hemoptysis, air bubbling from the wound, subcutaneous crepitus, and laryngeal tenderness. Because of their dynamic nature, cervical airway injuries may rapidly progress to obstruction. The patient, therefore, should be observed carefully and the trachea intubated at the first sign of problems.

Anatomic location of the penetrating neck injury is classified in to three zones. Zone I is the narrow area above the clavicles extending from the cricoid cartilage to the level of the sternal notch; zone II is the area between the cricoid cartilage and the angle of the mandible; and zone III comprises the area between the angle of the mandible and the cranial base. Penetrating injuries involving zones I and III are relatively infrequent and difficult to manage surgically because of availability of limited exposure. Neck injuries most commonly involve zone II. Physical examination as a screening tool for further overall management has utmost importance for these injuries. A prospective multicenter study showed that clinical signs and symptoms often reliably indicate the cervical structures injured and prevent unnecessary imaging, and, if imaging is needed, multidetector CT is a highly sensitive and specific screening tool.<sup>165</sup>

Patients present with hard and soft signs. Those with hard signs require urgent or emergent surgery, whereas those with soft signs can be evaluated further using CT angiography.<sup>166</sup> Hard signs include hypotension/shock, active bleeding, expanding hematoma, neurologic deficit, airway compromise, air bubbling through wound, massive subcutaneous emphysema, and hematemesis. Signs of airway compromise require management even before arrival at the OR.

Esophageal injuries, whether in the neck or in the chest, are insidious and difficult to diagnose. Dysphagia, odynophagia, hematemesis, subcutaneous crepitus, prevertebral air on a lateral cervical radiograph, and major concomitant injuries to other cervical structures suggest an esophageal injury and call for confirmation with an esophagram. A management algorithm for surgery of the esophageal injuries has been made available by the Western Trauma Association.<sup>167</sup>

The neurologic manifestations of a penetrating neck injury vary depending on the injured structure. Partial spinal cord transection produces Brown-Séquard syndrome with ipsilateral motor and contralateral sensory deficit below the injury. Complete spinal cord transection, depending on the level of injury, produces paraplegia or quadriplegia, usually with neurogenic shock. Occasionally, luminal occlusion of the carotid and vertebral arteries may lead to a hemispheric cerebrovascular accident; associated hypotension increases the likelihood of this event.

Blunt cervical vascular injuries usually present with a hematoma that may compress the cervical veins, displace the airway, and produce pharyngeal and laryngeal congestion. Injury to an artery may produce an intimal tear, pseudoaneurysm, fistula, or thrombosis. If a carotid or vertebral artery is involved, cerebral ischemia may occur. Often thrombosis develops gradually over minutes to a few hours; thus the appearance of neurologic symptoms is delayed in approximately 40% of patients. Symptomatic patients may present with a cervical bruit, altered mental status, or lateralizing neurologic deficits including hemiparesis, transient ischemic attacks, amaurosis fugax, or Horner syndrome. The mortality rate associated with blunt carotid injury varies between 15% and 28%, and 15% to 50% of survivors have neurologic deficits.<sup>168</sup> Identification of a blunt or penetrating carotid injury in an asymptomatic patient using ultrasound, CT, or CT angiography not only allows early institution of antiplatelet therapy, systemic anticoagulation, endovascular intervention, or surgical repair<sup>168,169</sup> but also occasionally prevents the neurologic deficits that may follow surgery for associated injuries in an unprotected patient.

Airway injuries after blunt trauma are rare but carry an overall mortality rate of 2%.<sup>168</sup> Their severity varies from a simple mucosal tear or hematoma to a comminuted laryngeal cartilage fracture or complete cricotracheal

separation (Table 53-1). They frequently require primary laryngeal repair or tracheostomy. Anesthetic management is complicated not only by relatively complex airway management problems<sup>45,48</sup> (discussed in the airway evaluation and intervention section) but also by associated skull base, intracranial, open neck, cervical spine, esophageal, or pharyngeal injuries.<sup>66,170</sup>

## Chest Injury

Although a high percentage of thoracic injuries can be treated conservatively, patients who need surgery may have major intraoperative physiologic disturbances.

### Chest Wall Injury

Rib, scapula, and sternal fractures, in addition to interfering with adequate respiration, may be associated with severe underlying thoracic, abdominal, cranial, and skeletal injuries. The management principles for these injuries are similar to those previously described for flail chest, although the need for mechanical ventilation is less likely in single rib fractures treated with systemic analgesics than in a flail chest. Effective pain relief, preferably with continuous thoracic epidural anesthesia or paravertebral or intercostal block, is central to management.<sup>66</sup>

### Pleural Injury

Occult pneumothorax is easy to miss in major trauma. The presence of subcutaneous emphysema, pulmonary contusion, and rib fractures should raise suspicion of coexisting pneumothorax.<sup>54</sup> Tension pneumothorax involving over 50% of a hemithorax presents with dyspnea, tachycardia, cyanosis, agitation, diaphoresis, neck vein distention, tracheal deviation, and displacement of the maximal cardiac impulse to the contralateral side.

Although an upright plain chest radiograph provides the best opportunity for detection of pneumothorax, this position may be impossible or contraindicated in patients who are experiencing major hemorrhage or those with suspected spine injury. Air in the pleural space tends to accumulate in the anteromedial sulcus first, and then in lateral and caudal regions, often producing hemodynamic alterations and the deep sulcus sign on the anteroposterior chest radiogram in supine or semirecumbent patients. Transthoracic ultrasound by positioning the ultrasound probe longitudinally over the intercostal space may be used for the emergency diagnosis of pneumothorax. Normally, movement of the lung beneath the chest wall, in

addition to pleural sliding, produces vertical B lines, so-called comet tail artifacts from echo-dense areas on the lung surface. In addition, a two-dimensional ultrasound image of the normal lung shows echogenic horizontal lines (A lines), which appear at the same distances as the distance between the probe and the first A line. Comet tail B lines that appear during breathing erase A lines. In the presence of pneumothorax, neither lung motion, sliding, or comet tails can be seen. In the time-motion mode (M mode), lung tissue has a granular appearance. Pneumothorax in this mode appears in a horizontal line pattern. Often in the supine position pleural air moves anteriorly, compressing the lung posteriorly on the dependent side. The junction between the two appears as a vertical line called the lung point, which, if noted, is pathognomonic for pneumothorax.<sup>171</sup> A lung point may be seen when there is a relatively small volume of pneumothorax and during expiration, pleural air comes under one side of the ultrasound probe, producing a time-motion image that shows a granular pattern (normal lung) on one side and a horizontal line pattern (pneumothorax) on the other side of the screen. During inspiration with expansion of the lung, the entire lung tissue is under the probe, and a normal granular appearance may be obtained with time-motion image. It should be emphasized that diagnosis of pneumothorax with ultrasound relies primarily on the movement of the lung rather than frozen images. Thus lung sliding and comet tail artifacts, which are produced by the movement of the lung, are the most commonly utilized features. Ultrasound examination may also be helpful in detecting residual pleural air after placement of the thoracostomy tube and diagnosis of pulmonary embolism (PE), pneumonia, and hemothorax.<sup>172</sup> Chest CT is the definitive test for diagnosis of pneumothorax.<sup>55</sup> It has been suggested that a small closed pneumothorax can be safely managed by observation alone without a chest tube even in those patients who require positive-pressure ventilation as long as continuing vigilance is maintained.<sup>173,174</sup> Based on the most recent Advanced Trauma Life Support recommendation<sup>174,175</sup> and our own experience, we strongly believe that once diagnosed, a traumatic pneumothorax, no matter how small, should be treated with thoracostomy drainage before tracheal intubation and positive-pressure ventilation.

Bleeding intercostal vessels are responsible for most hemothoraces. Severe airway deviation with respiratory distress and shock may be produced by a hemothorax, although it is not as common as it is after a pneumothorax. Treatment consists of drainage with a #30- to #40-French catheter chest tube (#26- to #32-French catheter is used for pneumothorax). Initial drainage of 1,000 mL of blood or collection of over 200 mL/hr for several hours is an indication for thoracotomy. Retained clotted blood after tube thoracostomy may be treated conservatively with intrapleural fibrinolytic agents.<sup>175</sup> Additional indications for thoracotomy are a “white lung” appearance on the

anteroposterior chest radiograph or a continuous major air leak from the chest tube, which may result from a direct airway injury or major lung laceration. Hemodynamically stable patients with persistent bleeding of less than 150 mL/hr are often managed with video-assisted thoracoscopic surgery (VATS) to control bleeding, which requires collapse of the lung on the involved side using a double-lumen tube or a bronchial blocker. VATS can also be useful in diagnosis of suspected diaphragmatic or mediastinal injuries, evaluation of some bronchopleural fistulas, and evacuation of clotted blood or an empyema that does not drain with a chest tube or respond to intrapleural fibrinolytic therapy.<sup>175</sup> Use of VATS decreases the need for open thoracotomy and the number of negative explorations in stable trauma patients.<sup>176</sup>

## Pulmonary Contusion

Pulmonary contusion often accompanies chest wall injury but may also develop in isolation. Its management is discussed in the management of breathing abnormalities section.

## Penetrating Cardiac Injury

 Pericardial tamponade, cardiac chamber perforation, and fistula formation between the cardiac chambers and the great vessels are the consequences of a penetrating cardiac trauma. Any penetrating wound of the chest, especially one within the “cardiac window” (midclavicular lines laterally, clavicles superiorly, and costal margins inferiorly), can cause this injury. These injuries are often fatal at the scene, especially if they are gunshot rather than stab wounds and involve the right rather than the thicker-walled left ventricle. Because of the dynamic nature of cardiac injuries and the risk of sudden hemodynamic deterioration, these patients must be transported directly to the OR, and immediate sternotomy or left thoracotomy must be performed as soon as the injury is suspected. Emergency cardiopulmonary bypass may be needed. Pneumopericardium visible on a plain chest radiograph after penetrating chest trauma should increase the suspicion, although it is not seen in all patients. TTE can be used for screening stable patients, but it may be inconclusive in obese patients and in those with pneumothorax. The central venous pressure (CVP) is not always accurate. TEE provides an accurate diagnosis in these patients, but it is impractical during the initial evaluation phase of trauma.<sup>177,178</sup> A subxiphoid pericardial window created in the OR, often under general anesthesia, may not drain all the blood in the pericardium, but even partial drainage can improve hemodynamics temporarily in this setting. Two penetrating chest trauma surgical decision-making algorithms, one for damage control strategies in the unstable patient and the other for the management of definitive repair in the stable patient,

are described by the Western Trauma Association.<sup>179</sup> Because of the high density of vital organs in the chest and their close proximity to each other, penetrating trauma often injures more than one organ, and as such the decision-making process requires consideration of the entire chest rather than a single organ such as the heart. These patients are often unstable, requiring immediate OR management, a damage-control surgical strategy with thoracic packing and vacuum-assisted closure of the open chest after control of life-threatening injuries, or intraoperative massive transfusion, and some may need postoperative renal replacement therapy for renal insufficiency and extracorporeal membrane oxygenation; mortality may be as high as 25%.<sup>180</sup>

### **Pericardial Tamponade**

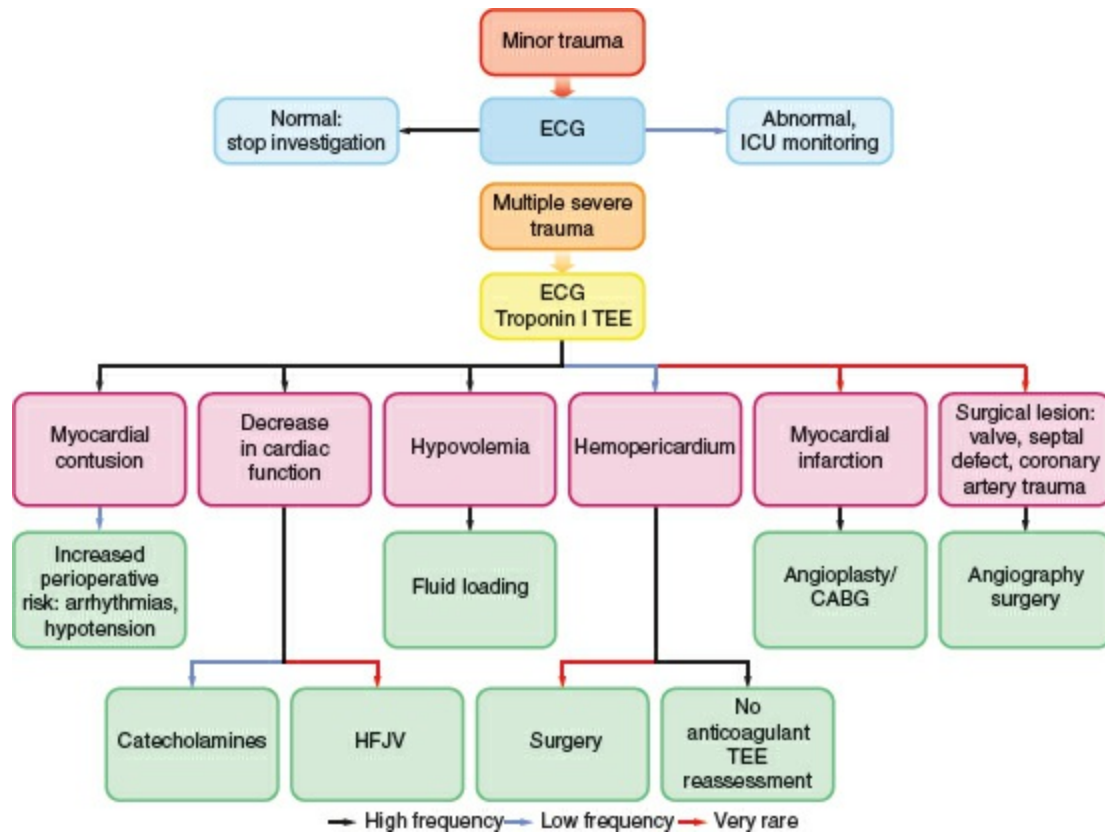

Both penetrating and blunt trauma can cause hemopericardium. The classic findings of pericardial tamponade—tachycardia, hypotension, distant heart sounds, distended neck veins, pulsus paradoxus, or pulsus alternans—are difficult to appreciate or may be absent in a hypovolemic trauma patient. A chest radiograph may reveal a globular heart, although this sign is often not appreciated. TTE with placement of the probe in the subxiphoid region, which is part of FAST, or intraoperative TEE can demonstrate blood in the pericardial sac and the presence of ventricular diastolic collapse, which indicates at least a 20% reduction in cardiac output.

Initial management consists of evacuation of the pericardial blood by ultrasound-guided pericardiocentesis or surgery as soon as possible. Even a small amount of blood drainage improves hemodynamics. Intracardiac volumes should be optimized with intravenous fluids. If anesthesia is contemplated for surgery, ketamine or etomidate, which produce relatively little myocardial depression, is preferred. Administration of anesthesia should be delayed until draping and preparation are completed. Patients in extremis with penetrating trauma-related pericardial tamponade may be candidates for ED thoracotomy. Rarely, laceration of the pericardium may permit complete or partial herniation of the heart through the defect with catastrophic consequences. Immediate thoracotomy and reduction of the heart are indicated.

### **Blunt Cardiac Injury**

The term blunt cardiac injury (BCI) has replaced myocardial contusion and encompasses varying degrees of myocardial damage, coronary artery injury, and rupture of the cardiac free wall, septum, or a valve following blunt trauma.<sup>181</sup> Myocardial injury consists of myofibrillar disintegration, edema, bleeding, or necrosis that depending on its severity presents as minor electrocardiographic (ECG) or enzyme abnormalities, complex arrhythmias,

or cardiac failure caused by direct mechanical impact or indirectly by coronary occlusion. Arrhythmias last no more than a few days, and ventricular wall motion abnormalities may persist longer. Pulmonary or systemic embolism may occur suddenly after a few days owing to development of clot in the hypokinetic cardiac chambers.

**Figure 53-6** Algorithm for management of various clinical scenarios produced by severe blunt cardiac injury. Evaluation of severe multiple trauma-induced blunt cardiac injuries uses electrocardiogram (ECG), troponin I, and transesophageal echocardiography (TEE). *Colored lines* represent the frequency of occurrence of each scenario and the frequency of management measures. CABG, coronary artery bypass graft; HFJV, high-frequency jet ventilation. (Adapted from Orliaguet G, Ferjani M, Riou B. The heart in blunt trauma. *Anesthesiology*. 2001;95:544.)

The prominent clinical findings are angina (sometimes responding to nitroglycerin), dyspnea, chest wall ecchymosis, and/or fractures; dysrhythmias of any type; and right-sided or left-sided congestive heart failure. Orliaguet et al.<sup>181</sup> proposed an algorithm for the diagnosis and treatment of several clinical scenarios caused by this injury (Fig. 53-6). The diagnosis is based on the 12-lead ECG, troponin I level, and echocardiography. The ECG is very sensitive, although not specific. A normal trace cannot rule out the diagnosis, but it is the best screening test. Common ECG abnormalities include almost any type of arrhythmia, ST- or T-wave changes, and conduction delays. Patients with a normal ECG undergoing

minor surgery do not require any further testing. Patients with severe injuries need measurement of troponin I and TEE to diagnose any abnormalities caused by the cardiac injury. Echocardiography can demonstrate wall motion abnormalities, valve malfunction, hemopericardium, intracardiac thrombi, venous or systemic embolism, and fractional ventricular wall area changes. It thus aids not only in the diagnosis of BCI but also in hemodynamic management. Treatment options depend on the diagnosis. They include antiarrhythmic agents, inotropes, fluid loading, high-frequency jet ventilation to optimize cardiac function, and surgery for hemopericardium, valvular or septal lesions, or coronary artery injury or disease.

Valvular injuries present as insufficiency of the aortic, mitral, or tricuspid valves. Acute traumatic insufficiency of the aortic and mitral valves is poorly tolerated, increasing the ventricular wall stress and rapidly progressing to pulmonary edema. Ventricular septal defects can be recognized by increased pulmonary vascularity with a normal heart size on the chest radiograph. An atrial septal defect is usually missed in clinical examination but may be recognized by echocardiography.

Commotio cordis (agitated heart) is an entity characterized by the development of sudden ventricular tachyarrhythmias, cardiac arrest, and often death following a blow to the chest in young people, most often during competitive or recreational sports. The blow would have occurred during the 10- to 20-millisecond period of the T-wave upstroke. Commotio cordis differs from myocardial contusion because of the absence of any structural cardiac injury. Treatment involves immediate defibrillation.<sup>182</sup>

## **Thoracic Aortic Injury**

Penetrating trauma can injure any part of the thoracic aorta, including its branches, to any extent. Blunt trauma, on the other hand, most commonly causes damage at the isthmus, the junction between the free and fixed portions of the descending aorta, which is just distal to the origin of the left subclavian artery. The ligamentum arteriosum and left main stem bronchus anchor the isthmus, fixing it in relation to the proximal aorta and making it vulnerable to traction forces and tearing. The thoracic aorta also may be injured at its root where it is fixed by the diaphragm, rendering it vulnerable to shearing forces of velocity changes. Blunt thoracic aortic injury is likely to be accompanied by various thoracic and abdominal visceral injuries.<sup>183</sup> The presenting symptoms, signs, and radiographic and ultrasound findings are shown in [Table 53-8](#), although there may be no clinical findings or a constellation of symptoms or signs in the ED. Only 20% to 30% of patients with mediastinal widening actually have this injury.

Contrast-enhanced spiral CT with volume-rendered image reconstruction

techniques permits a reliable noninvasive diagnosis of this injury. TEE is also capable of diagnosing subadventitial aortic injuries that require intervention.<sup>184</sup> Lesions of the intima and media and frequently encountered concomitant BCIs are also more likely to be detectable by TEE than CT.<sup>184</sup> However, CT, especially images obtained with multidetector devices, is generally preferred for diagnosis because it provides an accurate diagnosis, and introducing a TEE probe under these circumstances is impractical and probably fraught with the danger of aortic rupture. Furthermore, many of these patients have suspected craniofacial or esophageal injuries, preventing introduction of the probe. TEE is especially useful for the anesthesiologist intraoperatively when associated injuries require immediate surgery without time for CT scanning of the chest.

**Table 53-8** Common Clinical, Radiographic, and Ultrasound Features of Thoracic Aortic Injuries

Clinical	Radiographic	Spiral Computed Tomography	Ultrasound
Increased arterial pressure and pulse amplitude in upper extremities	Widened mediastinum	Mediastinal hematoma	Intimal flap
Decreased arterial pressure and pulse amplitude in lower extremities	Blurring of the aortic contours	Aortic wall irregularity	Turbulent flow
Absent or weak left radial artery pulse	Widened paraspinal interfaces	Intimal flap	Dilated aortic isthmus
Osler sign: discrepancy between left and right arm blood pressure	Left apical cap	False aneurysm	Acute false aneurysm
Retrosternal or interscapular pain	Opacified aortopulmonary window	Pseudocoarctation	Intraluminal medial flap
Hoarseness	Broadened paratracheal stripe	Intramural hematoma	Hemothorax
Systolic flow murmur over the precordium or medial to the left scapula	Displacement of the left main stem bronchus	Intraluminal clot or medial flap	Hemomediastinum
Neurologic deficits in the lower extremities	Displaced superior vena cava Rightward deviation of the esophagus and trachea Nasogastric tube shift Left hemothorax Sternal and/or upper rib fractures Lung contusion Pneumothorax		

Traumatic aortic injury can be classified into three categories: Grade 1 injury consists of an intramural hematoma, limited intimal flap, and/or mural thrombus; grade 2 injury consists of subadventitial rupture, injury to the media, altered aortic geometry, and/or small hemomediastinum; grade 3 injury consists of transection with massive blood extravasation and intraluminal obstruction, causing pseudocoarctation and ischemia (Fig. 53-7).<sup>185</sup> Severity of the injury may also be judged by TEE measurement of maximum aortic diameter, the ratio between injured and normal aortic diameters, the size of pseudoaneurysm, the esophagus-to-aortic distance, aortic isthmus-to-left visceral-pleural distance, and the presence of

hemothorax.<sup>185</sup> In another classification (Vancouver simplified classification), a fourth grade involving contrast extravasation is added.<sup>186</sup> Grade 1 injuries and some grade 2 injuries can be treated nonoperatively with serial observations using TEE or CT. Grade 2, 3, and 4 injuries require immediate or delayed surgery based on clinical findings.<sup>185,186</sup>

Management strategies in the diagnosis and treatment of blunt aortic injuries have gone through major changes during the past 10 years with substantially improved early outcomes (Table 53-9). In the area of diagnosis, contrast-enhanced CT angiography has practically replaced aortography and TEE, whereas endovascular thoracic aortic repair has replaced open surgery as the primary surgical treatment.<sup>187</sup> Intraoperatively, patients undergoing endovascular repair with a stent are monitored with contrast aortography and intravascular ultrasound. Thus, aortography has not been completely eliminated.

Although currently the vast majority of blunt thoracic aortic injuries **8** are managed using endovascular stents, repairs via the traditional open left thoracotomy are still occasionally performed. This technique requires lung isolation with a double-lumen tube or a bronchial blocker, partial heparinization, and, at times, partial left heart bypass to decompress the left heart and perfuse the distal aorta during a “clamp and sew” technique. A clamp is placed just distal to the takeoff of the left subclavian artery. Although bleeding may be excessive, mortality and morbidity, especially paraplegia or renal dysfunction, are also frequent with this technique.<sup>187,188</sup> Lung isolation with a double-lumen endobronchial tube is necessary to prevent contamination of the contralateral lung from blood entering the airway during dissection of the aorta in proximity to the lung. It should be inserted under direct vision via FOB after ensuring that the left main stem bronchus lumen is not obliterated by the periaortic hematoma. Systemic blood pressure and potassium ( $K^+$ ) should be monitored during aortic clamp release; a rise in  $K^+$  should be treated with insulin and glucose.

**Figure 53-7** Typical transesophageal echocardiographic appearances of three grades of traumatic aortic injury. **A:** Grade 3 injury. Adventitia of the aortic wall is damaged and a false aneurysm (FA) is communicating (*arrow*) with the aortic lumen (Ao). **B:** Grade 2 injury. Large medial flap moves back and forth during each cardiac cycle. Adventitia is intact. **C, D:** Grade 1 injury. Intimal flap (**C**) and intramural hematoma (**D**) (shown with *arrows*) without hemomediastinum or alteration of aortic geometry. (Reprinted from Goarin J-P, Cluzel P, Gosgnach M, et al. Evaluation of transesophageal echocardiography for diagnosis of traumatic aortic injury. *Anesthesiology*. 2000;93:1373.)

**Table 53-9** Change in the Management of Blunt Thoracic Aortic Injuries from 1997 to 2007

	AAST <sub>1</sub> N = 253	AAST <sub>2</sub> N = 193
<b>Diagnosis</b>		
Aortogram	220 (87%)	16 (8%)
CT scan	88 (35%)	180 (93%)
TEE	30 (12%)	2 (1%)
<b>Repair</b>		
Open	207 (100%)	68 (35%)
Endovascular	0	125 (65%)
<b>Outcomes</b>		
Mortality	53/241 (22%)	25/193 (13%)
Paraplegia		
All patients	18 (9%)	2 (2%)
Open repair	18 (9%)	2 (3%)
Endovascular	0	1/125 (1%)
Renal failure	18 (9%)	17 (9%)
Repair site complication	1/207 (1%)	25/125 (20%)

AAST<sub>1</sub>, American Association for the Surgery of Trauma 1997 Study; AAST<sub>2</sub>, American Association for the Surgery of Trauma 2007 Study; TEE, transesophageal echocardiogram; CT, computed tomography. Reproduced with permission from Demetriades D, Velmahos GC, Scalea TM, et al. Diagnosis and treatment of blunt thoracic aortic injuries: changing perspectives. *J Trauma*. 2008;64:1415.

Endovascular aortic repair is minimally invasive and is associated with fewer early complications such as paraplegia, stroke, bleeding, or death than are encountered after open thoracotomy ([Table 53-9](#)). An endoleak between the graft and the vascular wall is one of the early recognized complications. A radial artery cannula should be placed on the right side because sometimes the left subclavian artery is covered by the stent. A central venous catheter is placed for administration of vasoactive drugs. Embolization of aortic atheromas to the brain is one of the complications of this procedure. TEE may help to image the atheroma prior to stent deployment. During aortography and stent placement, ventilation may have to be stopped, and the systemic blood pressure may have to be lowered to a mean of 60 mmHg.

The incidence of long-term graft complications is not known, but it appears that the survival curves between open thoracotomy and endovascular techniques converge at 2 years, and the rates of aneurysm-related mortality converge at 6 years.<sup>188</sup>

Surgical prioritization when multiple injuries are present depends on the hemodynamic and neurologic status of the patient. Although the aorta should be repaired as early as possible, control of active hemorrhage from other sites and surgery for intracranial hematomas have a higher surgical priority, unless the aorta is leaking. Also heparinization needed for aortic repair may increase bleeding from associated injury sites. In most instances, a blood clot between the aorta and the mediastinal pleura occludes the vessel. Any disturbance of the tamponaded region may reinitiate bleeding. A rapid flow of blood in a large artery tends to pull its endothelium with it and thus may rupture an injured vessel that is sealed with a clot or a hematoma. Such an increase in the aortic blood flow is usually caused by increased myocardial contractility. Every effort should be made to prevent increased cardiac contractility and hypertension. The use of  $\beta$ -blocking agents should be considered.

## **Diaphragmatic Injury**

Injury to the diaphragm may permit migration of abdominal contents into the chest, where they may compress the lung, producing abnormalities of gas exchange, or the heart, resulting in dysrhythmias and/or hypotension. Because the defect produced by blunt injury is usually larger than that resulting from a penetrating injury, migration of abdominal contents, which requires a defect of at least 6 cm in diameter, is also more common after blunt trauma. The liver protects the right side of the diaphragm; thus traumatic herniation is more common on the left side, but right-sided diaphragmatic injuries are more frequently missed.<sup>189</sup>

Clinically noting that the end of a nasogastric tube is above the diaphragm on the chest radiograph is a certain sign that the stomach is displaced into the chest. A chest radiograph that shows intestinal markings and lung compression or a contrast-enhanced abdominal CT scan that includes the lower third of the thorax can provide important information. A diaphragmatic tear alone may require laparoscopy for diagnosis and repair. In diagnosed patients anesthetic induction should be tailored to avoid aspiration of gastric contents. For those diaphragmatic injuries without thoracic migration of abdominal contents, some centers prefer to place a prophylactic chest tube before surgery to prevent pneumothorax during positive-pressure ventilation.

## **Abdominal and Pelvic Injuries**

The abdomen, because of its lack of protection against external impacts, may be injured by blunt or penetrating trauma, producing solid organ, hollow viscus, and/or vascular injuries. Resulting intra- and retroperitoneal bleeding may cause hemorrhagic shock, which at times may be fatal. Spillage from intestines or another hollow viscus, if unrecognized, is responsible for the sepsis that may manifest hours or days after injury depending on the location of the injury; unrecognized left colonic injury may cause septic complications earliest. [Table 53-10](#) summarizes the strengths and weaknesses of the currently available diagnostic tools used to diagnose and treat abdominal injuries.<sup>190</sup> Because of the unpredictable course of bullets in the body, exploratory laparotomy or, in selected cases, laparoscopy is required in most patients after a gunshot wound to the abdomen. Occasionally, in hemodynamically stable patients, abdominal and flank gunshot wounds may be evaluated with an initial CT scan. Stab wounds may be managed with tractotomy to determine whether the peritoneum is involved. Laparoscopy or laparotomy may be indicated after a positive tractotomy.

Overt abdominal signs such as evisceration in penetrating trauma, tenderness, guarding, and gross distension in blunt trauma during physical examination of the abdomen suggest intra-abdominal pathology and necessitate further evaluation by CT scan unless the patient is hemodynamically unstable, in which case surgery without CT scan may be indicated. Absence of abdominal distention does not rule out intra-abdominal bleeding. At least 1 L of blood can accumulate before the smallest change in girth is apparent, and the diaphragm can also move cephalad, allowing further significant blood loss without any change in abdominal circumference. It is more likely for hemorrhagic shock to develop before perceptible distension.

**Table 53-10** Diagnostic Tools in Abdominal Trauma: Strengths and Weaknesses

Diagnostic Tool	Strength	Weakness
Physical examination	Expedient, safe, and inexpensive; potential for serial examination	Diagnosis of specific injury (e.g., diaphragm)
Diagnostic peritoneal lavage	Expedient, safe, and inexpensive	Diagnosis of diaphragmatic injury, hollow viscus injury, retroperitoneal injury; can be oversensitive and nonspecific
Computed tomography	Evaluation of peritoneum and retroperitoneum Staging of solid-organ injury	Diagnosis of diaphragmatic injury, hollow viscus injury Expensive; controversial need for contrast
Ultrasonography	Expedient, safe, and inexpensive; accurate for free peritoneal fluid Potential for serial examinations	Diagnosis of diaphragmatic injury, hollow viscus injury, penetrating injury, good specificity, but moderate sensitivity Less accurate in the presence of large retroperitoneal hematomas
Laparoscopy	Diagnosis of peritoneal penetration, diaphragmatic injury Evaluation of bleeding or solid-organ injury Potential for therapy	Diagnosis of hollow viscus injury, retroperitoneal injury Expensive
Video-assisted thoracoscopic surgery	Evaluation of lung, diaphragm, mediastinum, chest wall, and pericardium; potential for treatment	Requires operating room; expensive Diagnosis of abdominal injuries

Reprinted with permission from Villavicencio RT, Aucar JA. Analysis of laparoscopy in trauma. *J Am Coll Surg.* 1999;189:11.

Abdominal CT is capable of demonstrating solid-organ injuries and peritoneal bleeding. In fact CT is the best tool to grade the severity of solid-organ injuries. However, it is less likely to identify bowel and mesenteric injuries, unless relatively new 64-slice devices are used.<sup>191</sup>

The diagnostic ability of the FAST is inferior to CT scan evaluation, which has recently undergone significant technologic improvements. The FAST is operator dependent, has good specificity but only moderate sensitivity, can diagnose injuries associated with intraperitoneal fluid but not those without it, and cannot determine the severity of organ injury.<sup>192</sup> Nevertheless the FAST is most needed in hemodynamically unstable patients who may not be safely transported to the CT unit shortly after admission to the ED. Its sensitivity in those patients is found to be low, preventing the development of a reliable ultrasound-based clinical pathway to diagnose blunt abdominal injury and to decide between conservative and operative management.<sup>192</sup> Performing serial FAST examinations may decrease the false-negative results, but in the unstable patient there is often limited time for decision making. Known clinical conditions that decrease the sensitivity of the FAST include pelvic and spine injuries, subcutaneous emphysema, and obesity. On the other hand, the FAST requires one-third of the time, is less expensive to perform than CT, and is without the hazard of radiation. Screening with abdominal ultrasonography is performed by placing a 3.0- to 5.0-MHz probe on four distinct areas of the abdomen: subxiphoid, to detect pericardial blood; right upper quadrant, for blood in the hepatorenal pouch; left upper quadrant, to detect perisplenic blood; and just above the pubic symphysis, for blood in the rectovesical pouch.

Laparoscopy is an excellent screening tool in abdominal trauma patients.<sup>193</sup> An analysis showed that it avoided laparotomy in 63% of patients and missed only 1% of the injuries.<sup>190</sup> It is also possible to repair diaphragmatic, bladder, and solid-organ injuries with this technique. The complication rate of laparoscopy in trauma is approximately 1%, including pneumothorax, small bowel injury, intra-abdominal vascular injury, extraperitoneal CO<sub>2</sub> insufflation, and CO<sub>2</sub> embolization.<sup>190</sup>

“Selective surgical conservatism,” which involves nonoperative management by careful evaluation and performance of surgery on a timely manner only for those who actually demonstrate signs of injuries that are not amenable to conservative treatment, replaced the old concept of mandatory laparotomy during the past few decades. Patient selection for nonoperative management is important. Penetrating trauma patients with a high injury severity score and profuse bleeding from liver, spleen, or major abdominal vessels requiring transfusion are unlikely to benefit from nonoperative management; in fact, they may succumb to death with this approach. Similarly, patients with blunt trauma with advanced age, low admission systolic pressure, high injury severity score, metabolic acidosis, lower GCS, and requirement for multiple units of transfusion cannot be managed nonoperatively.

Hypotension on opening the peritoneal cavity filled with blood is caused not only by hemorrhage but also by the sudden release of compression on the splanchnic vessels causing capacitance vessel dilation. Management includes fluid, preferably plasma, infusion but also vasopressor therapy to prevent overloading. After the repair, most patients develop bowel edema, which may potentially result in abdominal compartment syndrome if abdominal closure is demanded. Leaving the abdomen open with vacuum drainage may prevent this complication.

## **Fractures of the Pelvis**

Pelvic fractures occur in widely varied anatomic forms and physiologic severity. Major hemorrhage, which is one of the major causes of mortality, occurs in about 25% of patients; exsanguination occurs in 1% of injuries. Other major causes of mortality include associated injuries, such as chest, brain, intra-abdominal, and long bone injuries, and postoperative complications, such as sepsis, PE, and renal failure. In most of these fractures, bleeding results from venous disruption by fragments of bone. Retroperitoneal pelvic bleeding is self-limited in most patients with venous injuries because of the tamponading effect, except in those with open fractures. Approximately 18% to 20% of patients have arterial bleeding that does not stop. The retroperitoneal space in these patients may serve as a

distensible container that expands superiorly and anteriorly and may totally obliterate the lower part of the abdominal cavity. Component therapy with blood products is important in these patients until the bleeding is controlled.<sup>194</sup> Large retroperitoneal hematomas may also cause respiratory difficulty because of pressure on the diaphragm. An increase in ICP is also likely if there is a concomitant head injury.

Early detection and intervention to control bleeding are important. Pelvic ring disruption, arterial extravasation (CT blush), and elevated bladder pressure secondary to compression by hematoma volumes greater than 500 mL are important signs that can be detected on CT examination, making it a key diagnostic measure. In addition, continuing hemodynamic instability after adequate fracture stabilization is suggestive of pelvic hemorrhage. Following external pelvic ring stabilization using external fixators, a pelvic binder, or a C-clamp to decrease the mobility of the bone fragments and help control blood loss, angiography can indicate the type and location of bleeding. Arterial bleeding is treated with embolization. The angiography suite should be prepared in advance not only for anesthesia but also for invasive monitoring and resuscitation. In hemodynamically unstable patients, deciding whether to transport the patient to the OR to control bleeding from associated injuries or to proceed to interventional radiology for angiography and possible embolization is difficult, although surgery of abdominal, thoracic, and head injuries is given priority. In most centers, it takes at least 45 minutes to begin angiography, during which time a considerable amount of blood may be lost. Recent data suggest that after external stabilization of the pelvis, extraperitoneal (preperitoneal) packing in the OR under general anesthesia followed by angiography and, if arterial bleeding is noticed, embolization may be more beneficial than only external fixation and angiography.<sup>195</sup> In this manner, pelvic venous bleeding is managed expeditiously. Packing involves a 6- to 7-cm midline vertical incision starting from the pubic symphysis to access the hematoma with introduction of two or three abdominal lap pads deep into the pelvis. The incision for packing is not continuous with the abdominal incision. Although this concept contrasts with the traditional understanding that opening a retroperitoneal hematoma caused by a pelvic fracture must be avoided to prevent excessive bleeding, with the present approach hematoma is entered extraperitoneally instead of intraperitoneally, which indeed increases the bleeding. Laparotomy may be indicated, although it should be based on solid indications. Nontherapeutic laparotomy may worsen the outcome.<sup>196</sup> Pelvic fractures may also injure the bladder and the urethra. Thus, a urethrogram should be performed before insertion of a urinary catheter.

## **Extremity Injuries**

Surgical repair of extremity fractures, whether open or closed, should be performed as soon as possible. Delayed fracture repair is associated with an increased risk of DVT, pneumonia, sepsis, and the pulmonary and cerebral complications of fat embolism. In open fractures, an additional important concern is infection. Wounds left unrepaired for more than 6 hours are likely to become septic.

Associated vascular trauma must be recognized early. Most vascular injuries exhibit at least some part of the classic syndrome of *pain, pulselessness, pallor, paresthesias, and paresis*. The definitive diagnosis is made with arteriography. In selected patients, a duplex ultrasound study may be used as a screening test. Patients with vascular trauma should be operated on expeditiously, often without preoperative angiography. The presence of a hybrid OR in the OR suite circumvents the need for an additional journey to the angiography unit. These patients may bleed slowly but substantially both pre- and intraoperatively; thus, delayed surgery and prolonged skeletal repair may lead to unrecognized hemorrhagic shock, which may at times become irreversible. Damage control, that is, controlling bleeding and external fixation of the fractures, may be the management of choice.

*Compartment syndrome*, which is characterized by severe pain in the affected extremity, should be recognized early so that emergency fasciotomy can be effective in preventing irreversible muscle and nerve damage. In unconscious patients, swelling and tenseness of the extremity indicate the presence of this complication. The definitive diagnosis is made by measuring compartment pressures using a transducer attached to a fluid-filled extension tube and a needle inserted into the various compartments of the extremity. A pressure exceeding 30 cm of H<sub>2</sub>O is an indication for immediate surgery. Caution must be exercised when using epidural or nerve block analgesia for perioperative pain relief in the presence of extremity fractures. Absence of pain can delay the diagnosis of compartment syndrome.

## Burns

Approximately 500,000 hospitalizations and 3,400 deaths resulted from burns and inhalation injuries in the US during 2013.<sup>4</sup> Significant improvement in outcome from burn injuries has been seen during recent decades because of effective resuscitation, modern nursing and critical care, early scar excision, infection control, and the ability to counteract the hypermetabolic response. Although during the 1950s, the lethal dose, 50%, of burn injury was about 40% to 50% of total body surface area (TBSA), the corresponding value is currently 90%, with a mortality of 4% in admitted patients.<sup>197</sup> Three risk factors determine the death rate: inhalation injury, burn size exceeding 40% of TBSA, and age greater than 60

years. Mortality has been shown to be 0.3%, 3%, 33%, and 90% in the presence of 0, 1, 2, and 3 risk factors, respectively.<sup>198,199</sup> Full-thickness burns involving over 10% of the TBSA; partial-thickness burns covering more than 25% of TBSA in adults or over 20% at the extremes of age; burns involving the face, hands, feet, or perineum; inhalation, chemical, and electrical burns; and burns in patients with severe pre-existing medical disorders are considered major burns.<sup>200</sup>

Clinically, burn injury is manifested in two phases: Burn shock is characterized by continued plasma loss from the intravascular space into burned and often into intact tissues for about the first day or two after injury, and the subsequent hypermetabolic or hyperdynamic phase, which may last for months.<sup>198,200</sup> Pathophysiologic changes in these two phases are somewhat different and often opposite to each other (Table 53-11).<sup>96,194</sup>

A severe burn is a systemic disease that stimulates the release of inflammatory mediators such as interleukins and tumor necrosis factor locally (producing wound edema) and into the circulation, resulting in immune suppression, hypermetabolism, protein catabolism, insulin resistance, sepsis, and multisystem organ failure. Patients with burns over 40% of TBSA consistently develop catabolism and weight loss, which may last up to 1 year. Prevention of sepsis, maintenance of normal body temperature, and pain management may decrease the extent of catabolism. Pharmacologically, recombinant human growth hormone, insulin-like growth factor 1, low-dose insulin infusion,  $\beta$ -blockade, and the synthetic testosterone analogue oxandrolone can decrease protein catabolism or improve anabolism.<sup>201,202</sup> Enteral and/or parenteral nutrition starting early after burn injury is effective in reducing the hypermetabolic response and replacing protein loss. Provided that the airway is secured, feeding via an ileostomy should continue during anesthesia for surgical procedures.<sup>198</sup> Enteral feeding should be stopped within a reasonable time before surgery if there is a chance that the airway will be unprotected intraoperatively for a period of time, as in tracheostomy.

**Table 53-11** Pathophysiologic Changes in the Early (First 2 Days) and Late Phases of the Burn Injury

	Early Phase	Late Phase
Cardiovascular system	<ul style="list-style-type: none"> <li>↑ Heart rate</li> <li>↓ Cardiac index</li> <li>↓ Stroke volume</li> <li>↓ Contractility</li> <li>↑ PVR and SVR</li> <li>↓ SvO<sub>2</sub></li> </ul>	<ul style="list-style-type: none"> <li>↑ Heart rate</li> <li>↑ Cardiac index</li> <li>Normal or ↑ stroke volume</li> <li>↓ Contractility</li> <li>↓ SVR</li> <li>↑ SvO<sub>2</sub></li> </ul>

PVR, pulmonary vascular resistance; SVR, systemic vascular resistance; SvO<sub>2</sub>, mixed venous O<sub>2</sub> saturation; ARDS, acute respiratory distress syndrome; FENa<sup>+</sup>, fraction of excreted sodium; GFR, glomerular filtration rate.

Determination of the size and depth of a burn sets the guidelines for resuscitation as well as the indications for surgical intervention.<sup>198,200</sup> A partial-thickness burn is red, blanches to touch, and is sensitive to painful stimuli and heat. Superficial partial-thickness (first-degree) burns involve the epidermis and upper dermis and heal spontaneously. Deep partial-thickness (second-degree) burns involve the deep dermis and require excision and grafting to ensure rapid return of function. A full-thickness (third-degree) burn does not blanch, even with deep pressure, and is insensate. Complete destruction of the dermis requires wound excision and grafting to prevent a wound infection that may lead to local sepsis and systemic inflammation. Fourth-degree burns involve muscle, fascia, and bone, necessitating complete excision and leaving the patient with limited function. Laser Doppler imaging can be used as an aid to judge the burn depth.<sup>203</sup> The size of the burned area is estimated by the “rule of nines” to determine the TBSA involved. In an adult, the head contributes 9%; the upper extremities, 18%; the trunk, 36%; and the lower extremities, 36% of the TBSA. These proportions are somewhat different in children, depending on the age and size. To estimate the size of a burn, the child’s palmar surface (excluding the digits) represents about 0.5% of the TBSA over a wide range of ages. More accurate age-specific estimation of the TBSA can be obtained by using the Lund–Browder table (Table 53-12).<sup>198</sup>

Information about the mechanism of injury facilitates the diagnosis of associated clinical abnormalities. For example, thermal trauma caused by flames in a closed space is likely to be associated with airway damage. Burns

resulting from motor vehicle, airplane, or industrial accidents may be complicated by other traumatic injuries. Finally, burns caused by electrocution may show little external evidence but may be associated with severe fractures, hematomas, visceral injury, and skeletal and cardiac muscle injury resulting in pain, myoglobinuria, and dysrhythmias or other ECG abnormalities.

## **Airway Complications**

Injury to various parts of the airway occurs following inhalation of heated air, steam, or toxic substances. Airway and lung injury also may occur in the absence of inhalation via the inflammatory mediators released from the burned tissues, infection, and fluid resuscitation. Respiratory distress in the initial phase of a burn is usually caused by direct heat or steam injury to the pharynx or larynx. Singed facial hair, facial burns, dysphonia or hoarseness, cough, soot in the mouth or nose, and swallowing difficulties in patients with or without respiratory distress should increase the suspicion of upper (frequent) and lower (occasional) airway injury. In the upper airway, glottic and periglottic edema and copious thick secretions may produce respiratory obstruction. This may be aggravated by fluid resuscitation even in the absence of significant inhalation injury.<sup>204</sup> Injuries below the larynx are caused by smoke, hot particles, and aspiration involving the trachea and primary bronchi. Secondary bronchi also may be involved if irritant gases are inhaled. In lower airway burns, decreased surfactant and mucociliary function, mucosal necrosis and ulceration, edema, tissue sloughing, and secretions produce bronchial obstruction, air trapping, and bronchopneumonia. The development of parenchymal lung injury takes approximately 1 to 5 days and presents with the clinical picture of ARDS. Pneumonia and PE are late complications that occur 5 or more days after burns. The presence of a lung injury markedly increases the fluid requirements (30% to 50%) and the mortality rate from thermal injuries.<sup>198,205</sup> Administration of the highest possible concentration of O<sub>2</sub> by face mask is the first priority in moderately to severely burned patients with a patent airway. In patients with massive burns, stridor, respiratory distress, hypoxemia, hypercarbia, loss of consciousness, or altered mentation, immediate tracheal intubation is indicated. The intubation technique selected depends on the operator's experience, the age of the patient, and the extent of airway compromise. In adults, awake fiberoptic intubation under adequate topical anesthesia, if feasible, is probably the safest approach, but other techniques using conventional blades or videolaryngoscopes with or without anesthetic induction or supraglottic airway-guided intubation may also be used. In most pediatric patients, awake intubation is not possible. An inhalation induction with O<sub>2</sub> and sevoflurane,

followed by intubation using an FOB or conventional laryngoscope, is appropriate.<sup>200</sup> Alternatively, sedation with ketamine, which preserves pharyngeal tone, may provide good intubating conditions for FOB-guided intubation. The presence of full stomach may preclude the use of a supraglottic airway, except as a bridge to a secure airway. Methylnaltrexone, which antagonizes the peripheral but not the central effects of morphine, antagonizes gastric effect of morphine and facilitates its emptying without causing agitation.<sup>198</sup> A surgical airway entails a significant risk of pulmonary sepsis and late upper airway sequelae and should be reserved for those whose airway management cannot be handled in any other way, or in those who are likely to develop complications such as dysphagia or dysphonia following prolonged tracheal intubation.<sup>198,200</sup> Immediately after securing the airway, ventilation with low levels of PEEP will prevent the pulmonary edema that may develop secondary to loss of laryngeal auto-PEEP in patients with significant airway obstruction before intubation. Airway humidification, bronchial toilet, and bronchodilators if needed for bronchospasm are also indicated.

**Table 53-12** Lund–Browder Body Surface Area Calculation Table Used during Admission of the Patient to Determine Percent Burn Size, Location, and Estimated Burn Depth

Area	Birth–1 yr	1–4 yr	5–9 yr	10–14 yr	15 yr	Adult	2°	3°	TOTAL
Head	9	17	13	11	9	7

									TOTAL

Only secondary and tertiary burns are included in the total burn percentage.

Adapted from Bittner E, Shank E, Woodson L et al. Acute and perioperative care of the burn-injured patient. *Anesthesiology* 2015;122: 448–464.

The pediatric airway is particularly challenging because its small diameter carries the risk of occlusion by minimal amounts of swelling. Prophylactic

intubation may therefore be required in children who are suspected of having an inhalation injury, even though they are not yet in respiratory distress. Prophylactic tracheal intubation may also be indicated in adults when the resources for careful follow-up are insufficient. Information obtained from radiologic, ABG, and endoscopic examinations and pulmonary function testing may be useful for predicting which patient will need tracheal intubation and possibly decreasing the risks of airway manipulation. Prophylactic intubation carries the risk of dislodgment, especially during intra- or interhospital transport. It has been demonstrated that many patients who, according to the hospital policy, had indications for intubation did not need to have their airway secured as determined by serial airway examination with FOB. Thus tracheal intubation should be based on clear criteria such as large full-thickness burns, inability to protect the airway, or signs of airway obstruction.<sup>198,206</sup>

Serial fiberoptic laryngoscopy is easy to perform and can provide direct information about the glottic and periglottic structures. It may avoid tracheal intubation in patients who would otherwise be considered candidates for this procedure. Fiberoptic bronchoscopy has the additional advantage of providing information about the lower airway, although it is more uncomfortable for the patient and requires topical anesthesia of the tracheobronchial tree.

The chest radiograph, ABGs, and pulmonary function tests are usually normal in the immediate postburn period, even in patients with pulmonary complications.<sup>198</sup> However, these tests should be performed at this time for later comparison. The treatment of smoke inhalation in burns involves ventilatory management, intensive care, and treatment of carbon monoxide (CO) and cyanide (CN<sup>-</sup>) toxicity.

## Ventilation and Intensive Care

Hypoxemia may persist despite tracheal intubation, ventilation with PEEP, bronchodilators, and suction of airway secretions. In the first 36 hours, this is caused by acute pulmonary edema. From days 2 to 5, hypoxia may result from atelectasis, bronchopneumonia, and airway edema resulting from mucosal necrosis and sloughing, viscous secretions, and distal airway obstruction. Later there may be nosocomial pneumonia, hypermetabolism-induced respiratory failure, and ARDS. Treatment of these complications is individualized, using ventilatory maneuvers such as low tidal volume (5 to 6 mL/kg) with titrated PEEP, bronchoscopic lavage, antibiotics, chest physiotherapy, and other supportive measures. Lack of response to therapy because of severe ventilation-perfusion mismatching or shunt may be an indication for the use of nitric oxide, a potent, short-acting vasodilator, via the airway.<sup>207</sup> Patients with ARDS may benefit from high-frequency

oscillatory ventilation, both intraoperatively and in the ICU.<sup>208</sup> Prophylactic measures against DVT, gastric ulcers, and hypothermia should be used routinely. Burns of at least 40% of TBSA and those necessitating ICU admission carry the risk of venous thromboembolism (VTE) requiring prophylaxis.<sup>209</sup> Further, pulmonary procoagulant activity with inhibited fibrinolysis in mechanically ventilated patients with burn and inhalation injuries results in alveolar fibrin deposition and pulmonary inflammation, which may decrease with anticoagulants.<sup>210</sup>

## **Carbon Monoxide Toxicity**

In burn victims, CO inhalation is almost always associated with smoke inhalation, which increases morbidity and mortality compared with CO toxicity alone. CO produces tissue hypoxia by impairing O<sub>2</sub> unloading; it produces this effect by its 200-fold greater affinity for hemoglobin than oxygen and by its ability to shift the hemoglobin dissociation curve to the left and alter its shape. It also interferes with mitochondrial function, uncoupling oxidative phosphorylation and reducing adenosine triphosphate production, thus causing metabolic acidosis. Probably because of this effect on the mitochondria, CO can be a direct myocardial toxin, preventing survival in patients who suffer cardiac arrest even though they have been resuscitated and treated with a high concentration of O<sub>2</sub> or hyperbaric oxygen.

A normal oxygen saturation reading on most pulse oximeters does not exclude the possibility of CO toxicity, although low arterial O<sub>2</sub> saturation measured by a co-oximeter should raise the suspicion.<sup>211</sup> Portable devices such as the Masimo Rad-5 (Masimo Corp., East Irvine, CA) are capable of measuring carboxyhemoglobin and methemoglobin levels noninvasively via a finger sensor along with pulse oximetry, alerting the clinician about spuriously high O<sub>2</sub> saturation values. If CO toxicity is not accompanied by a lung injury and thus by decreased PaO<sub>2</sub>, tachypnea is absent. The carotid bodies are sensitive to the arterial PO<sub>2</sub> and not to the O<sub>2</sub> content. The classic cherry-red color of the blood is also absent in most patients because it occurs only at carboxyhemoglobin (COHb) concentrations above 40%; it may also be obscured by coexistent hypoxia and cyanosis.

**Table 53-13** Symptoms of Carbon Monoxide Toxicity as a Function of the Blood COHb Level

Blood COHb Level (%)	Symptoms
<15–20	Headache, dizziness, and occasional confusion
20–40	Nausea, vomiting, disorientation, and visual impairment
40–60	Agitation, combativeness, hallucinations, coma, and shock
>60	Death

COHb, carboxyhemoglobin.

The greater the blood concentration of COHb, the more severe the presenting symptoms (Table 53-13). The patient's inspired oxygen should be maintained at the highest possible concentration, even when there is no evidence of significant smoke-induced lung injury, until CO toxicity is ruled out by measurement of blood COHb. A high fraction of inspired oxygen (FiO<sub>2</sub>) not only improves oxygenation but also promotes elimination of CO; an FiO<sub>2</sub> of 1.0 decreases the blood half-life of COHb from 4 hours in room air to about 60 to 90 minutes, and to 20 to 30 minutes at 3 atm in a hyperbaric chamber.<sup>198,200</sup> The decision to institute this treatment should be based on comparing its risks and benefits; the risks include interhospital transport because most centers lack a hyperbaric chamber, decreased patient access during treatment, and delay in emergency treatment for the possible neurologic sequelae. Currently, hyperbaric O<sub>2</sub> is recommended for patients with COHb over 30% at admission if the treatment of life-threatening problems—shock, neurologic injury, metabolic acidosis, myocardial ischemia, infarction, or arrhythmias—will not be compromised.

## Cyanide Toxicity

Another cause of tissue hypoxia in burned patients is CN<sup>-</sup> toxicity. Cyanide or hydrocyanic acid is produced by incomplete combustion of synthetic materials and may be inhaled or absorbed through mucous membranes. The usual clinical presentation is unexplained metabolic acidosis in the absence of cyanosis. Nonspecific neurologic symptoms such as agitation, confusion, or coma are also common findings. Elevated plasma lactate levels in severe burns may result from hypovolemia or CO or CN<sup>-</sup> toxicity. However, lactic acidosis after smoke inhalation in a patient without a major burn suggests CN<sup>-</sup> toxicity.<sup>212</sup> The definitive diagnosis can be made only by determination of the blood cyanide level, which is toxic above 0.2 mg/L and lethal at levels beyond 1 mg/L. A spectrophotometric assay using methemoglobin as a colorimetric indicator provides timely and reliable determination of blood CN<sup>-</sup>.<sup>213</sup> The pulse oximetry reading will be accurate in the absence of CO

toxicity and nitrate therapy–induced methemoglobinemia.

Increased  $\text{CN}^-$  in the blood can cause generalized cardiovascular depression and cardiac rhythm disturbances, especially in patients with lactic acidosis. Fortunately, the half-life of  $\text{CN}^-$  is short ( $\sim 1$  hour),<sup>212</sup> and rapid improvement of hemodynamics should be expected after rescue of the victim from the toxic environment. Immediate administration of  $\text{O}_2$ , which is required for all burn victims, may be lifesaving for this complication. Although there are specific therapies for  $\text{CN}^-$  toxicity (e.g., amyl nitrate, sodium nitrite, thiosulfate), given the short half-life of the ion, it is not clear whether these measures offer significant help to the patient, whose blood  $\text{CN}^-$  usually decreases to low levels during transport from the field to the hospital.<sup>214</sup> Nevertheless exogenous thiosulfate combined with fast-acting hydroxycobalamin (vitamin  $\text{B}_{12}$ ) can be administered to facilitate conversion to thiocyanate and cyanocobalamin, which are excreted in the urine.<sup>198</sup> Of course, if circumstances permit, hyperbaric  $\text{O}_2$  treatment can be used for all the complications of thermal injury:  $\text{CO}$  and  $\text{CN}^-$  poisoning, smoke-induced lung damage, and cutaneous burns.

## Fluid Replacement

Immediately after a serious burn microvascular permeability increases, causing the loss of a substantial amount of protein-rich fluid into the interstitial space. A major burn, a delay in initiation of resuscitation, or an inhalation injury increases the size of the leak.<sup>198,200</sup> Further, there seems to be a relation between inhalation injury and cutaneous burns in the production of edema: Pulmonary edema increases cutaneous edema and vice versa.<sup>215</sup> If resuscitation is successful, edema formation stops within 18 to 24 hours.<sup>215</sup> This fluid flux is enhanced by increased intravascular hydrostatic and interstitial osmotic pressures and decreased interstitial hydrostatic pressure. In addition, cardiac contractility may decrease because of circulating mediators, a diminished response to catecholamines, decreased coronary blood flow, and increased systemic vascular resistance.<sup>200,216</sup> This may result in shock, whose origin is primarily hypovolemic and, to a smaller extent, cardiogenic.<sup>216</sup> If the hypotension is treated appropriately with fluids, the hemodynamic picture is replaced within 24 to 48 hours by one resembling sepsis or septic shock, with increased heart rate, cardiac output, and diminished systemic vascular resistance caused by the release of inflammatory mediators.<sup>216</sup>

Fluid resuscitation is essential in the early care of the burned patient with an injury over 15% of TBSA. Smaller burns can be managed with oral or intravenous replacement at 150% of the calculated maintenance rate and **10** careful monitoring of fluid status. Intravascular volume should be restored

with utmost care to prevent excessive edema formation in both damaged and intact tissues resulting from the generalized increase in capillary permeability caused by the injury. Edema from overaggressive resuscitation has many deleterious and potentially life-threatening effects. Mention has already been made of the facilitation of upper airway edema after rapid fluid infusion in large cutaneous burns with or without smoke inhalation.<sup>204</sup> Likewise, chest wall edema may develop after administration of large quantities of fluid to patients with burns in this area, causing respiratory difficulties and necessitating excision of burned tissue from the anterior axillary line to improve breathing. Abdominal edema may also occur, and when resuscitation volume exceeds 300 mL/kg/24 hours, increased intra-abdominal pressure may produce *abdominal compartment syndrome* with impedance of venous return.<sup>217,218</sup> Edema formation may also increase the tissue pressure in the burned area, resulting in reduction of blood flow to distal sites. This, together with decreased tissue oxygen tension, may produce necrosis of damaged but viable cells, increasing the extent of injury and the risk of infection.

Crystalloid solutions are preferred for resuscitation during the first day following a burn injury; leakage of colloids during this phase may increase edema.<sup>219</sup> Nevertheless, crystalloid resuscitation, especially in children, may cause a rapid decline in plasma protein concentration and necessitate administration of 5% albumin in LR solution when the capillary leak stops after the first day following a burn greater than 30% of TBSA and/or significant inhalation injury.<sup>220</sup> It is believed that this will moderate the tendency to edema formation associated with the administration of large amounts of isotonic (0.9% saline or LR) solutions. Some centers use plasma with crystalloid routinely and partly attribute the good outcomes of their patients to this practice.<sup>221</sup> Administration of fluids in excess of the amount recommended by the Parkland formula appears to be relatively frequent in modern burn management and is termed *fluid creep*. Avoidance of early over-resuscitation, routine use of colloids, and adherence to protocols are recommended to prevent this problem.<sup>222</sup> Plasma exchange therapy may also remove inflammatory mediators and decrease capillary permeability, lowering fluid requirements and improving base deficit and blood lactate level in these patients.<sup>223</sup> Alternatively, hypertonic saline solutions draw intracellular water into the bloodstream and thus decrease the fluid volume needed to maintain perfusion and extracellular volume and limit the severity of edema in patients with burns occupying over 50% of TBSA, circumferential extremity burns, or inhalational injury.<sup>200</sup> Unfortunately, hypertonic solutions may cause hypernatremia and intracellular water depletion. Patients and experimental animals receiving these fluids for burn therapy often did not show an overall fluid-sparing effect and had an unacceptably high incidence of renal failure and death compared with those receiving LR solution.<sup>219,224,225</sup>

Of the many resuscitation formulas available, the Parkland (Baxter) and modified Brooke formulas are best tailored to the clinical condition of the **11** patient and are accepted in most centers (Table 53-14).<sup>220,226</sup> The addition of glucose is not necessary except in children, especially those weighing less than 20 kg. Albumin 5% may be administered after the first day following injury at a rate of 0.3, 0.4, or 0.5 mL/kg/24 hours for burns of 30% to 50%, 50% to 70%, or 70% to 100% of TBSA, respectively. These formulas are guidelines only, and none can be expected to provide adequate restoration of intravascular volume in all burn victims, especially small children and patients with inhalation injuries. Therefore, administration of fluids during the initial phase should be titrated to the specific goals described in Table 53-14, and, if a PAC is placed, to acceptable cardiac output, filling pressures, and a mixed venous oxygen tension (PvO<sub>2</sub>) of 35 to 40 mmHg. Careful monitoring of the Hct may also guide fluid management. An increase in Hct during the first day suggests inadequate fluid resuscitation because hemolysis and sequestration are actually expected to cause a decrease in this parameter. Acute anemia, as may occur during excision and grafting of burns, is usually well tolerated. Blood replacement is usually not initiated until the Hct is decreased to 20% to 24% in healthy patients requiring limited operations, to approximately 25% in those who are healthy but need extensive procedures, and to 30% or more when there is a history of pre-existing cardiovascular disease.

BP, blood pressure; MAP, mean arterial pressure.

\*50% of calculated volume is given during the first 8 hours, 25% is given during the second 8 hours, and the remaining 25% is given during the third 8 hours.

When in rare instances fluid resuscitation fails despite administration of crystalloids in excess of 6 mL/kg per percentage of TBSA, and invasive or semi-invasive monitoring suggests adequate intravascular volume, vasopressor and/or inotropic agents may be indicated. Dopamine in small doses (5 µg/kg/min) and/or β-adrenergic agents may improve urine output without further need for fluids.<sup>220</sup> Electrolyte abnormalities may occur after the first day for several reasons but are primarily a result of topical agents applied to control pain, decrease vapor loss, prevent desiccation, and slow bacterial growth.<sup>220</sup> Nonaqueous topicals (silver sulfadiazine), if administered without providing free water such as 5% dextrose, may result in hypernatremia and its CNS consequences, including intracranial bleeding. In contrast, aqueous topical agents such as 5% silver nitrate solution may cause hyponatremia and its consequences of cerebral edema and seizure secondary to electrolyte leaching. Central pontine demyelination may occur if the hyponatremia is corrected rapidly with salt solutions. Serum ionized calcium and magnesium should also be monitored.

**12** Traditionally, monitoring of fluid therapy for burn injury is limited to hourly urine output, heart rate, systemic blood pressure, and base deficit. The end points for these monitoring parameters are shown in [Table 53-14](#). Indeed there is some evidence to suggest that hourly monitoring of urine output as an end point of resuscitation compared to sophisticated hemodynamic monitoring provides similar outcomes in terms of mortality, organ function, length of hospital or intensive care stay, duration of mechanical ventilation, and burn-related complications such as pulmonary edema, compartment syndromes, or infection.<sup>227</sup> On the other hand, there are criticisms about not using available sophisticated monitoring techniques during the initial 48 hours of burn injury.<sup>226,228</sup> The argument centers around the fact that in the presence of normal urine output, organ blood flow may still be compromised.<sup>227,228</sup> Some data suggest that using the minimally invasive lithium dilution cardiac output monitor (LiDCO Ltd., London, UK) or Pulsioath thermistor-tipped catheter (Pulsion Medical Systems, Munich, Germany), which continuously measures systolic and pulse pressure variation (PPV) during positive-pressure ventilation and estimates preload dependence, resulted in administration of lower initial fluid volumes to burn patients than were administered with urine output and blood pressure measurement guidance.<sup>229</sup> Available monitoring tools that potentially can be used for this purpose are transthoracic echocardiography or TEE; hemodynamic parameters such as stroke volume variation (SVV), intrathoracic blood volume index, pulmonary artery occlusion pressure, cardiac index, and pulmonary capillary O<sub>2</sub> saturation; and markers of malperfusion such as base deficit, serum lactate level, near-infrared spectroscopy, or side-stream dark-field videomicroscopy.<sup>227</sup> Each of these monitoring tools provides distinct

advantages but may also be difficult or not feasible to apply to burn patients. They may not be readily available in some burn units, may lack proof of accuracy, and may be invasive, presenting a risk to patients who are already in a critical clinical state.<sup>227</sup>

It seems that the initial fluid requirement of acute burn patients is often miscalculated for two reasons: erroneous estimation of burn size and computation of fluid volume to be administered. Not using the Lund–Browder chart is considered one of the reasons for wrong estimation of burn size. Several measures are suggested to improve the accuracy of computing fluid requirement, such as a nomogram or an electronic calculator.<sup>230,231</sup> Attributing part of the error to complicated initial resuscitation formulas, some authors have developed a simpler formula, the “Rule of Ten,” which was designed and has been used by the US Army Institute of Surgical Research for the past several years.<sup>228</sup> With this method, the percentage of burned body surface area is multiplied by 10 to determine the estimated hourly fluid rate. For every 10 kg above 80 kg of body weight, 100 mL/hr is added to the calculated rate. The Rule of Ten appears accurate for patients weighing between 40 and 140 kg, overestimating the rate for patients below 40 kg and underestimating for those above 140 kg of body weight.<sup>228</sup> Generally, morbid obesity complicates initial fluid resuscitation. If actual body weight is used, the calculated fluid need is lower than that determined for normal-weight patients. If ideal body weight is used, which is rare in clinical practice, the patient may receive a higher resuscitation volume. Morbidly obese patients are likely to have higher acidosis, organ dysfunction, and mortality.<sup>232</sup>

Fluid management during the second 24-hour period after a burn is also important and involves the use of colloid, whether the Parkland or modified Brook formula is used as a guide. It has been shown that fluid intake in the second 24 hours correlates with that of the first 24-hour period; the higher the resuscitation volume during the first period, the higher the fluid intake during the second 24 hours.<sup>233</sup> Older victims, intubated patients, and those receiving high-dose narcotics require a larger volume of fluids during this period.<sup>233</sup> Although there are several formulae to calculate the hourly fluid volume needed, using 20% to 60% of the calculated plasma volume for colloid dose, or better the formula  $(25 + \%burn)(body\ surface\ area\ in\ m^2)\ mL\ for\ crystalloids + 0.3\ to\ 0.5\ mL/kg/\% burn\ for\ colloids + maintenance\ fluid$  provides a guideline for total fluid requirement. Generally the actual fluid volume administered exceeds the amount calculated by this formula by a factor of 1.5 to 1.9.<sup>233</sup> Maintenance fluid can be calculated by estimating 4 mL/kg/hr for the first 10 kg, 2 mL/kg/hr for the second 10 kg, and 1mL/kg/hr for additional weight thereafter.<sup>233</sup>

# Operative Management

## Monitoring

### Hemodynamic Monitoring

Direct intra-arterial pressure monitoring, which permits beat-to-beat data acquisition and sampling for measurement of blood gases, should be in place before surgery. An ultrasound-guided technique or a surgical cutdown may be necessary to facilitate access. The radial artery is the vessel of choice in abdominal or chest trauma in which the aorta may be cross-clamped, making a femoral or dorsalis pedis cannula nonfunctional. The right radial artery is preferred in cases of chest trauma in which cross-clamping of the descending aorta might result in occlusion of the left subclavian artery. In mechanically ventilated patients, the magnitude of systolic pressure variation (the difference between the maximum and minimum systolic pressures over the respiratory cycle) and its delta down component (the difference between systolic pressures at end-expiration and the lowest value during the respiratory cycle) can provide reliable information about the intravascular volume status and predict responsiveness to fluid loading. A systolic pressure variation over 5 mmHg and a delta down over 2 mmHg suggest hypovolemia and responsiveness to fluid.<sup>234</sup>

The ability to predict fluid responsiveness is of crucial importance in preventing over- or underinfusion of fluids and its consequences. Interest has been centered on *automatically* obtaining systolic blood pressure variation, PPV, and SVV during the mechanical ventilation cycle to predict fluid responsiveness. Indeed several devices, such as the PiCCO (Pulsion Medical Systems, Munich, Germany), LiDCO (Lidco Ltd., London, UK), and FloTrac/Vigileo CO monitor (Edwards Lifesciences, Irvine, CA), are able to display systolic blood pressure variation, PPV, and SVV, which appear to predict responsiveness to fluid administration with greater accuracy than static markers of preload such as CVP, pulmonary artery occlusion pressure, and even global end-diastolic volume or left ventricular end-diastolic area.<sup>235</sup> Threshold values to discriminate responders from nonresponders to fluid infusion have been determined (PPV or SVV >12% for responders). These dynamic indices of preload can be obtained with an arterial line without central venous catheters or PACs. Limitations of this technology include ability to work only in intubated and mechanically ventilated patients with tidal volumes over 7 to 8 mL/kg, in a closed chest, and with normal cardiac rhythm; doubtful reliability in patients with stiff lungs or those receiving PEEP; and, most important, lack of information about accuracy in acutely

injured patients.<sup>236</sup> An excellent review describing new methods of hemodynamic monitoring, including a pulse waveform analysis technique to determine fluid responsiveness and its possible application to trauma care, has recently become available.<sup>237</sup>

Delaying emergent surgery to place a central venous line is rarely indicated unless a large-bore catheter is needed for volume resuscitation. However, if the patient is elderly, if there is a likelihood of myocardial damage, or if there is multiple organ damage with a requirement for anticipated prolonged surgery, massive fluid replacement, and administration of vasoactive drugs, early placement of a CVP or PAC may be indicated before the development of coagulopathy renders it hazardous. If a PAC is placed, mixed venous O<sub>2</sub> and cardiac output measurement may convey information about organ perfusion. PACs with the capability of measuring right ventricular end-diastolic volume and ejection fraction (EF) provide better information about preload than regular PAC, but they are less accurate than TEE.<sup>237</sup>

The TEE provides valuable diagnostic information in BCI, cardiac septal or valvular damage, coronary artery injury, pericardial tamponade, and aortic rupture.<sup>178</sup> It also permits assessment of cardiac function, including right and left ventricular volume, EF, wall motion abnormalities, pulmonary hypertension, and cardiac output, and detects acute ischemia more accurately than either ECG or pulmonary artery pressure monitoring. Measuring the right ventricular volume alone can provide information about the adequacy of the intravascular volume. This technique also allows visualization of fat and air entry into the right heart, or into the left heart through a patent foramen ovale during internal fixation of lower extremity fractures.<sup>238</sup>

There is interest in using point-of-care TTE to qualitatively and quantitatively monitor preload and right and left cardiac function in trauma patients. Two excellent reviews have recently been published on this subject.<sup>237,239</sup> Obviously the purpose is not to perform a comprehensive TTE examination as practiced by cardiologists but to obtain goal-directed information about preload and cardiac function in symptomatic (hypotensive) trauma patients to select proper treatment. The TTE technique most commonly used in the trauma setting involves obtaining images through the subcostal long axis, subcostal inferior vena cava, parasternal long axis, parasternal short axis, and apical 4-chamber windows. Placement of a phased-array low-frequency (5 to 2 MHz) probe in these locations provides ideal views that are sufficient to inform the clinician of an underlying hemodynamic problem (Table 53-15 and Fig. 53-8).

Qualitatively, an empty heart and a flat IVC suggest hypovolemia. The patient is usually tachycardic and the ventricular walls contact each other (kissing) at the end of systole, producing a high EF. Likewise, the IVC

collapses during the respiratory cycle. There are some pitfalls in interpretation of these findings. For example, in mechanically ventilated patients, the IVC may be large and may not collapse despite hypovolemia because of increased intrathoracic pressure. Also, patients in chronic heart failure may not show an empty hyperdynamic heart. Other qualitative findings to be looked for during evaluation of heart function with the parasternal short axis view at the level of the papillary muscles are inward motion of the endocardium, myocardial thickening, longitudinal motion of the mitral annulus, and geometry of the left ventricle. In addition, the presence of trauma-induced structural abnormalities such as pericardial effusion, or acute PE, which causes pulmonary hypertension and right ventricular dilation with thinning of the walls, and tricuspid valve insufficiency can be detected.<sup>239</sup>

**Table 53-15** Transthoracic Echocardiographic Examination in the Trauma Setting

Window Used	Cardiac View	Probe Location	Direction of Probe Marker
Subcostal long axis	Four-chamber	Subcostal –45-degree cephalad angle	Patient's left shoulder
Subcostal inferior vena cava	Inferior vena cava	Subcostal vertical	Patient's left shoulder
Parasternal long axis	Left atrium, left ventricle, left ventricular outflow tract, aortic root, right ventricle	Left parasternal third to fifth intercostal space	Patient's right shoulder
Parasternal short axis	Left ventricle and small portion of right ventricle	Left parasternal third to fifth intercostal space	Patient's left shoulder
Apical	All four chambers	Below the nipple	Patient's left back toward 2- and 3-o'clock position

**Figure 53-8** Transthoracic echocardiographic windows used in trauma patients and images obtained through each window. The photograph on the upper left shows location and position of the ultrasound probe and the direction of its marker (circle on the probe) for images of subxiphoid long axis (1, SLAX), subxiphoid inferior vena cava

(2, SIVC), parasternal long axis (3, PLAX), parasternal short axis (4, PSAX) and apical four-chamber views (5, A4CH). [Table 53-15](#) provides more detail about probe positioning. RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle; IVC, inferior vena cava; HV, heart valve; LVOT, left ventricular outflow tract. Right pleural fluid is shown on the SIVC and pericardial fluid in the A4CH views. (Courtesy of Drs. Ambika Nayar and Kenneth Sutin.)

Quantitative evaluation of the TTE is more complex, but it permits calculation of stroke volume (SV), SVV after administration of fluids, EF, and cardiac output. These parameters can be determined from the two-dimensional image directly, or indirectly using the M mode, and by calculating fractional endocardial shortening during end-diastole and end-systole, which in turn provides end-diastolic and end-systolic volumes and thus permits calculation of SV, cardiac output, and EF.<sup>239</sup> The results of these measurements lead to four possibilities in the hypotensive trauma patient, each requiring different treatment: normal SV and EF requiring no treatment; low SV and high EF suggesting hypovolemia and necessitating fluids; low SV and low EF suggesting myocardial dysfunction and need for inotropic agents; or normal SV and high EF suggesting vasodilation, requiring vasopressor therapy.<sup>237</sup> With serial TTE determinations proper hemodynamic management is possible during the initial management of the trauma patient in shock whether in the ED or in the OR as long as access to the chest permits placement of the ultrasound probe. During ICU management, more detailed TTE examination is possible to guide therapy.

## Urine Output

Urine output is routinely monitored as an indicator of organ perfusion, hemolysis, skeletal muscle destruction, and urinary tract integrity after trauma. Its reliability in monitoring perfusion is decreased by prolonged shock prior to surgery and osmotic diuresis caused by administration of mannitol or radiopaque dye. Dark, cola-colored urine in the trauma patient suggests either hemoglobinuria resulting from incompatible blood transfusion or myoglobinuria caused by massive skeletal muscle destruction after blunt or electrical trauma. Although the definitive diagnosis is made by serum electrophoresis, rapid differential diagnosis can be made by centrifugation of a blood specimen. Pink-stained serum suggests hemoglobinuria, whereas unstained serum indicates myoglobinuria. Both of these conditions may result in acute renal failure. Prevention involves inducing diuresis with fluids and mannitol and, in myoglobinuria, although controversial, additional alkalinization of the urine with sodium bicarbonate to pH greater than 5.6. Red-colored urine usually is caused by hematuria, which, in the traumatized

patient, suggests urinary tract injury.

## Oxygenation

Trauma patients frequently develop hypoxemia ( $O_2$  saturation  $< 90\%$ ), hypothermia, hypotension, and/or decreased peripheral perfusion. Of the available  $O_2$  saturation ( $SpO_2$ ) devices, finger or earlobe pulse oximeters are more affected by decreased perfusion than forehead probes, probably because the latter senses the pulsation of the supraorbital artery, a branch of the carotid artery, which is presumably less affected by shock or hypothermia. However,  $SpO_2$  results with the forehead monitor may be affected by venous pulsation, especially in patients receiving positive-pressure ventilation or in any situation that distends the tributaries of the superior vena cava.<sup>240</sup> It has been suggested that using these sensors with a head band that exerts 10 to 20 mmHg of pressure may minimize the inaccuracy.<sup>240</sup>

With advances in technology, multi-wavelength pulse CO-oximeters are now capable of providing other physiologic data, including pulse rate,  $SpO_2$ , perfusion index, carboxyhemoglobin, and methemoglobin. They can also measure noninvasive continuous hemoglobin concentration with reasonable accuracy. The ability of these monitors (Masimo Rad-7 and Rad-57 Pulse CO-oximeters; Masimo, Irvine, CA) to measure methemoglobin and carboxyhemoglobin concentration noninvasively renders them useful in acute burn injury management. Although these devices are considered to provide more accurate information than conventional pulse oximeters, to the best of the authors' knowledge, they have not yet been systematically tested in major trauma victims.

## Organ Perfusion and Oxygen Utilization

**14** As discussed previously, unrecognized hypoperfusion may lead to splanchnic ischemia with resulting acidosis in the intestinal wall, permitting the passage of luminal microorganisms into the circulation and release of inflammatory mediators, causing sepsis and multiorgan failure.<sup>69,70</sup> Base deficit and blood lactate level, which have already been discussed in the section "Management of Shock," are considered acceptable markers of organ hypoperfusion in the *apparently* resuscitated patient and may be used intraoperatively to set the optimal end points of resuscitation.<sup>70</sup> Another parameter that may provide information about the global perfusion of the body is the arterial to end-tidal  $CO_2$  difference. Values greater than 10 mmHg after resuscitation predict mortality.<sup>241</sup> It may be useful in the decision about when to perform damage control surgery and intraoperatively in guiding resuscitation with fluids, inotropes, and vasopressors. A large gap is usually due to decreased lung perfusion resulting in high  $PaCO_2$  and low end-tidal

CO<sub>2</sub>. Severe chest trauma, hypotension, or metabolic acidosis also increases the likelihood of discordance between arterial and end-tidal CO<sub>2</sub>.<sup>242</sup>

Oxygen transport variables, once routinely monitored as markers of organ perfusion, especially in the ICU setting, are used less frequently and in a limited number of centers primarily because they require pulmonary artery catheterization. They consist of oxygen delivery (DO<sub>2</sub>), O<sub>2</sub> consumption (VO<sub>2</sub>), and O<sub>2</sub> extraction ratio. The DO<sub>2</sub> index (DO<sub>2</sub>I) is a particularly useful end point because it integrates three important variables: Hgb concentration, arterial oxygen saturation, and cardiac output. The minimum acceptable value for this marker is 500 mL/min/m<sup>2</sup>,<sup>243</sup> which is as effective as the previously recommended DO<sub>2</sub>I of at least 600 mL/min/m<sup>2</sup>. A computerized ICU decision protocol developed to standardize shock resuscitation in some centers uses DO<sub>2</sub>I above 500 mL/min/m<sup>2</sup> as a goal.<sup>243</sup> The oxygen consumption index (VO<sub>2</sub>I) is also an important variable. Subsequent organ failure may occur if it decreases below a value of 170 mL/min/m<sup>2</sup>, indicating a flow-dependent phase of O<sub>2</sub> utilization.<sup>70</sup> Increasing DO<sub>2</sub>I until VO<sub>2</sub>I attains flow independence may prevent organ failure; however, this approach is not practical clinically, mainly because there are also DO<sub>2</sub>I-independent regulators of VO<sub>2</sub>.<sup>243</sup>

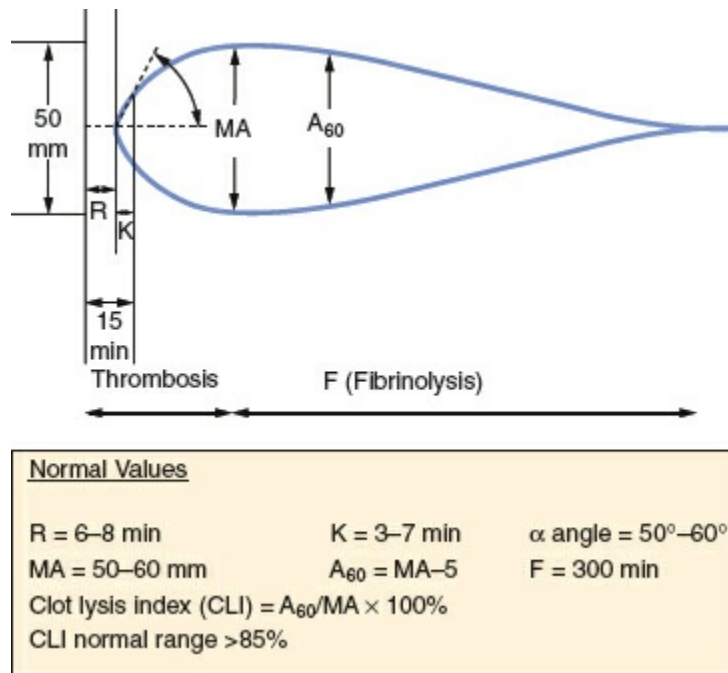

Finally, a global O<sub>2</sub> extraction ratio below 0.25 to 0.3 suggests absence of dysoxia. However, it is possible that dysoxia may be present in an individual organ in the presence of a normal overall O<sub>2</sub> extraction ratio. Monitoring of O<sub>2</sub> transport variables, the most useful of which is DO<sub>2</sub>I, is usually done in the ICU when invasive monitoring permits measurement of cardiac output and mixed venous O<sub>2</sub>. These values can also be monitored in the OR whenever arterial and pulmonary artery lines are present.

It has recently been demonstrated that central venous, instead of pulmonary artery, monitoring with CVP above 10 mmHg, mean systemic blood pressure of 65 mmHg, and Hgb over 10 g/dL as threshold values also suggests adequate organ perfusion.<sup>244</sup> It should be emphasized that various pre-existing and trauma-related conditions may affect the interpretations of these perfusion markers. For example, the base deficit may reflect a nongap acidosis, elevated lactate may be secondary to impaired clearance owing to hepatic dysfunction, and arterial to end-tidal CO<sub>2</sub> gradient may be caused by chronic obstructive lung disease. Thus, management decisions must be individualized, taking into account the patient's general condition.

## Coagulation

Conventional blood coagulation monitoring includes a baseline and subsequent serial measurements of INR, activated partial thromboplastin time (aPTT), platelet count, blood fibrinogen level, and fibrin degradation products

(FDPs). Although trauma center laboratories cannot provide results of the standard coagulation tests rapidly, at least INR can be monitored with a point-of-care device and provide some information. Thromboelastography (TEG; Haemonetics, Boston, MA) and rotation transmission electron microscopy (ROTEM; Pentapharm, Munich, Germany) are point-of-care devices that provide a relatively rapid, comprehensive, and quantitative graphic evaluation of clotting function.<sup>245,246</sup> The TEG determines the time necessary for initial fibrin formation, the rapidity of fibrin deposition, the clot consistency, the rate of clot formation, and the times required for clot retraction and lysis (Fig. 53-9).<sup>245</sup> Basically, the R and K values are indices of formation, buildup, and crosslinking of fibrin and depend on the function of coagulation factors. The maximum amplitude is the widest portion of the curve and indicates the absolute strength of the fibrin clot. It represents platelet function. The  $\alpha$ -angle is the slope of the external divergence of the tracing from the R-value point, indicating the speed of clot formation and fibrin crosslinking. The value of this parameter is determined by both coagulation factors and platelets. Hypothermia can cause coagulopathy by interfering with both platelets and coagulation factors.<sup>247</sup> When the blood of a cold and coagulopathic patient is placed in the TEG cuvette, which is normally heated to 37°C, a near-normal trace may be obtained. Newer TEG devices are temperature adjustable. Thus, the temperature in the cuvette can be adjusted to that of the patient. Likewise, by using activators, rapid TEG (r-TEG) can be performed to obtain timely results.<sup>248</sup> ROTEM is a modified TEM that uses a ball-bearing system for power transduction and is less susceptible to movement or vibration that may affect the TEG.<sup>246</sup> It measures clot formation and fibrinolysis. Results of coagulation parameters are obtained within 10 to 15 minutes because of activation with specific materials for each of clotting, platelet, and fibrinogen function. Figure 53-10 shows a typical TEM graph in which clotting time, clot formation time, maximum clot firmness (MCF), and the amplitude of clot at 10 minutes (CA<sub>10</sub>) and 15 minutes (CA<sub>15</sub>) can be determined.<sup>246</sup> After 30 to 60 minutes, the clot lysis index at 30 and 60 minutes (CLI<sub>30</sub> to CLI<sub>60</sub>), which is the ratio between the amplitudes at 30 and 60 minutes, and amplitude of the graph at the point of CT may be obtained. As in TEG, each parameter represents the status of a specific function.

**Figure 53-9** Thrombelastogram. R is the interval from blood deposition in the cuvette to an amplitude of 1 mm on the thrombelastogram; K is the time between the end of R and a point with an amplitude of 20 mm on the thrombelastogram; MA is the maximum amplitude of thrombelastogram;  $\alpha$  angle is the slope of the external divergence of the tracing from the R value point;  $A_{60}$  is the amplitude of thromboelastogram 60 minutes after maximum amplitude; F is the time from MA to return to 0 amplitude (normal >300 minutes).

**Figure 53-10** Rotation thromboelastometry graph depicting each clotting parameter. (Adapted with permission from Rugeri L, Levrat A, David JS, et al. Diagnosis of early coagulation abnormalities in trauma patients by rotation thromboelastography. *J Thromb Haemost.* 2007;5:289.)

## Anesthetic and Adjunct Drugs

**16** Apart from regional anesthesia techniques, which are used in patients with

minor extremity injuries and stable hemodynamics, anesthetic and adjunct drugs for general anesthesia need to be tailored to five major clinical conditions: airway compromise, hypovolemia, head or open eye injuries, cardiac injury, and burns. The varying contribution of these conditions to the clinical picture of a given patient necessitates priority-oriented planning.

## **Airway Compromise**

Anesthetics and muscle relaxants should be avoided before the airway is secured if there is significant airway obstruction or if there is doubt as to whether the patient's trachea can be intubated because of anatomic limitations. If time permits, lateral neck radiographs, CT scanning, and endoscopy can be used to define the problems better. Topical anesthesia with mild sedation can be used to secure the airway with a conventional blade, videolaryngoscope, or FOB. If a rapid-sequence induction is contemplated, ketamine and etomidate may confer advantages over propofol. In equipotent doses in normovolemic patients, they produce less cardiovascular depression. Contrary to findings of increased mortality with prolonged etomidate infusion, a single induction dose (0.3 mg/kg) of etomidate did not affect organ function and outcome in acutely ill patients any more than ketamine, suggesting minimal effect on steroidogenesis.<sup>249</sup> Although succinylcholine, with its short onset time and duration, is still the muscle relaxant of choice for rapid-sequence induction, rocuronium (1.2 to 1.5 mg/kg) has almost the same onset time and does not have the undesirable side effects associated with succinylcholine (e.g., increased intragastric, intraocular, and intracranial pressures and potassium release in patients with burns and neurologic diseases). Its longer duration of action may be disadvantageous and may lead to hypoxia, if both ventilation and intubation prove to be impossible. Under these circumstances, one of the available videolaryngoscopes or other aids can be employed to overcome the problem. Sugammadex can also be utilized to encapsulate rocuronium or vecuronium and recover spontaneous breathing in a reasonably short period.<sup>250,251</sup> Surgical standby for cricothyroidotomy should be considered if failure of these techniques is anticipated. Bradycardia, dysrhythmias, and cardiac arrest may occur after succinylcholine in the presence of hypoxia and hypercarbia. Some of these complications may also follow an apparently uneventful intubation performed without succinylcholine.

## **Hypovolemia**

In the absence of controlled human studies of anesthetic drug effects in hemorrhage and hemorrhagic shock, our current knowledge in this area is based on the results of experimental work, mostly in swine, and clinical

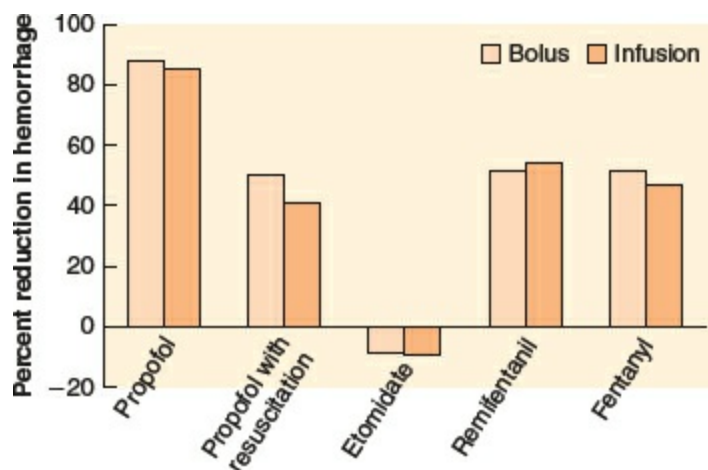

experience from managing trauma victims. Our planning process for deciding how to use anesthetic agents is further complicated by the damage control resuscitation principle, specifically permissive hypotension. The facts that should drive decision making in this regard are as follows: First, anesthetic agents not only have direct cardiovascular depressant effects but also inhibit compensatory hemodynamic mechanisms such as central catecholamine output and baroreflex (neuroregulatory) mechanisms, which maintain systemic pressure in hypovolemia. Second, hemorrhage and hypovolemia alter the pharmacokinetics and pharmacodynamics of almost all anesthetic agents and often lead to a higher than normal blood concentration of intravenous agents and increased sensitivity of the brain and heart. Preferential distribution of the cardiac output to the brain and the heart, cerebral hypoxia, dilutional hypoproteinemia producing a larger free fraction of intravenous drugs, and acidosis all seem to be responsible for these effects. Third, hemorrhage and hypovolemia have different hemodynamic effects in the absence and presence of trauma. In the presence of trauma pain and a catecholamine surge, maintain blood pressure despite significant intravascular volume depletion and ischemia of vital organs such as the brain and the heart. Based on this knowledge, reducing or eliminating anesthesia to avoid 17 abolishing the hemodynamic balance is a natural and often utilized practice, especially when permissive hypotension to limit bleeding is used. Dutton<sup>252</sup> recently suggested that proper management under these circumstances may be aggressive titrated administration of anesthetics and of blood products to produce a high-flow and low-pressure hemodynamic state with vasodilation to improve organ flow and oxygenation, which may reduce fibrinolytic activity and inflammation.<sup>252</sup> With serial blood lactate measurements the effect of either of these approaches can be monitored to aid further management. Further research is needed to help the clinician in selection of either of the approaches.

The pharmacokinetic and pharmacodynamic responses of intravenous agents to experimental hemorrhagic shock vary depending on the severity of the hemorrhage, the specific agent, and whether the effect analyzed is hypnosis or immobility to noxious stimuli. For example, in swine with compensated hemorrhage, when administered as a continuous infusion, blood propofol concentration increased by less than 20%, while during uncompensated shock (i.e., in hypotensive animals), it increased by almost four times.<sup>253</sup> On the other hand, under the same experimental conditions, plasma remifentanil concentration doubled during compensated shock but increased almost 27 times in uncompensated shock.<sup>253</sup> Remifentanil degradation relies on tissue and blood esterases. It is possible that hydrolysis by tissue esterases is more intense than by their blood counterparts because the decreased tissue blood flow in uncompensated shock is able to produce a

major reduction in remifentanil metabolism. Another example is that hemorrhage has a similar potentiating effect on the production of hypnosis and immobility by propofol.<sup>254</sup> In contrast, the potentiating effect of hemorrhagic shock on isoflurane-induced hypnosis is much smaller than on its immobilizing effect.<sup>254</sup>

Because of the decrease in size of the central compartment and in systemic clearance, plasma concentrations of fentanyl and remifentanil are increased.<sup>253,255</sup> A decreased volume of distribution also increases the blood level of etomidate by 20% in shock,<sup>256</sup> and for propofol this effect is even greater. There is also variation in the extent of brain sensitivity to these agents. Although etomidate pharmacodynamics are unchanged,<sup>257</sup> a significant increase in the sensitivity of the brain and heart to propofol is noted in animals, even after fluid resuscitation.<sup>256</sup> Based on these experimental findings, Shafer<sup>258</sup> calculated that in patients with shock, the dose of propofol should be only 10% to 20% of that given to a healthy patient. Although he calculated that etomidate dose should not require adjustment for shock, the authors decrease the dose by at least 25% to 50% when hypovolemia is suspected. As to the opioids, the calculated dose for fentanyl and remifentanil is approximately one-half that for healthy patients (Fig. 53-11).<sup>258</sup> Of the remaining intravenous agents, midazolam is also known to have significant cardiovascular depressant activity, whereas ketamine has stimulatory effects when the autonomic nervous system is intact.

**Figure 53-11** Calculated dose reduction of various anesthetics administered as bolus or infusion in moderate hemorrhagic shock. Calculation is based on pharmacokinetic and pharmacodynamic studies performed in experimental hemorrhagic shock. (Adapted from Shafer SL. Shock values. *Anesthesiology*. 2004;101:567.)

There are also differences among anesthetics in the direction and extent of their effects on compensatory mechanisms. For example, the baroreceptor depression produced by intravenous agents is usually milder than that of

inhalational agents. Opioid agents have little direct cardiovascular or baroreflex depressant effect; however, these agents can cause hypotension by inhibiting central sympathetic activity, especially in the hypovolemic trauma patient whose apparent hemodynamic stability is maintained by hyperactive sympathetic tone.

Two important principles in the use of anesthetic agents are accurate estimation of the degree of hypovolemia and reduction of doses accordingly. The presence of hypotension suggests uncompensated hypovolemia, in which case anesthetics almost invariably produce further deterioration of systemic blood pressure and sometimes cardiac standstill. Intravascular volume, to the extent possible, must be restored before their use. When time constraints or continuing hemorrhage prevent restoration of blood volume, the airway may be secured without the benefit of anesthesia (perhaps using only rapidly acting muscle relaxants and small doses of opioids, etomidate, or ketamine), even though this approach may result in recall of induction and intraoperative events in up to 40% of patients, and, as mentioned before, vital organ ischemia.<sup>259</sup> Hypothermia, alcohol intoxication, illicit drug use before anesthesia, and metabolic disturbances in the acute trauma patient cannot reliably prevent recall. However, scopolamine (0.6 mg), and midazolam, if the patient can tolerate it, given before airway management may decrease the likelihood of this complication. Intraoperative use of the bispectral index monitor and, whenever possible, titrating anesthetics to bispectral index levels lower than 60 may prevent recall in trauma patients.

In normotensive but hypovolemic patients, restoration of volume and selection of an agent with the least cardiovascular depressant effect appears logical. Ketamine and etomidate are the preferred induction agents,<sup>257</sup> although at low doses other intravenous anesthetics are also unlikely to produce hypotension. Therefore, the use of any of these drugs in reduced doses is probably more important than the particular agent chosen.

Maintenance of anesthesia in the hypovolemic trauma patient raises concerns similar to those pertaining to induction. Experimental data have shown that depending on its severity, hemorrhagic shock decreases minimum alveolar concentration (MAC) by approximately 25%. Restoration of intravascular volume did not, but administration of naloxone did normalize MAC in these animals, suggesting that shock-induced release of endorphins is primarily responsible for this effect.<sup>260</sup>

Although nitrous oxide's (N<sub>2</sub>O) myocardial depressant effect is normally somewhat counterbalanced by its ability to increase sympathetic outflow, in acute hemorrhage there is already a dramatic increase in sympathetic activity and stimulation of baroreceptors. Under these circumstances, patients are unlikely to respond to the sympathetic effect of N<sub>2</sub>O, and the cardiovascular depressant properties of the gas are unmasked. These may be similar to those

of other inhalation agents. In addition, by reducing  $\text{FiO}_2$ , use of  $\text{N}_2\text{O}$  incurs a risk of hypoxemia in patients with reduced cardiac output or pulmonary compromise. Despite causing little impairment of reflex tachycardia and having a vasodilatory activity that preserves organ blood flow in normovolemic patients, isoflurane can impair cardiac output and organ blood flow in hypovolemia—that is, it can cause cardiovascular depression. Desflurane and sevoflurane are not significantly better than isoflurane in this regard. However, because of their low solubility in blood, the severe hemodynamic depression produced by these agents can be rapidly reversed, preventing suboptimal perfusion for a significant period of time. In summary, in the hypovolemic patient all inhalational agents may reduce both global and regional blood flows and therefore should be used only in low concentrations ( $<1$  MAC). Opioid supplementation is usually well tolerated and often indicated.

## Head and Open Eye Injuries

The importance of deep anesthesia and adequate muscle relaxation during airway management of patients with head or open eye injuries has already been discussed. Anesthetic agents selected for management of brain injury should produce the least increase in ICP, the least decrease in mean arterial pressure, and the greatest reduction in cerebral metabolic rate ( $\text{CMRO}_2$ ). The most important factor causing cerebral ischemia is increased ICP from intracranial hematoma. Prompt decompression is the most crucial means of ensuring cerebral well-being. Hypotension caused by anesthetics or other factors contributes to the development or progression of cerebral ischemia. Utmost attention should be paid during anesthesia to avoidance of hypotension (mean arterial pressure  $<60$  to  $70$  mmHg or SBP  $<90$  to  $100$  mmHg). All intravenous anesthetics including ketamine cause comparable degrees of cerebrovascular constriction and ICP reduction.<sup>261</sup>  $\text{CMRO}_2$  is also reduced by all of the available intravenous anesthetics. An important drawback to these agents, with the possible exception of ketamine, is that their cardiovascular depressant effects may reduce CPP. This problem can be ameliorated by administering pretreatment doses of opioids (fentanyl,  $2$  to  $3$   $\mu\text{g}/\text{kg}$ ), which permit reduction of the anesthetic dose. This may also prevent the myoclonic movements associated with etomidate and occasionally with propofol, and thus reduce the risks of ICP and IOP increase. Nevertheless, myoclonus is best prevented by careful timing of the dose of muscle relaxants. Another measure to preserve CPP during anesthesia is to administer vasopressors, being aware that hypovolemia may be masked by their use.

Ordinarily, administration of succinylcholine should follow pretreatment doses of nondepolarizing agents to prevent fasciculation-induced elevation of

ICP and IOP.<sup>262</sup> Avoiding succinylcholine usually does not alleviate the problem because laryngoscopy and tracheal intubation produce a greater and longer-lasting increase in these pressures. Rocuronium, 1.2 to 1.5 mg/kg, has an onset time comparable with that of succinylcholine. None of the nondepolarizing muscle relaxants causes an elevation of ICP or IOP in the absence of associated tracheal intubation.

All inhalation anesthetics may increase CBF and cerebral blood volume, and thus the ICP. Cerebral autoregulation, CO<sub>2</sub> responsiveness, and CMRO<sub>2</sub> are reduced. Unlike intravenous anesthetics, which decrease both CBF and CMRO<sub>2</sub> in parallel, inhalational anesthetics decrease CMRO<sub>2</sub> while increasing the CBF. The extent of this uncoupling varies with the agent and the dose. Isoflurane has the least vasodilatory effect and thus is the most widely used inhalation anesthetic, although desflurane and sevoflurane have comparable effects on the cerebral circulation. In hyperventilated patients with cerebral tumors or mild edema, isoflurane does not raise the ICP if it is administered at an inspired concentration below 1 MAC. In the presence of severe head injury, when cerebral autoregulation and CO<sub>2</sub> responsiveness are impaired, isoflurane has the potential to increase CBF and ICP even at levels below 1 MAC and with hyperventilation. Therefore, it may be prudent not to use this agent in the presence of elevated ICP, at least until the skull is opened and the ICP is controlled. In these patients, anesthesia can be maintained initially with opioids plus propofol, midazolam, or etomidate.

Nitrous oxide may increase CBF, cerebral blood volume, and ICP when administered with inhalation anesthetics if the PaCO<sub>2</sub> is normal or increased. This effect may be eliminated when this agent is administered with adequate doses of barbiturates or hyperventilation. The effect on CMRO<sub>2</sub> is variable: Both increases and decreases have been observed. Thus, N<sub>2</sub>O probably is not deleterious in patients with head injury with minimal ICP elevation if it is used after a bolus dose or during infusion of intravenous anesthetics.

A survey by Grathwohl et al.<sup>16</sup> compared the results of total intravenous anesthesia using ketamine with volatile agent anesthesia in a series of combat-related head injuries from Iraq. Although there are unavoidable shortcomings to the study, it nevertheless indicates that the specific anesthetic agents chosen probably do not affect the neurologic outcome as long as the vital signs are maintained.

## **Cardiac Injury**

If there is pericardial tamponade, preload and myocardial contractility must be maintained. Any decrease in these parameters may exacerbate an already existing right ventricle (RV) inflow obstruction. A decrease in heart rate should also be treated promptly to maintain adequate cardiac output. Because

all of the available anesthetics can depress myocardial contractility and cause vasodilation, it is preferable to administer these agents after evacuation of the pericardial blood under local anesthesia. If general anesthesia is required to relieve the tamponade, induction should be delayed until the patient is prepared and draped. Both anesthetics and controlled ventilation, particularly with PEEP, impair cardiac output. Deep anesthesia and high airway pressures should be avoided before evacuation of the hemopericardium. In chronic pericardial effusion, ketamine supports the cardiac index better than other intravenous agents. In acute pericardial tamponade, even minor insults can bring cardiac activity to a halt. Ketamine thus remains the agent of choice. It should be given in small doses after adequate fluid infusion. Similar principles apply to the use of maintenance agents, which should be given in the smallest possible doses until the heart is decompressed.

In blunt myocardial injury, the objective is not only to maintain cardiac contractility but also to lower the elevated pulmonary vascular resistance that may result from concomitant pulmonary contusion, atelectasis, or aspiration. All anesthetics should preferably be administered after restoration of intravascular volume and titrated to maintain adequate systemic blood pressure and cardiac output. If necessary, inotropes, preferably amrinone or milrinone, which produce some pulmonary vasodilation, may be used. Anesthetic maintenance by intravenous anesthetics and opioids to avoid the myocardial depression produced by inhalational agents should also be considered.

## **Burns**

A hypermetabolic state characterized by tachycardia, tachypnea, catecholamine surge, increased O<sub>2</sub> consumption, and augmented catabolism follows the initial few hours of a burn and continues into the convalescent phase, necessitating increased oxygen, ventilation, and nutrition.<sup>200,202,216,263</sup> Early extensive and repeated escharotomies with coverage by skin grafts attenuate the postburn hypermetabolic response, decrease insulin resistance, decrease fluid loss, and improve survival.<sup>264</sup> They are usually performed between the second day and the second week, often necessitating massive transfusion, temperature control, and management of fluid, electrolyte, and coagulation abnormalities. Usually, an autograft harvested from either the patient, a cadaver, or both is used. An artificial skin substitute, INTEGRA (Integra Life Sciences, Plainsboro, NJ), consisting of a dermal inner layer made of bovine collagen and chondroitin-6-sulfate and a neopidermal outer layer made of polysiloxane polymer, may also be used; it results in more favorable reduction of resting energy expenditure and elevation of serum proteins compared with that of cadaver skin.<sup>265</sup>

Anesthetic management of escharotomies presents several difficulties. Burned tissue may prevent access for ECG, pulse oximeter, neuromuscular function, and noninvasive blood pressure monitoring. Needle electrodes or surgical staples, a reflectance pulse oximeter, and an arterial catheter may be necessary. Large-bore intravenous catheters are essential. Hyperthermia occurs, but hypothermia is more likely in the OR and is to be avoided. Exposure and evaporative fluid loss necessitate maintenance of the OR temperature between 28°C and 32°C, use of fluid and blood warming devices, surface heating with forced dry warm air, and humidified inspired gases. Blood loss can be controlled by restricting the escharotomy to 15% to 20% of TBSA, using extremity tourniquets, applying topical thrombin and fibrin sealants to the excised area, using dilute epinephrine solution topically (1:10,000) or by injection (0.5 mg per 1,000 mL), and using compression bandages.<sup>266</sup> Epinephrine doses of up to 6.7 mg topically or 0.8 mg by injection into the surgical area are well tolerated. The affinity of  $\beta$ -adrenergic receptors to ligands is decreased after burns. The administration of a large amount of blood and blood products subjects the patient to complications of transfusion, such as hypocalcemia and coagulopathy, requiring monitoring of coagulation status and administration of adequate replacement therapy.<sup>267</sup>

Shock, hyperdynamic circulation, decreased serum albumin levels, increased  $\alpha_1$ -acid glycoprotein concentration, and altered receptor sensitivity change the response to various drugs during the resuscitative and convalescent phases.<sup>198,200</sup> The doses of intravenous anesthetics should be reduced during the resuscitation phase to prevent excessive hemodynamic depression. During the hyperdynamic phase, blood flow to the liver and kidneys increases with increasing cardiac output. Thus drugs that rely on organ blood flow for elimination are cleared at a faster rate, requiring larger doses for effect, which may also be associated with hemodynamic depression.<sup>198</sup> Burn patients have excruciating pain and exceedingly high opioid requirements. Morphine may be the preferred opiate; in a preliminary study, patients receiving fentanyl experienced higher body temperatures than those who received morphine. This was attributed to the well-established anti-inflammatory properties of morphine.<sup>268</sup> A proven anesthetic regimen for excision and grafting of burns is volatile anesthetic agent plus large doses of opioid. Increased opioid requirement is related not only to the intense pain level but also to tolerance, which starts developing about 3 to 4 weeks after injury, reaching a maximum at 10 to 17 weeks and gradually declining to baseline about 6 months after injury. Similar tolerance to benzodiazepines may be noted.<sup>198</sup> Along with pharmacokinetic changes, pharmacodynamic alterations such as downregulation of the  $\mu$ -opioid receptors and upregulation of the protein kinase C-V<sup>o</sup> and N-methyl-D-aspartate receptors appear to be responsible for opioid, benzodiazepine, and ketamine tolerance.<sup>198</sup> Clinically

this problem can be overcome by supplementing opioids with clonidine, dexmedetomidine, ketamine, and, because of its long half-life, methadone.<sup>198</sup> A sedation analgesia guideline is proposed by Bittner et al.<sup>198</sup> for different burn-induced pain conditions.

For serial wound debridement, dressing or line changes, and insertion of urinary catheters in children, ketamine in intermittent doses provides a suitable alternative to inhalation anesthesia. Hemodynamic stability, preserved airway patency, bronchodilation, anti-inflammatory effect, counteraction of opioid hyperalgesia, and maintenance of hypoxic and hypercapnic responses are all advantages of this agent. Dysphoria and increased salivary output can be overcome by concomitant administration of benzodiazepines and anticholinergics. It should be kept in mind that in some catecholamine-depleted burn patients, hypotension may follow ketamine administration.

Regional anesthesia in its various forms can be effective to provide intraoperative anesthesia, postoperative analgesia, and assistance for rehabilitation. Pain in these patients originates from the burn site but also the area of skin harvesting, and often the latter is more intense. Tumescent infiltration in the form of continuous infusion of local anesthetic administered subcutaneously at the donor site may provide satisfactory analgesia. Lateral cutaneous nerve or transverse abdominis plane blocks provide analgesia to the lateral thigh, where skin harvesting is usually performed. These blocks may be combined with fascia iliaca blocks if the graft is taken from the anterior thigh. Paravertebral blocks with or without catheter placement can provide excellent analgesia to burnt areas at the torso. Brachial plexus and sciatic/femoral blocks can be useful for upper and lower extremity pain management. Finally, if the patient's back is free of burn injury, neuraxial blocks can be used.<sup>198</sup>

The response to depolarizing and nondepolarizing muscle relaxants remains unaltered during the first 24 hours after burn injury. After this period, succinylcholine should be avoided for at least 1 year because it can result in a potentially lethal increase of serum  $K^+$  when the burn size exceeds 10% of TBSA. The mechanism of this response is related to upregulation (increase) of acetylcholine receptors, which ultimately occupy the entire muscle membrane, and the additional expression of two newly described isoforms of the acetylcholine receptor, and nicotinic (neural)  $\alpha 7$ -acetylcholine receptors. The latter can be depolarized not only by acetylcholine and succinylcholine but also by choline, which thus plays an important role in the development of hyperkalemia.<sup>269</sup> Resistance develops to all nondepolarizing muscle relaxants including cisatracurium in patients with burns of more than 30% of TBSA starting at approximately 1 week and peaking 5 to 6 weeks after injury, probably from pharmacodynamic causes.<sup>198,200,203</sup> Increasing the dose

can partly overcome this resistance. For instance, rocuronium, which is important for rapid-sequence induction and treatment of laryngospasm when succinylcholine is contraindicated, has an onset time delayed by about 50 seconds (30% longer than patients without burn) when a 0.9 mg/kg dose is used. Increasing the dose to 1.2 mg/kg decreases the delay by 30 seconds, but the onset time remains about 25 to 30 seconds longer than that observed in patients without burns. Intubating conditions also improve by increasing the dose. Recovery time from the block is shorter in burned patients than in normal individuals.<sup>270</sup>

## *Management of Intraoperative Complications*

### **Persistent Hypotension**

Persistent hypotension following trauma is usually the result of one of four mechanisms: bleeding, tension pneumothorax, neurogenic shock, or cardiac injury. Although many other causes, such as citrate intoxication (hypocalcemia), hypothermia, coronary artery disease, allergic reactions, or incompatible transfusion may be responsible for this complication, they occur infrequently.

Hypotension is most likely due to bleeding. The source may be obvious, such as external bleeding from the skull or an open vessel in the extremities, or occult. The thoracic and abdominal cavities and the pelvic retroperitoneal space are the most common sites of occult hemorrhage that results in hypotension. Management includes early diagnosis and control of the bleeding site plus effective fluid resuscitation with a rapid-infusion system, which should be connected to a 14-gauge or larger cannula, preferably inserted into veins both above and below the diaphragm. The Rapid Infuser systems (RI-2, Belmont Instrument Corp, Bellerica, MA; ThermaCor 1200, Smisson-Carlledge Biomedical, Macon, GA), which consist of a reservoir, heating system, roller pump, and large-diameter (5-mm) tubing, are capable of delivering up to 1,000 mL/min of warm fluids once the infusion rate is programmed.

Of the isotonic crystalloid solutions, LR is preferred over normal saline. Resuscitation with normal saline during uncontrolled hemorrhage is associated with greater urine output and thus greater fluid requirement compared with LR, hyperchloremic acidosis, and dilutional coagulopathy.<sup>271</sup> Acidosis does not occur with LR, but tissue edema may result from its slight hypotonicity ( $\sim 255$  mOsm/L), and neutralization of the citrate anticoagulant in PRBCs may occur because of its  $\text{Ca}^{2+}$  content. Human serum albumin (5% and 25%) is the most commonly used colloid, if the volume of hemostatic FFP exceeds the amount calculated by its ratio with transfused PRBC.

Theoretically, the combined use of fluids and moderate doses of vasopressor may rapidly restore blood pressure to normal levels, limit the fluid volume infused, and improve short-term survival.

Neurogenic shock from spinal cord injury may be missed during initial evaluation, especially in unconscious patients. However, differentiation of neurogenic shock from hemorrhagic shock is important. Patients with spinal cord injury are often bradycardic and readily respond to catecholamine administration. Mistaking neurogenic shock for hemorrhagic shock may lead to excessive fluid infusion and pulmonary edema in the spinal cord-injured patient. The reverse error may also occur, depriving patients with hemorrhagic shock of fluids because of misdiagnosis of neurogenic shock. TTE or TEE may be helpful in differentiation. In some patients, of course, hemorrhagic shock and neurogenic shock may coexist.

Cardiac causes of persistent hypotension include BCI and pericardial tamponade. Intraoperative TEE can be useful in the differential diagnosis. The RV is most commonly involved in BCI. If there is a concomitant increase in pulmonary vascular resistance (e.g., from an associated pulmonary contusion), the RV pressure increases while its output decreases, resulting in an increased CVP. The raised RV pressure causes the interventricular septum to shift toward the left, decreasing left ventricular compliance, increasing its diastolic pressure, and decreasing cardiac output. These alterations in cardiac anatomy and ventricular dynamics can be displayed by TEE or TTE, information that can be useful during interpretation of elevated cardiac filling pressures.

In the absence of TEE, a PAC may be helpful. Equalization of pressures across the cardiac chambers during diastole suggests pericardial tamponade. A similar picture may also be seen in severe BCI, causing difficulty in differential diagnosis. This effect, however, is rare and is usually associated with critical hemodynamic instability. Differential diagnosis in these instances can be established by pericardiocentesis. Septal encroachment into the left ventricle from RV contusion results in an increase in pulmonary artery wedge pressure. Decreasing the rate of fluid infusion in these patients results in a further decrease in cardiac output. Treatment includes fluid infusion, pulmonary vasodilators if the systemic blood pressure is normal, and inotropic support if the systemic blood pressure is low. Absence of response to this treatment is an indication for placement of an intra-aortic balloon pump. Pulmonary artery catheterization may also help detect an oxygen step-up from a septal injury. During thoracotomy, a distended RV should also raise the suspicion of a septal defect.

## **Hypothermia**

Shock, alcohol intoxication, exposure to cold, fluid resuscitation, and abnormalities in thermoregulatory mechanisms render the major trauma patient hypothermic during the initial phase of injury. A core body temperature below 35°C is often associated with acidosis, hypotension, and coagulopathy, which in turn may lead to an increased risk of severe bleeding, need for transfusion, and mortality.<sup>89</sup> Admission hypothermia, which is present in approximately 50% of patients, is an independent risk factor after major trauma,<sup>272</sup> and the mortality rate increases with decreasing temperature. Severe hypothermia, which in the trauma patient is defined as core temperature below 32°C,<sup>273</sup> was associated with a 100% mortality rate in one study,<sup>274</sup> although survival of a few patients with admission temperatures even lower than 32°C has been reported.<sup>275</sup> The intraoperative risk of hypothermia is also higher for trauma victims than for electively operated patients. Increased heat loss is seen most commonly in patients with spinal cord, extensive soft tissue, and burn injuries and in patients who consumed ethanol preoperatively or those undergoing body cavity surgery.

Other deleterious effects of hypothermia are cardiac depression, myocardial ischemia, arrhythmias, peripheral vasoconstriction, impaired tissue oxygen delivery, elevated oxygen consumption during rewarming, blunted response to catecholamines, increased blood viscosity, metabolic acidosis, abnormalities of K<sup>+</sup> and Ca<sup>2+</sup> homeostasis, reduced drug clearance, and increased risk of infection.<sup>272,276</sup> Rewarming after hypothermia, especially at a rapid rate, may release accumulated metabolic products into the central circulation, causing further myocardial depression, hypotension, and increased acidosis.

Prevention of hypothermia and restoration of normal body temperature appear to decrease mortality rate, blood loss, fluid requirement, organ failure, and length of ICU stay.<sup>277</sup> Convective warming with forced dry air at 43°C can prevent a temperature drop in most trauma victims but cannot effectively treat severe hypothermia because the low specific heat of air has little heat content to transfer to the cold trauma patient, and often, owing to the nature of the surgical procedure, only a limited body surface area is exposed to warming.<sup>277</sup> Circulating-water warmers may produce faster rewarming even though they cover a relatively smaller body surface area than forced air warmers.<sup>278</sup> Airway warming can reduce the heat loss caused by the latent heat of vaporization, but this technique also transfers very little heat.<sup>278</sup> Administration of warm intravenous fluids may prevent and treat hypothermia in the trauma patient, provided they are administered at a relatively rapid rate. For each liter of fluid given at 40°C to a patient with a body temperature of 33°C, 29.33 kJ of heat energy are gained (the specific heat of water is 4.19 kJ/L/°C).

## Coagulation Abnormalities

Multiple factors may be responsible for coagulopathy after trauma; they can be divided into two main categories. ATC develops shortly after trauma from tissue injury and hypoperfusion; this activates thrombomodulin from the endothelial cells and the thrombomodulin–thrombin complex, which in turn activates protein C inhibiting factors V and VIII.<sup>279,280</sup> RAC develops later and results from dilution of coagulation factors and platelets; tissue hypoperfusion; disturbance of fibrinogen/fibrin polymerization and platelet activity caused by decreased serum ionized  $\text{Ca}^{++}$  from infusion of colloids or binding to citrate in PRBCs, FFP, and platelet units<sup>281</sup>; hypoxia, hypothermia and acidosis; and disseminated intravascular coagulation (DIC). Primary fibrinolysis may develop early as a component of ATC or later as part of the RAC.<sup>282,283</sup> DIC results from acute release of thromboplastin from injured brain, fat, amniotic fluid, or other sources or subacutely from endothelial inflammation or failure interfering with clearance of activated coagulation factors, causing microthrombi and consumption coagulopathy.<sup>284</sup> Fibrinolysis may develop by depleted plasminogen activator inhibitor-1 (PA-1), which accelerates the formation of plasmin. Normally thrombin facilitates the conversion of fibrinogen to fibrin. In severe trauma, thrombin binds to thrombomodulin, which slows or reduces the activation of thrombin-activated fibrinolysis inhibitor, leading to hyperfibrinolysis.<sup>285</sup> More recently Johansson et al.<sup>286</sup> demonstrated elevated admission circulating syndecan-1 levels, a marker of degradation of the subendothelial glycocalyx, in trauma patients, suggesting that the precipitating event is vascular damage resulting from catecholamine release and increasing permeability, inflammation, and coagulopathy, probably implying that the interplay among these mechanisms is the pathogenesis of trauma-induced coagulopathy.<sup>87,287</sup>

Hypothermia affects platelet morphology, function, and sequestration; retards enzyme activity; and decreases coagulation factor function by about 10% for each 1°C drop in temperature, slowing the initiation and propagation of platelet plugs and fibrin clot as well as enhancing fibrinolytic activity.<sup>101,282,288,289</sup> The mechanism of hypothermia-induced coagulopathy is complex and depends on the extent of temperature decrease. Down to 33°C, there is little alteration in coagulation enzyme activity, explaining the practically unchanged values reported for aPTT.<sup>290</sup> Within this temperature range, coagulopathy results from altered platelet aggregation or adhesion.<sup>290</sup> Thus, the aPTT at temperatures from 33° to 37°C does not provide any meaningful information about coagulation status, even when the test is performed at the hypothermic patient's temperature, because it does not measure platelet adhesion. In contrast, TEG at the patient's temperature may be reflective of the degree of coagulopathy.<sup>281</sup> Both enzymatic activity and platelet aggregation are abnormal below 33°C.<sup>290</sup> Metabolic acidosis is

probably a stronger coagulation enzyme inhibitor than hypothermia. It interferes with the generation of thrombin, a factor essential in activating cofactors, platelets, and enzymes, in addition to converting fibrinogen to fibrin. This effect of acidosis is potentiated by hypothermia.<sup>291</sup>

## Diagnosis

The perioperative diagnosis of coagulopathy is often made by observing bleeding from wounds or puncture sites, rather than by interpretation of laboratory tests. However, the differential diagnosis between consumptive and dilutional coagulopathy requires laboratory testing. The availability of point-of-care coagulation testing (INR, TEG, and thromboelastometry) reduces the delay in obtaining the results of these tests.<sup>248</sup> In the absence of TEG or ROTEM, INR has been shown to be an acceptable alternative for this purpose.<sup>292</sup> In general, the inability to determine the type of coagulopathy does not present a problem because the initial treatment is similar for both conditions. Nevertheless, the diagnosis of DIC has prognostic significance because its treatment involves elimination of its cause(s). The presence of elevated circulating FDP, especially when above 40 mg/mL, is suggestive of DIC, but the result of this study will reach the clinician long after the completion of initial resuscitation. A fibrinogen level below 100 mg/dL is also suggestive of DIC, but reduction to this value often takes a long time, decreasing the diagnostic value of the test, although serial measurements may be useful. A diagnostic scoring system consisting of platelet count, PT or INR, fibrinogen level, and FDP measurements has been suggested to rule DIC in or out.<sup>293</sup>

## Treatment

### *Red Blood Cell Transfusion and Hemostasis*

Platelets function better in the presence of higher Hct, and a component therapy with 1:1:2 formula where 2 represents PRBCs.<sup>294</sup> Red blood cell administration should continue at least to a Hct of 30, at which point factors and platelets are active and can produce a solid clot. At lower Hct level, clot may develop but may not be strong enough to overcome bleeding. The optimal ratio of PRBCs:FFP:platelet during transfusion of the massively bleeding patient appears to be between 1:1:1 and 2:1:1.

Component transfusion therapy, used universally in civilian trauma, is inferior to the whole blood transfusion practiced by the military. During the preparation of platelets and FFP, 100 mL of nonhemostatic anticoagulants is put in each bag. This additional fluid lowers factor levels by 20%. Similarly 100 mL of solution is added to PRBCs for storage injury protection in addition

to 100 mL of anticoagulant. During MTP, each blood product administered dilutes out the other two blood product components. FFP will decrease the Hct and platelet count. Likewise, PRBCs lower coagulation factors and platelet counts. Thus a 1:1:1 ratio cannot be compared with whole blood in its hemostatic ability.<sup>252,294</sup> Hemostatic capability of component therapy further decreases with storage injury of PRBCs. During storage, red cells undergo changes, including the loss of adenosine triphosphate, diphosphoglycerate, and potassium; oxidative injury to proteins, lipids, and carbohydrates; loss of shape and membrane; increased adhesiveness; decreased flexibility; reduced flow in capillaries; and decreased oxygen delivery. The success of a blood transfusion is defined as 75% of the red cells infused still being effective after 24 hours. The storage injury brings out the controversy about the safety and effectiveness of “new blood” versus “old blood.”

New blood is generally defined as blood collected less than 14 days before administration, whereas old blood is considered blood that is 14 to 28 days past collection. Although banked blood can be stored for 42 days, the average age of blood units used in busy trauma centers is 16 days, essentially slightly older than “new blood.” Blood at 42 days is rarely used. Of more than 15 studies on the effect of age of blood in trauma, all but one demonstrated that old blood transfusion had an increased risk of multiorgan failure, infection, vascular complications, greater ICU/hospital length of stay, and mortality.<sup>295</sup> From a clinical perspective, however, it is a challenge for the anesthesiologist to receive blood for massive transfusion that is always less than 14 days old.

Each unit of PRBCs as well as FFP has the additives of citrate, monobasic sodium phosphate, dextrose, and adenine.<sup>296</sup> Adenine extends red cell survival from 21 to 35 days and is intrinsic for the maintenance of red cell ATP levels. Dextrose and monobasic sodium monophosphate are nutritive. The significant complication of these additives is that citrate chelates calcium, which serves as a co-factor in the coagulation cascade, leading to hypocalcaemia. In addition to defective coagulation, signs and symptoms of hypocalcemia include hypotension, decreased pulse pressure, arrhythmias, change in mental status, and tetany. Citrate is in abundance in all component blood products.<sup>296</sup> Hypocalcemia is a rare event but must be considered after the goals of the MTP are met and the patient remains hypotensive. Citrate is metabolized by the liver, and in the condition of hypothermia, which is common in the trauma patient, liver metabolism is decreased and citrate intoxication may become the source of hypotension after administration of 6 units/hr or if a sustained rate of 35mL/min PRBC is transfused. Citrate metabolism is decreased by 50% at 31C°.

### *Fresh Frozen Plasma*

FFP contains most of the components of the coagulation cascade and

fibrinolytic and complement systems, proteins that enhance oncotic pressure and modulate immunity,<sup>296</sup> and fats, carbohydrates and minerals in similar concentrations to those in blood. In the trauma patient, FFP is used for hemostasis, intravascular volume restoration, reversal of coagulopathy in patients receiving vitamin K-antagonist oral anticoagulants (warfarin) who are actively bleeding or who require emergency surgery, and in patients who are anticoagulated with warfarin and are deficient in the functional vitamin K-dependent coagulation factors II, VII, IX, and X, as well as proteins C and S. The first-line treatment for warfarin reversal is prothrombin complex concentrate (PCC)<sup>89,297</sup>; if it is not available, FFP (or single-donor plasma) or factor IX concentrate can be used.

As discussed earlier, newer guidelines recommend administration of thawed AB Rh- FFP immediately after the arrival of severely traumatized, bleeding, coagulopathic patients.<sup>89,298</sup> The recommended dose is 10 to 15 mL/kg, but additional doses may be needed.<sup>89,298</sup> Following initial administration, FFP is indicated when the transfusion exceeds 10 units of PRBCs within a 6-hour period and when the PT and/or PTT values exceed 1.5 times normal.<sup>89,298</sup> Inspired by experience gained during recent wars, many trauma centers have changed their transfusion protocols and modified the PRBC to FFP ratio from 4:1 to 1:1 or 2:1. Many civilian studies indeed showed a benefit of early treatment with high FFP to PRBC ratios administered to bleeding trauma patients,<sup>88,299,300</sup> although others did not and suggested 2:1 or even 3:1 as a more optimal ratio.<sup>298,301</sup> Most recently, Holcomb et al.<sup>104</sup> in a multicenter study reported no difference in mortality between 1:1:1 and 1:1:2 ratios of FFP, platelet, and PRBC transfusion practices, but they noted less bleeding within the first 24 hours after trauma with a 1:1:1 ratio. It should be emphasized that large volumes of FFP may worsen traumatic intracerebral hematoma, increasing the mortality of head-injured patients.<sup>302</sup> The risks associated with FFP include circulatory overload, ABO incompatibility, transmission of infectious diseases, mild allergic reactions, and transfusion-related acute lung injury, in which platelet concentrates are also implicated.<sup>89</sup>

### *Platelets*

Platelet transfusion is indicated when the platelet count falls below  $50 \times 10^9/L$ . It is possible that in patients with DIC or hyperfibrinolysis and in those with head injury and massive bleeding, higher levels ( $75$  or  $100 \times 10^9/L$ ) may be beneficial. High platelet to PRBC ratios (1:1 or 1:2) appear to decrease mortality in trauma patients.<sup>299</sup> Platelets can be administered either as pooled concentrates or single-donor apheresis units. From each unit of whole blood, platelet concentrates of  $7.5 \times 10^{10}/L$  can be prepared, which increase platelet count by  $5$  to  $10 \times 10^9/L$ ; 4 to 8 U are usually sufficient.

Apheresis platelet units contain 3 to 6 × 10<sup>11</sup>/L of platelets, and a single unit is usually sufficient to provide hemostasis.<sup>89</sup> In the trauma patient who carries a high risk of infectious complications, is immunocompromised, and has tendency to develop ARDS, single-donor apheresis platelets are preferred over pooled concentrates.

### *Cryoprecipitate*

Cryoprecipitate is produced by slowly thawing FFP at 4°C. This process causes the “cryoproteins” to precipitate out.<sup>296</sup> Cryoproteins include factor VIII, fibrinogen, von Willebrand factor, fibronectin, and factor XIII. After centrifuging and removing the supernatant, the remaining precipitate contains high concentrations of procoagulant factors in a small volume of plasma. Factor VIII and von Willebrand factors are now produced as purified recombinant concentrates, meaning that cryoprecipitate can be dedicated to the treatment of hypo- or dysfibrinogenemia. Fibrinogen levels are commonly low upon arrival to the trauma emergency room and are effectively replaced with cryoprecipitate during the early phase of trauma management.

### *Fibrinogen*

In the trauma patient, a plasma fibrinogen level below 1.5 g/L (normal 2 g/L) in the presence of nonsurgical bleeding indicates replacement with 3 to 4 g of fibrinogen concentrate or cryoprecipitate, 50 mg/kg (15 to 20 units).<sup>89</sup> However, obtaining a fibrinogen level from the laboratory not only may take about an hour but also may be erroneous; for example in patients receiving colloids, the fibrinogen level may be overestimated.<sup>89</sup> Repeated use of point-of-care devices, TEG, or thromboelastometry allows titration of fibrinogen or cryoprecipitate and other blood products (Fig. 53-10). For example, in normal individuals an MCF of 7 mm measured with thromboelastometry corresponds to a plasma fibrinogen concentration of 2 g/L; MCF values less than 7 mm require administration of fibrinogen or cryoprecipitate.<sup>246</sup>

### *Antifibrinolytic Agents*

The synthetic lysin analogue antifibrinolytic agents, tranexamic acid and ε-aminocaproic acid, competitive inhibitors of plasmin and plasminogen, are effective in reducing bleeding in cardiac and elective surgery, even when a significant hyperfibrinolysis is absent.<sup>89</sup> The Clinical Randomization of Antifibrinolytics in Significant Hemorrhage (CRASH-2) study of 20,000 patients from 274 sites demonstrated that tranexamic acid given within 3 hours of injury (1 g in a 10-minute bolus and then 1 g infused over the next 8 hours) decreased mortality from hemorrhage; this reduction was 37% if the drug was given within 1 hour after injury. On the other hand, tranexamic acid

given beyond 3 hours of injury increased bleeding-related mortality.<sup>303</sup> A survival benefit of tranexamic acid was also demonstrated by the military when used in soldiers early after injury.<sup>304</sup> Tranexamic acid may possibly be protective for the mucus membrane barrier of the gut, which is easily destroyed in shock, permitting development of severe inflammation.<sup>305</sup> Thus tranexamic acid may improve survival by simply preventing the inflammatory response to injury. Antifibrinolytics, especially tranexamic acid, should be considered in patients who demonstrate fibrinolysis during serial thromboelastographic or thromboelastometric monitoring. Currently most trauma centers are using tranexamic acid routinely during the initial resuscitation with continuation into the intraoperative phase. The usual dose of tranexamic acid is 10 to 15 mg/kg followed by 1 to 5 mg/kg/hr. The dose of  $\epsilon$ -aminocaproic acid is 100 to 150 mg/kg followed by 15 mg/kg/hr.<sup>89</sup>

### *Factor VIIa*

Once used frequently in coagulopathic trauma patients, factor VIIa is now used infrequently, and often without any benefit. It is also associated with thrombotic complications. By activating factor X, factor VIIa produces a thrombin burst, which in turn converts fibrinogen to fibrin. This thrombin release is augmented by platelet activation. Severe acidosis, hypothermia, and hemodilution block the effects of factor VIIa. Thus to obtain any benefit, it should be administered after platelet and fibrinogen levels are adequate and pH and hypothermia are corrected to at least 7.25 and 33°C, respectively. An initial dose of 100 to 140  $\mu$ g/kg, with a similar dose repeated 1 and 3 hours later if needed, may provide adequate hemostatic plasma levels.<sup>306</sup>

### *Prothrombin Complex Concentrate (Factor IX Complex)*

PCC comes in two forms: Bebulin—three factors (II, IX, and X) (factor IX complex) and Kcentra—four factors (II, VII, IX, and X). In the trauma setting, they are used for rapid reversal of vitamin K-antagonist oral anticoagulants (warfarin), especially in patients with intracranial bleeding.<sup>307</sup> The four-factor form is preferred over three factors. A similar effect can be obtained by administering FFP, but at a much slower rate and a larger infused volume.<sup>308</sup> PCC is not effective for reversing the novel oral anticoagulants, which are direct thrombin inhibitors (dabigatran [Pradaxa] and Eliquis [apixaban]). Recently a new agent Praxbind (idarucizumab) has been marketed, which reverses only dabigatran and none of the other novel oral anticoagulants. Whether PCC is effective in bleeding trauma patients who are not on warfarin is not clear. As with recombinant factor VIIa, thrombotic complications are increased with PCC.<sup>308</sup>

### *Transfusion-related Acute Lung Injury*

Transfusion-related acute lung injury (TRALI) is responsible for 38% of deaths caused by transfusion, being the leading cause of mortality after blood product therapy.<sup>309</sup> All blood products have been associated with TRALI; however, the plasma-rich components, such as FFP and apheresis platelets, have been most frequently implicated. Although our understanding of TRALI is not yet comprehensive, we know that it occurs with transfusion of donor white blood cell antibodies (HLA class 1 or class 2 or human neutrophil antigen [HNA] antibodies).<sup>310</sup>

TRALI is a respiratory entity defined by pulmonary edema with subsequent hypoxia occurring within 6 hours of transfusion. Several other pulmonary disorders such as ARDS and aspiration pneumonia, which are seen in severe trauma, also may occur within 6 hours of transfusion but are unrelated to the transfusion itself. Thus the diagnosis remains clinical and is best determined by the unlikelihood of other trauma-related lung diseases following blood product administration.

TRALI occurs in the setting of the “two-hit model.” The model refers to the concept that the cause may (HNA) or may not be from antibodies (HNA). If the patient has elevated interleukin-8 levels, the syndrome may become more severe. Other nonantibody contributions are from biologically activated lipids or neutrophil activation–stimulated cytokines. Nonantibody “granulocyte activation” causes capillary leakage leading to pulmonary edema.

In the antibody model, transfused anti–HNA-3 reacts with and activates neutrophils, causing agglutination and subsequent release of mediators of pulmonary injury. This model holds for platelet administration; thorough washing can mitigate antibody transfer. Prevention of antibody transfer, also known as “mitigation,” is the first line of prevention. Treatment of TRALI is supportive, with mechanical ventilation, or extracorporeal membrane oxygenation in severe cases. Diuresis and steroids have not proven to be effective. The clinical course usually runs between 3 and 5 days.

## **Electrolyte and Acid–Base Disturbances**

Intraoperative hyperkalemia may develop as a result of three mechanisms. First, in patients with irreversible shock, cell membrane permeability is altered; thus massive  $K^+$  efflux results in severe hyperkalemia, and, in this situation, survival is unlikely. Second, after repair of a major vessel, subsequent reperfusion of the ischemic tissues results in a sudden release of  $K^+$  into the general circulation. Third, transfusion at a rate faster than 1 unit every 4 minutes in an acidotic and hypovolemic patient may cause an increase in plasma  $K^+$  levels. Frequent monitoring of serum  $K^+$ , gradual and intermittent unclamping of vascular shunts, and avoiding transfusion at higher

rates than needed help reduce the rate of  $K^+$  increase. If a rise in  $K^+$  is detected, treatment with regular insulin, 10 units intravenously; 50% dextrose, 50 mL; and sodium bicarbonate, 8.4%, 50 mL is indicated. If there is a dysrhythmia,  $CaCl_2$ , 500 mg, should also be administered. Insulin and dextrose can be repeated two or three times at 30- to 45-minute intervals, if necessary. Hemodialysis may be indicated in desperate situations.

Metabolic acidosis is caused by shock in most trauma patients. Other rare causes of acidosis in this population are alcoholic lactic acidosis, alcoholic ketoacidosis, diabetic ketoacidosis, and CO or  $CN^-$  poisoning after inhalation injuries. The differential diagnosis between hypovolemic, diabetic, and alcoholic acidosis, all of which have anion gaps, requires measurement of blood lactate, urinary ketone bodies, and blood sugar and assessment of intravascular volume. Alcoholic ketoacidosis is treated with intravenous dextrose, whereas diabetic ketoacidosis is managed with insulin. No specific treatment except intravenous normal saline exists for alcoholic lactic acidosis.

Treatment of metabolic acidosis involves correction of the underlying cause: management of hypoxemia, restoration of intravascular volume, optimization of cardiac function, or treatment of CO or  $CN^-$  toxicity. Symptomatic treatment with sodium bicarbonate has serious disadvantages, including leftward shift of the oxyhemoglobin dissociation curve causing decreased  $O_2$  unloading, a hyperosmolar state secondary to the excessive sodium load, hypokalemia, further hemodynamic depression, overshoot alkalosis a few hours after giving the drug, and intracellular acidosis if adequate ventilation or pulmonary blood flow cannot be provided. Nevertheless, because of the possibility that severe acidosis can cause dysrhythmias, myocardial depression, hypotension, and resistance to exogenous catecholamines, some clinicians administer bicarbonate to buy time if the pH is below 7.2.

## Intraoperative Death

Death is a much greater threat during emergency trauma surgery than it is in any other operative procedure. Approximately 0.7% of patients admitted for acute trauma die in the OR, accounting for approximately 8% of postinjury deaths.<sup>311</sup> Uncontrollable bleeding is the cause of approximately 80% of intraoperative mortality; brain herniation and air embolism are the most common causes of death in the remaining patients.<sup>311</sup> A multicenter, retrospective study has defined certain features that increase the likelihood of OR death (Table 53-16).<sup>311</sup> Rapid transport to the OR, rapid stabilization of life-threatening injuries while deferring definitive surgery (damage control), simultaneous thoracotomy and laparotomy for thoracoabdominal injuries, appropriate management of retroperitoneal hematoma, and early correction

of hypothermia and shock may reduce intraoperative mortality rates.<sup>311</sup>

Of these measures, the damage control principle has reduced not only the intraoperative but also the overall mortality from trauma surgery, although morbidity from sepsis, abscess formation, and gastrointestinal fistulas may increase.<sup>312,313</sup> Originally described in three stages, the current suggestion is that it should be managed in four phases. In the first phase, attention is directed in the ED to recognition of the pattern of injury, control of bleeding if possible, and rapid transport to the OR, as well as to the decision to initiate damage control resuscitation by limiting crystalloid infusion, allowing permissive hypotension, activating rewarming, and initiating blood component replacement with early administration of FFP and platelets at high ratios with PRBCs.<sup>313,314</sup>

**Table 53-16** Clinical Features Associated with Intraoperative Mortality

Category	Clinical Features
Mechanism of injury	Gunshot wound Pedestrian injuries
Injury severity	Mean injury severity score >41 Mean revised trauma score >3.0
Preoperative physiologic profile	Mean BP in the field <50 mmHg Mean BP on arrival to ED <60 mmHg Best systolic BP in the ED <90 mmHg Circulatory shock time >10 min Best mean pH <7.18 Mean preoperative crystalloid resuscitation >3,850 mL; mean red cell transfusion >834 mL
Type of injury	Significant head, chest, abdominal, and pelvic injuries individually or in combination after blunt trauma Significant chest and abdominal injuries individually or in combination after penetrating trauma
Organ injury	Brain Liver Aorta or other major vascular injury Cardiac injury
Operating room resuscitation and physiologic status	<b>Systolic BP &lt;90 mmHg during first h</b> Systolic BP <90 mmHg for >30 min Deterioration of mean pH from 7.19 to 7.01 Mean intraoperative blood loss 5,172 mL; mean blood replacement 4,541 mL Mean platelet transfusion 784 mL Mean fresh frozen plasma 1,418 mL Mean intraoperative temperature 32.2°C Intraoperative cardiac arrest

BP, blood pressure; ED, emergency department.

Data from Hoyt DB, Bulger EM, Knudson MM, et al. Death in the operating room: an analysis of a multi-center experience. *J Trauma*. 1994;37:426

The second phase occurs in the OR where, in addition to efforts to maintain the patient's intravascular volume, temperature, acid-base status, and coagulation at near-normal levels with damage control resuscitation, the surgeons rapidly control bleeding and leave the abdominal cavity open without fascial closure but temporarily covered by a vacuum pack dressing, which allows an enlarged space for edematous organs and controlled egress of fluid.

The third phase takes place in the ICU where intravascular volume,

hypothermia, acidosis, and coagulation abnormalities are corrected. In the fourth phase, the stabilized patient is returned to the OR for definitive surgery and abdominal closure. The fourth phase involves multiple returns to the OR at 24- to 48-hour intervals for organ repair, abdominal washout, and debridement before the final closure of the abdomen. The damage control principle, originally proposed for abdominal trauma, is now applied to injuries at other anatomic sites, including chest, pelvis, extremities, and soft tissues.<sup>315</sup>

## Early Postoperative Considerations

To prevent multiple moves, major trauma patients should be admitted directly to the ICU. Postoperative care may involve obtaining a further medical history and description of the mechanism of injury from the patient, if he or she is awake, or from relatives, and performing tertiary survey to identify possible missed injuries. The concerns in the early postoperative period are similar to those of the intraoperative phase. Re-evaluation and optimization of the circulation, oxygenation, temperature, CNS function, coagulation, electrolyte and acid–base status, and renal function are the hallmarks of postoperative management. Pain control in this group of patients may have more than a humanitarian purpose; it can improve pulmonary function, ventilation, and oxygenation, especially in patients with chest and abdominal injury. A multidimensional pain control strategy may be used, including various combinations of regional analgesia, if coagulopathy is not a concern; intravenous opioids as patient-controlled analgesia or as bolus doses; nonsteroidal anti-inflammatory agents, if nephrotoxicity, gastric ulceration, or bleeding risks do not exist; acetaminophen; and low-dose (20 to 30 mg/hr) ketamine, particularly in patients with a known history of opioid. For sedation in mechanically ventilated patients, both propofol (25 to 75  $\mu\text{g}/\text{kg}/\text{min}$ ) and midazolam (0.1 to 20  $\mu\text{g}/\text{kg}/\text{min}$ ) infusions alone or in combination are equally effective and safe, although wake-up time in patients receiving midazolam is longer ( $660 \pm 400$  minutes) than in those receiving propofol alone ( $110 \pm 50$  minutes) or both agents combined ( $190 \pm 200$  minutes).<sup>316</sup> Morphine, 0.02 to 0.04 mg/kg/hr, or fentanyl, 1 to 3  $\mu\text{g}/\text{kg}/\text{hr}$ , may be added for analgesia. Small boluses of midazolam (3 to 5 mg), propofol (50 mg), morphine (2 to 3 mg), or fentanyl (25 to 50  $\mu\text{g}$ ) may also be given as required.<sup>316</sup>

## Ventilatory Support

Hypoxemia secondary to atelectasis due to bronchial plug, decreased breathing efforts, and pulmonary edema due to cardiac, neurologic, fluid

overload, airway postobstructive, and various intrinsic pulmonary etiologies can occur, requiring chest physiotherapy, bronchoscopy, and artificial ventilatory maneuvers. PaO<sub>2</sub>/FiO<sub>2</sub> ratio values of 300 or above, or 200 to 300, suggest the presence of ARDS or its less severe form, acute lung injury, respectively. Mechanical ventilation with VT no more than 6 mL/kg; an appropriate level of PEEP, allowing titration of FiO<sub>2</sub> to lowest possible level, plateau airway pressures below 35 cm H<sub>2</sub>O, and avoidance of auto-PEEP with consideration of adjustment to hypo- or hypercapnia; and prevention of ventilator-induced pneumonia should be undertaken.

### **Acute Kidney Injury**

Acute kidney injury (AKI), formerly called acute renal failure, is a possibility if prolonged shock or crush syndrome occurs during early management. In a study aimed at finding the predictors of acute renal failure, trauma was one of the seven independent predictors of this complication.<sup>317</sup> Following an episode of shock in patients who have not received an osmotic load (radiopaque material, mannitol) or diuretic, determination of 2- or 6-hour creatinine and free water clearances may help predict the development of posttraumatic renal dysfunction.<sup>318</sup> Creatinine clearance below 25 mL/min and free water clearance of at least 15 mL/hr suggest the likelihood of acute renal failure. Decreased urine flow rate alone is not a good predictor, and the blood urea nitrogen does not rise until at least 24 hours after surgery or trauma.<sup>318</sup> In parallel with the reduction of glomerular filtration rate, AKI develops in varying intensities. Two diagnostic tools have been developed to predict and define each of these presentations: the RIFLE and AKIN classification schemes. They are comparable in their ability to differentiate the type and severity of kidney injury.<sup>319,320</sup> The RIFLE system is the most commonly used and defines the *risk*, *injury*, *failure*, *loss* and *end-stage* damage of kidney function based on increase in serum creatinine and duration of urine flow decrease ([Table 53-17](#)). Acute kidney injury network (AKIN) criteria also uses serum creatinine and urine flow parameters with somewhat different values than that used by RIFLE to define stages 1 to 3 of kidney dysfunction.

**Table 53-17** Risk, Injury, Failure, Loss, and End-Stage Kidney Disease (RIFLE) Classification for Acute Kidney Injury

Class	Serum Creatinine Increase	GFR Decrease	Urine Output
Risk	×1.5	>25%	<0.5 mL/kg/h × 6 h
Injury	×2	>50%	<0.5 mL/kg/h × 12 h
Failure	×3	>75%	<0.3 mL/kg/h × 24 h or anuria × 12 h
Loss	Persistent ARF = complete loss of kidney function >4 wks		
ESKD	End-stage kidney disease (> 3 mos)		

GFR, glomerular filtration rate; ARF, acute renal failure; ESKD, end-stage kidney disease.

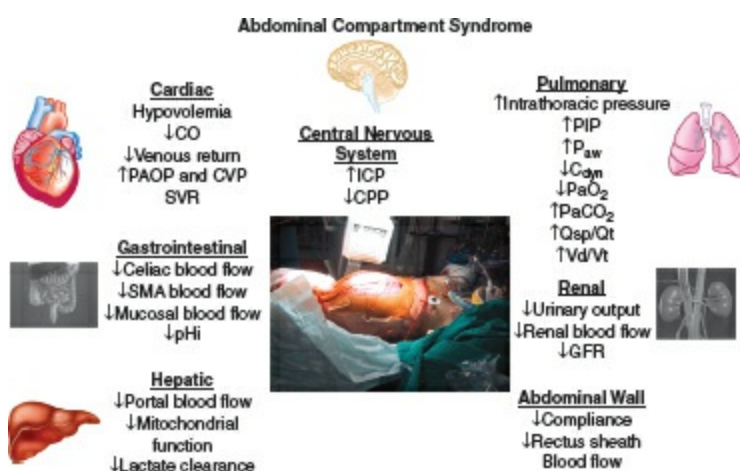

The cause of renal failure in crush syndrome is probably rhabdomyolysis-induced myoglobin release into the circulation. Serum creatinine kinase levels increase in these patients; levels above 5,000 units/L are associated with renal failure.<sup>321</sup> The differentiation of myoglobinuria from hemoglobinuria is described in the “Urine Output” section. A clear supernatant suggests myoglobin, whereas a rose color indicates hemoglobin. The traditional prophylaxis for renal failure after rhabdomyolysis includes fluids, mannitol, and bicarbonate. However, more recent data suggest that bicarbonate and mannitol are ineffective.<sup>321</sup> Additional causes of AKI after trauma are massive transfusion, sepsis, ureteral or urethral injury leading to obstruction, retroperitoneal hematoma compressing the kidney or ureters, and abdominal compartment syndrome. Often some of these etiologic factors coexist after trauma. Depending on the severity of kidney injury a nephrology consultation and renal replacement therapy is indicated.

### **Abdominal Compartment Syndrome**

Abdominal compartment syndrome results from intra-abdominal hypertension with organ dysfunction after major abdominal trauma and surgery (primary syndrome), although other patients may develop the syndrome without surgery, for example, during massive fluid resuscitation following major trauma or burns (secondary syndrome).<sup>322–324</sup> The syndrome results from massive edema of abdominal organs produced by shock-induced inflammatory mediators, excessive fluid resuscitation, surgical manipulation, and closure of the abdominal fascia. The significant cardiac, pulmonary, renal, gastrointestinal, hepatic, and CNS dysfunctions caused by this syndrome result in a high mortality rate (Fig. 53-12).

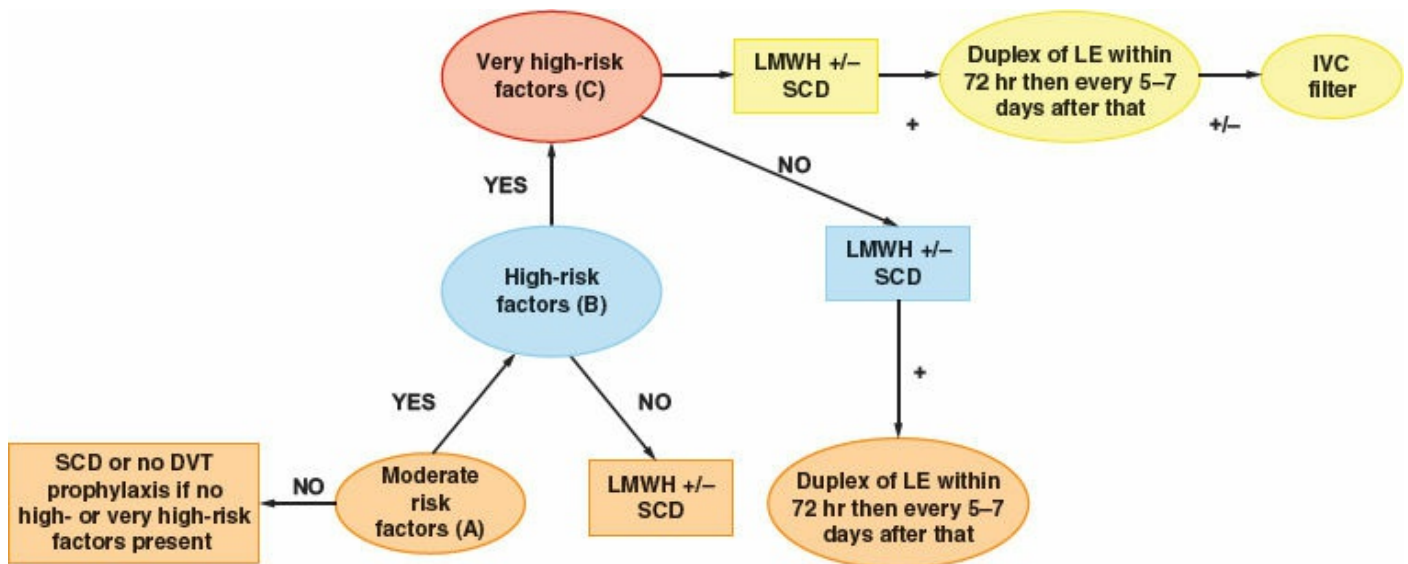

Clinically, a tense severely distended abdomen, raised peak airway

pressure, CO<sub>2</sub> retention, and oliguria should direct the clinician to measure the intravesical pressure, which reflects the intra-abdominal pressure, via a Foley catheter. Values above 20 to 25 mmHg may indicate inadequate organ perfusion and necessitate abdominal decompression, which, if delayed, may result in progression to multiorgan failure and death.<sup>322,323</sup> Almost all of these patients require mechanical ventilation. If a PAC is in place, attributing a relatively high PCWP to the ventilator and continuing high-volume fluid infusion may further increase intra-abdominal edema and increase mortality.<sup>325</sup> Interestingly, patients who will develop abdominal compartment syndrome often do not respond to fluid administration with elevated cardiac output, despite an increasing PCWP.<sup>325</sup>

**Figure 53-12** Physiologic effects of abdominal compartment syndrome. Image in the center is a patient whose abdomen was left open but covered with nonadhesive dressing. C<sub>dyn</sub>, dynamic pulmonary compliance; CO, cardiac output; CPP, cerebral perfusion pressure; CVP, central venous pressure; GFR, glomerular filtration rate; ICP, intracranial pressure; PAOP, pulmonary artery occlusion pressure; P<sub>aw</sub>, mean airway pressure; pHi, intramucosal pH; PIP, peak inspiratory pressure; Qsp/Qt, intrapulmonary shunt; SMA, superior mesenteric artery; SVR, systemic vascular resistance; Vd/Vt, dead space ventilation. (Adapted from Cheatham ML. Intra-abdominal hypertension and abdominal compartment syndrome. *N Horizons*. 1999;7:96.)

**20** It should be emphasized that recent advances in the management of acute trauma and critical care, such as limiting crystalloid infusion, hemostatic resuscitation, damage control, and open abdomen strategies, have substantially decreased the incidence of postinjury abdominal compartment syndrome.<sup>324</sup> Postinjury intra-abdominal hypertension still occurs commonly in severely injured high-risk patients, but it is not associated with multiorgan failure in most instances. In other words, unlike in the past, intra-abdominal hypertension is seldom a harbinger of abdominal compartment syndrome or multiorgan failure. It is believed that limiting crystalloid infusion is the most important factor in this salutary evolution.<sup>324</sup>

**A. Moderate risk factor**  
 Age >40<sup>a</sup>  
 ISS >9<sup>a</sup>  
 Surgical procedure within 72 hr<sup>a</sup>  
 Immobilization<sup>a</sup>  
 Pregnancy<sup>a</sup>  
 Estrogen therapy<sup>a</sup>  
 History of DVT or PE<sup>a</sup>  
 Malignancy<sup>a</sup>  
 Hypercoagulability<sup>a</sup>  
 Extensive soft tissue trauma<sup>a</sup>  
 CHF<sup>a</sup>

**B. High risk factors**  
 Age >50<sup>a</sup>  
 ISS >16<sup>a</sup>  
 Femoral line placed in bay<sup>a</sup>  
 GCS <9<sup>a</sup>  
 Venous injury<sup>a</sup>  
 Major lower extremity injury<sup>b</sup>

**C. Very high/"refractory" risk factors**  
 Spinal cord injury<sup>a,b</sup>  
 AIS (head and neck ≥3)-long bone fracture<sup>a</sup>  
 Multiple ≥3 long bone fractures<sup>a</sup>  
 Severe pelvic fracture<sup>a,b</sup>  
 Mechanical ventilation longer than 3 days<sup>b</sup>  
 Severe LE fracture + ISS >16<sup>b</sup>  
 Cannot be anticoagulated high- or very high-risk factors<sup>a</sup>

**Figure 53-13** Prophylaxis model based on combination of Eastern Association for Surgery of Trauma (EAST) recommendations and the data from Baldwin et al. in blunt trauma patients. Venous thromboembolism risks are classified as moderate, high, and very high. Risk criteria in each of these groups are marked with a superscript of “a” (meaning based on EAST guidelines) or “b” (meaning based on Baldwin et al. data). Low-molecular-weight heparin (LMWH) is used unless contraindicated. AIS, abbreviated injury score; CHF, congestive heart failure; DVT, deep vein thrombosis; GCS, Glasgow coma score; IVC, inferior vena cava; ISS, injury severity score; LE, lower extremity; PE, pulmonary embolism; SCD, sequential compression device. (Adapted with permission from Baldwin K, Namdari S, Esterhai SL, et al. Venous thromboembolism in patients with blunt trauma: are comprehensive guidelines the answer? *Am J Orthop.* 2011;40:E83. Copyright © 2016, Frontline Medical Communications Inc.)

## Thromboembolism

The overall incidence of VTE involving DVT and PE is 3.2% in blunt trauma patients.<sup>326</sup> However, DVT occurs in 30% of major lower extremity injuries, 30% of spine injuries, 46% of major head injuries, 33% of major thoracic injuries, and 15% of serious injuries of the face or abdomen despite implementation of effective clinical management guidelines.<sup>326</sup> When injuries

involve more than one of these high-risk regions, the likelihood of DVT is even higher.<sup>326</sup> Fortunately, only a relatively small fraction (0.3%) of severely injured patients have PE.<sup>326</sup> Statistically significant risk factors for VTE are mechanical ventilation for longer than 3 days, injury severity score above 15, spinal cord injury, major lower-extremity bony trauma, and pelvic ring injury.<sup>326</sup> In most instances, DVT is asymptomatic, and in many of those in whom leg swelling develops, concurrent lower-extremity injuries may be implicated. The diagnosis of proximal DVT in symptomatic patients can be made by duplex ultrasonography, but this method has low sensitivity in the absence of symptoms.<sup>327</sup> Venography, which is the gold standard, can be performed in equivocal cases, although it is associated with complications and inherent logistical problems. Hypoxemia, especially when sudden and associated with dyspnea and hemodynamic abnormalities, even very early after injury, is highly suggestive of PE. The definitive diagnosis is established by spiral CT and pulmonary angiography. In hemodynamically unstable patients, resuscitation takes precedence over radiologic diagnosis. Management is symptomatic and includes tracheal intubation, positive-pressure ventilation with FiO<sub>2</sub> of 1.0, administration of fluids and inotropes (amrinone or milrinone), and continuous arterial and CVP monitoring. TEE or TTE is helpful because it may demonstrate RV performance, tricuspid regurgitation, or, in some cases, the thrombus within the pulmonary artery, the right heart chambers, or in transit through a patent foramen ovale to the left atrium.

Baldwin et al.<sup>326</sup> reviewed their experience of VTE in more than 10,000 blunt trauma patients over a period of 10 years. These patients were managed using the clinical management guidelines recommended by the Eastern Association for the Surgery of Trauma.<sup>328</sup> Based on their experience, they proposed the management pathway shown in [Figure 53-13](#), which combined their defined risks with their own for moderate, high, and higher risk factors; their modified pathway is based on this. Currently, prophylaxis involves application of sequential compression devices, even if one of the lower extremities is free of trauma, and low-molecular-weight heparin if bleeding is unlikely to exacerbate the injury. Low-dose unfractionated heparin appears to be ineffective in trauma patients.<sup>329</sup> Mechanical devices such as sequential compression boots should be applied as early as possible after injury. Late (>4 days) initiation of prophylaxis, whether because of massive transfusion, low anticipated risk owing to absence of comorbidity, or fear of intracranial bleeding after a severe head injury, has been shown to triple the risk of VTE.<sup>330</sup> Consideration should be given to placement of a vena cava filter if the risk of bleeding is unacceptably high. Removable vena cava filters are now available and are likely to be used prophylactically in high-risk patients more often than permanent filters, which are associated with long-term

complications. In patients with severe hemodynamic depression or cardiac arrest unresponsive to resuscitative measures, thrombolytic agents may be considered despite the risk of hemorrhage.

Persistent Sedation/Delayed Emergence  
Altered Mental Status  
Postoperative Nausea and Vomiting

## **KEY POINTS**

- 1 The postoperative planning begins when a patient is scheduled for surgery. With emerging protocols for enhanced recovery after surgery (ERAS), specific evidence-based and best practice structure for patient care has the goal of providing care that is coordinated with the surgical team to provide the best outcomes and reduce unnecessary use of resources.
- 2 The level of postanesthesia care unit (PACU) care depends on the type/approach of surgery, type of anesthetic, intraoperative course of events, as well as patient pre-existing and evolving comorbidities. Typical recovery settings include inpatient recovery, ambulatory recovery (phase I for more intensive needs and phase II for less intensive needs), short stay (23-hour admit), and recovery from nonoperating room anesthesia (NORA) procedures (i.e., computed tomography, magnetic resonance imaging, invasive radiology, cardiac, pediatric, and radiation procedures).
- 3 The transfer of care to a PACU nurse includes assuring that the patient has had appropriate monitoring applied, admission vital signs were taken, and a direct and thorough report was received that allows for rapid evaluation should complications arise, as well as a nurse capable of

- handling the acuity of the patient's medical/surgical problems.
- 4 Postoperative analgesia should be individualized to requirements and expectations. A multimodal approach includes the appropriate use of nonsteroidal anti-inflammatory drugs, narcotics, adjuncts, regional and local anesthetics, as well as anxiety relief and appropriate emotional support.
  - 5 Discharge criteria should be tailored to the individual patient's underlying disease, recovery course, and postdischarge level of care.
  - 6 The cardiac risks during the postoperative stay include myocardial ischemia, which may be minimized with continued use of  $\beta$ -blockers, analgesia, nitrates, supplemental oxygen, adequate circulating volume, oxygen-carrying capacity, heart rate control, and an understanding of hypercoagulable states.
  - 7 The respiratory risks of a patient must take into account the preoperative respiratory disease status. Residual anesthetics, muscle relaxants, opioids, and sedatives all impair responsiveness to increasing CO<sub>2</sub> and decreasing O<sub>2</sub> levels. Pain itself can decrease respiration/minute ventilation, leading to CO<sub>2</sub> retention and hypoxemia. Supplemental O<sub>2</sub> application alone does not guarantee hypoxemia will not occur.
  - 8 The evaluation of a patient's ability to void may be affected by type of surgery (i.e., genitourinary surgery, hernia repairs) or type of anesthetic (i.e., regional, neuraxial, or opioids).
  - 9 Relative hypovolemia should be evaluated and managed in PACU based on the patient's comorbidities, preoperative status (i.e., bowel preparation, postdialysis), type and duration of surgery, blood loss, and urine output.
  - 10 Glycemic monitoring and control should persist as a continuum from intraoperative management. Good glycemic control may help with fighting infection and improve wound healing, which can result in better surgical outcomes. Hypoglycemia occurs because of nothing by mouth status, intraoperative administration of insulin, as well as the patient using programmable insulin pumps.
  - 11 Hypothermia can lead to an increased length of stay in PACU, lethargy, decreased minute ventilation, decreased strength, and increased cardiac demand. It is important to assure that the patient is dry and insulated. The use of air warming blankets, warming mats, and intravenous fluid warmers all minimize hypothermia.
  - 12 Many elderly patients experience a varied degree of postoperative confusion, delirium, or cognitive dysfunction in the PACU. Many pediatric patients also experience postemergence delirium leading to increased length of stay in the PACU.
  - 13 Postoperative nausea and vomiting is a major cause of patient discomfort

and dissatisfaction, as well as an aspiration risk and causes prolonged PACU stay.

## Postanesthesia Recovery

Each patient recovering from an anesthetic has circumstances that require an individualized problem-oriented approach. Postanesthesia recovery must continue to adapt to meet the needs of the changing perioperative landscape, advances in technology, and changing surgical techniques, and to respond to improved evidence-based research. Dissemination of anesthesia services beyond the perisurgical arena has brought changes and greater demands on recovery units.

### *Standards for Postanesthesia Care*

The American Society of Anesthesiologists (ASA) House of Delegates approved Standards for Postanesthesia Care on October 12, 1988. These standards were last amended on October 14, 2014.<sup>28</sup> These five standards of care are used to determine who needs managed recovery, types of recovery, who is responsible, and how the patient is monitored prior to discharge.

## Value and Economics of Postanesthesia Care Unit

The quality of postanesthesia care is composed of many variables such as tracking of complications, time per patient spent in recovery, overall clinical outcomes, and patient satisfaction. The value of postanesthesia care is a measure of the quality of care provided compared with the amount of resources spent per patient outcome. The postanesthesia care unit (PACU) helps to use resources efficiently by having trained staff that routinely care for postsurgical patients, thereby recognizing/preventing complications, and by having physicians instituting appropriate and timely therapies.

The actual cost of PACU care incorporates costs of staffing, space, disposables, and hardware (resource utilization). Triage and discharge policies affect both how many admissions occur and what resources each admission consumes. Nurse staffing continues to be the largest direct cost in the PACU. The mix of nursing staff, experience of nurses, staffing ratios, and the complexity and duration of PACU stay affect the overall personnel cost per admission. The level of monitoring provided affects the capital expenditure for equipment, and disposable items account for operating expenditures. The patient acuity mix also determines needs for staffing and equipment such as ventilators, additional monitors, intravenous pumps, and patient-controlled analgesia pumps. The type of physician coverage—such as dedicated coverage

versus on-demand coverage—can affect response time, efficiency of care, costs, and patient outcomes. The use of routine postoperative diagnostic testing and therapies without evidence-based need can lead to unnecessary treatments, increasing cost per patient and possible worse patient outcomes.

Cost comparisons between institutions are difficult because charges and cost factors vary widely across institutions, in different regions of the United States, and between countries. They constantly change over time. Regulatory requirements, standards of care, medical-legal climates, and institutional requirements vary greatly between regions and even between facilities in the same locale. It is difficult to establish cost-effectiveness goals of a single PACU because of the differing requirements of individual patients having the same procedures. This difference can be the result of levels of patient comorbidities, level of procedure complexity, surgeon, type of anesthetic, as well as patient perception and expectations. These are just some of the factors that can determine the type of care needed postoperatively. Continued pressures from many fronts to contain costs and maximize cost-effectiveness force each surgical facility to continually evaluate the value of its PACU care to each individual patient.

PACU directors are challenged to optimize clinical results while minimizing expenditures. Innovative PACU practices should guarantee safe care, minimize cost, and fulfill regulatory and institutional requirements. Medical professionals (physicians, nursing, and support staff) must work in concert to identify practices that are wasteful versus those that have proven yield/benefit. The impact of many PACU-proposed interventions on clinical outcomes are not easily substantiated by controlled scientific analysis. Useless testing, unnecessary or unjustifiable therapy, and inappropriate PACU admissions should be eliminated. However, using a more expensive therapy may generate real savings by decreasing additional therapies, testing, admissions, or length of stay. Another important element essential for patient safety and efficiency in the PACU is communications with the intraoperative anesthesiology service. Communication is perhaps the least expensive tool in medicine and the one most universally proven to be involved in human error events. Utilization of PACU resources is directly related to anesthetic duration and technique. In one study, 22.1% of 37,000 patients had a minor anesthesia-related event or complication that prolonged PACU stays and consumed PACU resources.<sup>1</sup> Another study showed how postoperative adverse events increase the amount of nursing resources needed in the PACU.<sup>2</sup> Close coordination between the PACU and the anesthesiology service should reduce the frequency and impact of such events.

**1** Continued collaboration with surgical teams and developing enhanced recovery after anesthesia (ERAS) protocols might create an opportunity to shorten the length of stay in the PACU. Providers in the recovery unit must be

aware of these protocols and manage patients accordingly. Observed change is frequently seen by reducing transportation delays, persistence of pain or nausea, waiting for space, or surgeon discharge delays.<sup>3</sup> Cost-saving measures in other areas may also increase the cost of PACU care; for example, fast-tracking to discharge to home rather than to a hospital bed. The cost savings of not occupying a hospital bed is offset by an increase in PACU stay and therefore greater consumption of PACU resources.<sup>4</sup> The savings may be a cost savings for the patient and beneficial for the facility as a whole but at a greater expense to the PACU. True savings are only realized when operational changes yield a decrease in expenditures for staff, supplies, or equipment. For example, patients who are able to bypass the PACU create a savings opportunity only if paid nursing hours are reduced or if more surgical cases are covered with the same hours. With the use of less-invasive surgical techniques combined with innovative anesthetic techniques, such as regional anesthetics, shorter PACU stays can result in real savings opportunities. However, the areas of scheduling, clerical, or maintenance tasks must not consume excess staffing hours, without savings realized. Finally, trimming costs could entail an increase in unwanted risk to patients. Differentiating between cost-effective postanesthesia care and unsafe practice remains a matter of constant professional judgment and debate daily in most PACUs.

## **2** Levels of Postoperative/Postanesthesia Care

With continued demand to increase overall health-care efficiency, caution must be taken to provide the most appropriate care for each patient. As anesthesia services expand to cover a variety of patient types in ever-increasing areas outside the operating room, selecting the correct type of recovery is essential. For the many differing anesthesia areas ranging from inpatient surgery, ambulatory surgery, to off-site procedures, the level of postoperative care that a patient requires is determined by the degree of underlying illness, comorbidities, and the duration as well as the type of anesthesia and surgery. These factors are used to assess the risk of postoperative complications. Less-invasive surgeries or procedures combined with shorter-duration anesthetic regimens facilitate high levels of arousal and minimal cardiovascular or respiratory depression at the end of surgery.

Using a less intensive postanesthesia setting for selected patients can reduce costs for a surgical procedure and allow the facility to divert scarce PACU resources to patients with greater needs. Alert patients are more satisfied when spared the unnecessary assessments in interventions of PACU care. Amenities such as recliners, reading material, television, music, and food improve perceptions (emotional satisfaction) without affecting quality or safety. Earlier reunion with family or visitors in the low-intensity setting is

desirable assuming that postoperative care is safe and appropriate. This notion is especially important in the pediatric population.

Creation of separate PACUs for inpatients, ambulatory, or off-site patients is one possible way to streamline PACU care for appropriately triaged patients. Phase I recovery would be reserved for more intense recovery and would require more one-on-one care for staff. Phase II recovery should be less intensive and is appropriate for patients after less invasive procedures requiring less attention from nursing while recovering. If separation of different phases of care is not possible, then providing the appropriate level of monitoring and coverage to the degree of postoperative impairment achieves similar results in a single PACU area. However, care equal to a full-intensity PACU must always be available, given the incidence of complications after anesthesia and surgery.<sup>5</sup> As the aging population generates an increase in the complexity of surgical care in the face of tighter control of resources, maintaining appropriate PACU capacity and safety by observing applicable PACU guidelines and standards will be increasingly important.<sup>6,7</sup>

## Postanesthetic Triage

Patients must be carefully evaluated to determine which level of care is appropriate. Triage should be based on clinical condition, length/type of procedure and anesthetic, and the potential for complications that require intervention. Alternatives to PACU care must be used in a discriminatory fashion. Arbitrary criteria based on age, ASA classification, ambulatory versus inpatient versus off-site procedure status, or type of insurance should not be used for determining the level of recovery care. An individual patient undergoing a specific procedure or anesthetic should receive the same appropriate level of postoperative care whether the procedure is performed in a hospital operating room, an ambulatory surgical center, an endoscopy room, an invasive radiology suite, or an outpatient office. In accordance with the ASA Standards of Post Anesthesia Care, Standard I, an anesthesiologist familiar with the patient can determine which level of care is required or if time in a recovery area is needed. If doubt exists about a patient's safety in a lower intensity setting, the patient should be admitted to a higher level of care for recovery. Patient safety should always be favored regardless of the cost.

After superficial procedures using local infiltration, minor blocks, or sedation, patients can almost always recover with less intensive monitoring and coverage. Healthy patients undergoing more extensive procedures (e.g., hernia repairs, arthroscopic procedures, minor orthopedic procedures) under local, plexus, or peripheral nerve blockade might also bypass phase I recovery

and go directly to phase II. The increasing use of continuous peripheral nerve catheters for surgery has shortened PACU times and can eliminate many hospital admissions.<sup>8</sup> Innovative anesthetic techniques, advanced surgical techniques, and use of bispectral index monitoring help facilitate fast-track postoperative care.<sup>9</sup>

For more intensive procedures and patients with greater acuity, bypassing the PACU and direct admission to intensive care units can reduce demands on the PACU as well as reduce errors with decreased number of hand offs. This transfer still requires proper postoperative reporting to the accepting unit including how to communicate with the surgical service and anesthesiologist. The intensive care units must be trained and prepared to receive immediate postoperative patients as well as meet the standards of the PACU.

## **Safety in the Postanesthesia Care Unit**

Every PACU should have medical oversight in the form of a medical director. The PACU medical director must ensure the PACU environment is as safe as possible for both patients and staff. Beyond usual safety policies, maintain staffing and training to ensure that an appropriate coverage and skill mix is available to deal with unforeseen crises. Incidence of adverse events in the PACU correlates with nursing workload and staff availability.<sup>2</sup> Ideally, all staff should have PACU certification, and staffing ratios should never fall below acceptable standards.<sup>7</sup> Less-skilled or training staff must be appropriately supervised, and a sufficient number of certified personnel must always be available to handle worst-case scenarios.

The PACU staff protects patients who are temporarily incompetent and preserves patients' rights to observance of advanced directives and to informed consent for additional procedures. The staff is obligated to optimize each patient's privacy and dignity, and to minimize the psychological impact of unpleasant or frightening events. Observance of procedures for handwashing, sterility, and infection control should be strictly enforced.<sup>10</sup> Medical directors must safeguard against potential for personal assault of patients during recovery such as unwarranted restraints and procedures without consent. Access to the PACU should be strictly controlled. With increasing acceptance of reuniting patients with family/friends, safety and privacy issues need to be continually addressed.

The PACU environment must also be safe for professionals. Air handling should guarantee that personnel are not exposed to unacceptable levels of trace anesthetic gases (although trace gas monitoring is not necessary), and ensure that staff members receive appropriate vaccinations, including those for hepatitis B, flu, and others required by their institution. Practitioners must adhere to policies for radiation safety, infection control, disposal of sharps,

universal precautions for bloodborne diseases, and safeguarding against exposure to pathogens such as methicillin-resistant *Staphylococcus*, vancomycin-resistant *Enterococcus*, *Clostridium difficile*, or tuberculosis. Personal protective equipment (PPE) such as gloves and eye protection must be worn to protect both the patient and provider, and having masks, gowns, and appropriate particulate respiratory equipment easily accessible is needed for particular cases. Following current infection control policies and guidelines are essential for patient and staff safety. Ensure that sufficient help is available to avoid injury while lifting and positioning patients or while dealing with emergence situations. Precise documentation and clear delineation of responsibility is essential for proper care of patients and can protect staff against unnecessary medicolegal exposure.

## Admission to the Postanesthesia Care Unit

Every patient admitted to a PACU should have vital signs, airway patency, peripheral oxygen saturation, ventilatory rate/character, and level of pain recorded and periodically monitored.<sup>6</sup> Assessment of the patient with periodic recording every 5 minutes for the first 15 minutes and every 15 minutes thereafter is a minimum. Document temperature, level of consciousness, mental status, neuromuscular function, hydration status, degree of nausea on admission/discharge, and more frequently if appropriate, are also minimum standards of care. Every patient should be continuously monitored with a pulse oximeter and at least a single-lead electrocardiogram (ECG). Extra leads, particularly precordial V3-6, are appropriate if left ventricular ischemia is likely. Capnography is necessary for patients receiving mechanical ventilation or those at risk for compromised ventilatory function. Transduction and recorded output from invasive monitors such as arterial, central venous, or pulmonary arterial catheters must be accomplished. Diagnostic (laboratory) testing should be ordered only for specific indications or part of a designed recovery protocol.

Anesthesiology personnel should manage the patient until a PACU nurse secures admission vital signs, attaches appropriate monitors, and care is transferred with a complete report to the nursing staff. A succinct but thorough report that includes sufficient information to allow rapid evaluation and intervention for postoperative complications must be legibly recorded using a standardized format printed on the PACU record or embedded in the PACU electronic medical record ([Table 54-1](#)). This report should be similar to the operating room (OR) timeout, providing patient identification, **3** procedure performed, anesthetic type and continuing therapies. Documentation of the time and amount of all neuromuscular relaxants, respiratory depressant medications, and reversal agents should be standard.

Outlined orders, specific therapeutic end points, and, most importantly, how to contact the responsible anesthesiologist all must be transmitted. The anesthesiologist should never transfer responsibility to PACU personnel until the patient's airway status, ventilation, and hemodynamics are appropriate for the caregivers to whom he or she entrusts the patient's care. Leaving a patient in the hands of someone unfamiliar or incapable of adequately handling the acuity of the medical situation in a rush to perform "the next case" may constitute abandonment of care. Check the function of indwelling cannulae, intravenous catheters, and monitors, and verify medication type and rates of any intravenous infusions before leaving.

## **Postoperative Pain Management**

Relief of surgical pain with minimal side effects is a major goal during PACU care and a top priority for patients.<sup>6,11-13</sup> Level of pain should be assessed and documented periodically throughout recovery. The Joint Commission for Accreditation of Health Organizations mandated that a numerical pain scale be used with periodic recording and an acceptable score for discharge. Inadequate postoperative analgesia is a major source of preoperative fear and postoperative dissatisfaction for surgical patients. In addition to improving comfort, analgesia reduces sympathetic nervous system response, thereby avoiding hypertension, tachycardia, and dysrhythmias. In hypovolemic patients, the sympathetic nervous system activity may mask relative hypovolemia. Administration of analgesics can precipitate hypotension in an apparently stable patient, especially if direct or histamine-induced vasodilation occurs. It is important to carefully assess a tachycardic patient with low or normal blood pressure who complains of pain before giving analgesics that might precipitate or accentuate hypotension.

**Table 54-1** Components of a Postanesthesia Care Unit Admission Report

**Preoperative History/Procedures**

- Medication allergies or reactions
- Pertinent earlier surgical procedures
- Underlying medical illness
- Chronic medications
- Acute problems (e.g., ischemia, acid–base status, dehydration)
- Premedications (e.g., antibiotics and time given,  $\beta$ -adrenergic blockers, antiemetics)
- Preoperative pain control (e.g., nerve blocks, adjunct medications, narcotics)
- Preoperative pain assessment (chronic and acute pain scores)
- NPO, *nil per os*, status

**Intraoperative Factors**

- Surgical procedure
- Type of anesthetic
- Type and difficulty of airway management
- Relaxant/reversal status
- Time and amount of opioids administered
- Type and amount of intravenous fluids administered
- Estimated blood loss
- Urine output
- Unexpected surgical or anesthetic events
- Intraoperative vital sign ranges
- Intraoperative laboratory findings
- Drugs given (e.g., steroids, diuretics, antibiotics, vasoactive medications, antiemetics)

**Assessment and Report of Current Status**

- Airway patency
- Ventilatory adequacy
- Level of consciousness
- Level of pain
- Heart rate and heart rhythm
- Endotracheal tube position
- Systemic pressure
- Intravascular volume status
- Function of invasive monitors
- Size and location of intravenous catheters
- Anesthetic equipment (e.g., epidural catheters, peripheral nerve catheters)
- Overall impression

**Postoperative Instructions**

- Expected airway and ventilatory status
- Acceptable vital sign ranges
- Acceptable urine output and blood loss
- Surgical instructions (e.g., positioning, wound care)
- Anticipated cardiovascular problems
- Orders for therapeutic interventions
- Diagnostic tests to be secured
- Therapeutic goals and end points before discharge
- Location of responsible physician

NPO, nothing by mouth.

The actual degree of postoperative pain can be difficult to establish. Severity of pain varies among surgical procedures and anesthetic techniques. Staff members may be relatively ineffective at quantifying level of discomfort. Patients are often able to communicate despite having received

sedative hypnotic drugs. Furthermore, patients may be impaired in their communication abilities coming into the hospital or may be affected by the entire medical experience, and thereby may be afraid to express their needs. Inexperienced nurses overestimate a patient's pain, whereas more experienced nurses tend to underestimate the pain.<sup>14</sup> Either error can lead to inappropriate treatment. Use of a numeric pain scale yields more reliable results but requires that a patient be willing to communicate. A wide divergence can exist between a patient's cognitive perception of pain and sympathetic nervous system response, and may be related to psychological, cultural, and cardiovascular differences among individuals. Some patients perceive severe pain with minimal sympathetic nervous system activity, whereas others exhibit hypertension and tachycardia with minimal complaint of discomfort. The best measure of analgesia is the patient's perception. Heart rate, respiratory rate and depth, sweating, nausea, and vomiting all may be signs of pain but their absence or presence is not in itself reliable as a measure of the presence of pain.

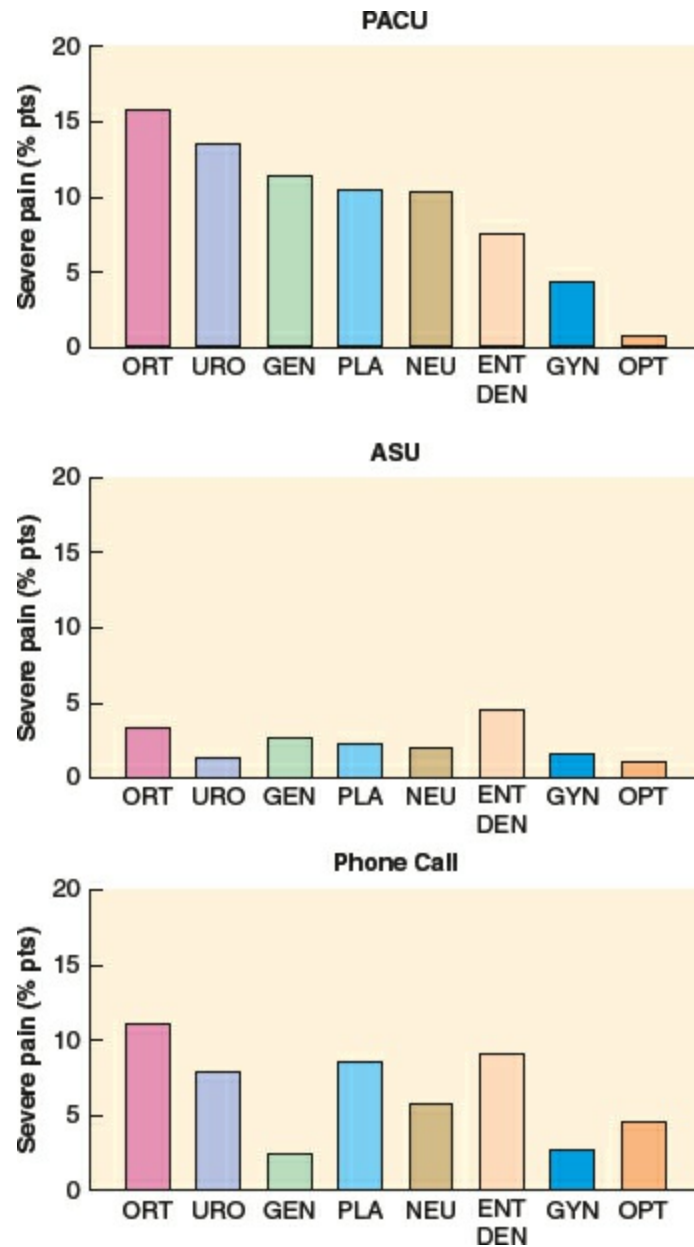

Careful identification of patient subgroups, assessment of individual analgesic requirements, and implementation of a planned, multimodal approach will provide seamless pain control through and beyond the PACU interval.<sup>15</sup> In a study of postoperative pain in 10,008 ambulatory patients, only 5.3% reported severe pain in the PACU and 1.7% in the discharge area (Fig. 54-1). However, a much higher percentage of patients report that moderate-to-severe pain recurs after discharge.<sup>16,17</sup> To avoid masking signs of an unrelated condition or a surgical complication, ascertain that the nature and intensity of pain are appropriate for the surgical procedure. The central nervous system (CNS) signs of hypoxemia, acidemia, or cerebral hypoperfusion often mimic those of pain, especially during emergence. Administration of parenteral analgesics or sedatives can acutely worsen hypoventilation, airway obstruction, or hypotension, causing sudden deterioration. Evaluating orientation, the level of arousal, and cardiovascular or pulmonary status usually identifies such patients.

Surgical pain can be effectively treated with a multimodal approach. **4** Although usage of opioids continues, the use of regional and local anesthetic techniques and drugs such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), neurologics, and  $\alpha$  agonists also have proven to be an effective in reducing pain. Sufficient analgesia is the end point, even if large doses of opioids are necessary in tolerant patients. Short-acting opioids are useful to expedite discharge and minimize nausea in ambulatory settings,<sup>18</sup> although duration of analgesia can be a problem. During intravenous titration of opioids, the patient should be assessed for incremental respiratory or cardiovascular depression. Oral and transdermal analgesics have a limited role in the PACU but are helpful for ambulatory patients

transitioning to PACU discharge. Rectal analgesics are sometimes useful in small children. Interventions such as repositioning, reassurance, or extubation also help minimize discomfort.

Other analgesic modalities provide pain relief in and beyond the PACU.<sup>19</sup> Titration of intravenous opioids in the PACU is important for smooth transition to intravenous patient-controlled analgesia. Injection of opioids into the epidural or subarachnoid space during anesthesia or in the PACU yields prolonged postoperative analgesia in selected patients.<sup>20,21</sup> Nausea and pruritus are troubling side effects, and immediate or delayed ventilatory depression can occur related to vascular uptake and cephalad spread in cerebrospinal fluid. Nausea should resolve with antiemetics, whereas pruritus and ventilatory depression often respond to naloxone infusion. Addition of local anesthetic or clonidine to neuraxially administered drugs enhance analgesia and decrease the risk of side effects from epidural opioids, although local anesthetics add risk of hypotension and motor blockade. Epidural analgesia is effective after thoracic or abdominal procedures and helps wean obese patients or those with chronic obstructive pulmonary disease (COPD) from mechanical ventilation.

Continuous flow catheters with pressure delivery systems of local anesthetics have been used within the wound to reduce pain and opioid requirements, increase patient satisfaction, and reduce length of hospital stay.<sup>22</sup> These same delivery systems have been safely used with continuous peripheral nerve catheters for inpatient as well as outpatient use.<sup>23,24</sup> With the use of ultrasound-guided techniques for catheter placement, appropriately selected outpatients can safely receive the pain control benefits of regional anesthesia.<sup>8</sup> However, extensive written and oral postoperative instructions must be provided, with systems in place for 24-hour access by patients for catheter-related complications.

**Figure 54-1** Percentage of patients experiencing severe pain in the postanesthesia care unit (PACU), the ambulatory surgery unit (ASU), and during phone call follow-up at 24 hours. ORT, orthopedics; URO, urology; GEN, general; PLA, plastics; NEU, neurology; ENT, ear, nose, throat; DEN, dental; GYN, gynecology; OPT, ophthalmology. Placement of long-acting regional analgesic blocks reduces pain, controls sympathetic nervous system activity, and often improves ventilation.<sup>19</sup> After shoulder procedures, interscalene block yields almost complete pain relief with only moderate inconvenience from motor impairment. Paralysis of the ipsilateral diaphragm can impair postoperative ventilation in patients with marginal reserve, although the impact is small in most patients.<sup>25</sup> Suprascapular nerve block might be an alternative to avoid this potentially serious side effect. Percutaneous intercostal or paravertebral blocks reduce analgesic requirements after thoracic, breast, or high abdominal incision.

Transversus abdominis plane (TAP) blocks are effective for lower abdominal surgeries as well as those innervated by the ilioinguinal and iliohypogastric nerves. Caudal analgesia or paravertebral blocks can also be effective in children after inguinal or genital procedures, whereas infiltration of local anesthetic into joints, soft tissues, or incisions decreases the intensity of pain. Other modalities, such as guided imagery, hypnosis, transcutaneous nerve stimulation, music, massage, or acupuncture, have limited utility for surgical pain but may provide a positive patient experience.

Use of patient-controlled analgesia, spinal opioids, or neural blockade mandates anticipation of risk beyond the PACU. The plan for extended postoperative analgesia should be established before induction of surgical anesthesia, and then the anesthetic and PACU care should be oriented toward that plan. These plans should be in agreement with the patient, surgeon, and anesthesiologist. If one analgesic modality proves inadequate, the team should take particular care when implementing a second technique.

Fear, anxiety, and confusion often accentuate postoperative pain during recovery, especially after general anesthesia. Titration of an intravenous sedative such as midazolam may attenuate this psychogenic component. It is important to distinguish between requirements for analgesia and anxiolysis. Opioids are poor sedatives and anxiolytics, whereas benzodiazepines are poor analgesics. However, when pain control modalities appear larger than what might be anticipated, one should consider the possibility that anxiety is playing a large role in the dysphoric event in the PACU.

## **Discharge Criteria**

Before discharge from the postoperative unit to a lower level of care, each patient should be sufficiently oriented to assess his or her physical condition and be able to summon assistance. Airway reflexes and motor function must be adequate to maintain patency and prevent aspiration. One should ensure that ventilation and oxygenation are acceptable, with sufficient reserve to cover minor deterioration in unmonitored settings. Blood pressure, heart rate, and indices of peripheral perfusion should be relatively constant for at least 15 minutes and appropriately near baseline. Achieving normal body temperature is not an absolute requirement, but there should be resolution of shivering. Acceptable analgesia must be achieved and vomiting appropriately controlled. Patients should be observed for at least 15 minutes after the last intravenous opioid or sedative is administered to assess peak effects and side effects. If regional anesthetics have been administered, longer observation could be appropriate to assess effectiveness and rule out local toxicity. One should monitor oxygen saturation for 15 minutes after discontinuation of supplemental oxygen to detect hypoxemia. Ruling out likely complications of

surgery (e.g., bleeding, vascular compromise, pneumothorax) or of underlying conditions (e.g., hypertension, myocardial ischemia, hyperglycemia, bronchospasm). One should also document a brief neurologic assessment to assure patient is at their baseline and review results of diagnostic tests. If these generic criteria cannot be met, postponement of discharge or transfer to a specialized unit is advisable. There is no demonstrable benefit from a mandatory minimum duration of PACU care.

Scoring systems such as the Modified Aldrete Score or Postanesthesia Discharge Scoring System (Table 54-2) are two commonly used systems for patient assessment and attempt to simplify and standardize patient discharge criteria. Fixed PACU discharge criteria must be used with caution because **5** variability among patients is tremendous. Scoring systems that quantify physical status or establish thresholds for vital signs are useful for assessment but cannot replace individual evaluation.<sup>26,27</sup> Ideally, each patient should be evaluated for discharge by an anesthesiologist using a consistent set of criteria, considering the severity of underlying disease, the anesthetic and recovery course, and the level of care at the destination (Table 54-2). A plan for the continued management of likely postdischarge symptoms such as pain, nausea, headache, dizziness, drowsiness, and fatigue must be made prior to discharge.<sup>17</sup>

**Table 54-2** Two Most Commonly Used Postanesthesia Care Unit Discharge Criteria Systems

Modified Aldrete Scoring System	Postanesthetic Discharge Scoring System
<b>Respiration</b>	<b>Vital signs</b>
2 = Able to take deep breath and cough	2 = BP + pulse within 20% preop baseline
1 = Dyspnea/shallow breathing	1 = BP + pulse within 20%–40% preop baseline
0 = Apnea	0 = BP + pulse >40% preop baseline
<b>O<sub>2</sub> saturation</b>	<b>Activity</b>
2 = Maintains SpO <sub>2</sub> >92% on room air	2 = Steady gait, no dizziness or meets preop level
1 = Needs O <sub>2</sub> inhalation to maintain O <sub>2</sub> saturation >90%	1 = Requires assistance
0 = O <sub>2</sub> saturation <90% even with supplemental oxygen	0 = Unable to ambulate
<b>Consciousness</b>	<b>Nausea and vomiting</b>
2 = Fully awake	2 = Minimal/treated with PO medication
1 = Arousable on calling	1 = Moderate/treated with parenteral medication
0 = Not responding	0 = Severe/continues despite treatment
<b>Circulation</b>	<b>Pain</b>
2 = BP ± 20 mmHg preop	Controlled with oral analgesics and acceptable to patient:
1 = BP ± 20–50 mmHg preop	2 = Yes
0 = BP ± 50 mmHg preop	1 = No
<b>Activity</b>	<b>Surgical bleeding</b>
2 = Able to move four extremities voluntarily or on command	2 = Minimal/no dressing changes
1 = Able to move two extremities	1 = Moderate/up to two dressing changes required
0 = Unable to move extremities	0 = Severe/more than three dressing changes required
Score ≥9 for discharge	Score ≥9 for discharge

BP, blood pressure; PO, oral.

## Postoperative Evaluation

The Centers for Medicare and Medicaid Services (CMS) have instituted compliance policies for those entities that participate in the Medicare and Medicaid programs. The policy for postanesthesia follow-up requires a written follow-up that is performed by an individual that is qualified to administer anesthesia no later than 48 hours post procedure. The time frame starts as soon as the patient arrives to the recovery area or intensive care unit (ICU). The evaluation should be performed only after the patient has sufficiently recovered from anesthesia to be able to participate, such as answer questions or perform simple tasks. The postanesthesia evaluation must contain the following elements:

- Respiratory function, including respiratory rate, airway patency, and oxygen saturation
- Cardiovascular function, including pulse rate and blood pressure
- Mental status
- Temperature
- Pain
- Nausea and vomiting
- Postoperative hydration

## Cardiovascular Complications

The purpose of this section is not to entirely review all the possible cardiovascular events that might beset a patient in the PACU, rather it is to help the reader decide what events might be unique to the PACU. In the PACU, some reflexes previously blunted by general anesthetics, sedatives, and opioids return toward baseline revealing an unexpected cardiovascular compromise. Perhaps the two most common types of patients to encounter troubles will be the patient with coronary artery disease and the patient with congestive heart failure. Patients in the PACU may not complain of angina due to residual anesthetics and pain medications. The first sign of myocardial ischemia may well be hypotension, and the use of sedation techniques using drugs like dexmedetomidine can lead to hypotension postoperatively, which can cloud the picture of a patient's cardiac disease. The most common sign of myocardial ischemia is tachycardia. Tachycardia is very often a reaction to, not the cause of, myocardial ischemia. That does not mean that all tachycardia heralds myocardial ischemia, but in a patient who seems at risk for coronary artery disease, new-onset tachycardia that is not caused by pain should be taken seriously. The ECG may show classic ST-T wave elevation or depression depending on lead placement and area of ischemia. But the lack of ST-T wave elevation does not rule out coronary

artery disease. Transmural myocardial infarctions outside the PACU show no ECG diagnostic changes 10% to 30% of the time. So, the clinician must be especially suspicious of a series of hemodynamic changes in a person at risk for coronary artery disease. Early intervention with nitrates, opioids,  $\beta$ -blockers, and even anticoagulants may save a life. Cardiology should be involved to gain immediate and timely access to the cardiac catheterization laboratory or for anxiolytic drug therapy. With increasing use of bare metal and drug eluting stents (DES), recognition of those patients that have stopped antiplatelet therapy and are in postoperative hypercoagulable states can quickly occlude these stents. This requires quick recognition and response for intervention. Involvement and communication with the surgical service must be immediate and decisions, especially as to anticoagulation and lytic therapy, should be made among several services in consultation.

Congestive heart failure is epidemic in our ever-aging population. The outpatient cardiology services have an expanding armamentarium of new inotropic/vasodilator therapy, devices, and interventions that allow patients to compensate for their congestive heart failure. It is helpful to know not only the ejection fraction but also the activities of daily living, exercise tolerance, and other risk indices. The ejection fraction is only an estimate of the fractional shortening of the myocardial actin and myosin fibrils. Although it is a useful estimate of severity of impairment, one is struck by how stable some patients may be with a large dilated heart contracting at a 15% ejection fraction. They are compensated but have little reserve. The potential problems of bleeding, volume shifts, and respiratory compromise in the PACU could quickly cause decompensation. There are also no absolute numbers with regard to fluid restriction but precaution should be taken when giving fluid challenges. The usage of transesophageal echocardiography and transthoracic echo may be of great use in the PACU. Within a very few minutes a puzzling hypotensive situation might be explained by an echocardiogram. The echocardiogram allows rapid viewing of myocardial contractility, regional wall motion, volume status, and valvular dysfunction.

With evolving cardiac treatments and less invasive techniques, specialized PACU care can be safe and more cost effective than ICU admission. The natural extension is to establish some highly specialized PACUs that function as step-down or short-term ICUs. In a study of 85 prospective patients<sup>29</sup> undergoing “off-pump” coronary artery bypass graft procedures, the patients were extubated in  $12 \pm 2$  minutes after the chest was closed. They were then taken to a special part of the PACU where they were monitored for a number of hours (up to 480 minutes in some situations). Patients were then either discharged to the cardiac floors or sent to an ICU. Of the 85 patients in this study, only 4 failed the PACU stay and had to be admitted to an ICU. Bradycardia was the cause for failure in three cases; the cause for the fourth

failure was myocardial infarction. Two patients later returned to the ICU from the cardiac ward; there was one case of atrial fibrillation and another case of myocardial infarction. During the same time 304 patients who were not undergoing off-pump coronary artery bypass graft surgery were admitted to the cardiac ICU. The cost for PACU stay was \$5,140.00 less than for an ICU-admitted patient. Although this study seems quite favorable, the two groups of patients were not comparable.

High-risk vascular and thoracic surgery patients have shown that they could each be adequately cared for in an adequately staffed and prepared PACU.<sup>30</sup> Hospitals can improve patient throughput by putting more resources into expanded PACU care and less into ICU services. Nursing reviews are available to give input as to how to structure such new units.<sup>31,32</sup>

Anesthesiology services are in increased demand throughout most hospitals. The PACU will likely need to prepare to care for those patients. Some facilities may elect to have separate recovery facilities and staff different from the traditional operating room PACU. Invasive cardiology suites are used for ablation techniques for dysrhythmias, and automated implantable defibrillators are placed in hybrid suites, operating rooms, or catheterization laboratories; these facilities may also be the sites of percutaneous valve replacements as well as some hybrid and percutaneous coronary revascularization procedures. If patients require deep sedation or general anesthesia, they will also require PACU care.

The cardiac patient is the common patient today. The new procedures and pressure to ever streamline operating room care is pressuring the PACU to become more and more a cardiac mini-ICU. The smart PACU medical director and hospital administrator will see that with targeted resources, patients may well be safely cared for in a more cost-effective manner with quicker throughput by using a PACU approach.

## Postoperative Pulmonary Dysfunction

7

Mechanical, hemodynamic, and pharmacologic factors related to surgery and anesthesia impair ventilation, oxygenation, and airway maintenance.<sup>33</sup> Heavy smoking, obesity, sleep apnea, severe asthma, and COPD increase the risk of postoperative ventilatory events.<sup>34</sup> Preoperative pulmonary function testing has limited predictive value for postoperative complications,<sup>35</sup> perhaps with the exception of postoperative bronchospasm in smokers.<sup>36</sup>

### *Inadequate Postoperative Ventilation*

In PACU patients, mild respiratory acidemia due to atelectasis and decreased minute ventilation is expected; thus, elevated PaCO<sub>2</sub> does not necessarily

indicate inadequate postoperative ventilation. Inadequate ventilation should be suspected when (1) respiratory acidemia occurs coincident with tachypnea, anxiety, dyspnea, labored ventilation, or increased sympathetic nervous system activity; (2) hypercarbia reduces the arterial pH below 7.30; or (3) PaCO<sub>2</sub> progressively increases with a progressive decrease in arterial pH.

### *Inadequate Respiratory Drive*

During early recovery from anesthesia, residual effects of intravenous and inhalation anesthetics blunt the ventilatory responses to both hypercarbia and hypoxemia. Sedatives augment depression from opioids or anesthetics and reduce the conscious desire to ventilate (a significant component of ventilatory drive).

Hypoventilation and hypercarbia can evolve insidiously during transfer and admission to the PACU. Although effects of intraoperative medications are usually waning, the peak depressant effect of an intravenous opioid given just before transfer occurs in the PACU. Coincident depression of medullary centers that regulate the sympathetic nervous system can blunt signs of acidemia or hypoxemia such as hypertension, tachycardia, and agitation, concealing hypoventilation. Patients might communicate lucidly and even complain of pain while experiencing significant opioid-induced hypoventilation. A balance must be struck between an acceptable level of postoperative ventilatory depression and a tolerable level of pain or agitation. Patients with abnormal CO<sub>2</sub>/pH responses from morbid obesity, chronic airway obstruction, or sleep apnea are more sensitive to respiratory depressants.<sup>37</sup> Risk for apnea after anesthesia in preterm infants depends on type of anesthetic, postconceptual age, and preoperative hematocrit. Preterm infants should be monitored for at least 12 hours. Children with active or recent upper respiratory infection are more prone to breath-holding, severe cough, and arterial desaturations below 90% during recovery, especially if they have a history of reactive airway disease or secondhand smoke exposure or have undergone intubation and/or airway surgery.<sup>38</sup> If hypoventilation from opioids is excessive, forced arousal and careful titration (20 to 40 µg at a time) of intravenous naloxone reverses respiratory depression without affecting analgesia. Flumazenil (0.1 mg titrated to effect up to 1.5 mg) directly reverses depressant effects of benzodiazepines on ventilatory drive but is usually unnecessary.

The abrupt diminution of a noxious stimulus (e.g., tracheal extubation, placement of a postoperative block) may promote hypoventilation or airway obstruction by altering the balance between arousal from discomfort and depression from medication. Intracranial hemorrhage or edema sometimes presents with hypoventilation, especially after posterior fossa craniotomy.

Bilateral carotid body injury after endarterectomy can ablate peripheral hypoxic drive. Chronic respiratory acidemia from COPD alters CNS sensitivity to pH and makes hypoxic drive dominant, but hypoventilation from supplemental oxygen rarely occurs.

### **Increased Airway Resistance**

High resistance to gas flow through airways increases work of breathing and CO<sub>2</sub> production. If inspiratory muscles cannot generate sufficient pressure gradients to overcome resistance, alveolar ventilation fails to match CO<sub>2</sub> production and progressive respiratory acidemia occurs.

In postoperative patients, increased upper airway resistance is caused by obstruction in the pharynx (posterior tongue displacement, change in anteroposterior and lateral dimensions from soft tissue collapse), in the larynx (laryngospasm, laryngeal edema), or in the large airways (extrinsic compression from hematoma, tumor, or tracheal stenosis). Weakness from residual neuromuscular relaxation,<sup>39</sup> myasthenia gravis or myasthenic syndromes can contribute, but it is seldom the primary cause of airway compromise. If the airway is clear of vomitus or foreign bodies, simple maneuvers such as improving the level of consciousness, lateral positioning, chin lift, mandible elevation, or placement of an oropharyngeal or nasopharyngeal airway may relieve obstruction. A nasopharyngeal airway may be better tolerated when the patient has functional gag reflexes. Acute extrinsic upper airway compression (e.g., an expanding neck hematoma) must be relieved.

During emergence, stimulation of the pharynx or vocal cords by secretions, blood, foreign matter, or extubation can generate laryngospasm.<sup>40</sup> Laryngeal constrictor muscles occlude the tracheal inlet and reduce gas flow. Patients who smoke or are chronically exposed to smoke have irritable airway conditions, have copious secretions, or have undergone upper airway surgery are at higher risk.<sup>33,38</sup> Laryngospasm usually can be overcome by providing gentle continuous positive pressure (10 to 20 mmHg) in the oropharynx by mask with 100% O<sub>2</sub>. Prolonged laryngospasm is relieved with a small dose of succinylcholine (e.g., 0.1 mg/kg) or deepening sedation with propofol. An intubating dosage of succinylcholine should not be used to break postoperative laryngospasm, especially if the alveolar partial pressure of oxygen (PAO<sub>2</sub>) is decreased by hypoventilation. As little as 5 to 10 mg of succinylcholine can break the laryngospasm. Unless assisted ventilation is provided, declining PAO<sub>2</sub> causes serious hypoxemia before spontaneous ventilation resumes (Fig. 54-2).<sup>41</sup> If the functional residual capacity (FRC) is abnormally reduced, the decreased volume of O<sub>2</sub> available in the lungs accelerates the development of hypoxemia. Severe laryngeal obstruction can

occur secondarily because of acute hypocalcemia after parathyroid excision.

**Figure 54-2** Rate of SpO<sub>2</sub> decline after onset of apnea. (Reprinted with permission from Benumof JL, Dagg R, Benumof R. Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg intravenous succinylcholine. *Anesthesiology*. 1997;87:979.)

Soft-tissue edema worsens airway obstruction, especially in children and adults recovering from procedures on the neck. Nebulized vasoconstrictors like epinephrine help somewhat, but steroids have little effect acutely. Patients with C1 esterase inhibitor deficiency can develop severe angioneurotic edema after even slight trauma to the airway. Pathologic airway obstruction (e.g., severe edema, epiglottitis, retropharyngeal abscess, encroaching tumors) might require emergency tracheal intubation, but airway manipulation is dangerous because minor trauma from intubation attempts can convert a marginal airway into a total obstruction. Judgment by the individual anesthesiologist regarding timing, patient status, available equipment along with airway management skills all play a part of the decision as to where, when, and how to intubate. Sedatives or muscle relaxants used to facilitate intubation can worsen obstruction by compromising the patient's volitional efforts to maintain the airway and by eliminating spontaneous ventilation. Equipment and personnel necessary for emergency cricothyroidotomy or tracheostomy should be available. Needle cricothyroidotomy using a 14-gauge intravenous catheter or a commercially available kit permits oxygenation and marginal ventilation until the airway is secured, especially if jet ventilation with 100% oxygen is used.

Reduction of cross-sectional area in small airways increases overall airway resistance because resistance varies inversely with the fourth power of radius

during turbulent flow. Pharyngeal or tracheal stimulation from secretions, suctioning, aspiration, or a tracheal tube can trigger a reflex constriction of bronchial smooth muscle in emerging patients with reactive airways. Histamine release precipitated by medication or allergic reactions also increases airway smooth muscle tone. Decreased radial traction on small airways reduces cross-sectional area in patients with COPD or with decreased lung volume secondary to obesity, surgical manipulation, excessive lung water, or splinting. Preoperative spirometric evidence of increased airway resistance predicts an increased risk of postoperative bronchospasm.<sup>36</sup> Smokers and patients with bronchospastic conditions are at highest risk.<sup>42</sup> If ventilatory requirements are increased by warming, hyperthermia, or work of breathing, high flow rates convert laminar flow to higher-resistance turbulent flow. Prolonged expiratory time or audible turbulent air flow (wheezing) during forced vital capacity expiration often unmasks subclinical airway resistance. Resistance is higher during expiration because intermediate-diameter airways are compressed by positive intrathoracic pressure. High airway resistance does not always cause wheezing because flow might be so impeded that no sound is produced. Signs of increased resistance mimic those of decreased pulmonary compliance. Spontaneously breathing patients exhibit accessory muscle recruitment, labored ventilation, and increased work of breathing with either condition. Mechanically ventilated patients exhibit high peak inspiratory pressures.

The treatment of small airway resistance is directed at an underlying etiology. One must eliminate laryngeal or airway stimulation. Patients often respond to their pre-existing regimen of their inhalers. Levalbuterol or metaproterenol nebulized in oxygen resolves postoperative bronchospasm with minimal tachycardia. Nebulized racemic epinephrine effectively relaxes smooth muscle, but side effects of tachycardia and flushing can be seen. Isoproterenol has also been nebulized with good results. Intramuscular or sublingual terbutaline can be added. Administration of steroid therapy offers little acute improvement, but may prevent later recurrence. Bronchospasm that is resistant to  $\beta_2$ -sympathomimetic medication may improve with an anticholinergic medication such as atropine or ipratropium. If bronchospasm is life-threatening, an intravenous epinephrine infusion yields profound bronchodilation. Increased small airway resistance caused by mechanical factors (e.g., loss of lung volume, retained secretions, pulmonary edema) usually does not resolve with bronchodilators. Restoration of lung volume with incentive spirometry or deep tidal ventilation increases radial traction on small airways. Reducing left ventricular filling pressures might relieve airway resistance caused by increased lung water, although interstitial fluid accumulation can persist. Also, extended contraction of airway smooth muscle obstructs venous and lymphatic flow, leading to airway wall edema that

resolves slowly.

### **Decreased Compliance**

Reduced pulmonary compliance increases the elastic work of breathing. In the extreme, low compliance causes progressive respiratory muscle fatigue, hypoventilation, and respiratory acidemia. Parenchymal changes also affect compliance. Reduction of FRC leads to small airway closure and distal lung collapse, requiring greater energy expenditure to re-expand the lung. Pulmonary edema increases the lung's weight and inertia and elevates surface tension by interfering with surfactant activity, making expansion more difficult. Pulmonary contusion or hemorrhage interferes with lung expansion, as do restrictive lung diseases, skeletal abnormalities, intrathoracic lesions, hemothorax, pneumothorax, or cardiomegaly. Obesity affects pulmonary compliance, especially when adipose tissue compresses the thoracic cage or increases intra-abdominal pressure in supine or lateral positions. Extrathoracic factors such as tight muscles of the chest or abdominal dressings and gas in the stomach or bowel reduce chest wall compliance. Most notably after intra-abdominal laparoscopic procedures, retained CO<sub>2</sub> may impair diaphragm movement. The CO<sub>2</sub> has the capability to dissecting into the thorax, creating either a pneumothorax or pneumomediastinum, which is usually a self-limited event as the CO<sub>2</sub> is relatively rapidly absorbed. There is usually no need for chest tube intervention. An intra-abdominal tumor, hemorrhage, ascites, bowel obstruction, or pregnancy impairs diaphragmatic excursion and reduces compliance.

Work of breathing is improved by resolving problems that reduce compliance. Allowing patients to recover in a semi-sitting (semi-Fowler) position reduces work of breathing. Incentive spirometry and chest physiotherapy help restore lung volume, as does positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). In patients with COPD and highly compliant lungs, positive airway pressure might force the rib cage and diaphragms toward their excursion limits, accentuating inspiratory muscular effort.

### **Neuromuscular and Skeletal Problems**

Postoperative airway obstruction and hypoventilation are accentuated by incomplete reversal of neuromuscular relaxation. Residual paralysis compromises airway patency, ability to overcome airway resistance, airway protection, and ability to clear secretions.<sup>43</sup> In the extreme, paralysis precludes effective spontaneous ventilation. Intraoperative use of shorter-acting relaxants might decrease the incidence of residual paralysis but does

not eliminate the problem. Marginal reversal can be more dangerous than near-total paralysis because a weak, agitated patient exhibiting uncoordinated movements and airway obstruction is more easily identified. A somnolent patient exhibiting mild stridor and shallow ventilation from marginal neuromuscular function might be overlooked, allowing insidious hypoventilation and respiratory acidemia or regurgitation with aspiration to occur. PACU staff should be aware of patients who have received nondepolarizing muscle relaxants but no reversal agents because they often exhibit low levels of residual paralysis.<sup>44</sup> Safety of techniques designed to avoid reversal of short- and intermediate-duration relaxants has not been substantiated, and reversal of nondepolarizing relaxants is recommended.<sup>6</sup> The selective relaxant binding agent used widely in Europe and recently available in the United States,  $\gamma$ -cyclodextrins (i.e., Sugammadex), is a reversal drug that can avoid the side effects of other anticholinesterases and anticholinergics.<sup>45</sup> Patients with neuromuscular abnormalities such as myasthenia gravis, Eaton–Lambert syndrome, periodic paralysis, or muscular dystrophies exhibit exaggerated or prolonged responses to muscle relaxants. Even without relaxant administration, these patients can exhibit postoperative ventilatory insufficiency. Medications (e.g., antibiotics, furosemide, propranolol, phenytoin) potentiate neuromuscular relaxation, as does hypocalcemia or hypermagnesemia.

Diaphragmatic contraction is compromised in some postoperative patients, forcing more reliance on intercostal muscles and reducing the ability to overcome decreased compliance or increased ventilatory demands. Impairment of phrenic nerve function from interscalene block, trauma, or thoracic and neck operations can “paralyze” one or rarely both diaphragms.<sup>25</sup> Adequate ventilation will normally be maintained with only one diaphragm, and marginal ventilation by external intercostal muscles alone. However, with high work of breathing, muscle weakness, or increased ventilatory demands, a nonfunctional diaphragm impairs minute ventilation. Thoracic spinal or epidural blockade interferes with intercostal muscle function and reduces ventilatory reserve, especially in patients with COPD. Abnormal motor neuron function (e.g., Guillain–Barré syndrome, cervical spinal cord trauma), flail chest, or severe kyphosis or scoliosis can cause postoperative ventilatory insufficiency.

Simple tests help assess mechanical ability to ventilate. The ability to sustain head elevation in a supine position, a forced vital capacity of 10 to 12 mL/kg, an inspiratory pressure more negative than  $-25$  cm H<sub>2</sub>O, and tactile train-of-four assessment imply that strength of ventilatory muscles is adequate to sustain ventilation and to take a large enough breath to cough. However, none of these clinical end points reliably predicts recovery of airway protective reflexes,<sup>44</sup> and failure on these tests does not necessarily indicate

the need for assisted ventilation.

The use of noninvasive mechanical ventilation techniques such as CPAP or bilevel ventilation can help safely extubate some patients earlier or prevent reintubation. By using these noninvasive techniques, patients can often overcome some of the above discussed issues interfering with normal respiration, thus reducing the risk of remaining intubated or reintubation. Units other than ICUs are able to manage these patients thereby offloading the burden of the ICU.

Occasionally, a clinical picture suggests ventilatory insufficiency when ventilation is adequate. Voluntary limitation of chest expansion to avoid pain (splinting) causes labored, rapid, shallow breathing characteristic of inadequate ventilation. Splinting seldom causes actual hypoventilation and usually improves with analgesia and repositioning. Ventilation with small tidal volumes due to thoracic restriction or reduced compliance seems to generate afferent input from pulmonary stretch receptors, leading to dyspnea, labored breathing, and accessory muscle recruitment in spite of appropriate minute ventilation. Occasional large, “satisfying” lung expansions often relieve these symptoms. Finally, spontaneous hyperventilation to compensate for a metabolic acidemia might generate tachypnea or labored breathing, which is mistaken for ventilatory insufficiency.

### *Increased Deadspace*

Ventilation of unperfused deadspace or of poorly perfused alveoli with high ventilation/perfusion ( $V/Q$ ) ratios is less effective in removing  $CO_2$ . Expansion of deadspace volume or reduction of tidal volume increases the fraction of each breath wasted in deadspace ( $V_D/V_T$ ) and the amount of  $CO_2$  from the previous exhalation that is rebreathed. A proportionally larger increase in total minute ventilation is required to meet any increase in  $CO_2$  production. Patients with high  $V_D/V_T$  are at greater risk for postoperative ventilatory failure.

Occasionally, an acute increase in deadspace contributes to respiratory acidemia in postoperative patients. Although upper airway deadspace is reduced after tracheal intubation and tracheostomy, excessive tubing volume or valve reversal in breathing circuits promotes rebreathing of  $CO_2$ . PEEP or CPAP elevates physiologic deadspace, especially in patients with high pulmonary compliance. Pulmonary embolization with air, thrombus, or cellular debris increases physiologic deadspace, although impact on  $CO_2$  excretion is often compensated by accelerated minute ventilation from hypercarbic and hypoxic drives or reflex responses. Decreased cardiac output can transiently increase  $V_D/V_T$  by decreasing perfusion to well-ventilated, nondependent lung and is the most common cause of acute increase in

deadspace in the acute care setting. Irreversible increases in deadspace occur if adult respiratory distress syndrome (ARDS) related to sepsis, transfusion-related acute lung injury (TRALI), or hypoxia destroys pulmonary microvasculature. Deadspace may appear high if an inhalation interrupts the previous exhalation and spent alveolar gas is retained. This “gas trapping” occurs when high airway resistance lengthens the time required to exhale completely, or if improper inspiration/expiration ratios or high ventilatory rates are used during mechanical ventilation.

### *Increased Carbon Dioxide Production*

Carbon dioxide production varies directly with metabolic rate, body temperature, and substrate availability. During anesthesia, CO<sub>2</sub> production falls to approximately 60% of the normal 2 to 3 mL/kg/min as hypothermia lowers metabolic activity and neuromuscular relaxation reduces tonic muscle contraction. Therefore, during recovery, metabolic rate and CO<sub>2</sub> production can increase by 40%. Shivering, high work of breathing, infection, sympathetic nervous system activity, or rapid carbohydrate metabolism during intravenous hyperalimentation accelerates CO<sub>2</sub> production. Malignant hyperthermia generates CO<sub>2</sub> production many times greater than normal, which rapidly exceeds ventilatory reserve and causes severe respiratory and metabolic acidemia. Even mild increases of CO<sub>2</sub> production can precipitate respiratory acidemia if low compliance, airway resistance, or neuromuscular paralysis interferes with ventilation. With the exception of adjusting hyperalimentation, improving work of breathing, reducing shivering, or treating hyperthermia, there is little yield from addressing CO<sub>2</sub> production in PACU patients.

### *Inadequate Postoperative Oxygenation*

Systemic arterial partial pressure of oxygen (PaO<sub>2</sub>) is the best indicator of pulmonary oxygen transfer from alveolar gas to pulmonary capillary blood. Arterial hemoglobin saturation monitored by pulse oximetry yields less information on alveolar-arterial gradients and is not helpful in assessing impact of hemoglobin dissociation curve shifts or carboxyhemoglobin.<sup>46</sup> Evaluation of metabolic acidemia or mixed venous oxygen content yields insight into peripheral oxygen delivery and utilization. Adequate arterial oxygenation does not mean that cardiac output, arterial perfusion pressure, or distribution of blood flow will maintain tissue oxygenation. Sepsis, hypotension, anemia, or hemoglobin dissociation abnormalities can generate tissue ischemia despite adequate oxygenation.

In postoperative patients, the acceptable lower limit for PaO<sub>2</sub> varies with

individual patient characteristics. A PaO<sub>2</sub> below 65 to 70 mmHg causes significant hemoglobin desaturation, although tissue oxygen delivery might be maintained at lower levels. Maintaining PaO<sub>2</sub> between 80 and 100 mmHg (saturation 93% to 97%) ensures adequate oxygen availability. Little benefit is derived from elevating PaO<sub>2</sub> above 110 mmHg because hemoglobin is saturated and the amount of additional oxygen dissolved in plasma is negligible. During mechanical ventilation, a PaO<sub>2</sub> above 80 mmHg with 0.4 FiO<sub>2</sub> and 5-cm H<sub>2</sub>O PEEP,<sup>46</sup> CPAP or spontaneous breathing trial usually predicts sustained adequate oxygenation after tracheal extubation.

### *Distribution of Ventilation*

Loss of dependent lung volume commonly causes V·/Q· mismatching and hypoxemia. A reduction in FRC decreases radial traction on small airways, leading to collapse and distal atelectasis that can worsen for 36 hours after surgery.<sup>47</sup> Reduced ventilation in dependent lung is particularly damaging because gravity directs pulmonary blood flow to dependent areas. Obese patients sustain large decreases in FRC during surgery. Older patients normally exhibit some airway closure at end expiration, and those with COPD have more severe closure that is exacerbated by small reductions in FRC. Retraction, packing, manipulation, or peritoneal insufflation during upper abdominal surgery reduces FRC, as does compression from leaning surgical assistants.<sup>48</sup> Prone, lithotomy, or Trendelenburg positions are disadvantageous, especially in obese patients. Right upper lobe collapse secondary to partial right main stem intubation is a frequently overlooked cause. During one-lung anesthesia, the weight of unsupported mediastinal contents, pressure from abdominal contents on the dependent diaphragm, and lung compression all reduce dependent lung volume. Gravity and lymphatic obstruction promote interstitial fluid accumulation and further V·/Q· mismatching. This “down lung syndrome” may appear as unilateral pulmonary edema on the chest film.

Postoperatively, acute pulmonary edema from overhydration, ventricular dysfunction, airway obstruction, or increased capillary permeability (e.g., including TRALI, drug reactions) leads to hypoxemia by interfering with both V·/Q· matching and diffusion of oxygen. Strong inspiratory efforts against an obstructed airway decrease FRC and promote negative-pressure pulmonary edema. Small airway occlusion from compression, retained secretions, or aspiration leads to distal hypoventilation and hypoxemia, as does main stem intubation. Pneumothorax or hemothorax also reduce lung volume.

Conservative measures that restore lung volume often improve oxygenation. If possible, patients should recover in a semisitting or reverse Trendelenburg position to reduce abdominal pressure on the diaphragms. Pain

with ventilation encourages shallow breathing, so analgesia helps maintain FRC, especially with upper abdominal or chest wall incisions. Deep ventilation, cough, chest physiotherapy, and incentive spirometry seem to help expand FRC, mobilize secretions, and accustom a patient to incisional discomfort, but actual efficacy is debated.<sup>49,50</sup> For serious postoperative reduction of FRC, positive pressure is effective. CPAP (5 to 7 cm H<sub>2</sub>O) or bilevel ventilation can be delivered by face mask for several hours until factors promoting loss of lung volume resolve. If hypoxemia is severe or patient acceptance of CPAP or the often more tolerable bilevel mask is poor, tracheal intubation is usually required. Intubation for delivery of noninvasive ventilation does not mandate positive-pressure ventilation. Ventilatory requirements should be assessed independently, considering PaCO<sub>2</sub>, arterial pH, and work of breathing. Usually, 5 to 10 cm H<sub>2</sub>O of CPAP or PEEP improves PaO<sub>2</sub> without risking hypotension, increased intracranial pressure, or barotrauma. If PaO<sub>2</sub> does not improve, one must re-evaluate the etiology. An occasional patient with ARDS or pulmonary contusion might require expiratory pressures in excess of 10 cm H<sub>2</sub>O for improved oxygenation.

Tracheal intubation eliminates normal expiratory resistance and the “physiologic PEEP” (2 to 5 cm H<sub>2</sub>O) that helps maintain lung volume during spontaneous ventilation. Exposing an intubated trachea to ambient pressure may cause a gradual reduction in FRC. Healthy, slender patients will often tolerate short periods of intubation without positive pressure, but generally it is prudent to use 5 cm H<sub>2</sub>O CPAP for intubated postoperative patients.

### *Distribution of Perfusion*

Poor distribution of pulmonary blood flow also interferes with V<sub>·</sub>/Q<sub>·</sub> matching and oxygenation. Flow distribution is primarily determined by hydrodynamic factors (PA and venous pressures, vascular resistance), which are affected by gravity, airway pressure, lung volume, and cardiac dynamics. Flow distribution is modulated by hypoxic pulmonary vasoconstriction (HPV), which diverts flow from air spaces that exhibit low PaO<sub>2</sub>. In postoperative patients, position affects oxygenation if gravity forces blood flow to areas with reduced ventilation. For example, placing a poorly ventilated lung in a dependent position can reduce PaO<sub>2</sub>. Postoperative changes in PA pressure, airway pressure, and lung volume also have complex effects on blood flow distribution that can adversely affect V<sub>·</sub>/Q<sub>·</sub> matching. Residual inhalation anesthetics, vasodilators, and sympathomimetics directly affect vascular tone and HPV, partially explaining larger alveolar-arterial oxygen gradients after general anesthesia. (Changes in distribution of ventilation also contribute.) Patients with liver cirrhosis exhibit poor V<sub>·</sub>/Q<sub>·</sub> matching caused by small arteriovenous shunts that form throughout their lungs. Circulating endotoxin

impairs HPV, contributing to hypoxemia in septic patients.

In the PACU, few interventions are useful to improve  $V/Q$  matching by changing the distributions of pulmonary blood flow. It is best to maintain pulmonary arterial (PA) and airway pressures within an acceptable range. When possible, avoid placing an atelectatic or diseased lung in a dependent position. Placing poorly ventilated parenchyma in a nondependent position could improve  $V/Q$  matching, but positioning a diseased lung in an “up” position may promote drainage of purulent material into the unaffected lung. Avoiding vasodilatory medications may improve  $PaO_2$  but benefits from the medication usually outweigh drawbacks of impaired HPV.

### *Inadequate Alveolar $PAO_2$*

Postoperative hypoxemia is occasionally caused by a global reduction of  $PAO_2$ , usually from inadequate ventilation, and marked increase in  $PACO_2$  (see the alveolar gas equation in [Chapter 15](#)). Hypoventilation must be severe to cause hypoxemia based on the alveolar gas equation, and can be completely masked by even small amounts of supplemental oxygen administration. Complete apnea or airway obstruction by a foreign body, soft-tissue edema, or laryngospasm as well as very high small airway resistance all lead to rapid depletion of alveolar oxygen, and preclude effective ventilation. If cessation of ventilation does occur, the rate of  $PAO_2$  decline varies with age, body habitus, degree of underlying illness, and initial  $PAO_2$  ([Fig. 54-3](#)).<sup>41</sup> Hypoxemia might also occur if opioids or residual anesthetic levels severely depress ventilatory drives. Partial airway obstruction does not usually reduce  $PAO_2$ , especially when patients are receiving supplemental oxygen. Increasing the oxygen content of the FRC with supplemental oxygen safeguards against hypoxemia from hypoventilation or airway obstruction, and eliminates the use of the pulse oximeter as a monitor of hypoventilation. Rarely, excessive concentrations of other gases reduce  $PAO_2$ . After general anesthesia, rapid outpouring of nitrous oxide displaces alveolar gas and can lower  $PAO_2$  if a patient is hypoventilating or breathing ambient air, but this “diffusion hypoxia” would usually occur before PACU admission. Volume displacement of oxygen could also occur during severe hypercarbia in a patient breathing ambient air, although acidemia is often a greater problem.

### *Reduced Mixed Venous $PO_2$*

Systemic venous partial pressure of oxygen  $P_vO_2$  is affected by  $>30$  events/hour arterial oxygen content, cardiac output, distribution of peripheral blood flow, and tissue oxygen extraction. If arterial oxygen content decreases

or tissue extraction increases,  $P_{\bar{v}O_2}$  falls. The lower the  $P_{\bar{v}O_2}$  in blood that is shunted or flows through low  $V/Q$  units, the greater the reduction of  $PaO_2$ . Blood with a low  $P_{\bar{v}O_2}$  also extracts larger volumes of oxygen from alveolar gas, amplifying the effect of hypoventilation or airway obstruction on  $PAO_2$ . Very low  $P_{\bar{v}O_2}$  increases the risk of resorption atelectasis in poorly ventilated alveoli. In postoperative patients, shivering, infection, and hypermetabolism lower  $P_{\bar{v}O_2}$  by increasing peripheral oxygen extraction. Low cardiac output and hypotension also lower  $P_{\bar{v}O_2}$  by decreasing tissue oxygen delivery. Supplemental oxygen reduces the impact of low  $P_{\bar{v}O_2}$  on alveolar oxygen extraction and on arterial oxygenation.

**Figure 54-3** SpO<sub>2</sub> versus postanesthesia care unit time in patients spontaneously ventilating in room air after general anesthesia (Group 1, 0 to 1 year of age; group 2, 1 to 3 years; group 3, 3 to 14 years; group 4, 14 to 58 years). (Reprinted with permission from Xue FS, Huang YG, Tong SY, et al. A comparative study of early postoperative hypoxemia in infants, children, and adults undergoing elective plastic surgery. *Anesth Analg.* 1996;83:709.)

### Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is a syndrome in which patients exhibit a period of partial or complete obstruction of the upper airway. This obstruction in turn interrupts sleep patterns, resulting in daytime

hypersomnolence, decreased ability to concentrate, increased irritability, as well as aggressive and distractible behavior in children. The airway obstruction may cause episodic oxygen desaturation, hypercarbia, and possibly lead to cardiac dysfunction. It is estimated that 9% of women and 24% of men in the United States show disordered breathing while asleep, and 2% of women and 4% of men show overt symptoms of OSA.<sup>51</sup> These numbers are likely to increase as the population ages and become increasingly obese. In February 2014, the ASA Task Force on Perioperative Management of Patients with OSA issued guidelines based on the ASA scoring system for OSA and classifying patients as having mild, moderate, or severe OSA based on the apnea–hypopnea index (the number of apnea and hypopnea events per hour of sleep)<sup>52</sup>:

Mild OSA apnea–hypopnea index 5–14 events/hour

Moderate OSA apnea–hypopnea index 15–29 events/ hour

Severe OSA apnea–hypopnea index >30 events/hour

The perioperative management of the OSA patient must start preoperatively with a well-planned anesthetic, taking into account the type, location, and recovery of surgery. Postoperative management concerns include analgesia, oxygenation, patient positioning, and monitoring. Regional anesthesia with minimal sedation is best for recovery versus increased use of opioids. Supplemental oxygen should be used immediately postoperatively. Patients who use CPAP or noninvasive positive-pressure ventilation should continue to use these therapies. Positioning should be used to minimize the patient's ability to obstruct the airway, which can be limited based on the type of surgery. Adult OSA patients show improvement in apnea–hypopnea index scores while in lateral, prone, and sitting positions compared with supine. With regard to monitoring, there is agreement among the consultants on the task force that pulse oximetry should be used until the patient's oxygen saturation remains above 90% on room air while sleeping. The use of telemetry for monitoring pulse oximetry, ECG, or ventilation can be beneficial in reducing adverse postoperative events and should be used on a patient need basis. With increasing studies in the area of OSA, the increased standardization of information regarding this patient population will lead to greater evidence-based treatment and supported clinical care.

## **Anemia**

Preoperative hematocrit and intraoperative hemorrhage determine a patient's red cell mass and oxygen-carrying capacity after surgery. Reduction of hematocrit caused by dilution has less impact. The hematocrit at which oxygen delivery becomes insufficient to match tissue needs varies with cardiac reserve, oxygen consumption, hemoglobin dissociation, PaO<sub>2</sub>, and

blood flow distribution. The actual level at which shock, or lack of tissue oxygen delivery, occurs is known as the *critical DO<sub>2</sub>* level. For animals and humans who have normal myocardial function and are euvolemic, critical DO<sub>2</sub> requires at least 3 to 3.5 g/dL hemoglobin concentration. Of course, this level of hemoglobin may be too low to be an appropriate transfusion trigger. However, it does illustrate the large excess of hemoglobin available to meet metabolic O<sub>2</sub> demands. Each patient has a minimum hematocrit below which tissues use inefficient anaerobic metabolism, generating a lactic acidemia. Patients with vascular disease are at increased risk of vital organ ischemia as hematocrit falls. Work from the ASA and the cardiac anesthesia/surgery societies (Society of Thoracic surgeons and Society of Cardiovascular Anesthesiologists) published guidelines for transfusion and blood management. It is well accepted now that patients who are stable, not bleeding, and euvolemic can tolerate a hemoglobin of 6.0 g/dL. Transfusion may be of some benefit between 6 and 8 g/dL and it is rarely useful above 10 g/dL. Furthermore, transfusion of red cells to assist in weaning a patient from the ventilator has been shown to make the weaning process prolonged and/or make it far more difficult to discontinue mechanical ventilation.

**Table 54-3** Common Oxygen Delivery Systems with Correlating O<sub>2</sub> Flow Rates to Delivered FiO<sub>2</sub> Ranges

System	O <sub>2</sub> Flow Rate (L/min)	FiO <sub>2</sub>
Nasal cannula	1	0.21–0.24
	2	0.23–0.28
	3	0.27–0.32
	4	0.31–0.36
	5	0.35–0.40
	6	0.39–0.44
Simple mask	5	0.30–0.40
	8	0.40–0.60
Partial rebreathing mask	10	0.50–0.65
Nonrebreathing mask	10–15	0.60–near 1.00

### Supplemental Oxygen

The incidence of hypoxemia in postoperative patients is high. In PACU patients placed on room air, 30% of patients younger than 1 year of age, 20% aged 1 to 3 years, 14% aged 3 to 14 years, and 7.8% of adults had hemoglobin saturations fall below 90%, with many falling below 85% (Fig. 54-3).<sup>53</sup> Clinical observation and assessment of cognitive function do not accurately screen for hypoxemia, so monitoring with pulse oximetry is essential throughout the PACU admission.<sup>54</sup> One cannot predict which patients will become hypoxemic or when hypoxemia will occur. Patients with

lung disease or obesity, those recovering from thoracic or upper abdominal procedures, and those with preoperative hypoxemia are at increased risk.<sup>55</sup> Postoperative hypoxemia occurs in children, especially those with respiratory infections or chronic adenotonsillar hypertrophy. Hypoxemia occurs frequently after regional anesthesia.<sup>21</sup>

Supplemental oxygen should be administered only to patients at high risk of hypoxemia or with low SpO<sub>2</sub> readings (Table 54-3). However, some recommend supplemental oxygen be administered in the PACU during initial recovery and perhaps during transport to the PACU.<sup>6</sup> Supplemental oxygen does not address underlying causes of hypoxemia in postoperative patients, its use does not guarantee that hypoxemia will not occur, and it is likely to mask hypoventilation.<sup>56</sup> Although oxygen might cause minor mucosal drying, routine humidification is of little benefit unless intubation bypasses natural humidification. Oxygen apparatus can increase the risk of corneal abrasion during emergence.

## 2 *Perioperative Aspiration*

During anesthesia, depression of airway reflexes places patients at risk for intraoperative pulmonary aspiration that may manifest in the PACU, or for aspiration during recovery. Pulmonary morbidity from perioperative aspiration varies with the type and volume of the aspirate. Although aspiration of gastric contents is most widely feared, surgical patients also experience other aspiration syndromes.

Aspiration of clear oral secretions during induction, face mask ventilation, or emergence is common and usually insignificant. Cough, mild tracheal irritation, or transient laryngospasm are immediate sequelae, although large-volume aspiration predisposes to infection, small airway obstruction, or pulmonary edema. Aspiration of blood secondary to trauma, epistaxis, or airway surgery generates marked changes on the chest radiograph that are out of proportion with clinical signs. Aspirated “sterile” blood causes minor airway obstruction but is rapidly cleared by mucociliary transport, resorption, and phagocytosis. Massive blood aspiration or aspiration of clots obstructs airways, interferes with oxygenation, and leads to fibrinous changes in air spaces and to pulmonary hemorrhage from iron accumulation in phagocytic cells. Secondary infection is a threat, especially if tissue or purulent matter is also aspirated.

Aspiration of food, small objects, pieces of teeth, or dental appliances causes persistent cough, diffuse reflex bronchospasm, airway obstruction with distal atelectasis, or pneumonia. Complications are often localized and treated with antibiotics and supportive care once the foreign matter is expelled or removed. Secondary thermal, chemical, or traumatic airway injury from

aspirated objects can occur. Of course, complete upper airway or tracheal obstruction by an aspirated object is a life-threatening emergency.

Aspiration of acidic gastric contents during vomiting or regurgitation causes chemical pneumonitis characterized initially by diffuse bronchospasm, hypoxemia, and atelectasis.<sup>57</sup> Morbidity associated with aspiration increases directly with volume of the aspirate and inversely with the pH of the aspirate (more acidic is worse). Aspiration of partially digested food worsens and prolongs pneumonitis, especially if vegetable matter is present. Food particles mechanically obstruct airways and are a nidus for secondary bacterial infection. In serious cases, epithelial degeneration, interstitial and alveolar edema, and hemorrhage into air spaces rapidly progresses to ARDS with high-permeability pulmonary edema. Destruction of pneumocytes, decreased surfactant activity, hyaline membrane formation, and emphysematous changes can follow, leading to V/Q mismatching and reduced compliance. Destruction of microvasculature increases pulmonary vascular resistance and deadspace ventilation.

The incidence of serious aspiration is relatively low in PACU patients, but the risk associated with aspiration is significant. Frequency of postoperative vomiting remains high, especially if gas has accumulated in the stomach. Protective airway reflexes such as cough, swallowing, and laryngospasm are suppressed by depressant medications such as inhalation anesthetics, sedatives, and opiates, so observe carefully patients with decreased levels of consciousness. Persisting effects of laryngeal nerve blocks or topical local anesthetics used to reduce airway irritability decrease postoperative airway protection, as does residual sedation. Reflexes are also impaired by residual neuromuscular paralysis.<sup>44,58</sup> Patients can sustain airway patency and spontaneous ventilation, pass a head lift test, have a tactile train-of-four T4/T1 ratio greater than 0.7, and still have impaired airway reflexes from residual paralysis. The T4/T1 ratio should exceed 0.9 before reflexes are completely competent.<sup>58</sup> Risk of aspiration also increases if reversal is omitted. Hypotension, hypoxemia, or acidemia cause both emesis and obtundation, increasing aspiration risk.

Preventing aspiration is critical because effective therapy is limited.<sup>59</sup> For patients at high risk, preoperative administration of nonparticulate antacids such as sodium citrate increases the pH of gastric fluid without excessively increasing volume. Avoid particulate antacids. Histamine type 2 receptor blockers such as famotidine or ranitidine reduce the volume and increase the pH of gastric secretions. Metoclopramide increases gastroesophageal sphincter tone and accelerates gastric emptying. Inserting a nasogastric tube is often ineffective to remove particulate matter and interferes with gastroesophageal sphincter integrity.

In the PACU, vigilance against aspiration is important. Trendelenburg

position might promote regurgitation but aids in airway clearance if regurgitation or vomiting occurs. High-risk patients should not have the trachea extubated until airway reflexes are restored. Even though a patient is awake and able to follow commands he or she may still have depressed gag reflex for several hours after anesthesia. The introduction of opioids and other sedatives may turn a situation of relatively good airway protection into one of potential aspiration. Aspiration of acidic fluid can still occur around an inflated tracheal tube cuff, so nurses should frequently monitor the upper airway for secretions or vomitus. One should avoid cuff deflation until extubation because the rigid tube impairs laryngospasm, swallowing, and other protective reflexes. The pharynx should be suctioned and the trachea extubated at end inspiration with positive airway pressure to promote expulsion of material trapped below the cords but above the inflated cuff. Observation is essential after extubation because airway reflexes might be temporarily impaired. Anatomic distortion in the airway from soft tissue trauma or surgical intervention interferes with airway protection. Mandibular fixation makes expulsion of vomitus, blood, or secretions difficult, so have equipment for release of mandibular fixation available and ensure patients demonstrate cognitive and physical ability to clear the airway before the trachea is extubated.

Discovery of gastric secretions in the pharynx mandates immediate lateral head positioning (assuming cervical spine integrity) and suction of the airway. If airway reflexes are compromised, tracheal intubation is often appropriate. After intubation, the trachea is suctioned through the tracheal tube before positive-pressure ventilation, thus avoiding wide dissemination of aspirated material into distal airways. Instillation of saline or alkalotic solutions is not recommended. Assessing the pH of tracheal aspirate is useless because buffering is immediate. Checking pharyngeal aspirate pH is more accurate but of little practical value. Suspicion that aspiration has occurred mandates 24 to 48 hours of monitoring for development of aspiration pneumonitis. If the likelihood of aspiration is small in an ambulatory patient, outpatient follow-up can be done, assuming hypoxemia, cough, wheezing, or radiographic abnormalities do not appear within 4 to 6 hours. The patient should receive explicit instructions to contact a medical facility at the first appearance of malaise, fever, cough, chest pain, or other symptoms of pneumonitis. If likelihood of aspiration is high, the patient should be admitted to the hospital. Observation includes serial temperature checks, white blood cell counts with differential, chest radiograph, and blood gas determination. Chest physiotherapy, incentive spirometry, and restarting medications for pre-existing pulmonary conditions minimize the loss of lung volume, V/Q mismatching, and infection. Fluffy infiltrates may appear on the chest radiograph any time within 24 hours. Hypoxemia might develop quickly or

evolve insidiously as injury progresses, so frequent pulse oximetry monitoring is important.

If hypoxemia, increased airway resistance, consolidation, or pulmonary edema evolves, the patient should be supported with supplemental oxygen, PEEP, or CPAP. Mechanical ventilation may be necessary. Steroids yield no improvement and may increase the risk of bacterial superinfection. Bacterial infection does not always follow aspiration, so prophylactic antibiotics merely promote colonization by resistant organisms. If bacterial infection is apparent, institute antibiotic therapy based on culture results. If cultures are equivocal, use broad-spectrum antibiotics with coverage for Gram-negative rods and anaerobes, including *Bacteroides fragilis*. Overall therapy is similar to that for ARDS. Pulmonary edema from increased capillary permeability should not be treated with diuretics unless high filling pressures or hypervolemia exist.

## Postoperative Renal Complications

### Ability to Void

8

The ability to void should be assessed because opioids and autonomic side effects of regional anesthesia interfere with sphincter relaxation and promote urine retention. Urinary retention is common after urologic, inguinal, and genital surgery, and retention frequently delays discharge.<sup>3</sup> Observation after these operations is needed to determine if inability to urinate is a possible surgical complication. Neither the patient nor staff can accurately estimate bladder volume through sensation or palpation. An ultrasonic bladder scan helps assess bladder volume before discharge and avoid the archaic practice of routine “straight catheterization.” It is reasonable to discharge selected ambulatory patients from the facility and inpatients to a floor before they void.<sup>6,60,61</sup> When inpatients are transferred prior to voiding, ensure urination can be monitored to avoid complications from urinary retention. Ambulatory patients who are discharged without voiding should receive a specific time interval in which to void (i.e., 10 to 12 hours after discharge). If retention persists, the patient must contact a health-care facility. High return rates after urologic procedures are related to urinary retention.<sup>62</sup>

### Renal Tubular Function

Analysis of urine yields information about postoperative renal tubular function. Urine color is not useful for assessing concentrating ability, but it does assist recognition of hematuria, hemoglobinuria, or pyuria. Urine osmolarity (reflecting the number of particles in solution) is a more reliable index of tubular function than specific gravity, which is affected by molecular

weight of solutes. An osmolarity above 450 mOsm/L indicates intact tubular concentrating ability. A urine sodium concentration far below or a potassium concentration above serum concentrations also indicates tubular viability, as does acidification or alkalinization of urine. Osmolarity, electrolyte, and pH values close to those in serum may indicate poor tubular function or acute tubular necrosis.

Inorganic fluoride released during metabolism of certain inhalation anesthetics (sevoflurane, enflurane, and methoxyflurane) can cause a transient reduction of tubular concentrating ability after long anesthetics. Higher fluoride levels cause renal tubular necrosis. Interaction of sevoflurane with dry carbon dioxide absorbents (often found in first cases or peripheral locations) generates compound A, a vinyl ether that degrades to release inorganic fluoride. Although transient impairment of protein retention and concentrating ability may occur, use of sevoflurane does not seriously affect renal function. This complication may be avoided entirely if lithium-based CO<sub>2</sub> absorbents are used.

## Oliguria

Oliguria ( $\leq 0.5$  mL/kg/hr) occurs frequently during recovery and usually 9 reflects an appropriate renal response to hypovolemia. The stress response of surgery also increases antidiuretic hormone (ADH), which can lead to decreased urine output. However, decreased urine output might indicate abnormal renal function. The acceptable degree and duration of oliguria vary with baseline renal status, the surgical procedure, and the anticipated postoperative course. In patients without catheters, one should assess interval since last voiding, and bladder volume, to help differentiate oliguria from inability to void. One should check indwelling urinary catheters for kinking, for obstruction by blood clots or debris, and for the catheter tip being positioned above the urinary level in the bladder, and aggressively evaluate oliguria if intraoperative events could jeopardize renal function (e.g., aortic cross-clamping, severe hypotension, possible ureteral ligature, massive transfusion). Systemic blood pressure must be adequate for renal perfusion, based on preoperative pressures. Administration of desmopressin for hematologic purposes seldom affects postoperative urinary output. After urine is sent for electrolyte and osmolarity determinations, a 300- to 500-mL intravenous crystalloid bolus helps assess whether oliguria represents a renal response to hypovolemia. If output does not improve, consider a larger bolus or a diagnostic trial of furosemide, 5 mg intravenously. Furosemide increases urine output if oliguria reflects tubular resorption of fluid. Patients receiving chronic diuretic therapy might require a diuretic to maintain postoperative urine output.

Persistence of oliguria despite hydration, adequate perfusion pressure, and a furosemide challenge increases the likelihood of acute tubular necrosis, ureteral obstruction, renal artery or vein occlusion, or inappropriate ADH secretion. Cystoscopy, intravenous pyelography, angiography, or radionuclide scanning may help clarify renal status. Osmotic or loop diuretics may be useful to attenuate renal damage. The use of low-dose dopamine or dobutamine has not proven to improve renal function. Fenoldopam used perioperatively has been shown to reduce the risk of acute kidney injury for select high-risk cardiac surgical patients.<sup>63</sup> Consultation with a nephrologist is prudent.

## ***Polyuria***

Relying on high postoperative urinary output to gauge intravascular volume status or renal viability can be misleading. Profuse urine output often reflects generous intraoperative fluid administration, but osmotic diuresis caused by hyperglycemia and glycosuria is another common cause, particularly if glucose-containing crystalloid solutions are infusing. Polyuria might also reflect intraoperative diuretic administration. However, sustained polyuria (4 to 5 mL/kg/hr) can indicate abnormal regulation of water clearance or high-output renal failure, especially if urinary losses compromise intravascular volume and systemic blood pressure. Diabetes insipidus occurs secondary to intracranial surgery, pituitary ablation, head trauma, or increased intracranial pressure. A urine specific gravity of 1.005 or less and a urine osmolality 200 mOsm/kg or less are the hallmark of diabetes insipidus. A random plasma osmolality is generally above 285 mOsm/kg. Diagnostic or therapeutic administration of vasopressin is useful.

## **Metabolic Complications**

### ***Postoperative Acid–Base Disorders***

Categorization of postoperative acid–base abnormalities into primary and compensatory disorders is difficult because rapidly changing pathophysiology can often generate multiple primary disorders.

### **Respiratory Acidemia**

Respiratory acidemia is frequently encountered in PACU patients because anesthetics, opioids, and sedatives promote hypoventilation by depressing CNS sensitivity to pH and PaCO<sub>2</sub>. In awake, spontaneously breathing patients with adequate analgesia, hypercarbia and acidemia are usually mild (PaCO<sub>2</sub>

45 to 50 mmHg, pH 7.36 to 7.32). Deeply sedated patients exhibit more profound acidemia unless supplemental ventilation is administered. Patients with residual neuromuscular paralysis, increased airway resistance, or decreased pulmonary compliance might not sustain adequate ventilation despite an intact CNS drive, especially if CO<sub>2</sub> production is elevated by fever, shivering, or hyperalimentation. The kidneys require hours to generate a compensatory metabolic alkalosis, so compensation for acute postoperative respiratory acidemia is limited.

Symptoms of respiratory acidemia include agitation, confusion, ventilatory dissatisfaction, and tachypnea. Sympathetic nervous system response to low pH causes hypertension, tachycardia, and dysrhythmias. Respiratory acidemia caused by CNS depression often produces less intense signs of sympathetic nervous system activity. In patients with head injury, intracranial tumors, or cerebral edema, respiratory acidemia increases cerebral blood flow and intracranial pressure. At very low pH, catecholamines cannot interact with adrenergic receptors, so heart rate and blood pressure decrease precipitously. Treatment consists of correcting the imbalance between CO<sub>2</sub> production and alveolar ventilation. Raising the level of consciousness by the judicious reversal of opioids or benzodiazepines improves ventilatory drive. It is important to ensure that the patient does not have increased airway resistance or residual neuromuscular blockade. If spontaneous ventilation cannot maintain CO<sub>2</sub> excretion, tracheal intubation and mechanical ventilation are necessary. Reducing CO<sub>2</sub> production by controlling fever or shivering may be helpful.

## **Metabolic Acidemia**

Evaluation of acute postoperative metabolic acidemia is relatively straightforward (Table 54-4). Occasionally, ketoacidosis occurs in diabetic patients. During ketoacidosis, serum glucose levels are elevated and ketones are detectable in blood or urine. Patients with renal failure or renal tubular acidosis usually exhibit a preoperative metabolic acidemia. Large volumes of saline infusions during surgery can generate a mild hyperchloremic, metabolic acidemia, but use of lactated Ringer solution avoids this problem.<sup>64</sup> Rarely, a patient manifests acidemia from toxic ingestion of aspirin or methanol. Once these unusual causes are excluded, postoperative metabolic acidemia almost always represents lactic acidemia secondary to insufficient delivery or utilization of oxygen in peripheral tissues. Peripheral hypoperfusion is often caused by low cardiac output (hypovolemia, cardiac failure, dysrhythmia) or peripheral vasodilation (sepsis, catecholamine depletion, sympathectomy). Arteriolar constriction from hypothermia or pressor administration reduces tissue perfusion and induces abnormal blood flow distribution. Hypoxemia,

severe anemia, impaired hemoglobin dissociation, CO poisoning, and inability to use oxygen in the mitochondria (cyanide or arsenic poisoning) also generate lactic acidemia.

**Table 54-4** Causes of Acidemia

<b>Normal anion gap acidosis</b>
GI loss of bicarbonate
Diarrhea
Urinary diversion
GI fistulas or drains
Renal loss of bicarbonate
Renal tubular acidosis
Renal insufficiency
Recovery phase of ketoacidosis
<b>Increased anion gap acidosis</b>
Ketoacidosis (diabetic, alcoholic, severe cachexia)
Lactic acidosis (seizures, neuroleptic malignant syndrome, MH, severe asthma, pheochromocytoma, cardiogenic shock, hypovolemia, severe anemia, regional ischemia, sepsis, hypoglycemia)
Respiratory acidosis

GI, gastrointestinal; MH, malignant hyperthermia.

A spontaneously breathing patient will increase minute ventilation in response to metabolic acidemia and quickly generate a respiratory alkalosis to compensate for metabolic acidemia. However, general anesthetics and analgesics suppress this ventilatory response. The sympathetic response to acute postoperative metabolic acidemia is often milder than the response to respiratory acidemia because hydrogen and bicarbonate ions cross the blood–brain barrier with more difficulty than CO<sub>2</sub>. Treatment consists of resolving the condition causing accumulation of metabolic acid. For example, ketoacidosis is treated with intravenous potassium, insulin, and glucose. Improving cardiac output or systemic blood pressure will reduce lactic acid production, as will rewarming. If conditions causing lactate accumulation are improved and acidemia is mild, renal excretion of hydrogen ions will restore normal pH. For severe or progressive acidemia, intravenous bicarbonate or calcium gluconate helps restore pH.

## Respiratory Alkalemia

Pain or anxiety during emergence causes hyperventilation and acute respiratory alkalemia. Excessive mechanical ventilation also generates respiratory alkalemia, especially if hypothermia or paralysis has decreased CO<sub>2</sub> production. Pathologic causes of “central” hyperventilation include sepsis, cerebrovascular accident, or paradoxical CNS acidosis (an imbalance of bicarbonate concentration across the blood–brain barrier caused by prolonged hyperventilation). Acute respiratory alkalemia can generate confusion,

dizziness, atrial dysrhythmias, and abnormal cardiac conduction. Alkalemia decreases cerebral blood flow, causing hypoperfusion and even stroke in patients with cerebrovascular disease. If the alkalemia is severe, reduced serum ionized calcium concentration precipitates muscle fasciculation or hypocalcemic tetany. Very high pH depresses cardiovascular, CNS, and catecholamine receptor functions. Metabolic compensation for acute respiratory alkalemia is limited because time constants for bicarbonate excretion are large. Treatment necessitates reducing alveolar ventilation, usually by administering analgesics and sedatives for pain and anxiety. Rebreathing of CO<sub>2</sub> has little application in the PACU.

### **Metabolic Alkalemia**

Metabolic alkalemia is rare in PACU patients unless vomiting, gastric suctioning, dehydration, alkaline ingestion, or potassium-wasting diuretics caused an alkalemia that existed before surgery. Excessive intraoperative bicarbonate administration causes postoperative metabolic alkalemia, but alkalemia from metabolism of lactate or citrate usually does not appear within the first 24 hours. Respiratory compensation through retention of CO<sub>2</sub> is rapid but limited because hypoventilation eventually causes hypoxemia. Hydration and correction of hypochloremia and hypokalemia allow the kidney to excrete excess bicarbonate.

### ***Glucose Disorders and Control***

10

Adequate glucose control has been recommended to reduce morbidity in a variety of postsurgical patients. The control of glucose in diabetic and nondiabetic patients has been shown to reduce complications and hospital length of stay and improve patient outcomes. However, the potential for hypoglycemia and coma should not be discounted. Insulin therapy should be based on serum glucose levels and requires careful and timely monitoring of blood glucose levels to avoid hypoglycemia. This includes clear and concise hand off of information when patient care is transferred. Urine glucose measurements should be reserved to assess osmotic diuresis and estimate renal transport thresholds by comparison with serum levels.

### **Hyperglycemia**

Glucose infusions and stress responses commonly elevate serum glucose levels after surgery. For most patients during anesthesia, glucose should not be included in maintenance intravenous solutions. Moderate postoperative hyperglycemia (150 to 250 mg/dL) resolves spontaneously and has little

adverse effect in the nondiabetic patient. Higher glucose levels cause glycosuria with osmotic diuresis and interfere with serum electrolyte determinations. Severe hyperglycemia increases serum osmolality to a point that cerebral disequilibrium and hyperosmolar coma occur. Type 1 diabetic patients are at risk for ketoacidosis. Potassium replacement and serial blood glucose determinations are essential.

## **Hypoglycemia**

Hypoglycemia in the PACU can be caused by endogenous insulin secretion or by excessive or inadvertent insulin administration. Serious postoperative hypoglycemia is rare and easily treated with intravenous 50% dextrose followed by glucose infusion. Either sedation or excessive sympathetic nervous system activity masks signs and symptoms of hypoglycemia after anesthesia. Diabetic patients and especially patients who have received insulin therapy intraoperatively must have serum glucose levels measured to avoid the serious problems related to hypoglycemia. Extreme care with documenting and reporting the use of insulin is paramount to provide safe and appropriate care.

## ***Electrolyte Disorders***

### **Hyponatremia**

Postoperative hyponatremia occurs if free water is infused during surgery or if sodium-free irrigating solution is absorbed during transurethral prostatic resection or hysteroscopy. Accumulation of serum glycine or its metabolite, ammonia, might exacerbate symptoms. Free water retention is also caused by inappropriate ADH secretion, prolonged labor induction with oxytocin, or respiratory uptake of nebulized droplets. Theoretically, excessive infusion of isotonic saline leads to excretion of hypertonic urine, desalination, and iatrogenic hyponatremia. Symptoms of moderate hyponatremia include agitation, disorientation, visual disturbances, and nausea, whereas severe hyponatremia causes unconsciousness, impaired airway reflexes, and CNS irritability that progress to grand mal seizures. Therapy includes intravenous normal saline and intravenous furosemide to promote free water excretion. Infusion of hypertonic saline may be useful for severe hyponatremia, in which diligence not to increase serum sodium by 0.5 mEq/hr is needed to avoid CNS lesions or pulmonary edema. Monitor serum sodium concentration and osmolarity.

### **Hypokalemia**

Postoperative hypokalemia is often inconsequential but might generate serious dysrhythmias, especially in patients taking digoxin. A potassium deficit caused by chronic diuretic therapy, nasogastric suctioning, or vomiting often underlies hypokalemia. Urinary and hemorrhagic losses, dilution, and insulin therapy generate acute hypokalemia that worsens during respiratory alkalemia. Excess sympathetic nervous system activity, infusion of calcium, or  $\beta$ -mimetic medications exacerbates effects of hypokalemia. Adding potassium to peripheral intravenous fluids often restores serum concentration, but concentrated solutions infused through a central catheter may be necessary. So often practitioners think 10 to 30 mEq of potassium will bring the patient back to normal. Potassium is an intracellular ion and a plasma potassium deficit is indicative of a far greater intracellular deficit. It is the intracellular-to-extracellular ratio that may well be important, and rapid changes can contribute to as many dysrhythmias as can mild hypokalemia alone.

## **Hyperkalemia**

A high serum potassium level raises the suspicion of spurious hyperkalemia from a hemolyzed specimen or from sampling near an intravenous catheter containing potassium or banked blood. Postoperative hyperkalemia occurs after excessive potassium infusion or in patients with renal failure or malignant hyperthermia. Acute acidemia exacerbates hyperkalemia. Treatment with intravenous insulin and glucose acutely lowers potassium, whereas intravenous calcium counters myocardial effects. Hemodialysis may be necessary for high potassium levels or symptomatic patients.

## **Calcium and Magnesium**

Although underlying parathyroid disease or massive fluid replacement reduces total body and ionized calcium, symptomatic hypocalcemia seldom occurs in the PACU. A rare patient might exhibit upper airway obstruction from hypocalcemia after parathyroid excision. Reduction of the ionized fraction by acute alkalemia may cause myocardial conduction and contractility abnormalities, decreased vascular tone, or tetany. Transfusion of blood containing chelating agents (e.g., citrate) rarely causes symptomatic hypocalcemia. Administration of calcium chloride or calcium gluconate to hypocalcemic patients improves cardiovascular dynamics.

Magnesium plays a key role in restoration of neuromuscular function after surgery and in maintenance of cardiac rhythm and conduction. Hypermagnesemia is rare because the kidneys are effective at excreting excessive magnesium. Obstetric patients who have been receiving magnesium for tocolysis or control of severe pregnancy-induced hypertension can present postoperatively hyporeflexivity, and at higher serum levels show prolonged

atrioventricular conduction or complete heart block. Treatment entails intravenous calcium and diuretics.

## Miscellaneous Complications

### *Incidental Trauma*

Each patient admitted to the PACU should be carefully evaluated for traumatic complications. Discovery of a complication necessitates careful documentation, notification of physicians responsible for extended care, consultation with specialists, and follow-up.

### **Ocular Injuries and Visual Changes**

Corneal abrasion caused by drying or by inadvertent eye contact during face mask ventilation or intubation is a common intraoperative eye injury. The incidence of this type of injury in a nonophthalmic patient is estimated to be between 0.034 and 0.17%, with the higher incidence related to prone or lateral positioning.<sup>65</sup> Corneal injury can occur during emergence in the PACU from patients rubbing their eyes, if a rigid oxygen face mask rides up on the eye, or if the eye is rubbed with a pulse oximeter probe and from eye make-up being rubbed in the eyes. Abrasions cause tearing, decreased visual acuity, pain, and photophobia. Fluorescein staining aids diagnosis. Abrasions usually heal spontaneously within 72 hours without scarring, but severe injury can cause cataract formation and impair vision. There is no standard treatment for corneal abrasions, but symptomatic treatment includes artificial tears, topical antibiotics, topical analgesics, and eye closure. Daily follow-up with patients with corneal abrasions should be done to verify healing and rule out other causes. If a patient has not had improvement in 48 hours, consultation with an ophthalmologist should be made.

Visual acuity is often impaired after anesthesia. Autonomic side effects of medications impair accommodation, and residual ocular lubricant clouds vision. Impairment of retinal perfusion by ocular compression generates postoperative visual disturbances ranging from loss of acuity to permanent blindness.<sup>66,67</sup> Ischemic optic atrophy can also occur in the absence of external compression.<sup>68</sup> Risk of blindness is higher after long procedures in the prone position, as well as in patients with vascular disease, pre-existing hypertension, diabetes, and sickle cell anemia. A significant percentage of postoperative patients suffer deficits in acuity unrelated to ocular trauma, some of whom require permanent refractive adjustment.<sup>69</sup> Anesthesiologists should be alert for visual impairment and check acuity when assessing

patients at higher risk for ischemic optic atrophy.

## **Hearing Impairment**

Hearing impairment after anesthesia and surgery is relatively common.<sup>70</sup> Although impairment is often subclinical, patients sometimes experience decreased auditory acuity, tinnitus, or roaring. Incidence of detectable hearing impairment is particularly high after dural puncture for spinal anesthesia (8% to 16%), and varies with needle size, needle type, and patient age. Impairment can be unilateral or bilateral and usually resolves spontaneously. Hearing loss also occurs after general anesthesia for both noncardiac and cardiac surgery, and is often related to disruption of the round window or tympanic membrane rupture. Eustachian tube inflammation and otitis secondary to endotracheal intubation can also impact hearing.

## **Oral, Pharyngeal, and Laryngeal Injuries**

Laryngoscope blades, surgical instruments, rigid oral airways, and dentition can all cause trauma of oral soft tissues. Lip, tongue, or gum abrasions are treated with an ice pack and analgesia. Penetrating injuries caused by tissue entrapment between teeth and rigid devices may require topical antibiotics. After a traumatic tracheal intubation, hematoma or edema might cause partial upper airway obstruction. Nebulized racemic epinephrine often improves stridor more quickly than steroids. Dental damage can occur during airway manipulations or during emergence if a patient bites on a rigid oral airway or forcefully clenches his or her teeth. Document tooth or dental appliance damage, obtain a dental consultation, and observe for signs of foreign body aspiration.<sup>71</sup>

Sore throat and hoarseness after tracheal intubation occur in 20% to 50% of patients, depending on the degree of trauma during laryngoscopy and oropharyngeal suctioning, the duration of intubation, and the type of endotracheal tube. Mucosal irritation also presents as an unquenchable dryness in mouth and throat. The use of local anesthetic ointments to lubricate endotracheal tubes may cause additional mucosal irritation. Topical viscous lidocaine attenuates irritation from nasogastric tubes but may increase risk of aspiration during recovery. In children, the severity of postextubation laryngeal edema or tracheitis varies with age, intubation duration, and degree of trauma or tube movement. Most recover with cool mist therapy, but nebulized racemic epinephrine and dexamethasone may be needed in more severe cases. Laryngoscopy and intubation can also cause hypoglossal, lingual, or recurrent laryngeal nerve damage, vocal cord evulsion, desquamation of laryngeal or tracheal mucosa, edema or ulceration, and tracheal perforation. Postoperative sore throat and dysphagia also occurs without intubation,

related to use of laryngeal mask airways,<sup>72</sup> oral airways, trauma from suctioning, or drying from unhumidified gases. Neck and jaw soreness is commonly seen after face mask anesthetics.

## **Nerve Injuries**

Nerve injuries caused by improper positioning during anesthesia generate serious long-term complications.<sup>73</sup> Spinal cord injury can be caused by positioning for intubation or by hematoma accumulation after placement of neuraxial anesthetics. Peripheral nerve compression during general or regional anesthesia sometimes causes permanent sensory and motor deficits, as do stretch injuries from hyperextension of an extremity.<sup>74</sup> Any bruising or skin breakdown noted postoperatively should prompt evaluation for underlying nerve damage. Many postoperative neuropathies have no identifiable cause, particularly for ulnar neuropathy, which may be related to subtle positioning problems, pre-existing impairment, or sensitivity of the nerve to ischemia.<sup>75</sup> Every complaint of nonsurgical pain, numbness, or weakness from a postoperative patient should be carefully evaluated. In the event of neuropathic weakness, electromyographic studies may determine the location of the lesion and possible reversibility of the nerve deficit. Sensory neuropathies rarely last longer than 5 days and should be referred to a neurologist if the deficit exceeds this time or if it progresses.<sup>76</sup>

Postdural puncture headache may first occur in the PACU, although most appear within 24 to 48 hours. Headache is more frequent after difficult subarachnoid anesthesia with multiple attempts and after dural puncture during attempted epidural placement. Subarachnoid air bubbles from loss-of-resistance testing may contribute. In the PACU, treatment is supportive with hydration, analgesics, and positioning. In severe cases, early intervention with the definitive treatment of epidural blood patch might be considered. Nerve injury secondary to needle contact or intraneuronal injection during placement of regional anesthesia is rare but does occur.<sup>74,77</sup> In one study, 6.3% of 4,767 patients experienced paresthesia during placement of spinal anesthesia, but only 0.126% had persisting symptoms.<sup>78</sup> In the PACU, patients often complain of pain, focal numbness, residual paresthesia, or dysesthesia. Symptoms are usually transient. Administer analgesia, reassure the patient, document findings, and follow for the possibility of an evolving neurologic deficit.

During recovery from spinal anesthesia, some patients exhibit lower extremity discomfort, buttock pain, and other signs of sacral or lumbar neurologic irritation. This problem is more common in obese patients, after procedures in lithotomy position, and after spinal anesthesia with 5% lidocaine.<sup>77</sup> Symptoms are transient and treated supportively. Rarely, a

patient exhibits headache and meningeal signs caused by chemical meningitis after injection of a spinal drug that is contaminated or outside the acceptable pH range.

## **Soft Tissue and Joint Injuries**

If pressure points are improperly padded, soft tissue ischemia and necrosis occur, especially with lateral or prone positioning. Prolonged scalp pressure causes localized alopecia, whereas entrapment of ears, breasts, genitalia, or skin folds causes inflammation or necrosis. Regional ischemia from major arterial compression is rare. Thermal, electrical, or chemical burns from cautery equipment, preparatory solutions, or adhesives also occur. Extravasation of intravenous medications or fluids can cause sloughing, localized chemical neuropathy, or compartment syndromes. Excessive joint or muscle extension leads to postoperative backache, joint pain, stiffness, and even joint instability. After regional anesthesia, extremities must be properly secured and padded to prevent nerve injury.

## ***Skeletal Muscle Pain***

Postoperative muscle pain is caused by many intraoperative factors. Prolonged lack of motion or unusual muscle stretch during positioning often contributes to muscle stiffness and aching. Postoperative myalgia has been reported to range between 5% and 83% of patients after the use of succinylcholine,<sup>79</sup> whereas the pathogenesis of this myalgia remains unclear.<sup>77,80</sup> Acute myalgia also occurs after administration of other relaxants and in patients receiving no relaxant. Delayed-onset muscle fatigue can appear days after surgery and resolves spontaneously.

## ***Hypothermia and Shivering***

Although intraoperative temperature maintenance is a goal, patients still exhibit postoperative hypothermia. During anesthesia, heat is redistributed and also is lost by evaporation during skin preparation, by humidification of dry gases in the airway, and by radiation and convection from the skin and wound. Temperature reduction is accelerated by cold intravenous fluids and low ambient temperatures. The thermoregulatory threshold, below which humans actively regulate body temperature, is decreased during general anesthesia and is less effective under anesthesia. Ability to maintain body temperature is also compromised because paralysis and anesthesia impair shivering and thermoregulatory vasoconstriction, and because nonshivering thermogenesis is ineffective in

adults. Rate of heat loss is similar during general or regional anesthesia, but rewarming is slower after regional anesthesia because residual vasodilation and paralysis impede heat generation and retention. Cachectic, traumatized, or burned patients experience greater temperature reduction, as do infants because of a low ratio of body mass-to-surface area.

Hypothermia complicates and prolongs care in the PACU.<sup>81</sup> Average PACU stay is increased by 40 to 90 minutes for hypothermic patients.<sup>82</sup> **11** Postoperative hypothermia increases sympathetic nervous system activity with increased epinephrine and norepinephrine levels,<sup>83</sup> elevates peripheral vascular resistance, and decreases venous capacitance. Risk of myocardial ischemia<sup>84</sup> and dysrhythmia from mechanical myocardial stimulation is increased. Vasoconstriction interferes with the reliability of pulse oximetry and intra-arterial pressure monitoring. Hypoperfusion jeopardizes marginal tissue grafts and promotes tissue hypoxia and metabolic acidemia. The higher affinity of hemoglobin compromises oxygen unloading to hypothermic tissues. Platelet sequestration, decreased platelet function, and reduced clotting factor function contribute to coagulopathy. Moderate hyperglycemia occurs, cellular immune responses are compromised, and postoperative infection rates increase.<sup>85</sup> A decrease in the minimal alveolar concentration of inhalation anesthetics (5% to 7% per 1°C cooling) accentuates residual sedation. Low perfusion and impaired biotransformation might increase the duration of neuromuscular relaxants and sedatives. Moderate hypothermia (28° to 32°C) is associated with cardiac dysrhythmias. Severe hypothermia ( $\leq 28^\circ\text{C}$ ) interferes with cardiac rhythm generation and impulse conduction. On ECG, the PR, QRS, or QT intervals lengthen, and J waves appear. Spontaneous ventricular fibrillation occurs at temperatures less than 28°C.

During emergence, hypothalamic regulation generates shivering to increase endogenous heat production.<sup>86</sup> Shivering increases the risk of incidental trauma, disrupts medical devices, and interferes with ECG and pulse oximetry monitoring. Oxygen consumption and CO<sub>2</sub> production can increase 200%. Associated increases in minute ventilation and cardiac output might precipitate ventilatory failure in patients with limited reserve or myocardial ischemia in those with coronary artery disease.<sup>84</sup> Shivering is accentuated by tremors related to emergence from inhalation anesthesia. Tremors exhibit clonic and tonic components, and likely reflect decreased cortical influence on spinal cord reflexes.

Restoration of normothermia is an important goal during recovery. Forced-air warming devices are the most efficacious for treating hypothermia. Intravenous fluids and blood should be warmed. For most patients, shivering from mild-to-moderate hypothermia is uncomfortable but self-limited, and needs no treatment other than rewarming and reassurance. Many medications have been recommended to suppress shivering, but meperidine is most

effective in conjunction rewarming.<sup>6</sup> Fentanyl has also been used with patients in whom meperidine is contraindicated. Withholding reversal of relaxants in ventilated, sedated patients attenuates shivering but increases rewarming time. If temperature is near normal ( $>36^{\circ}\text{C}$ ) and shivering is resolved, transfer from PACU to an inpatient floor or a discharge area is acceptable.

The Surgical Care Improvement Project sponsored by CMS, The Joint Commission (TJC), and other national partners is a program that uses several quality measures to help improve the safety and outcomes of surgical patients. One of those measures important to anesthesiologists is maintaining a patient's temperature above  $36^{\circ}\text{C}$ . Although this measure really begins with care in the operating room, the PACU has a 15-minute period from admission to observe a measured patient temperature of at least  $36^{\circ}\text{C}$ . Maintaining adequate temperature has been shown to reduce wound infections in surgical patients, producing better outcomes and reducing length of stay complications.

### **Hyperthermia**

Hyperthermia is relatively uncommon in the PACU. Occasionally, a patient exhibits short-lived hyperthermia from close draping or aggressive intraoperative heat preservation. Postoperative fever sometimes reflects a pre-existing infection (e.g., sinusitis, upper respiratory or urinary tract infection) or an infection exacerbated by the surgical procedure (e.g., resection of infected tonsils or appendix, abscess drainage, urinary tract manipulation). Elevated temperature might indicate a drug or transfusion reaction. Muscarinic blocking agents such as atropine interfere with cooling and might contribute to fever, but they are seldom the cause in adults. Other hypermetabolic states such as thyroid storm must be considered. High fever occurs with malignant hyperthermia, but signs such as tachycardia, muscle rigidity, dysrhythmia, hyperventilation, and acidemia establish the diagnosis first.

Ambient cooling, chest physiotherapy, incentive spirometry, and antipyretics are usually sufficient to treat postoperative fever. One should withhold offending medications or blood products if a drug or transfusion reaction is suspected and notify the physician responsible for extended care to ensure postdischarge evaluation. Therapy for thyroid storm or malignant hyperthermia is well described elsewhere.

### **Persistent Sedation/Delayed Emergence**

Approximately 90% of patients regain consciousness within 15 minutes of

admission to the PACU; unconsciousness persisting for a greater period is considered prolonged. Even a highly susceptible patient should respond to a stimulus within 30 to 45 minutes after a reasonably conducted anesthetic. In a patient with prolonged sedation, one should research the level of preoperative responsiveness to uncover intoxication with drugs and alcohol or pre-existing mental dysfunction. One should note the time and amount of preoperative and intraoperative sedative medications, and review any unusual intraoperative events. The rate and character of spontaneous ventilation helps judge residual opioid effect; opioids are the *only* class of drugs that cause decreased respiratory rate. Physical assessment should include a tactile stimulus such as a light skin pinch, which elicits greater arousal than verbal stimulation, perhaps because sensory input is amplified through the reticular activating system. Diagnostic value of pupillary response is low.

Residual sedation from inhalation anesthetics might cause prolonged unconsciousness in obese patients, especially after long procedures, or when high concentrations are continued through the end of surgery. Prolonged sedation is less likely after anesthesia with low solubility agents such as sevoflurane or desflurane. Premedications that have sedative effects (e.g., diphenhydramine, hydroxyzine, promethazine, droperidol, lorazepam, midazolam, meclizine, and scopolamine) contribute to postoperative somnolence. Sedation from intraoperative opioid or sedative administration is dose-related. Opioids are the only drugs that cause bradypnea; thus, regardless of what other drug effects are present, if the respiratory rate is less than 14 to 16, then opioids are clearly affecting the patient's level of consciousness. To assess sedation from opioids, one can administer low-dose intravenous naloxone (0.04-mg increments every 2 minutes, up to 0.2 mg). With careful titration, respiratory depression and sedation can be reversed without dangerous reversal of analgesia. If unconsciousness is related to residual opioid effects, ventilatory rate and arousal will increase with 0.2 mg or less of intravenous naloxone, unless a patient has received a massive opioid overdose.

Flumazenil (0.2 mg/min intravenously to a total of 1.0 mg), a competitive benzodiazepine antagonist, differentiates sedation from midazolam and diazepam, although duration of action is short. Risk of inducing seizures must be considered in reversing chronic benzodiazepine users. Neither naloxone nor flumazenil should be used as a routine element of postoperative care.<sup>6</sup> Pharmaceutical reversal should be reserved for specific indications in individual patients. Administration of intravenous physostigmine (0.5 to 1 mg) counteracts but does not reverse sedation caused by inhalation anesthetics, other sedatives, and anticholinergics. If administration of naloxone, flumazenil, or physostigmine does not improve the level of consciousness,

unconsciousness is most likely not related to reversible residual anesthetic medications. However, it is still possible that an unrecognized, preoperative overdose with depressant oral drugs (i.e., anticholinergic and antihistamines) is responsible.

The increasing use of dexmedetomidine for sedation cases can lead to persistent sedation in the PACU. These patients are usually easy to arouse and follow commands readily. They tend to have few respiratory issues unless other respiratory depressant medications have also been given. The minimal effect on respiratory drive by dexmedetomidine allows safe discharge from the PACU as long as the destination of the patient is sufficient to care for the level of sedation.

Profound residual neuromuscular paralysis could mimic unconsciousness by precluding any motor response to stimuli. This phenomenon could occur after gross overdosage, if reversal agents are omitted, in patients with unrecognized neuromuscular disease, with phase II blockade from succinylcholine, or its use in a patient with pseudocholinesterase deficiency. Observation of purposeful motion, spontaneous ventilation, or reflex muscular movement eliminates residual paralysis as an explanation. CNS depression secondary to intravenous local anesthetic toxicity or inadvertent subarachnoid injection can mimic postoperative coma. Children who were exhausted before surgery are often difficult to arouse after anesthesia, especially if sleep patterns are disrupted by emergency surgery at night. Hypothermia below 33°C impairs consciousness and increases the depressant effect of medications. Core temperatures below 30°C can cause fixed pupillary dilation, areflexia, and coma. A serum glucose level will eliminate severe hypoglycemia or hyperglycemic hyperosmolar coma as causes. Suspicion that unresponsiveness is caused by hypoglycemia indicates an immediate empiric trial of intravenous 50% dextrose. Hyposmolar states (<260 mOsm/L) such as acute hyponatremia (Na <125 mEq/L) are ruled out by checking serum electrolyte and osmolarity. Arterial blood gas analysis reveals CO<sub>2</sub> narcosis (PaCO<sub>2</sub> >80 to 100 mmHg) as well as carboxyhemoglobin levels for carbon monoxide poisoning. A patient may also be feigning unresponsiveness or having a hysterical reaction that presents as unconsciousness, and is a diagnosis of exclusion.

If a diagnosis remains elusive, consult a neurologist for a thorough neurologic evaluation. Occasionally, unresponsiveness reflects subclinical grand mal seizures secondary to delirium tremens or an underlying seizure disorder. Cerebral anoxia from hypoperfusion or prolonged profound hypoxemia must be considered. In injured patients or those recovering from intracranial surgery, evaluate for unrecognized head trauma, intracerebral hemorrhage, or increased intracranial pressure. Patients sometimes awaken very slowly after long intracranial procedures.<sup>88</sup> Cerebral thromboembolism

is another possibility in patients who have undergone internal jugular or subclavian cannulation. Patients with atrial fibrillation, carotid bruits, or hypercoagulable states are also at increased risk of thromboembolism. Paradoxical air or fat embolism through a right-to-left intracardiac shunt should be considered. After cardiac, proximal major vascular, or invasive neck surgery, risk of postoperative stroke ranges from 2.2% to 5.2%.<sup>89</sup> Postoperative cerebrovascular accidents in other patients are rare, showing a 0.03% to 0.08% incidence in the fourth decade but increasing to 3% to 4% by the eighth decade, and usually become evident after the PACU interval.<sup>90</sup>

### **Altered Mental Status**

Recovering patients sometimes exhibit inappropriate mental reactions, ranging from lethargy and confusion to physical combativeness and extreme disorientation.

### **Emergence Reactions**

Aside from the disturbance to staff and other patients, a stormy emergence reaction has significant medical consequences. The risk of incidental trauma increases, including contusion or fracture, corneal abrasion, and sprains from struggling. Thrashing jeopardizes suture lines, orthopedic fixations, vascular grafts, drains, tracheal tubes, and vascular catheters. Agitated patients manifest high levels of sympathetic nervous system tone, tachycardia, and hypertension. Less appreciated is the risk of injury to staff struggling to protect a combative patient.

For a short period after regaining consciousness, some patients appear unable to appropriately process sensory input. Most exhibit somnolence, slight disorientation, and sluggish mental reactions that rapidly clear. Others experience wide emotional swings such as weeping or escalating resistance to positioning and restraint. Predicting which patients will have adverse psychological reactions is difficult. Emergence delirium, which is prevalent in children and young adults, is difficult to predict preoperatively and does not appear to be related to specific types of anesthesia.<sup>91</sup> In young children, anxiety is heightened by parental separation. Heightened anxiety seems to be the one consistent factor in predicting emergence delirium.<sup>92</sup> Many therapies have been tried to prevent or stop emergence delirium in pediatric patients without much success; however, the use of dexmedetomidine has shown promise in reducing this phenomenon without increasing time to extubate or time to discharge.<sup>93</sup> Ketamine and propofol have also been used with some success.<sup>94</sup> Very young children may react inappropriately to sound when hearing acutely improves after myringotomies. Patients with reduced mental

capacity, psychiatric disorders, organic brain dysfunction, or hostile preoperative interactions manifest those problems after surgery. Inability to speak due to oral fixation or tracheal intubation generates frustration or fear that exaggerates emergence reactions. Ethnic, cultural, and psychological characteristics play some role. A language barrier or a new postoperative hearing impairment accentuates an emergence reaction because input from PACU staff might not be understood. The incidence of stormy emergence is probably higher after procedures with high emotional significance. Recall of intraoperative events can generate severe panic and anxiety during emergence.<sup>95</sup> In patients who are physically dependent on alcohol, opioids, cocaine, or other illicit drugs, intoxication or withdrawal can elicit bizarre emergence behavior. Disorientation, paranoia, and combativeness occur after use of scopolamine as a premedication or antiemetic, which can be treated with intravenous physostigmine. Ketamine can cause dysphoria and hallucination, although acute reactions are rare. Etomidate can be a cause of restlessness.

Pain amplifies agitation, confusion, and aggressive behavior during emergence<sup>96</sup>; therefore, it is helpful to ensure adequate postoperative analgesia early in the PACU course. Urinary urgency or gastric distention from trapped gas generates discomfort and agitation, as do tight dressings, painful phlebotomy, and poor positioning. Endotracheal or nasogastric tubes and urinary catheters are also uncomfortable. Check for unusual pain sources such as corneal abrasion, entrapment of body parts, infiltrated vascular catheters, or small devices left beneath a patient. Nausea, dizziness, and pruritus are distressing during emergence. Some patients struggle to move from a supine into a more comfortable semisitting or lateral position, especially those with gastroesophageal reflux, pulmonary congestion, or obesity. Emerging patients often resist physical restraint. Residual paralysis elicits agitation or uncoordinated motions that make a patient appear disoriented and combative. Observation of weakness or a peculiar flapping nature of voluntary motion helps in the diagnosis. However, patients can appear fully recovered by head lift and train-of-four monitoring but still perceive impaired swallowing, visual acuity, and sense of strength.<sup>97</sup>

Combativeness, confusion, or disorientation might reflect respiratory dysfunction. Moderate hypoxemia often presents with clouded mentation, disorientation, and agitation resembling that caused by pain. Respiratory acidemia elicits profound agitation, although acidemia caused by ventilatory center depression generates less agitation because higher CNS functions are also depressed. Hypercarbia is more likely to cause lethargy or somnolence. Limitation of inspiratory volume by chest dressings, gastric distention, or splinting causes a vague dissatisfaction with lung inflation similar to air hunger. Inability to generate a forceful cough or clear secretions causes

distress. Interstitial pulmonary edema elicits symptoms of air hunger before airway flooding occurs. Agitation can be profound, even with adequate ventilation and oxygenation.

Metabolic abnormalities interfere with lucidity. Lactic acidemia causes anxiety and mild disorientation; acute hyponatremia clouds the sensorium; and hypoglycemia causes first agitation and then diminished responsiveness. Seizure activity might mimic agitation and combativeness. Seizures should be higher in the differential diagnosis in patients with epilepsy, head trauma, and chronic alcohol or cocaine abuse. Cerebral hypoperfusion can produce disorientation, agitation, and combativeness, which can be seen after head trauma or space-occupying lesions. Action such as increasing the mean arterial pressure might be required to assure cerebral perfusion pressure.

There are few interventions that prevent combative emergence reactions.<sup>92</sup> Altered mental status is treated supportively because most emergence reactions often disappear within 10 to 15 minutes. Verbal reassurances that surgery is completed and that the patient is doing well are invaluable. One should use the patient's name frequently with reassurance of well-being, and stress the time and location. When practical, one should allow patients to choose their own position and provide adequate analgesia. In selected cases, parenteral sedation relieves fear or anxiety and smoothes emergence. Identifying whether a patient is reacting to pain or to anxiety is important. Benzodiazepines and barbiturates are ineffective analgesics, whereas opioids are poor anxiolytics. One should not administer sedative or analgesic medications if altered mental status might reflect a physiologic abnormality such as hypoxemia, hypoglycemia, hypotension, or acidemia, and use restraints only if a patient's or staff's safety is jeopardized.

## **Delirium and Cognitive Decline**

**12** A high percentage of elderly patients (5% to 50%) experience some degree of postoperative confusion, delirium, or cognitive decline.<sup>98,99</sup> Patients exhibit fluctuations in level of consciousness and orientation, or deterioration of memory, mental functions, and acquisition of new information. Delirium may be exhibited by two subtypes; hypoactive patients predominate, whereas a smaller percentage is hyperactive. The problem may be related to exacerbation of central cholinergic insufficiency by narcotics, sedatives, or anticholinergics. However, stress of surgery, fever, pain, emesis, sleep deprivation, and loss of routine undoubtedly contribute. Presence of pre-existing dementia, cognitive abnormalities, organic brain syndrome, or hearing and visual impairment predicts postoperative delirium, as does evidence of physical infirmity such as high ASA physical status or lack of stress response to surgery. Cognitive dysfunction also occurs at lower

incidence (15% greater than control) in younger patients, more frequently resolves within 3 months, and may be related to inactivity during recuperation.<sup>100</sup> Although signs often appear on the first to third postoperative day, onset is often evident in the PACU.

Overall, recovery of cognitive function is slower in the elderly.<sup>101</sup> Because older patients are often skilled at concealing declining capabilities, careful assessment of preoperative capabilities helps identify deficits that affect postoperative status. Postoperative lethargy, clouded sensorium, or delirium sometimes reflects an acute physiologic change. Hyperosmolarity from hyperglycemia or hypernatremia as well as hyponatremia can alter consciousness. Cerebral fluid shifts with decreased mentation occur in patients on dialysis and after rapid correction of severe dehydration. Patients receiving atropine premedication or chronic meperidine therapy might exhibit anticholinergic-induced delirium. Disorientation or clouded sensorium can reflect chronic use of psychogenic drugs, premedication with long-acting sedatives, or unrecognized intoxication. Life-threatening conditions such as seizures, hypoxemia, hypoglycemia, hypotension, acidemia, or cerebrovascular accident sometimes present with confusion, disorientation, inability to vocalize, or reduced level of consciousness, especially if earlier signs and symptoms are misinterpreted.

Although there is no anesthetic technique known to be better at avoiding postoperative delirium, there are things to avoid that might reduce its incidence.<sup>102</sup> Avoiding known factors such as benzodiazepines, anticholinergics, and meperidine will reduce a patient's risk.<sup>103</sup> Setting protocols to enhance a safe and efficient recovery begins with the initial planning of surgery. Recovery personnel in the PACU should be aware of and implement these protocols to remain consistent with the continuum of care. Pain management is a major factor for reducing the incidence of delirium. Ensure that patients are properly hydrated, remove catheters that are no longer needed, restore cognitive stimulation by returning eyeglasses and hearing aids, reorientate the patients, and provide frequent human interaction, all of which may aid in limiting or reducing delirium.

### **Postoperative Nausea and Vomiting**

Postoperative nausea and vomiting (PONV) continues to be a significant challenge to be avoided after many types of anesthetics. Not only is PONV considered by many patients the most unpleasant aspect following an anesthetic, but many also describe it as their greatest fear of subsequent anesthetics.<sup>104</sup> Patients are often more concerned about PONV than pain or other risks associated with anesthesia and surgery. In addition to patients' dissatisfaction with nausea and vomiting, there exist medical risks

13

(increased abdominal pressure, increased central venous pressure, aspiration of gastric contents, sympathetic nervous system response with increasing blood pressure and heart rate as well as parasympathetic responses producing bradycardia and hypotension). PONV represents a significant burden to be avoided due to patient satisfaction and safety as well as the economic impact of prolonged PACU stays and unanticipated admissions.

The incidence of PONV varies with many potential causes. Patients often experience nausea and emesis after discharge from the PACU, which may coincide with increased oral intake or waning effect of antiemetics. Surgeries associated with a higher risk of PONV are eye procedures, peritoneal or intestinal irritation, ear–nose–throat procedures, especially with middle ear manipulation, dental, and cosmetic procedures. Patient groups at increased risk are those with a previous history of PONV, a history of motion sickness, menstruating females, children over the age of two, obesity, and nonsmokers.<sup>105</sup> Perioperative factors that may increase the incidence include no PO intake (starvation, dehydration), autonomic imbalance, pain, and the effects of anesthetics on the chemotactic center.

Incidence of PONV is lower following regional rather than general anesthesia especially with decreased use of opioids.<sup>106</sup> The use of nonopioid analgesics may reduce the frequency of emesis while providing adequate pain control. Induction agents such as propofol and barbiturates are associated with reduced incidence compared to etomidate and ketamine. A total intravenous anesthetic (TIVA) technique with propofol greatly reduces PONV incidence compared to a pure inhalation anesthetic. There is little significant difference among inhalation agents, although sevoflurane and desflurane might generate slightly higher rates of nausea. The choice of anticholinergic reversal agents may be a contributing factor to PONV, but it remains unclear to what degree.

Several interventions have been evaluated and can be implemented to reduce the incidence of PONV. The use of meclizine 25 mg preoperatively for patients predisposed to motion sickness can be effective. Prophylaxis with 5-HT<sub>3</sub> receptor antagonists (i.e., ondansetron) prior to emergence significantly reduces incidence and is cost effective. Dexamethasone also has antiemetic effects and can be used effectively with other prophylactic agents. Hydration is effective, easy, and cost effective. The use of droperidol prophylaxis decreased due to a 2001 FDA black box warning with prolonged QT on ECG as well as manufacturing issues beginning in 2013. The FDA letter regarding the use of droperidol did not address the usual prophylaxis dose of 0.625mg, but recommended ECG monitoring for 2 to 3 hours after administration. In September of 2011, the FDA came out with a similar safety announcement regarding prolonged QT with the use of ondansetron. There were no recommendations regarding routine ECG monitoring with the use of

ondansetron but caution and monitoring should be used with those patients with known prolonged QT syndromes.<sup>107</sup> Rescue with nonselective antihistamines (i.e., promethazine) is effective, but caution is advised in patients where increased sedation can be problematic in children and patients with OSA. Acupuncture, acupressure, and TENS therapy can provide relief, but due to provider proficiency, patient acceptance, and proven efficacy compared to antiemetic medications, these methods are less frequently used.<sup>108</sup> More serious causes of nausea and vomiting such as hypotension, hypoxia, hypoglycemia, increased intracranial pressure, or gastric bleeding should be considered prior to treatment.

Epidural Neuraxial Analgesia

Peripheral Nerve Blocks in Children

## Conclusion

## KEY POINTS

- 1 The inadequate relief of postoperative pain has adverse physiologic effects that can contribute to significant morbidity and mortality, resulting in the delay of patient recovery and return to daily activities.
- 2 The pain pathway is not “hardwired” and nociceptive input is not passively transmitted from the periphery to the brain. Tissue injury tends

to fuel neuroplastic changes within the nervous system, which results in both peripheral and central sensitization.

- 3 In order for preventive analgesia to be successful, three critical principles must be adhered to: (1) The depth of analgesia must be adequate enough to block all nociceptive input during surgery, (2) the analgesic technique must be extensive enough to include the entire surgical field, and (3) the duration of analgesia must include both the surgical and postsurgical periods.
- 4 The various opioid analgesics available today have distinct pharmacologic differences that we can credit to their intricate interaction with the classical three main opioid receptors  $\mu$ ,  $\delta$ , and  $\kappa$ . The opioid receptors are members of a G protein-coupled (guanosine triphosphate regulatory proteins) receptor family, which signals via a second messenger such as cyclic adenosine monophosphate or an ion channel.
- 5 Recommendations, which can decrease the risk of opioid-related respiratory depression, include the liberal use of opioid-sparing multimodal pharmacotherapy, regional anesthesia techniques and the continuous monitoring of patient ventilation with pulse oximetry and capnography, particularly in the high-risk individual.
- 6 The therapeutic benefit of nonsteroidal anti-inflammatory drugs is believed to be mediated through the inhibition of cyclooxygenase enzymes, types 1 and 2, which convert arachidonic acid to prostaglandins.
- 7 Short-term use of parecoxib and valdecoxib in patients following coronary artery bypass surgery is associated with an increased risk of thromboembolic events. The authors, therefore, do not recommend prescribing a cyclooxygenase-2 inhibitor for patients with a known history of coronary artery disease or cerebrovascular disease.
- 8 The five variables associated with all modes of patient-controlled analgesia include (1) bolus dose, (2) incremental (demand) dose, (3) lockout interval, (4) background infusion rate, and (5) 1- and 4-hour limits. A typical patient-controlled analgesia regimen in an otherwise healthy adult would be an incremental dose of 1 to 2 mg of morphine with an 8- to 10-minute lockout. The authors do not recommend a background infusion of opioid in the opioid-naive patient.
- 9 *Epidural analgesia* is a critical component of multimodal perioperative pain management and improved patient outcome. Meta-analyses investigating the efficacy of epidural analgesia found epidural analgesia to be superior to systemically administered opioids.
- 10 Continuous peripheral nerve block has proven to be an effective technique for postoperative pain management, which is superior to opioid analgesia with fewer opioid-related side effects and rare

neurologic and infectious complications.

- 11 Should a perioperative nerve injury occur, it is incumbent on the physician to determine which combination of anesthetic, surgical, and patient risk factors are involved in any nerve injury and to not assume a priori that the regional anesthetic is the basis for the injury.
- 12 Ultrasound-guided regional anesthesia hastens the onset time of sensory and motor blockade and can decrease the performance time of a peripheral nerve block.
- 13 Although UGRA has not been shown to decrease the incidence of postoperative neurologic symptoms it is associated with a decreased risk for local anesthetic systemic toxicity and a lower incidence of pneumothorax following the performance of ultrasound-guided supraclavicular blockade.
- 14 The opioid-dependent patient is often identified just moments prior to surgery and the anesthesia team needs to be innovative. The anesthesiologist needs to be flexible enough to tailor an individual anesthetic that incorporates a multimodal approach, combining regional anesthesia with general anesthesia and nonopioid coanalgesics with opioid analgesics. Opioids remain the mainstay of perioperative pain management, and an adequate dose of opioid needs to be maintained to avoid precipitating withdrawal symptoms.
- 15 Perioperative management of the opioid-tolerant patient requires prudent use of both opioid and nonopioid analgesics as well as the application of site-specific regional anesthesia/analgesia.
- 16 The key components to establishing a successful perioperative pain management service begins with an institutional commitment to support the service. The team must be built around a physician leader with training and experience in pain medicine. There must be other anesthesiologists available to support the service.

Approximately 75 million surgical procedures are performed each year in the United States, and more than half are performed in the inpatient setting. Appropriate management of acute perioperative pain using multimodal or balanced analgesia is therefore crucial. In 1992 clinical practice guidelines were promulgated by the Agency for Health Care Policy and Research, which provided guidelines for physicians for the treatment of acute pain.<sup>1</sup> Soon thereafter the American Society of Anesthesiologists developed treatment guidelines for acute postoperative pain,<sup>2</sup> which has been recently updated and amended in a document promulgated by the American society of Pain Medicine, the American Society of Regional Anesthesia (ASRA), and the American Society of Anesthesiologists.<sup>3</sup> Despite significant advances in our knowledge and treatment of acute pain and dissemination of these guidelines,

significant deficits continue to persist and the management of acute postoperative pain is still less than optimal.

**1** The inadequate relief of postoperative pain has adverse physiologic effects that can contribute to significant morbidity and mortality, resulting in the delay of patient recovery and return to daily activities.<sup>4</sup> In addition, poor postoperative pain control contributes to patient dissatisfaction with the surgical experience and may have adverse psychological consequences.<sup>5</sup> Poorly managed postoperative pain can also increase the incidence of persistent postoperative pain conditions. Because aggressive treatment of acute postoperative pain is considered to be so beneficial, the Joint Commission on Accreditation of Healthcare Organizations (JACHO) has declared that “pain is the fifth vital sign” and all institutions seeking accreditation from this group must develop pain management programs.

## Acute Pain Defined

Acute pain has been defined as “the normal, predicted, physiologic response to an adverse chemical, thermal, or mechanical stimulus.”<sup>6</sup> Generally, acute pain resolves within 1 month. However, poorly managed acute pain that might occur following surgery can produce pathophysiologic processes in both the peripheral and central nervous systems that have the potential to produce chronicity.<sup>5</sup> Acute pain-induced change in the central nervous system is known as *neuronal plasticity*. This can cause sensitization of the nervous system, resulting in allodynia and hyperalgesia. Surgical procedures that can be associated with chronic painful conditions include amputation of a limb, lateral thoracotomy, inguinal herniorrhaphy, abdominal hysterectomy, saphenous vein stripping, open cholecystectomy, nephrectomy, and mastectomy.<sup>5</sup>

## Anatomy of Acute Pain

**1** The nociceptive pathway is an afferent (Fig. 55-1) three-neuron dual ascending (e.g., anterolateral and dorsal column medial lemniscal pathways) system, with descending modulation (Fig. 55-2) from the cortex, thalamus, and brainstem.<sup>7</sup> Nociceptors are free nerve endings located in skin, muscle, bone, and connective tissue with cell bodies located in the dorsal root ganglia. The first-order neurons that make up the dual ascending system have their origins in the periphery as A- $\delta$  and polymodal C fibers (Table 55-1). A- $\delta$  fibers transmit “first pain,” which is described as sharp or stinging in nature and is well localized. Polymodal C fibers transmit “second pain,” which is more diffuse in nature and is associated with the affective and motivational aspects of pain. First-order neurons synapse on second-order neurons in the

dorsal horn primarily within laminae I, II, and V, where they release excitatory amino acids and neuropeptides (Figs. 55-3 and 55-4). Some fibers can ascend or descend in Lissauer tract prior to terminating on neurons that project to higher centers. Second-order neurons consist of nociceptive-specific and wide dynamic-range (WDR) neurons. Nociceptive-specific neurons are located primarily in lamina I, respond only to noxious stimuli, and are thought to be involved in the sensory-discriminative aspects of pain. WDR neurons are predominately located in laminae IV, V, and VI, respond to both nonnoxious and noxious input, and are involved with the affective-motivational component of pain. Axons of both nociceptive-specific and WDR neurons ascend the spinal cord via the dorsal column-medial lemniscus and the anterior lateral spinothalamic tract to synapse on third-order neurons in the contralateral thalamus, which then project to the somatosensory cortex, where nociceptive input is perceived as pain (Fig. 55-1).

## Pain Processing

A key development in our understanding of pain processing is that the pain pathway is not “hardwired” and nociceptive input is not passively transmitted from the periphery to the brain.<sup>8</sup> Tissue injury tends to fuel neuroplastic changes within the nervous system, which results in both peripheral and central sensitization. Clinically this can manifest as *hyperalgesia*, which is defined as an exaggerated pain response to a normally painful stimulus, and *allodynia*, which is defined as a painful response to a typically nonpainful stimulus (Fig. 55-5).<sup>8</sup>

The four elements of pain processing include (1) transduction, (2) transmission, (3) modulation, and (4) perception (Fig. 55-6). *Transduction* is the event whereby noxious thermal, chemical, or mechanical stimuli are converted into an action potential. *Transmission* occurs when the action potential is conducted through the nervous system via the first-, second-, and third-order neurons, which have cell bodies located in the dorsal root ganglion, dorsal horn, and thalamus, respectively. *Modulation* of pain transmission involves altering afferent neural transmission along the pain pathway. The dorsal horn of the spinal cord is the most common site for modulation of the pain pathway, and modulation can involve either *inhibition* or *augmentation* of the pain signals.<sup>7</sup> Examples of *inhibitory* spinal modulation include (1) release of inhibitory neurotransmitters such as  $\gamma$ -amino butyric acid (GABA) and glycine by intrinsic spinal neurons, and (2) activation of descending efferent neuronal pathways from the motor cortex, hypothalamus, periaqueductal gray matter, and the nucleus raphe magnus, which results in the release of norepinephrine, serotonin, and endorphins in the dorsal horn. Spinal modulation, which results in *augmentation* of pain pathways, is

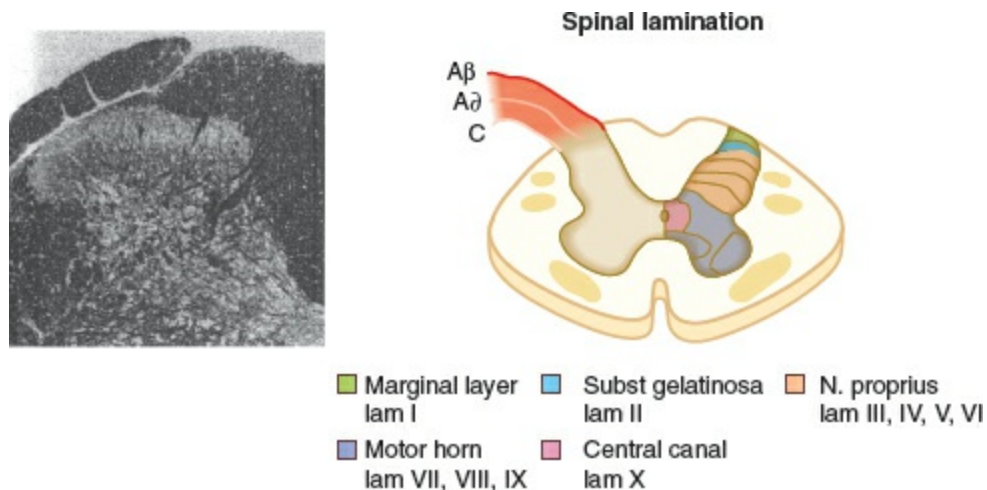

manifested as central sensitization, which is a consequence of neuronal plasticity. The phenomenon of “wind-up” is a specific example of central plasticity that results from repetitive C-fiber stimulation of WDR neurons in the dorsal horn. *Perception* of pain is the final common pathway, which results from the integration of painful input into the somatosensory and limbic cortices. Generally speaking, traditional analgesic therapies have only targeted pain *perception*. A *multimodal approach* to pain therapy should target all four elements of the pain processing pathway.

**Figure 55-1** Afferent nociceptive pathway.

**Figure 55-2** Efferent pathways involved in nociceptive regulation.

**Figure 55-3** Schematic on the right showing the Rexed lamination and the approximate organization of the approach of the afferent to the spinal cord as they enter at the dorsal root entry zone and then penetrate into the dorsal horn to terminate in laminae I and II (A/C) or penetrate more deeply to loop upward to terminate as high as the dorsum of lamina III (A $\beta$ ). Inset on the left shows histologic appearance of the left dorsal quadrant, and large, myelinated axons. (Reprinted with permission from Warfield CA, Bajwa ZH, eds. *Principles and Practice of Pain Medicine*. 2nd ed. New York, NY: McGraw-Hill; 2004.)

**Figure 55-4** Schematic summarizing the organization of dorsal horn systems that contribute to the processing of nociceptive information. (1) Primary afferent C fibers release peptide (e.g., substance P [sP], calcitonin gene-related peptide [CGRP], and so on) and excitatory amino acid (glutamate) products. Small dorsal root ganglion (DRG) cells, as well as some postsynaptic elements contain nitric oxide synthase (NOS) and are able, upon depolarization, to release NO (nitric oxide). (2) Peptides and excitatory amino acids evoke excitation in second-order neurons. For glutamate, direct monosynaptic excitation is mediated by non-*N*-methyl-*D*-aspartate (NMDA) receptors (i.e., acute primary afferent excitation of WDR neurons is not mediated by the NMDA or neurokinin 1 [NK-1] receptor). (3) Interneurons excited by afferent barrage induce excitation in second-order neurons via an NMDA receptor. This leads to a marked increase in intracellular  $\text{Ca}^{2+}$  and the activation of kinases and phosphorylating enzymes. Prostaglandins (PGs) generated by cyclooxygenase-2 (COX-2) and NO by NOS are formed and released. These agents diffuse extracellularly and facilitate transmitter release (retrograde transmission) from primary and nonprimary afferent terminals, either by a direct cellular action (e.g., NO) or by an interaction with a specific class of receptors (e.g., EP receptors for prostanoids). (4) Nonneuronal sources of prostaglandins may include activated astrocytes and microglia that are stimulated by circulating cytokines, which are released secondary to peripheral nerve injury and inflammation. Terminal excitability can be altered by activation of a variety of receptors located on the sensory terminal, including those for,  $\mu$ ,  $\delta$ , and  $\kappa$  opioids. (Adapted with permission from Warfield CA, Bajwa ZH, eds. *Principles and Practice of Pain Medicine*. 2nd ed. New York, NY: McGraw-Hill; 2004.)

## Chemical Mediators of Transduction and Transmission

Tissue damage following surgical procedures leads to the activation of small nociceptive nerve endings and local inflammatory cells (e.g., macrophages, mast cells, lymphocytes, and platelets) in the periphery. Antidromic release of substance P and glutamate from small nociceptive afferents results in vasodilation, extravasation of plasma proteins, and stimulation of inflammatory cells to release numerous algogenic substances (Table 55-2 and Fig. 55-7). This chemical milieu will both directly produce pain transduction via nociceptor stimulation as well as facilitate pain transduction by increasing the excitability of nociceptors. *Peripheral sensitization* of polymodal C fibers and high-threshold mechanoreceptors by these chemicals leads to *primary hyperalgesia*, which by definition is an exaggerated response to pain at the site of injury.

**Table 55-1** Primary Afferent Nerves

Fiber Class <sup>a</sup>	Velocity	Effective Stimuli
Aβ (myelinated) (12–20 μ dia)	Group II (>40–50 m/s)	Low-threshold mechanoreceptors Specialized nerve endings (Pacini corpuscles)
Aδ (myelinated) (1–4 μ dia)	Group III (10 < x< 40 m/s)	Low-threshold mechanical or thermal High-threshold mechanical or thermal Specialized nerve endings
C (unmyelinated) (0.5–1.5 μ dia)	Group IV (<2 m/s)	High-threshold thermal, mechanical, and chemical Free nerve endings

<sup>a</sup>Aβ/Aδ/C is the Erlanger–Gasser classification and refers to axon size; I/II/III/IV is the Lloyd–Hunt classification and is defined on conduction velocity in muscle afferents. Because of the relationship between size and state of myelination with conduction velocity, these designations are often used interchangeably.

Reprinted with permission from Warfield CA, Bajwa ZH, eds. *Principles and Practice of Pain Medicine*. 2nd ed. New York, NY: McGraw-Hill; 2004:14.

As is the case in the periphery, the dorsal horn of the spinal cord contains numerous transmitters and receptors involved in pain processing. Three classes of transmitter compounds integral to pain transmission include (1) the excitatory amino acids glutamate and aspartate, (2) the excitatory neuropeptides substance P and neurokinin A, and (3) the inhibitory amino acids glycine and GABA. The various pain receptors include (1) the *N*-methyl-D-aspartate (NMDA), (2) the  $\alpha$ -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), (3) the kainate receptor, and (4) the metabotropic receptor (Fig. 55-8).

**Figure 55-5** Pain sensitization. (From Dave Klemm, <http://www.georgetown.edu/dml/facs/graphics/index.htm>.)

**Figure 55-6** The four elements of pain processing: transduction, transmission, modulation, and perception. 5HT, serotonin; NE, norepinephrine; NMDA, *N*-methyl-D-aspartate; NSAIDs, nonsteroidal anti-inflammatory drugs; CCK, cholecystokinin; NO, nitric oxide.

The AMPA and kainate receptors, which are sodium channel dependent, are essential for fast synaptic afferent input. On the other hand, the NMDA receptor, which is calcium channel dependent, is only activated following prolonged depolarization of the cell membrane. Release of substance P into the spinal cord will remove the magnesium block on the channel of the NMDA receptor, giving glutamate free access to the NMDA receptor. Repetitive C-fiber stimulation of WDR neurons in the dorsal horn at intervals of 0.5 to 1 Hz can precipitate the occurrence of windup and *central sensitization* (Fig. 55-

9). This leads to *secondary hyperalgesia*, which, by definition, is an increased pain response evoked by stimuli outside the area of injury.

**Figure 55-7** Schematic of the neurochemistry of somatosensory processing at peripheral sensory nerve endings. (Adapted with permission from Benzon HT, Raja SN, Molloy RE, et al., eds. *Essentials of Pain Medicine and Regional Anesthesia*. 2nd ed. Philadelphia, PA: Elsevier; 2005:8.)

## The Surgical Stress Response

Although similar, postoperative pain and the surgical stress response are not the same. Surgical stress causes release of cytokines (e.g., interleukin-1, interleukin-6, and tumor necrosis factor- $\alpha$ ) and precipitates adverse neuroendocrine and sympathoadrenal responses, resulting in detrimental physiologic responses, particularly in high-risk patients.<sup>5</sup>

The increased secretion of the catabolic hormones such as cortisol, glucagon, growth hormone, and catecholamines and the decreased secretion of the anabolic hormones such as insulin and testosterone characterize the neuroendocrine response. The end result of this is hyperglycemia and a negative nitrogen balance, the consequences of which include poor wound healing, muscle wasting, fatigue, and impaired immunocompetency.

**Table 55-2** Algogenic Substances

Substance	Source	Effect
Bradykinin	Macrophages and plasma kininogen	Activates nociceptors
Serotonin	Platelets	Activates nociceptors
Histamine	Platelets and mast cells	Produces vasodilation, edema, and pruritus Potentiates the response of nociceptors to bradykinin
Prostaglandin	Tissue injury and cyclooxygenase pathway	Sensitizes nociceptors
Leukotriene	Tissue injury and lipoxygenase pathway	Sensitizes nociceptors
Excess H <sup>+</sup> ions	Tissue injury and ischemia	Increases pain and hyperalgesia associated with inflammation
Cytokines (e.g., interleukins and tissue necrosis factor)	Macrophages	Excites and sensitizes nociceptors
Adenosine	Tissue injury	Pain and hyperalgesia
Neurotransmitters (e.g., glutamate and substance P)	Antidromic release by peripheral nerve terminals following tissue injury	Substance P activates macrophages and mast cells Glutamate activates nociceptors
Nerve growth factor	Macrophages	Stimulates mast cells to release histamine and serotonin Induces heat hyperalgesia Sensitizes nociceptors

Data from Dougherty PM, Raja SN. Neurochemistry of somatosensory and pain processing. In: Benzon HT, Raja SN, Molloy RE, et al., eds. *Essentials of Pain Medicine and Regional Anesthesia*. Philadelphia, PA: Elsevier; 2005:7.

**Figure 55-8** Schematic representation of peripheral and spinal mechanism involved in neuroplasticity. Primary hyperalgesia results from tissue release of toxic substances. These toxic substances spread to adjacent tissues, prolonging the hyperalgesic state (secondary hyperalgesia). As C fiber terminals increase in frequency of release of neurotransmitters, such as glutamate, substance P, tachykinins, brain-derived neurotrophic factor, and calcitonin gene-related peptide, the effects of these

neurotransmitters are summated, resulting in prolonged depolarizations of second-order neurons (wind-up). Function changes at the second-order neuron occur as a result of neurotransmitter binding to postsynaptic receptors, which results in activity-dependent plasticity of the spinal cord. AMPA,  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; NK, neurokinin; NMDA, *N*-methyl-D-aspartate.

**Figure 55-9** Primary nociceptive transmission in the spinal cord. Primary afferent nociceptive input is transmitted via  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), neurokinin-1 (NK1), and calcitonin gene-related peptide (CGRP) synapses, whose signals work their way to the thalamus. Glutamatergic (*N*-methyl-D-aspartate [NMDA]) synapses do not participate significantly in primary nociceptive transmission, but instead play a crucial role in spinal sensitization. Accordingly, even after complete NMDA blockade in the spinal cord, primary afferent nociceptive information is transmitted to the thalamus. NMDA antagonists thus have an antihyperalgesic rather than an analgesic effect in the spinal cord. Glu, glutamate; SP, substance P. (Adapted with permission from the International Association for the Study of Pain. *Pain control updates. IASP Newlett.* 2005;13[2]:3.)

The sympathoadrenal response has detrimental effects on numerous organ systems; these are listed in [Table 55-3](#).<sup>9</sup>

**Table 55-3** Consequences of Poorly Managed Acute Pain<sup>5,9</sup>

Cardiovascular	Tachycardia, hypertension, and increase in cardiac work load
Pulmonary	Respiratory muscle spasm (splinting), decrease in vital capacity, atelectasis, hypoxia, and increased risk of pulmonary infection
Gastrointestinal	Postoperative ileus
Renal	Increased risk of oliguria and urinary retention
Coagulation	Increased risk of thromboemboli
Immunologic	Impaired immune function
Muscular	Muscle weakness and fatigue. Limited mobility can increase the risk of thromboembolism
Psychological	Anxiety, fear, and frustration results in poor patient satisfaction

## Preventive Analgesia

Preventive analgesia includes any antinociceptive regimen delivered at any time during the perioperative period that will attenuate pain-induced sensitization. The term “preventive analgesia” replaces the older terminology “preemptive analgesia,” which is defined as an analgesic regimen that is administered prior to surgical incision and is more effective at pain relief than the same regimen administered after surgery. Although use of the term preemptive analgesia has been popular in the past, evidence of its clinical benefit in humans has been mixed and the term should be considered obsolete.<sup>10</sup> The goal of preventive analgesia is to block the development of sustained pain. Theoretically, this occurs by preventing NMDA receptor activation in the dorsal horn that is associated with windup, facilitation, central sensitization expansion of receptive fields, and long-term potentiation, all of which can lead to a chronic pain state.<sup>8</sup> In order for preventive analgesia to be successful, three critical principles must be adhered to: **3** (1) The depth of analgesia must be adequate enough to block all nociceptive input during surgery, (2) the analgesic technique must be extensive enough to include the entire surgical field, and (3) the duration of analgesia must include both the surgical and postsurgical periods. Patients with pre-existing chronic pain may not respond as well to these techniques because of pre-existing sensitization of the nervous system.<sup>10</sup>

## Strategies for Acute Pain Management

The majority of postoperative pain is nociceptive in character, but there are a small percentage of patients who can experience neuropathic pain postoperatively. It is critical to recognize this fact because patients with

neuropathic pain are at increased risk of progressing to a chronic pain state. Neuropathic pain is a result of accidental nerve injury secondary to cutting, traction compression, or entrapment.<sup>5</sup> Clinical features may include continuous burning, paroxysmal shooting, or electric pain with associated allodynia, hyperalgesia, and dysesthesias. There can be a delay in the onset of the pain, and it can follow a nondermatomal distribution. Surgical procedures that are a relatively high risk for neuropathic pain include limb amputations, breast surgery, gallbladder surgery, thoracic surgery, and inguinal hernia repair.<sup>5</sup> Nociceptive pain responds best to opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), para-aminophenol agents, and regional anesthesia techniques.<sup>11</sup> Neuropathic pain, on the other hand, may benefit from the addition of the nonopioid analgesic adjuvants such as the NMDA receptor antagonists,  $\alpha_2$ -agonists, and the  $\alpha_2$ - $\delta$  subunit calcium channel ligands, which will be discussed in detail. The recommended components for multimodal perioperative pain management of routinely performed surgical procedures are listed in [Table 55-4](#).

Strategies for acute pain management should also consider the sex of the patient as sex differences appear to exist for pain perception as well as response to opioid analgesics. Evidence suggests that women experience more pain following surgery than men, and therefore require more morphine to achieve a similar level of pain relief.<sup>12</sup>

Finally, as knowledge of the human genome and understanding of the neurobiology of nociception evolve, we will be able to tailor pain management to the individual patient based on genetic variation. This strategy, known as pharmacogenetics, takes advantage of polymorphic genes, which can impact the pharmacokinetics of a drug by altering drug-metabolizing enzymes, drug transport proteins, and drug receptors. The net effect will determine both the efficacy and side effects of individual drugs in each patient based on their personal genetic profile.

**Table 55-4** Options for Components of Multimodal Therapy for Commonly Performed Surgeries

Type of Surgery	Systemic Pharmacologic Therapy	Local, Intra-articular, or Topical Techniques*	Regional Anesthetic Techniques*	Neuraxial Anesthetic Techniques*	Nonpharmacologic Therapies
Thoracotomy	Opioids <sup>a</sup> NSAIDs <sup>b</sup> and/or acetaminophen Gabapentin or pregabalin <sup>b</sup> IV ketamine <sup>c</sup>		Paravertebral block	Epidural with local anesthetic (with or without opioid), or intrathecal opioid	Cognitive modalities TENS
Open laparotomy	Opioids <sup>a</sup> NSAIDs <sup>b</sup> and/or acetaminophen Gabapentin or pregabalin <sup>b</sup> IV ketamine IV lidocaine	Local anesthetic at incision IV lidocaine infusion	Transversus abdominis plane block	Epidural with local anesthetic (with or without opioid), or intrathecal opioid	Cognitive modalities TENS
Total hip replacement	Opioids <sup>a</sup> NSAIDs <sup>b</sup> and/or acetaminophen Gabapentin or pregabalin <sup>b</sup> IV ketamine <sup>c</sup>	Intra-articular local anesthetic and/or opioid	Site-specific regional anesthetic technique with local anesthetic	Epidural with local anesthetic (with or without opioid), or intrathecal opioid	Cognitive modalities TENS
Total knee replacement	Opioids <sup>a</sup> NSAIDs <sup>b</sup> and/or acetaminophen Gabapentin or pregabalin <sup>b</sup> IV ketamine <sup>c</sup>	Intra-articular local anesthetic and/or opioid	Site-specific regional anesthetic technique with local anesthetic	Epidural with local anesthetic (with or without opioid), or intrathecal opioid	Cognitive modalities TENS
Spinal fusion	Opioids <sup>a</sup> Acetaminophen <sup>d</sup> Gabapentin or pregabalin <sup>b</sup> IV ketamine <sup>c</sup>	Local anesthetic at incision		Epidural with local anesthetic (with or without opioid), or intrathecal opioid	Cognitive modalities TENS
Cesarean section	Opioids <sup>a</sup> NSAIDs <sup>b</sup> and/or acetaminophen	Local anesthetic at incision	Transversus abdominal plane block	Epidural with local anesthetic (with or without opioid), or intrathecal opioid	Cognitive modalities TENS
Coronary artery bypass grafting	Opioids <sup>a</sup> Acetaminophen Gabapentin or pregabalin <sup>b</sup> IV ketamine <sup>c</sup>				Cognitive modalities TENS

Blank cells indicate techniques generally not used for the procedure in question.

\*Intra-articular, peripheral regional, and neuraxial techniques typically not used together.

<sup>a</sup>Use IV PCA when parenteral route needed for more than a few hours and patients have adequate cognitive function to understand the device and safety limitations.

<sup>b</sup>May be administered preoperatively.

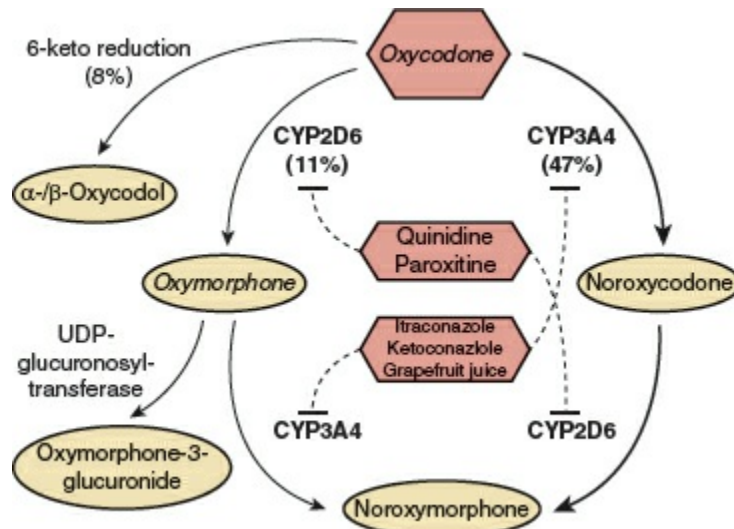

<sup>c</sup>On the basis of panel consensus, primarily consider for use in opioid-tolerant or otherwise complex patients.

<sup>d</sup>Use as adjunctive treatments.

NSAIDs, nonsteroidal anti-inflammatory drugs; TENS, transcutaneous electrical nerve stimulation. Reprinted with permission from Chou R, Gordon DB, de Leon-Casasola OA, et al. Management of postoperative pain: a clinical practice guideline from the American Pain Society, the American Society of Regional Anesthesia and Pain Medicine, and the American Society of Anesthesiologists' Committee on Regional Anesthesia, Executive Committee, and Administrative Council. *J Pain*. 2016;17(2):131–157.

There are numerous examples of CYP (cytochrome P450) and UGT (Uridine 5'-diphospho-glucuronosyltransferase) genes that are polymorphic and will result in various responses to opioid analgesics. *Hydrocodone* is the most widely prescribed opioid analgesic in the United States. It has weak affinity for the  $\mu$  receptor; however, demethylation by the CYP2D6 enzyme converts hydrocodone into hydromorphone, which has stronger  $\mu$  receptor

binding. Patients with the extensive metabolizer (EM) phenotype report better opioid effects and fewer adverse opioid effects than the patients with the poor metabolizer (PM) phenotype. Point-of-care phenotype-based dosing strategies would preclude prescribing hydrocodone to patients with the poor metabolizer phenotype.

**Figure 55-10** Oxycodone metabolism. (Adapted with permission from Landau R, Bollag LA, Kraft JC. Pharmacogenetics and anaesthesia: the value of genetic profiling. *Anaesthesia*. 2012;67(2):165–79.)

*Oxycodone* (Oxycontin, Percocet) is another commonly prescribed semisynthetic opioid analgesic that is used for the treatment of both acute and chronic pain. The drug is predominantly metabolized by CYP3A4 to inactive metabolites; however, approximately 11% of an oxycodone dose is cleared by CYP2D6 (Fig. 55-10) to produce the minor metabolite oxymorphone, which is reported to be eight times as potent as the parent drug. It is theoretically possible that toxicity or overdose could occur in CYP2D6 ultrarapid metabolizers or in patients who are concomitantly taking a CYP3A4 inhibitor (e.g., diltiazem, verapamil).

Both *codeine* and *tramadol* are examples of prodrugs that require metabolism by the CYP2D6 enzyme to an active intermediate that has analgesic effects. Whereas slow metabolizers of codeine display poor analgesia from the drug, rapid metabolizers can experience toxicity from the active metabolite, morphine (Fig. 55-11). Like codeine, tramadol is also a prodrug that requires CYP2D6 to be converted into the active metabolite O-desmethyltramadol. Poor metabolizers display incomplete analgesia. The frequency of poor metabolizers varies by ethnicity and is reported to be 8% in whites, 2% to 7% in African Americans and 0% to 0.5% in Asian populations. *Methadone* is also subject to genetic polymorphism secondary to modifications by genetic variations in CYP2D6, the OPRM1  $\mu$  opioid receptor, and the ABCB1 drug transport protein. Methadone fatalities are associated with the

slow metabolizer phenotype.

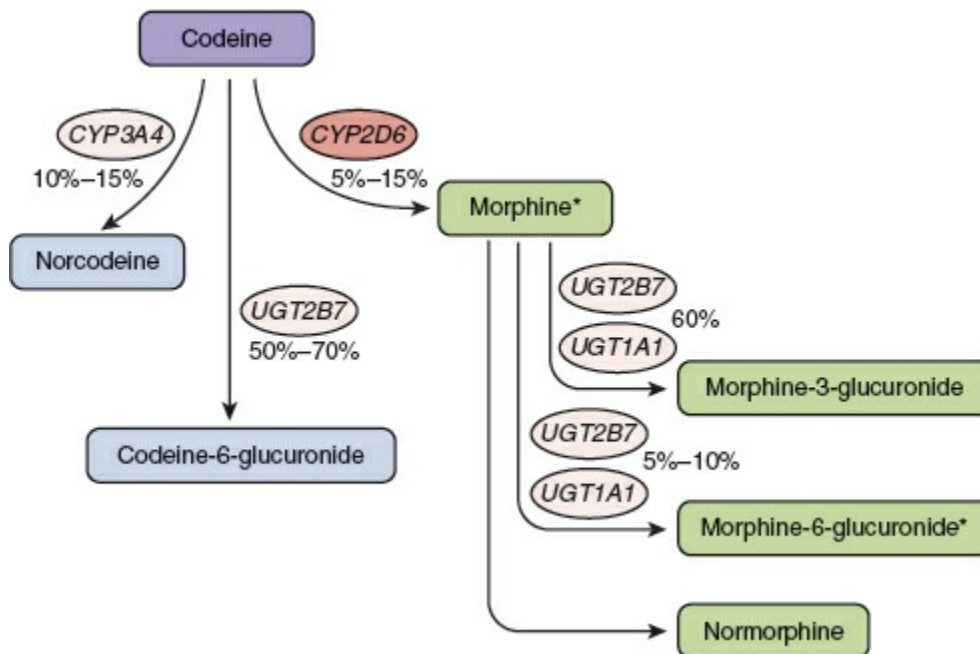

Finally, genetic variants of the CYP2C9 enzyme and the melanocortin-1 receptor gene (*MC1R*) display poor metabolism of *celecoxib* and reduced effects of subcutaneous *lidocaine*, respectively. Future strategies will likely incorporate pharmacogenetic approaches to design individualized gene-based pain therapy for each patient, to optimize pain control and minimize adverse effects.<sup>13,14</sup>

## Assessment of Acute Pain

The need for assessment of the patient in pain is illustrated by the postoperative patient who is said to be relatively pain-free, but who, on inspection, is lying almost completely still in bed. Too often, such a patient has had a recent cursory evaluation that included the traditional verbal analogue score (VAS) 0 to 10 scale (“on a scale of 0 to 10, with 0 being no pain and 10 being the worst pain you can imagine, how much pain are you in” from which the patient reported a low VAS score of 1/10) (Fig. 55-12). The treating team took that to be reassuring information and moved along. No one asked the patient about pain with movement, breathing, moving bowels, and so forth, all potentially important functional goals for the postoperative course that may be undermined by untreated pain.

A variety of well-studied pain measurement scales exist that can be helpful yet are not definitive. Unidimensional instruments such as the familiar numerical pain scale already mentioned, the visual analogue scale, and the “faces” (Fig. 55-12) pain rating scale can provide some degree of guidance about a patient’s experience of pain, but all of these are completely subjective and are open to wide variation between subjects and within subjects at different times.

**Figure 55-11** Codeine metabolism pathway in an individual with cytochrome P450 2D6 (CYP2D6) extensive metabolism. Asterisks denote active metabolites. (Adapted with permission from Crews KR, Gaedigk A, Dunnenberger HM, et al. Clinical Pharmacogenetics Implementation Consortium guidelines for cytochrome P450 2D6 genotype and codeine therapy: 2014 update. *Clin Pharmacol Ther.* 2014;95(4):376–382.)

Universal Pain Assessment Tool											
This pain assessment tool is intended to help patient care providers assess pain according to individual patient needs. Explain and use 0–10 scale for patient self-assessment. Use the faces or behavioral observations to interpret expressed pain when patient cannot communicate his/her pain intensity.											
	0	1	2	3	4	5	6	7	8	9	10
Verbal descriptor scale	No pain		Mild pain		Moderate pain		Moderate pain		Severe pain		Worst pain possible

Japanese	痛みがない	少し痛い	いくらか痛い	かなり痛い	ひどく痛い	ものすごく痛い					

**Figure 55-12** Linear verbal analogue score and “faces” pain assessment tool.

Multidimensional instruments, such as the McGill Pain Questionnaire or the Brief Pain Inventory, provide a broader picture of a patient’s experience, but are usually more cumbersome to administer and, in the end, suffer the same limitations as all other attempts to measure pain. A number of tools to assess cancer-related and noncancer chronic pain have been advanced and validated.<sup>15</sup> Most of these focus on persistent background pain and do not help identify intermittent or breakthrough pain. Several assessment scales specifically address breakthrough or episodic pain. The Breakthrough Pain Questionnaire was introduced by Portenoy and Hagen to assess breakthrough pain in cancer patients, and has also been studied in patients with acute noncancer pain, for which it can offer a picture of both breakthrough and background pain states.<sup>16</sup>

Ultimately, we are left with a maxim first attributed to Dr. John Bonica, the father of pain medicine: “Pain is what a patient says it is.” The best way to begin assessing a patient’s pain is to *ask* about it and *listen* to the answers. Attempts to reduce the experience to finite details may lead to failure to ask the right questions, distance us from our patients, focus us away from the whole person, and potentially miss golden diagnostic clues that could lead to effective interventions.

Effective treatment of acute pain requires assessment as well as vigilant reassessment to determine if the primary goals are met, adversity has occurred, or changes are necessary. Acute pain may be viewed as breakthrough, intermittent, or background in nature (Table 55-5). The assessment process for each of these is relatively similar and will help to resolve the related condition into broad pathophysiologic groups such as cancer versus noncancer, and nociceptive versus neuropathic, or mixed pain states. Such an approach supports a rational process for developing a useful differential diagnosis and approaches. Table 55-6 lists the common features of pain that are usually reviewed during the assessment for acute pain. A thorough physical examination must also be performed with particular attention to the neurologic examination, which may offer clues to aberrant neural processing. Such neurologic findings may indicate nerve injury, alerting the astute clinician to a neuropathic rather than a nociceptive pain state that requires a different analgesic approach.<sup>17</sup> A provocative physical examination may include examination of the affected areas with maneuvers that may provoke pain such as range of motion testing, walking, and cough. The benefits of provocative testing must outweigh the associated suffering incurred by the patient. Medical imaging is also a common part of the acute pain workup. Overemphasis on imaging data should, however, be avoided as this can potentially lead to misinterpretation of the patient’s underlying pain

syndrome.

**Table 55-5** Three Classes of Acute Pain

Class	Description
Breakthrough	Pain that escalates above a persistent background pain
Transitory and intermittent	Pain that is episodic in the absence of background pain
Background	Pain that is persistent but may vary over time

**Table 55-6** Features of Pain Commonly Addressed during Assessment

Onset of pain
Temporal pattern of pain
Site of pain
Radiation of pain
Quality (character) of pain
Intensity (severity) of pain
Exacerbating factors (what makes the pain start or get worse?)
Relieving factors (what prevents the pain or makes it better?)
Response to analgesics (including attitudes and concerns about opioids)
Response to other interventions
Associated physical symptoms
Associated psychological symptoms
Interference with activities of daily living

## Opioid Analgesics

Opioids are the mainstay for the treatment of acute postoperative pain, and **4** morphine is the “gold standard.” The various opioid analgesics available today have distinct pharmacologic differences that we can credit to their intricate interaction with the main opioid receptors:  $\mu$ ,  $\delta$ ,  $\kappa$ , and opioid  receptor-like 1 (ORL1). The opioid receptors are members of a G protein–coupled (guanosine triphosphate regulatory proteins) receptor  family, which signals via a second messenger such as cyclic adenosine monophosphate or an ion channel. In the ascending pain pathway, opioid receptors are located in three areas that include (1) the periphery, following inflammation; (2) the spinal cord dorsal horn; and (3) supraspinally in the brainstem, thalamus, and cortex.  $\mu$  Opioid receptors are also found in the periaqueductal grey, the nucleus raphe magnus, and the rostral ventral medulla, which constitutes the descending inhibitory pain pathway. The three primary mechanisms of action for opioid analgesia at the level of the spinal cord include (1) inhibition of calcium influx presynaptically, resulting in inhibition of depolarization of the cell membrane and decreased release of neurotransmitters and neuropeptides into the synaptic cleft; (2) enhanced

potassium efflux from the cell postsynaptically, resulting in hyperpolarization of the cell and a decrease in pain transmission, and (3) activation of a descending inhibitory pain circuit via inhibition of GABAergic transmission in the brainstem. Peripheral opioid receptors, which mediate analgesia, are located on primary afferent neurons. Activation of these receptors inhibits the release of pronociceptive and proinflammatory substances like substance P, which accounts for the analgesic and anti-inflammatory effects. The “broad-spectrum” opioid, methadone, has NMDA receptor antagonist properties and inhibits the reuptake of serotonin and norepinephrine, which may make it useful in the treatment of neuropathic pain.

There is great diversity in the available routes of administration of opioid analgesics. [Table 55-7](#) is a list of relevant pharmacokinetic data. [Table 55-8](#) offers equianalgesic dosing guidelines for the various opioids. The reader is referred to Perioperative Pain Management of the Opioid-Dependent Patient for a detailed discussion of incomplete cross-tolerance between the different opioids and dosing considerations.

Common adverse side effects associated with opioid therapy include nausea, vomiting, constipation, urinary retention, delirium, hallucinations, myoclonus, falls, hypotension, aspiration pneumonia, dizziness, sedation, and respiratory depression. Opioid-related adverse effects have the potential to increase the utilization of health-care resources, which can have profound economic consequences. In a recent retrospective review of 402 patients undergoing orthopedic surgery, the authors concluded that constipation, emesis, and confusion were associated with significant increase in postoperative hospital length of stay (p-LOS) and of all of the adverse effects opioid-induced constipation (OIC) had the greatest effect on p-LOS.<sup>18</sup> Unfortunately tolerance rarely develops to the constipating effects of the opioids. Numerous different pharmacologic approaches have been developed to combat OIC, which includes prolonged release formulations that contain naloxone, tapentadol, and the peripherally acting  $\mu$  opioid receptor antagonists methylnaltrexone and alvimopan.<sup>19</sup>

Of all the side effects the most serious is respiratory depression, which is, generally speaking, preceded by sedation. During sleep, patients who are on chronic opioid therapy develop a variety of sleep-related breathing disorders (SRBDs) which manifest as irregular breathing, secondary to both obstructive sleep apnea (OSA) and central sleep apnea (CSA). Hypoxia and hypercapnia are common. “Many opioid users are found dead in bed and at autopsy no cause is found. It is well known that the sine qua non of opioid intoxication is a terminal lethal apnea.”<sup>20</sup>

This side effect is so serious, in fact, that it generated a *Sentinel Event Alert* in August of 2012 by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).<sup>21</sup> Patient characteristics, which increase the risk of

sedation and respiratory depression, are listed in [Table 55-9](#).<sup>5</sup> Recommendations, which can decrease the risk of opioid-related respiratory depression, include the liberal use of opioid-sparing multimodal pharmacotherapy, regional anesthesia techniques, and the continuous monitoring of patient ventilation with pulse oximetry and capnography, particularly in the high-risk individual. See [Table 55-4](#) for recommendations for multimodal therapy for some commonly performed surgeries.

Respiratory assist devices can also be very helpful. Continuous positive airway pressure (CPAP) is recommended for the treatment of OSA in the opioid-dependent patient. However, patients can fail CPAP and CSA can emerge. These patients may be better candidates for either a bilevel device with backup rate or an adaptive servoventilation (ASV) device. A more comprehensive discussion of this topic is beyond the scope of this chapter and the reader is referred to the excellent review by Javaheri and Randerath.<sup>20</sup> Finally, Evzio is a take-home naloxone auto-injector that patients, family members, or caregivers can use in the event of an opioid overdose in the patient on chronic opioid therapy. The product received Food and Drug Administration (FDA) approval in April of 2014.

Other disconcerting side effects associated with the chronic use of opioids include opioid-induced hyperalgesia (OIH) and immune modulation. OIH is a relatively rare phenomenon whereby patients who are receiving opioids suddenly and paradoxically become more sensitive to pain despite continued treatment with opioids. Evidence suggests that OIH is more likely to develop following high doses of phenanthrene opioids such as morphine.<sup>22,23</sup> Changing the opioid to a phenyl piperidine derivative such as fentanyl may thwart OIH. There is also evidence that coadministration of an NMDA receptor antagonist can abolish opioid-induced tolerance and OIH.<sup>22</sup> Finally, opioid analgesics have profound immunomodulatory effects, which include inhibition of cellular and humoral immune functions, depressed natural killer cell activity, promotion of angiogenesis, and inhibition of apoptosis. Such effects can be beneficial or deleterious depending upon the clinical situation.<sup>24,25</sup>

**Table 55-7 Opioid Analgesic Pharmacokinetics**<sup>32</sup>

Drug	Onset of Effect	Peak Effect	Duration of Effect	Elimination t <sub>1/2</sub>	VD (L/kg)	Protein Binding (%)	Metabolism Pathway	Active Metabolites	Major Excretion Pathway
Alfentanil	Immediate	1.5–2 min	<10 min	1.5–1.85 h	0.4–1	92%	Liver	—	Urine

**Table 55-8 Opioid Equianalgesic Dosing**<sup>158,189,190</sup>

Drug	Dosage	
	IV/IM/SQ	Oral (mg)
Morphine (MS Contin)	10 mg	30
Hydromorphone (Dilaudid)	1.5–2 mg	6–8
Hydrocodone (Vicodin)	NA	30–45
Oxymorphone (Opana IR and ER)	1 mg	10
Oxycodone (Percocet, Oxycontin)	10–15 mg	20
Levorphanol (Levo-Dromoran)	2 mg	4
Fentanyl	100 µg	NA
Meperidine (Demerol)	100 mg	300
Codeine	100 mg	200
Methadone	The conversion ratio for methadone is variable.	

IV, intravenous; IM, intramuscular; SQ, subcutaneous; IR, immediate release; ER, extended release.

*Morphine* is the prototype opioid and is the “gold standard” to which all other analgesics are compared. Although the plasma half-life of the drug is approximately 2 hours its analgesic duration of action is closer to 4 to 5

hours. Morphine undergoes hepatic glucuronidation to morphine-6-glucuronide and morphine-3-glucuronide, both of which are cleared by the kidney. Morphine-6-glucuronide is an active metabolite of morphine and is thought to be responsible for most of the analgesia associated with chronic dosing of the drug. Morphine-3-glucuronide, on the other hand, is considered to be devoid of analgesic activity. With chronic dosing these metabolites can accumulate and can be particularly problematic in patients with renal failure. Dosing adjustment is therefore necessary and monitoring of side effects is important. Morphine-6-glucuronide contributes to side effects such as drowsiness, nausea and vomiting, coma, and respiratory depression. Morphine-3-glucuronide, on the other hand, is thought to cause agitation, myoclonus, delirium, and hyperalgesia.

*Hydromorphone* is a semisynthetic opioid that has four to six times the potency of morphine. It is available for oral, rectal, parenteral, and neuraxial administration. Whereas the oral bioavailability of the drug is reported to be 20% to 50%, its bioavailability via the subcutaneous route is 78%, making it the ideal drug for long-term subcutaneous administration in the opioid-tolerant patient. Like morphine, hydromorphone is biotransformed in the liver. The active metabolites are dihydromorphone and dihydroisomorphine and the inactive metabolite is hydromorphone-3-glucuronide. Although hydromorphone has traditionally been the preferred opioid for patients with acute pain and impaired kidney function, evidence suggests that hydromorphone-3-glucuronide can accumulate in those with renal failure and may contribute to side effects such as neuroexcitation and cognitive impairment. Opioid-related side effects such as nausea, vomiting, sedation, cognitive impairment, and pruritus are reported to be less intense with hydromorphone vis-à-vis morphine. In fact, the incidence of pruritus following neuraxial administration of hydromorphone is reported to be approximately 5% versus the 11% to 77% range reported for neuraxial morphine.<sup>26</sup>

*Codeine* is an opioid agonist that has both analgesic and antitussive properties. In the United States, codeine is available for oral, subcutaneous, and intramuscular administration. As previously mentioned, codeine is a prodrug that is devoid of analgesic activity and requires metabolic conversion by the CYP2D6 enzyme into morphine, which has a 200-fold greater affinity for the  $\mu$ -opioid receptor than the parent drug codeine. In *extensive metabolizers* O-demethylation of the drug by the CYP2D6 enzyme accounts for only 5% to 10% clearance of codeine; however, this conversion to morphine is critical for opioid activity (Fig. 55-11). In *poor metabolizers* and *ultrarapid metabolizers* codeine is contraindicated because of lack of efficacy in the former and the potential for toxicity in the latter (Table 55-10).<sup>27</sup>

Oxycodone (Oxycontin, Percocet) is used for the treatment of both acute and chronic pain and in the United States the drug is only available for oral administration. Please refer to the section Strategies for Acute Pain Management for further details. The drug is available only for oral administration. Oxycodone is predominantly metabolized by CYP3A4 to inactive metabolites; however, approximately 11% of an oxycodone dose is cleared by CYP2D6 to produce the minor metabolite oxymorphone, which is reported to be eight times as potent as the parent drug.<sup>27</sup> It is theoretically possible that toxicity or overdose could occur in CYP2D6 ultrarapid metabolizers or in patients who are concomitantly taking a CYP3A4 inhibitor (e.g., diltiazem, verapamil) (Fig. 55-10).

*Fentanyl*, a synthetic opioid chemically related to the phenylpiperidines, is a relatively selective  $\mu$  receptor agonist, which is considered to have 80 times the potency of morphine following intravenous administration. It is extensively metabolized in the liver to norfentanyl and other inactive metabolites, which are excreted in the urine and bile. Fentanyl is therefore suitable for patients in renal failure. The drug is available for intravenous, subcutaneous, transdermal, transmucosal, and neuraxial administration. The

transdermal administration of fentanyl using iontophoresis (Ionsys, The Medicine Company) is a novel on-demand drug delivery system that does not require venous access. Ionsys is designed to deliver a 40- $\mu$ g dose of fentanyl over a 10-minute period of time following activation of the dose button and is strictly intended for inpatient use only.

*Sufentanil*, *alfentanil*, and *remifentanil* are analogues of fentanyl that have analgesic effects similar to those of morphine and the other  $\mu$  receptor agonists. *Sufentanil* has approximately 1,000 times the potency of morphine and is primarily used in the operating room either intravenously or neuraxially.<sup>28</sup> Like fentanyl, sufentanil is very lipophilic, and although their pharmacokinetic and pharmacodynamic profiles are similar, sufentanil has a smaller volume of distribution and shorter elimination half-life.<sup>28</sup> The high intrinsic potency of sufentanil makes it an excellent choice for epidural analgesia in the opioid-dependent patient.<sup>29</sup> *Alfentanil* has approximately 10 times the potency of morphine and, like sufentanil, is used primarily in the operating room either intravenously or neuraxially. *Remifentanil* is an ultra-short-acting synthetic opioid. The potency of the drug is approximately equal to that of fentanyl. Remifentanil is rapidly degraded by tissue and plasma esterases, which accounts for its incredibly short terminal elimination half-life of 10 to 20 minutes.<sup>28</sup> Rapid clearance and lack of accumulation make this a very desirable opioid in the operative setting, particularly during neurosurgery when remifentanil is combined with propofol as part of a total intravenous anesthetic (TIVA). One disadvantage, however, is that discontinuation of a remifentanil infusion results in rapid loss of analgesia. There is also evidence to suggest that remifentanil infusions may be associated with the development of OIH. Further studies are clearly needed to better define this phenomenon.

**Table 55-10** Assignment of Likely Codeine Metabolism Phenotypes Based on Cytochrome P450 2D6 (*Cyp2d6*) Diplotypes

Phenotype	Implications for Codeine Metabolism	Recommendations for Codeine Therapy	Classification of Recommendation for Codeine Therapy <sup>a</sup>	Considerations for Alternative Opioids
Ultrarapid metabolizer	Increased formation of morphine following codeine administration, leading to higher risk of toxicity	Avoid codeine use due to potential for toxicity.	Strong	Alternatives that are not affected by this CYP2D6 phenotype include morphine and nonopioid analgesics. Tramadol and, to a lesser extent, hydrocodone and oxycodone are not good alternatives because their metabolism is affected by CYP2D6 activity. <sup>b,c</sup>
Extensive metabolizer	Normal morphine formation	Use label-recommended age- or weight-specific dosing.	Strong	—
Intermediate metabolizer	Reduced morphine formation	Use label-recommended age- or weight-specific dosing. If no response, consider alternative analgesics such as morphine or a nonopioid.	Moderate	Monitor tramadol use for response.
Poor metabolizer	Greatly reduced morphine formation following codeine administration, leading to insufficient pain relief	Avoid codeine use due to lack of efficacy.	Strong	Alternatives that are not affected by this CYP2D6 phenotype include morphine and nonopioid analgesics. Tramadol and, to a lesser extent, hydrocodone and oxycodone are not good alternatives because their metabolism is affected by CYP2D6 activity; these agents should be avoided. <sup>b,c</sup>

<sup>a</sup>Rating scheme is described in Supplementary Data online.

<sup>b,c</sup>There is substantial evidence for decreased efficacy of tramadol in poor metabolizers and a single case report of toxicity in an ultrarapid metabolizer with renal impairment following tramadol use postsurgery. Use of other analgesics in CYP2D6 poor and ultrarapid metabolizers may therefore be preferable. Some other opioid analgesics, such as hydrocodone and oxycodone, are metabolized by CYP2D6. To avoid treatment complications, opioids that are not metabolized by CYP2D6 including morphine, oxymorphone, buprenorphine, fentanyl, methadone, and hydromorphone, along with nonopioid analgesics, may be considered as alternatives for use in CYP2D6 poor and ultrarapid metabolizers.

Reprinted with permission from Crews KR, Gaedigk A, Dunnenberger HM, et al. Clinical Pharmacogenetics Implementation Consortium guidelines for cytochrome P450 2D6 genotype and codeine therapy: 2014 update. *Clin Pharmacol Ther.* 2014;95(4):376–382.

**Meperidine**, a phenylpiperidine, is a synthetic  $\mu$  opioid receptor agonist with a short half-life. The drug is recommended for the short-term management of acute pain only and has absolutely no role in the management of chronic pain. The drug is biotransformed by the liver to normeperidine, a potentially neurotoxic metabolite, which has a 12- to 16-hour half-life. Repetitive dosing of meperidine can cause accumulation of normeperidine, which may precipitate tremulousness, myoclonus, and seizures. It is therefore recommended that the total daily intravenous dose in an otherwise healthy adult without renal or central nervous system disease should not exceed 600 mg/day and should not be administered for longer than 48 hours.<sup>30</sup> We do not recommend administration of meperidine as an intravenous patient-controlled analgesia (PCA). The drug is contraindicated in patients receiving monoamine oxidase inhibitors, as this may precipitate a syndrome characterized by muscle rigidity, hyperpyrexia, and seizures.

*Methadone* is a relatively inexpensive synthetic opioid considered to be a broad-spectrum opioid because it is a (1)  $\mu$  receptor agonist, (2) NMDA antagonist, and (3) inhibitor of monoamine transmitter reuptake, making it potentially useful for the treatment of neuropathic pain. The drug is well absorbed from the gastrointestinal tract with a reported bioavailability approximating 80%. The drug is extensively metabolized in the liver by the cytochrome P450 (CYP450) system to inactive metabolites, which are cleared in the bile and urine; unlike morphine, it is generally not necessary to adjust the dosage of methadone in patients with renal insufficiency. Methadone has an elimination half-life of 22 hours, and following a single dose the duration of analgesia is approximately 3 to 6 hours. With repetitive dosing, however, methadone can accumulate and slow tissue release into the blood stream can result in a long elimination half-life of up to 128 hours and duration of analgesia of 8 to 12 hours. This long half-life explains the potential risk for cumulative toxicity, and therefore the importance of monitoring for side effects such as excessive sedation and confusion following the initiation of an around-the-clock dosing regimen.

**Table 55-11** Conversion Ratios from Morphine to Methadone<sup>32,189,191</sup>

Daily Chronic Oral Morphine Dose		Conversion Ratio (Oral Morphine: Oral Methadone)	
<100 mg	(e.g., 90 mg PO morphine)	3:1	(e.g., 30 mg PO methadone)
100–300 mg	(e.g., 300 mg PO morphine)	5:1	(e.g., 60 mg PO methadone)
300–600 mg	(e.g., 600 mg PO morphine)	10:1	(e.g., 60 mg PO methadone)
600–800 mg	(e.g., 720 mg PO morphine)	12:1	(e.g., 60 mg PO methadone)
800–1,000 mg	(e.g., 900 mg PO morphine)	15:1	(e.g., 60 mg PO methadone)
>1,000 mg	(e.g., 1,200 mg PO morphine)	20:1	(e.g., 60 mg PO methadone)

PO, by mouth.

Finally, opioid rotation is a very useful technique to restore analgesic sensitivity in the highly tolerant patient, and methadone is a common choice for opioid rotation. Because cross-tolerance is incomplete, the calculated equianalgesic dose of any new opioid is always lower than expected. One must be particularly cautious, however, when converting from morphine to methadone as the morphine/methadone equianalgesic ratio appears to be curvilinear; whereas the morphine-to-methadone conversion ratio is 3:1 at morphine doses of less than 100 mg/day, the ratio is 20:1 at morphine doses of more than 1,000 mg/day (Table 55-11). Methadone is principally metabolized by the CYP3A4 subtype enzyme of the CYP450 system and, to a lesser extent, by the CYP1A2 and CYP2D6 subtypes. Consequently, there is the potential for numerous drug interactions with methadone, as shown in Table 55-12. Whereas inhibition of methadone metabolism will theoretically provoke toxicity, induction of methadone metabolism could potentially

precipitate inadequate analgesia or even withdrawal symptoms. Frequent adjustments of the methadone dosage may therefore be required if medications are added to or eliminated from a patient’s drug regimen. A rare side effect associated with methadone is a pause-dependent dysrhythmia associated with bradycardia, QT prolongation, and Torsades de pointe.

*Buprenorphine* is a highly lipophilic partial  $\mu$  opioid receptor (MOR) agonist,  $\kappa$  receptor (KOR) antagonist, and ORL1 agonist. It is a lipophilic opioid with moderate intrinsic activity and a high affinity for the  $\mu$  opioid receptor. The elimination half-life of the drug following intravenous administration is 1.2 to 7.2 hours (mean 2.2 hours). The terminal half-life of the drug following sublingual administration, however, is considerably longer secondary to sequestration of the drug in the oral mucosa and buccal fat. The drug is metabolized in the liver by the CYP3A4 enzyme to norbuprenorphine, a weak  $\mu$  agonist responsible for respiratory depression. Buprenorphine and norbuprenorphine are rapidly conjugated via phase II reaction to buprenorphine-3-glucuronide and norbuprenorphine-3-glucuronide and neither metabolite decreases respiratory rate. In humans, buprenorphine is reported to have a ceiling effect for respiratory depression but not for analgesia. Buprenorphine is reported to be effective in a broader variety of pain phenotypes than fentanyl. In animal models, it has proven to be efficacious in the treatment of neuropathic pain and in a human pain model it can block secondary hyperalgesia and central sensitization. Buprenorphine also produces less constipation and less cognitive dysfunction than other  $\mu$  opioid receptor agonists and does not prolong the QTc interval like methadone.<sup>31</sup>

**Table 55-12** Methadone Drug Interactions

Clinical Significance	Increase Methadone Concentration/Effects	Decrease Methadone Concentration/Effects
Documented clinical effects	Ciprofloxacin (Cipro), diazepam (Valium), ethanol (acute use), fluconazole (Diflucan), urinary alkalinizers	Amprenavir (Agenerase), efavirenz (Sustiva), nelfinavir (Viracept), nevirapine (Viramune), phenobarbital, phenytoin (Dilantin), rifampin (Rifadin), ritonavir (Norvir), urinary acidifiers
Documented enzyme effects	Cimetidine (Tagamet), fluoxetine (Prozac)	Carbamazepine (Tegretol)
Clinical effects uncertain	Omeprazole (Prilosec), quinidine, paroxetine (Paxil)	
Predicted interaction	Delavirdine (Rescriptor), grapefruit juice, or fruit	Ethanol (chronic use)
No current clinical evidence	Ketoconazole (Nizoral), macrolide antibiotics (erythromycin, clarithromycin [Biaxin], troleandomycin [TAO]), tricyclic antidepressants, verapamil (Calan)	

Buprenorphine is an excellent alternative for the treatment of acute pain in the patient who cannot tolerate morphine secondary to allergy or other sensitivity. In the adult patient the parenteral dose of buprenorphine is 300  $\mu$ g, which is equivalent to 10 mg of morphine.<sup>32</sup> The recommended dosing

interval is every 6 hours. Additional routes of administration include intramuscular, neuraxial, subcutaneous, sublingual, and transdermal.

A novel (off-label) route of administration of buprenorphine is the perineural application of the drug with local anesthetic. In an effort to prolong the duration of a single injection peripheral nerve block at the brachial and lumbar plexuses buprenorphine may be combined with a long-acting local anesthetic (bupivacaine or ropivacaine) with clonidine and dexamethasone and is referred to as *multimodal perineural analgesia*. This multimodal four-drug combination is reported to provide upwards of 40 hours of analgesia, which is vastly superior to less than 12 to 16 hours with a single long-acting local anesthetic! This single injection technique can be quite useful in austere environments or in situations which preclude placement of a continuous perineural catheter. The block can be performed quickly and offers an inexpensive alternative to a continuous perineural catheter. Please refer to the excellent review by Williams and colleagues for dosing guidelines.<sup>33</sup>

*Tramadol (Ultram)* and *Tapentadol (Nucynta)* are orally active, centrally acting synthetic analgesics possessing a novel mechanism of action which combines  $\mu$  receptor agonist activity with monoamine reuptake inhibition. Whereas tramadol inhibits reuptake of both norepinephrine and serotonin, tapentadol only inhibits the reuptake of norepinephrine. Tramadol is a prodrug which is metabolized in the liver by the CYP450 CYP2D6 system to the active metabolite O-desmethyltramadol (M1), which has 200 times greater  $\mu$  receptor affinity, greater potency, and longer half-life than the parent drug. This can be significant, because there can be an attenuated analgesic effect in the 5% to 15% of the population that has decreased CYP2D6 activity, as is the case with codeine. Tapentadol, on the other hand, is metabolized in the liver to an inactive metabolite via phase II glucuronidation and the drug does not require enzymatic conversion to an active drug. As such, tapentadol offers a distinct advantage over tramadol in terms of reduced variability in analgesia secondary to genetic polymorphism. Tapentadol metabolism will also not be subject to drug/drug interactions at the level of the CYP2D6 enzyme.<sup>27,34</sup>

Tramadol (Ultram) is indicated for mild to moderately severe acute pain. The drug is available as 50-mg tablets. Recommended dosing is 50 to 100 mg q 4 to 6 hours, not to exceed 400 mg in 24 hours. The drug is also available in extended release formulations and a combination product with acetaminophen. Tapentadol (Nucynta) is indicated for moderate to severe acute pain. It is available as 50-mg, 75-mg, and 100-mg tablets, which can be dosed q 4 to 6 hours not to exceed 700 mg on the first day of dosing and 600 mg every day thereafter. Tapentadol IR 50 and 75 mg provides postoperative analgesia similar to oxycodone IR 10 mg and with fewer gastrointestinal side effects. Advantages of tapentadol over tramadol include (1) lack of CYP450

drug interactions, (2) lower risk of seizures and serotonin syndrome, (3) superior analgesia, (4) fewer GI side effects, and (5) less variation in individual drug response secondary to genetic polymorphism.<sup>35</sup>

Both drugs should be administered with caution in patients at risk for respiratory depression. In addition, both drugs have the potential to produce serotonin syndrome (mental status changes, autonomic instability, and neuromuscular aberrations), particularly if administered with serotonergic drugs (selective serotonin reuptake inhibitors [SSRIs], selective norepinephrine uptake inhibitors, tricyclic antidepressants [TCAs], monamine oxidase inhibitors [MAOIs], and triptans). Caution is advised when dosing these drugs in patients with a seizure disorder.

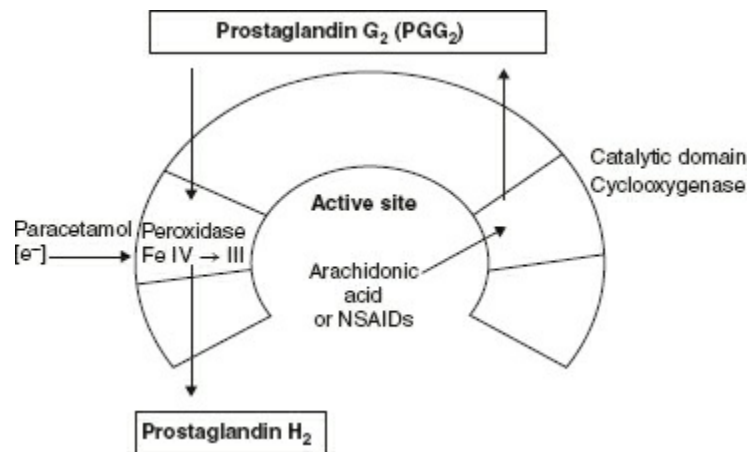

## Nonopioid Analgesic Adjuncts

The NSAIDs are among the most commonly used drugs in the world because of their anti-inflammatory, analgesic, and antipyretic effects (Table 55-13). The therapeutic benefit of NSAIDs is believed to be mediated through the inhibition of cyclooxygenase (COX) enzymes (prostaglandin H<sub>2</sub> [PGH<sub>2</sub>] synthetases), types 1 and 2, which convert arachidonic acid to PGH<sub>2</sub>. The COX enzyme consists of two active sites: (1) the COX site and (2) the peroxidase site. NSAIDs mediate their effects by binding to the COX site (Fig. 55-13).

COX-1 is the constitutive enzyme that produces prostaglandins, which are important for general “house-keeping” functions such as gastric protection and hemostasis. COX-2, on the other hand, is the inducible form of the enzyme that produces prostaglandins that mediate pain, inflammation, fever, and carcinogenesis. Prostaglandin E<sub>2</sub> is the key mediator of both peripheral and central pain sensitization. Peripherally, prostaglandins do not directly mediate pain; rather, they contribute to hyperalgesia by sensitizing nociceptors to other mediators of pain sensation such as histamine and bradykinin.<sup>36</sup> Centrally, prostaglandins enhance pain transmission at the level of the dorsal horn by (1) increasing the release of substance P and glutamate from first-order pain neurons, (2) increasing the sensitivity of second-order pain neurons, and (3) inhibiting the release of neurotransmitters from the descending pain-modulating pathways.

NSAIDs have proved effective in the treatment of postoperative pain. In addition, they are opioid-sparing and can significantly decrease the incidence of opioid-related side effects such as postoperative nausea and vomiting and sedation.<sup>37</sup> Unlike the opioids, NSAIDs exhibit a “ceiling effect” with respect to maximum analgesic effects. Parenteral NSAIDs such as ketorolac are commonly employed as part of a multimodal approach for acute perioperative pain management. The optimal dose of ketorolac for postoperative pain

control is 15 to 30 mg intravenously every 6 to 8 hours, not to exceed 5 days. The dose should be decreased in patients with renal failure.

**Figure 55-13** Paracetamol inhibits prostanoid synthesis. Arachidonic acid (AA) enters the active site of COX. The enzyme cyclizes AA and adds hydroperoxy group to form PGG<sub>2</sub>. This hydroperoxy group is reduced to the hydroxyl group of prostaglandin H<sub>2</sub> (PGH<sub>2</sub>) by peroxidase. Paracetamol does not enter the active site COX but reduces Fe IV to Fe III and prevents activation of the peroxide catalytic moiety and therefore inhibits PGH<sub>2</sub> synthesis. NSAIDs, nonsteroidal anti-inflammatory drugs. (Adapted from Kam PCA, So A. COX-3: uncertainties and controversies. *Curr Anaesth Crit Care*. 2009;20:50.)

**Table 55-13** Nonopioid Analgesics (Adult Dosing Guidelines)<sup>30,32</sup>

Drug	Route	Half-Life (h)	Dose (mg)	Comments
<b>Para-aminophenols</b>				
Acetaminophen	PO and IV	2	500–1,000 mg q4–6h Maximum daily dose (MDD) in the healthy adult is 4,000 mg. Intravenous dosing guidelines: Adult >50 kg: 1 g q4–6h not to exceed 4 g/day Adult <50 kg: 15mg/kg q4–6h not to exceed 3 g/day. Pedi >33 kg: 15 mg/kg q4–6h not to exceed 3 g/day. Pedi 10–33 kg: 15 mg/kg q4–6h not to exceed 2 g/day	Hepatotoxicity can occur in chronic alcoholics receiving therapeutic doses Administer intravenous formulation over 15 minutes
<b>Salicylates</b>				
Acetylsalicylic acid	PO	0.25	500–1,000 mg q4–6h MDD is 4,000 mg in the healthy adult	Salicylic acid has a $T_{1/2}$ 2–3 h at low doses and >20 h at higher doses. Because of the risk of Reyes syndrome avoid the use of aspirin in children <12 years old
Diflunisal	PO	8–12	500 mg q8–12h	Decrease the dose in the elderly to 500–1,000 mg/day
Choline magnesium trisalicylate	PO	9–17	Loading dose (LD) = 1,000 mg 1,000–1,500 mg q12h	Unlike aspirin does not increase bleeding time; MDD = 2,000–3,000 mg
<b>NSAIDs Propionic Acids</b>				
Ibuprofen Intravenous formulation (Caldolor) available in the United States in 2009.	PO and IV	2	400 mg q4–6h	Intravenous ibuprofen: Infuse over 30 minutes to avoid phlebitis Limit adult dose to 3,200 mg/day
Naproxen	PO	12–15	250 mg q6–8h	LD = 500 mg; MDD = 1,500 mg
Ketoprofen	PO	2.1	25–50 mg q6–8h	MDD = 300 mg
Oxaprozin	PO	42–50	600 mg q12–24h	MDD = 1,200 mg
<b>Indolacetic Acids</b>				
Indomethacin	PO	2	25 mg q8–12h	MDD = 200 mg
Sulindac	PO	7.8	150 mg q12h	MDD = 400 mg Active metabolite has a half-life of 16 h
Etodolac	PO	7.3	300–400 mg q8–12h	MDD = 1,000 mg
<b>Pyrrolacetic Acids</b>				
Ketorolac	IV	6	30 mg initially followed by 15–30 mg q6–8h not to exceed 5 days	MDD = 120 mg; hypovolemia should be corrected prior to administration  Decrease the dose in the elderly (>65 years of age) and in renal failure
<b>Phenylacetic Acids</b>				
Diclofenac potassium	PO	2	50 mg q8h	MDD = 150 mg
<b>Enolic Acids (Oxicams)</b>				
Meloxicam	PO	15–20	7.5–15 mg q24h	COX-2 selectivity similar to celecoxib
Piroxicam	PO	50	20–40 mg q24h	
<b>Naphthylalkanone</b>				
Nabumetone	PO	22.5	500–750 mg q8–12h	LD = 1,000 mg MDD = 2,000 mg Active metabolite has half-life = 22.5 h
<b>COX-2 Inhibitor</b>				
Celecoxib	PO	11	100–200 mg q12h	LD = 400 mg; MDD = 400 mg Avoid this drug in patients with coronary heart disease, cerebrovascular disease or in patients allergic to sulfonamides

PO, by mouth; IV, intravenously; COX-2, cyclooxygenase; LD, loading dose; MDD, maximum daily dose.

Despite the benefits of NSAIDs in the perioperative period they are not without some significant side effects. Platelet dysfunction, gastrointestinal ulceration, and an increased risk of nephrotoxicity are several reasons why the nonselective NSAIDs may be avoided in the perioperative period. The risk of nephrotoxicity is increased in patients with hypovolemia, congestive heart failure, and chronic renal insufficiency.<sup>36</sup> The COX-2–selective inhibitors were developed in an attempt to minimize their side effects. The COX-2–specific inhibitor celecoxib (Celebrex) is available in the United States. Rofecoxib (Vioxx) and valdecoxib (Bextra), also released in the same period, were recalled by the manufacturers because of concerns about adverse cardiovascular risks. Celecoxib is the only COX-2–specific inhibitor currently available in the United States for acute postoperative pain. The recommended oral loading dose is 400 mg followed by 200 mg orally every 12 hours for several days.

Unlike the nonselective NSAIDs, however, COX-2–specific inhibitors offer the potential advantages of a reduced incidence of gastrointestinal ulceration and they do not inhibit platelet function. Because prostaglandins play a crucial role in renal function through their effect on blood flow, natriuresis and glomerular filtration, traditional NSAIDs, and the COX-2 inhibitors can cause fluid retention and hypertension.

The authors, therefore, do not recommend prescribing a COX-2 inhibitor for patients with a known history of coronary artery disease or **7** cerebrovascular disease. Both COX-1 and COX-2 play significant roles in bone fusion following fracture, and the use of the traditional NSAIDs has been found to inhibit the healing process, particularly following lumbar spinal fusion surgery. The effect of COX-2 inhibitors on bone fusion following orthopedic procedures continues to be controversial, and no recommendations can be made at this time. NSAIDs and COX-2–selective inhibitors should not be administered to patients with known hypersensitivity to the drugs or to patients with Samters triad (aka aspirin triad), which is a medical condition characterized by asthma, aspirin insensitivity, and nasal polyposis. Finally, avoid celecoxib and valdecoxib in patients with allergic-type reactions to sulfonamides.

The *para-aminophenol* derivative acetaminophen (paracetamol) has both analgesic and antipyretic properties, similar to aspirin, but is devoid of any anti-inflammatory effects. The drug is primarily a centrally acting inhibitor of the COX enzyme with minimal peripheral effects. Acetaminophen neither enters the active site of the COX enzyme nor binds to the COX site, but instead it prevents COX activation by reducing heme at the peroxidase site of the enzyme. In addition, there may be modulation of descending inhibitory serotonergic pathways and the drug may act on the opioid, cannabinoid, transient potential receptor of vanilloid type 1 (TRPV<sub>1</sub>), and NMDA

receptors.<sup>38</sup> Acetaminophen is devoid of many of the side effects generally associated with the NSAIDs, such as gastrointestinal ulceration, impaired platelet function, adverse cardiorenal effects, and impairment of bone fusion following orthopedic procedures. Acetaminophen is opioid-sparing and can be used in conjunction with an NSAID as part of a multimodal analgesic program. The combination of acetaminophen with an NSAID is thought to provide analgesia that is superior to using either drug alone.<sup>39</sup> In adults, 2 g of oral acetaminophen is equivalent to 200 mg of celecoxib.

Intravenous acetaminophen (Ofirmev) was released in the United States in November of 2010. The drug is available as a 1 g (1,000 mg/100 mL) infusion that does not require reconstitution and can be infused through a peripheral intravenous (IV) line over 15 minutes. See [Table 55-13](#) for dosing guidelines.

The *NMDA receptor antagonists* such as ketamine and dextromethorphan may be useful analgesic adjuncts. Excitatory neurotransmitter stimulation of the NMDA receptor is believed to be involved in the development and maintenance of several phenomena including (1) persistent postoperative pain, (2) hypersensitivity, windup, and allodynia, (3) opioid-induced tolerance, and (4) OIH. *Low-dose intravenous ketamine* has proven to be very effective in the management of perioperative pain. Numerous meta-analyses have described the opioid-sparing effect of the drug, and although the magnitude of the effect varies from one study to the next, it appears that the use of perioperative intravenous ketamine, for up to 48 hours postoperatively, can reduce opioid consumption by upwards of 40%.<sup>40</sup> Intravenous ketamine also reduces pain scores and no major complications have been reported following 48 hours of continuous infusion. Low-dose intravenous ketamine is defined as a bolus dose of ketamine that is 1 mg/kg or less or an infusion that is 1.2 mg/kg/hr or less ( $\leq 20 \mu\text{g/kg/min}$ ).<sup>40</sup> The mechanism of action of ketamine is NMDA receptor blockade, but in addition the drug interacts with opioidergic, cholinergic, and monoaminergic receptors and blocks sodium channels.<sup>41</sup>

NMDA receptor antagonists may act synergistically when combined with an opioid. The ideal intravenous PCA morphine–ketamine combination ratio is 1:1 with an 8-minute lockout.<sup>42</sup> A double-blind study, however, demonstrates that the combination of ketamine (1 mg/mL) with morphine (1 mg/mL) administered as an intravenous PCA to patients following major abdominal surgery does not significantly improve pain relief.<sup>43</sup> In patients with morphine-resistant pain, however, the combination of 250  $\mu\text{g/kg}$  of ketamine plus 15  $\mu\text{g/kg}$  of morphine, as a bolus dose, has been reported to provide significant analgesia.<sup>41</sup> Results are promising, but more studies will certainly be required to clearly define the role of ketamine for postoperative analgesia.

Dextromethorphan, the d-isomer of the codeine analogue levorphanol, is a noncompetitive NMDA receptor antagonist that has been used for many years

as an antitussive. Dextromethorphan does not have a direct analgesic effect; rather, analgesia is likely mediated by its NMDA receptor antagonism. The drug can be administered orally, intravenously, and intramuscularly. There is a sustained-release suspension available that contains dextromethorphan, 30 mg/5 mL, and is marketed as Delsym (Adams Respiratory Therapeutics). Following oral administration, the drug is metabolized to dextrorphan, which is the metabolite that accounts for most of the side effects, the most common of which are nausea and vomiting. Because the intravenous administration of large doses can lead to hypotension and tachycardia, the intramuscular route may be the preferred route of delivery. Dextromethorphan has been shown to both inhibit secondary hyperalgesia following peripheral burn injury and cause a reduction in temporal summation of pain. The preoperative administration of 150 mg of oral dextromethorphan can reduce the PCA morphine requirements of patients undergoing abdominal hysterectomy, and the preincisional administration of 120 mg of intramuscular dextromethorphan provides preemptive analgesia in patients undergoing elective upper abdominal surgery. Finally, a randomized double-blind placebo-controlled study has demonstrated that dextromethorphan dosed 200 mg orally every 8 hours (e.g., 2 hours prior to surgery, then 8 hours and 16 hours thereafter) can provide a modest reduction in morphine consumption following knee surgery.<sup>44</sup>

The  $\alpha_2$ -adrenergic agonists clonidine (half-life, 9 to 12 hours) and dexmedetomidine (half-life, 2 hours) may be administered perioperatively to provide analgesia, sedation, and anxiolysis. The presynaptic activation of  $\alpha_2$ -receptors that results in the decreased release of norepinephrine is believed to mediate analgesia. Whereas clonidine is a selective partial agonist for the  $\alpha_2$ -adrenoreceptor, dexmedetomidine is superselective for the receptor. Their respective  $\alpha_2/\alpha_1$  binding ratios are 220:1 for clonidine versus 1,620:1 for dexmedetomidine. Analgesia is mediated supraspinally (locus coeruleus), spinally (substantia gelatinosa), and peripherally. Dexmedetomidine is reported to have greater affinity for the 2A subtype of the receptor, which may account for the drug's superior analgesic properties vis-à-vis clonidine. Clonidine can be administered orally, transdermally, intravenously, perineurally, and neuraxially for perioperative pain management. Premedication with 5  $\mu\text{g}/\text{kg}$  of oral clonidine in patients undergoing knee surgery can decrease the use of PCA morphine and decrease the incidence of postoperative nausea and vomiting. In addition, the combination of oral clonidine, 3 to 5  $\mu\text{g}/\text{kg}$  with 0.2 mg/24 hours of transdermal clonidine can decrease postoperative PCA morphine requirement by 50% following prostatectomy surgery. In a double-blind, placebo-controlled study, investigators demonstrated that addition of 25  $\mu\text{g}$  of intrathecal clonidine to a bupivacaine (15 mg) morphine (250  $\mu\text{g}$ ) spinal anesthetic cocktail, for total

knee arthroplasty (TKA), could reduce postoperative morphine use and improve VAS pain scores at 24 hours.<sup>45</sup> In combination with a local anesthetic clonidine in doses of 0.5 to 1.0 µg/kg may enhance the efficacy and increase the duration of perineural blocks. A four-drug combination including bupivacaine (2.5 mg/mL), clonidine (3 µg/mL), buprenorphine (18 µg/mL), and dexamethasone (66 µg/mL) has been reported to provide greater than 24 hours of postoperative analgesia.<sup>33</sup> The authors of this study encourage further research in this area of motor-sparing perineural analgesia. Side effects from clonidine include sedation, hypotension, and bradycardia if the dose exceeds 150 µg.

Dexmedetomidine is a potent and highly selective  $\alpha_2$ -adrenoreceptor agonist which demonstrates cardioprotective, neuroprotective, and renoprotective effects against hypoxic/ischemic injury.<sup>46</sup> The drug has been described as a useful and safe adjunct in numerous clinical situations, which include (1) premedication prior to intubation and extubation, (2) procedural sedation, (3) awake intubations, (4) as an adjuvant to regional anesthesia, (5) awake craniotomies, and (6) intraoperative and postoperative analgesia as part of a multimodal protocol. See [Table 55-14](#) for dosing guidelines. The drug does not decrease gut motility and prevents postoperative nausea and vomiting and shivering. In the intensive care unit (ICU) dexmedetomidine has proven to be a very useful drug that decreases central nervous system sympathetic outflow in a dose-dependent manner. It provides adequate sedation without significant respiratory depression and analgesia that is opioid sparing. Unlike propofol and midazolam, dexmedetomidine is not a GABAergic drug, has no anticholinergic effects and promotes more physiological sleep pattern attributes, which attenuates neurocognitive impairment (delirium and agitation) and promotes early extubation and shorter length of stays (LOS) in the ICU.<sup>47</sup> The most frequently observed adverse effects associated with the use of dexmedetomidine are bradycardia and hypotension, which can be adequately treated with atropine, glycopyrrolate, and ephedrine.

**Table 55-14** Dexmedetomidine Dosing Guidelines

Route	Dose
Intravenous	Loading dose: 1 µg/kg over 10–20 minutes Maintenance dose: 0.2–0.7 µg/kg/hr
Intramuscular	2.5 µg/kg as premedication
Spinal	0.1–0.2 µg/kg
Epidural	1–2 µg/kg
Peripheral nerve block	1 µg/kg
Buccal	1–2 µg/kg
Intranasal	1–2 µg/kg

The *gabapentinoids* ( $\alpha_2$ - $\delta$  subunit calcium channel ligands), gabapentin (Neurontin) and pregabalin (Lyrica), are indicated for the treatment of partial onset seizures, neuropathic pain (e.g., postherpetic neuralgia), and other chronic pain states (e.g., fibromyalgia); however, there is now a growing body of evidence supporting the use of these drugs during the perioperative period to decrease postoperative pain and opioid use. Likewise, because the gabapentinoids can prevent the establishment of surgery-induced central sensitization, these drugs may play a role in preventing the transition from acute pain to chronic pain. As an added bonus, there is a decreased incidence of postoperative delirium, vomiting, pruritus, and urinary retention associated with the perioperative use of these drugs, probably secondary to their opioid-sparing effects. Common side effects associated with these drugs include sedation, headache, dizziness, and visual disturbances.<sup>48,49</sup>

Compared to traditional analgesics, which decrease afferent input from the site of tissue injury, the gabapentinoids decrease the hyperexcitability of dorsal horn neurons caused by tissue damage.<sup>50</sup> Although structurally similar to GABA these drugs are not GABAergic and do not bind GABA<sub>A</sub>, GABA<sub>B</sub>, GABA<sub>C</sub> radioligand sites or allosteric GABA receptor sites. The antinociceptive mechanism of action of the gabapentinoids has two aspects: modulation of the calcium-induced release of glutamate centrally in the dorsal horn, and activation of descending noradrenergic pathways in the spinal cord and brain (Fig. 55-14).<sup>49</sup>

When administered orally, both drugs are absorbed by amino acid carrier systems in the small intestines. The gastrointestinal absorption of *gabapentin* occurs only in the duodenum through a saturable transport system resulting in bioavailability that decreases with increasing doses. Consequently, increased doses of gabapentin result in incrementally smaller increases in plasma drug concentration (e.g., nonlinear pharmacokinetics).<sup>51</sup> *Pregabalin*, on the other hand, is absorbed throughout the small intestines through a nonsaturable transport system and has a linear pharmacokinetic profile (dose-independent

absorption), and is more potent than gabapentin. Gabapentin oral absorption is significantly impaired by antacids, including bicitra. Both drugs are renally excreted and undergo insignificant liver metabolism.
