**Figure 24-4** Excitation–contraction coupling and malignant hyperthermia. The action potential generated at the endplate region of the neuromuscular junction is propagated down the sarcolemma (muscle plasma membrane) by the opening of voltage-dependent  $\text{Na}^+$  channels (1). The action potential continues down into the t-tubules (2) to the dihydropyridine receptors (3). The dihydropyridine receptors in skeletal muscle function as voltage sensors and are coupled to the  $\text{Ca}^{2+}$  release channels (4). Through this coupled signaling process, the  $\text{Ca}^{2+}$  release channels are opened, some of the available terminal cisternae  $\text{Ca}^{2+}$  stores (5) are released, and the levels of myoplasmic  $\text{Ca}^{2+}$  are elevated. The  $\text{Ca}^{2+}$  then diffuses to the myofibrils (6) and interacts with the troponin/tropomyosin complex associated with actin (*thin lines*) and allows interaction of actin with myosin (*thick lines*) for mechanical movement. The  $\text{Ca}^{2+}$  diffuses away from the myofibrils and this  $\text{Ca}^{2+}$  signal is terminated by an adenosine triphosphate (ATP)-driven  $\text{Ca}^{2+}$  pump (7), which pumps  $\text{Ca}^{2+}$  into the longitudinal sarcoplasmic reticulum (8). The  $\text{Ca}^{2+}$  diffuses from the longitudinal sarcoplasmic reticulum to the terminal cisternae, where it is concentrated for release by  $\text{Ca}^{2+}$  binding proteins.  $\text{Na}^+$  entering during the action potential is subsequently extruded from the cell by the  $\text{Na}^+/\text{K}^+$ -ATPase (9) and possibly through  $\text{Na}^+/\text{Ca}^{2+}$  exchange (10). This latter process would elevate intracellular  $\text{Ca}^{2+}$  and could result from delayed inactivation of  $\text{Na}^+$  currents. A major form of energy for supplying cellular ATP for the ion pumps and numerous other energy-consuming processes is fatty acids (FA) derived from the serum (dietary FA), or from intramuscular triglyceride (TG) stores. Therefore, a defect in the intracellular  $\text{Ca}^{2+}$  regulating processes (increased  $\text{Ca}^{2+}$  release or decreased  $\text{Ca}^{2+}$  uptake), or a defect in the sarcolemma could account for an increase in myoplasmic  $\text{Ca}^{2+}$ .

## Management of the Malignant Hyperthermia Susceptible Patient

The most definitive test for MH susceptibility is the caffeine–halothane

contracture test that must be performed at an experienced center. Supplemental genetic testing may detect an identifiable receptor mutation within the family.

Avoidance of known triggering agents is central to developing a plan for anesthesia for an MHS patient. Most intravenous agents such as propofol, benzodiazepines, opioids, nondepolarizing muscle relaxants, and nitrous oxide are safe for MHS patients (Table 24-11). Preparation of the anesthesia machine includes removal or closure of vaporizers, change of all disposable components, and flushing the machine with 100% oxygen (may require >2 hours). Charcoal filters attached to both limbs of the anesthesia breathing circuit before and during the procedure are effective for reducing halogenated anesthetics to less than trace amounts.<sup>60</sup> Preoperative administration of prophylactic dantrolene is not recommended. Dantrolene should, however, be readily available. The Malignant Hyperthermia Association of the United States (MHAUS) has detailed recommendations for management of MHS patients.

## Porphyria

The porphyrias are caused by enzymatic deficiencies in the heme synthesis pathway. Heme is an essential component of hemoglobin, myoglobin, and cytochromes. Heme is synthesized in the liver and erythroid tissue from succinyl co-enzyme A and glycine in a process that requires eight enzymatic steps. Each of the porphyrias is caused by a deficiency of one of the eight enzymes that results in an accumulation of porphyrin precursors with toxic effects ( $\delta$ -aminolevulinic acid, porphobilinogen). The four acute porphyrias that result in acute attacks are: (1) acute intermittent porphyria (AIP, most common), (2) hereditary coproporphyria (HCP), (3) variegate porphyria (VP), and (4) ALA-dehydratase-deficient porphyria (ADP, rarest) (Table 24-12).<sup>61</sup>

AIP typically occurs in young adults and is more common in women. The clinical features of AIP are fever, tachycardia, nausea, emesis, severe abdominal pain, weakness, seizures, confusion, and hallucinations. Muscle weakness can be so severe that respiratory failure ensues. Hyponatremia may occur secondary to inappropriate secretion of ADH. Rarely, severe hypertension and encephalopathy develop. The mental changes that occur during an acute attack are often misdiagnosed as a primary psychiatric disorder. Attacks may last for 1 to 2 weeks and can be triggered by hormone changes during the menstrual cycle, fasting, infections, and exposure to triggering drugs (Table 24-13). Treatment consists of removal of triggering agents, resolution of infection, and supportive care for skeletal muscle weakness. Specific therapy for an acute attack is the infusion of hemin

solution that inhibits 5-aminolevulinic acid synthase and decreases the production of toxic intermediates. Liver transplantation has been effective for some patients with AIP.

**Table 24-9** Malignant Hyperthermia Clinical Grading Scale

<b>Process I: Muscle Rigidity</b>	
Generalized rigidity	15
Masseter rigidity	15
<b>Process II: Myonecrosis</b>	
Elevated CK >20,000 (after succinylcholine administration)	15
Elevated CK >10,000 (without exposure to succinylcholine)	15
Cola-colored urine	10
Myoglobin in urine >60 mg/L	5
Blood/plasma/serum K <sup>+</sup> >6 mEq/L	3
<b>Process III: Respiratory Acidosis</b>	
PetCO <sub>2</sub> >55 with controlled ventilation	15
PaCO <sub>2</sub> >60 with controlled ventilation	15
PetCO <sub>2</sub> >60 with spontaneous ventilation	15
Inappropriate hypercarbia	15
Inappropriate tachypnea	10
<b>Process IV: Temperature Increase</b>	
Rapid increase in temperature	15
Inappropriate temperature >38.8°C in perioperative period	10
<b>Process V: Cardiac Involvement</b>	
Inappropriate tachycardia	3
Ventricular tachycardia or fibrillation	3

CK, creatine kinase.

See Larach, et al.<sup>56</sup> for full details of this scoring system. Briefly, a case may receive 15 points for the worst presentation in five of the first six categories. A sum of more than 50 points is termed *D6*, almost certainly a case of malignant hyperthermia (MH). A sum of 35 to 49 points is *D5*, very likely to be a case of MH.

**Table 24-10** Treatment of an Acute Episode of Malignant Hyperthermia

Discontinue triggering agents
Halogenated, inhaled anesthetics
Succinylcholine
Attach charcoal filters to the anesthesia breathing circuit
Hyperventilate with 100% oxygen
Administer dantrolene 2.5 mg/kg
Titrate dantrolene to heart rate, temperature, and PaCO <sub>2</sub>
Serial monitoring of arterial blood gases
Correction of metabolic acidosis with NaHCO <sub>3</sub>
Control of dysrhythmias
Lidocaine
Avoid calcium channel blockers
Active cooling
Surface ice packs, body cavity lavage
Cardiopulmonary bypass for severe cases
Cease cooling when temperature decreases to 38°C
Correction of hyperkalemia
Glucose, insulin, bicarbonate, hyperventilation
Calcium if hyperkalemia causes cardiac dysfunction
After acute episode subsides, monitor for recrudescence of MH
Disseminated intravascular coagulation (DIC)
Myoglobinuria

**Table 24-11** Safe versus Unsafe Drugs in Malignant Hyperthermia

<i>Safe Drugs</i>	<i>Unsafe Drugs</i>
Antibiotics	Halothane
Antihistamines	Isoflurane
Barbiturates	Enflurane
Benzodiazepines	Sevoflurane
Dexmedetomidine	Desflurane
Droperidol	Succinylcholine
Ketamine	
Local anesthetics	
Nitrous oxide	
Nondepolarizing muscle relaxants	
Opioids	
Propofol	
Propranolol	
Vasoactive drugs	

The most common of the cutaneous porphyrias is porphyria cutanea tarda (PCT). Other porphyrias that develop skin lesions are congenital erythropoietic porphyria (CEP), erythropoietic protoporphyria (EPP), and X-linked erythropoietic protoporphyria (XLP). Sunlight can cause skin fragility, blisters, vesicles, and bullae.

### Management of Anesthesia

The main goal for anesthesia is avoidance of drugs that may trigger acute porphyria. Susceptible patients, however, are rarely identified preoperatively and the triggering potential for many drugs is unknown. More than 300

mutations in the heme synthesis pathway have been identified and many variations in clinical response may occur. Barbiturates and etomidate should be avoided. Propofol, isoflurane, sevoflurane, desflurane, fentanyl, morphine, and ketamine have been administered without complications. Succinylcholine, cisatracurium, and rocuronium are acceptable for muscle relaxation. Regional anesthesia may be administered as well.

**Table 24-12** Types of Porphyria

<b>Acute</b>
Acute intermittent porphyria (AIP)
Hereditary coproporphyria (HCP)
Variegate porphyria (VP)
ALA-dehydratase-deficient porphyria (ADP)
<b>Nonacute</b>
Porphyria cutanea tarda (PCT)
Congenital erythropoietic porphyria (CEP)
Erythropoietic protoporphyria (EPP)
X-linked erythropoietic protoporphyria (XLP)

**Table 24-13** Drugs Known to Precipitate Acute Porphyria

<b>Sedatives</b>	<b>Miscellaneous</b>
Barbiturates	Calcium channel blockers
Etomidate	Clonidine
Benzodiazepines	Aminophylline
<b>Analgesics</b>	Amiodarone
Pentazocine	Hydralazine
Antipyrine	Estrogens
Aminopyridine	Metoclopramide
Ropivacaine	
Ketorolac	
Ketamine	
<b>Anticonvulsants</b>	
Phenytoin	
Carbamazepine	
Valproic acid	
Oxcarbazepine	
Ethosuximide	
Antimicrobials	
Sulfonamides	
Chloramphenicol	
Erythromycin	
Fluconazole	
Griseofulvin	
Clindamycin	
Rifampin	
Nitrofurantoin	

Acute porphyria should be considered in patients with unexplained delayed emergence from anesthesia or postoperative muscle weakness.<sup>62</sup> Urinary porphobilinogen is markedly elevated during an acute attack and can be

detected with a rapid test kit within 5 minutes.

## **Cholinesterase Disorders**

Plasma cholinesterase (pseudocholinesterase, butyrylcholinesterase) is an enzyme synthesized in the liver. This enzyme hydrolyzes succinylcholine, mivacurium, procaine, chlorprocaine, tetracaine, and cocaine. The most significant complication for the anesthesiologist is prolonged apnea after succinylcholine. The molecular genetics of cholinesterase inheritance is not simple as 20 variants have been described. Some variants produce cholinesterase with very little activity and succinylcholine-induced paralysis may last for several hours. Individuals with other variants may have a prolongation of succinylcholine activity that is not clinically discernible. A few genetic variants produce a cholinesterase that accelerates the hydrolysis of succinylcholine, thereby producing a shorter duration of action. Individuals with genetically deficient cholinesterase are not known to have other pathologic conditions. There is some evidence that plasma cholinesterase variants in some ethnic groups may impart a protective effect against atherosclerosis.

Acquired deficiencies of cholinesterase are most notably caused by hepatic disease. Other diseases associated with decreased cholinesterase activity include carcinomas, uremia, connective tissue diseases, malnutrition, and myxedema. Plasma cholinesterase, however, must be decreased by more than 75% for there to be a clinically significant decrease in succinylcholine hydrolysis. Drugs that may interfere with succinylcholine metabolism include neostigmine, pyridostigmine, echothiophate, cyclophosphamide, chlorpromazine, and organophosphate insecticides.

## **Management of Anesthesia**

Preoperative knowledge of a plasma cholinesterase abnormality allows the anesthesiologist to avoid the use of drugs that are hydrolyzed by cholinesterase and the course of anesthesia will be uneventful. The usual clinical presentation, however, of a cholinesterase abnormality is prolonged apnea after succinylcholine. Apnea can be very prolonged if additional succinylcholine is administered after tracheal intubation, or a nondepolarizing muscle relaxant is given followed by reversal with neostigmine.

A prudent clinical practice is to be certain that recovery from the initial dose of succinylcholine has occurred before administering more muscle relaxant. Mechanical ventilation and adequate sedation should be continued until full recovery of neuromuscular function is assured.

If prolonged apnea after succinylcholine occurs, laboratory testing should

be performed after the patient has fully recovered. Inheritance of atypical cholinesterase is classic and there are three genotypes: normal (EuEu), heterozygous (EuEa), and homozygous abnormal (EaEa). The two tests that provide the most information are a cholinesterase activity level, and the dibucaine number (Table 24-14).

## Glycogen Storage Diseases

The glycogen storage diseases (GSD) are inherited disorders caused by abnormal enzymes that regulate glycogen synthesis and breakdown (Fig. 24-5). These diseases have various manifestations and organ involvement (Table 24-15). There are, however, three common critical components: (1) *acidosis* related to fat and protein metabolism in metabolically active glycogen stores; (2) hypoglycemia is a constant risk and results from failure to metabolize glycogen to glucose; and (3) *cardiac and hepatic dysfunction* secondary to destruction and replacement of normal tissue by accumulated glycogen.

Many of the enzymes involved in glycogen metabolism have different isoforms controlled by many different genes. The clinical features can vary markedly within each type of GSD.

### Management of Anesthesia

#### *Type 1 (Von Gierke Disease; Glucose-6-phosphatase Deficiency)*

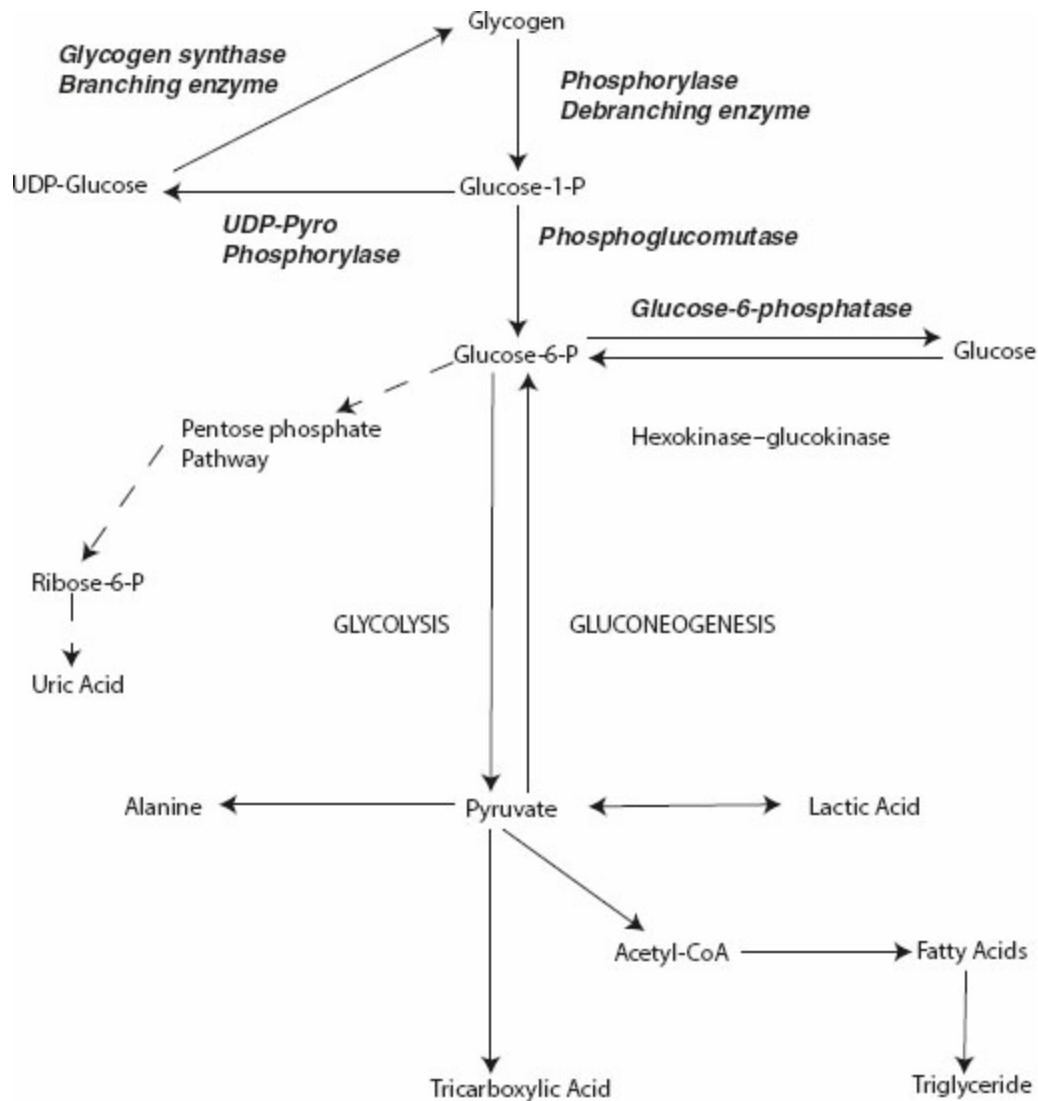

Von Gierke disease is inherited as an autosomal recessive trait. Many patients survive to adulthood. Short stature and hepatomegaly are characteristic. Hypoglycemia, acidosis, and seizures are common. Prolonged bleeding due to platelet dysfunction has been described. These patients do not tolerate fasting and should have preoperative intravenous glucose containing fluid therapy. Preoperative hyperalimentation is often used to reduce liver glycogen stores. Anesthesia and surgery cause release of counterregulatory hormones (epinephrine, norepinephrine) that can result in severe lactic acidosis. Cardiac dysrhythmias and cardiac arrest have occurred during anesthesia when acidosis develops. Preoperative intravenous glucose should be administered at 1.5 times the estimated hepatic production rate of glucose. This will reduce insulin secretion and minimize the effects of the stress response. If acidosis develops, a continuous infusion of bicarbonate should be administered. Portacaval shunting has been performed with limited success in patients with hepatic cirrhosis.

**Table 24-14** Classic Cholinesterase Genotypes

Genotype	Cholinesterase Activity	Dibucaine Number	Succinylcholine Apnea (min)
Normal (EuEu)	+++	78–86	5
Heterozygote (EuEa)	++	51–70	15
Homozygote (EaEa)	+	18–26	120–300

### *Type II (Pompe Disease; Lysosomal Acid Glucosidase Deficiency)*

The infantile form is a devastating disease with a very poor prognosis. There is a deficiency of lysosomal acid glucosidase with an accumulation of glycogen in heart, liver, muscle, and CNS. Infants present with generalized weakness, hypotonia, and massive cardiomegaly. Glycogen infiltration of cardiac muscle leads to concentric hypertrophic cardiomyopathy. These patients are prone to tachydysrhythmias. If enzyme replacement therapy (ERT) is started by 9 months of age, it can decrease cardiac glycogen accumulation. Late-onset Pompe disease may manifest in older children or adults and has a milder clinical course.<sup>63</sup> The late onset form is characterized by a slow progressive myopathy culminating in respiratory failure. Preoperative evaluation should include an ECG, echocardiogram, and liver function tests. There are a significant number of reported cases of cardiac arrest during anesthesia in patients with the infantile form and mortality is high.<sup>64</sup> Induction of anesthesia with sevoflurane or high-dose propofol is more likely to result in adverse cardiac events, especially in patients with a left ventricular mass index (LVMI) greater than 350 g/m<sup>2</sup>. A preoperative echocardiogram with measurement of LVMI is highly recommended.<sup>65</sup> If feasible, surgery should be performed with local or regional anesthesia.<sup>66</sup> If general anesthesia is required, a carefully monitored induction with ketamine is recommended.

**Figure 24-5** Simplified pathway of glycogen synthesis and degradation. (Adapted from Ozen H. Glycogen storage diseases: new perspectives. *World J Gastroenterol.* 2007;13:2541–2553.)

### *Type III (Forbes or Cori Disease)*

Type III GSD is due to a deficiency of amylo-1,6-glucosidase (glycogen debrancher). Symptoms are due to defective catabolism of glycogen and excessive glycogen deposition in the liver. Hepatomegaly and short stature are common. Mild hyperlipidemia and elevated serum transaminase concentrations are characteristic. Fasting induces ketotic hypoglycemia. Cirrhosis develops in the third and fourth decade of life. The enzyme deficiency in skeletal and cardiac muscle leads to weakness and cardiomyopathy. There are subgroups based on skeletal muscle involvement. Anesthetic concerns include macroglossia, hypotonia, sensitivity to nondepolarizing muscle relaxants, hypertrophic cardiomyopathy, and tachydysrhythmias. Hypoglycemia is a particular risk as it may occur within 4 to 6 hours of fasting. Continuous administration of intravenous glucose should be done in the preoperative period. Metabolic acidosis with ketoacids may occur even with careful management of anesthesia. Administration of lactate

containing intravenous fluids is generally avoided. Succinylcholine should also be avoided because of the potential for rhabdomyolysis. Postoperative respiratory complications may occur due to respiratory muscle weakness, ineffective cough, poor clearance of secretions, and residual effects of anesthetics.<sup>67,68</sup>

**Table 24-15** Classification of Glycogen Storage Diseases

Type <i>Eponym</i>	Prevalence	Enzyme Defect	Main Clinical Features	Laboratory Abnormalities	Progressive Skeletal Muscle Deformities	Progressive Cardiac Involvement
Type I <i>Von Gierke</i>	1:200,000	Glucose-6-phosphatase	Short stature, hepatomegaly, hepatic adenomas, seizures, developmental delay, failure to thrive, vomiting, xanthomata, nephromegaly, osteoporosis, inflammatory bowel disease	Symptomatic hypoglycemia, lactic acidosis, elevated triglycerides, platelet dysfunction, elevated uric acid, glucosuria, high urinary calcium	Muscle cramping, exercise intolerance	Severe cardiac arrhythmias, sudden death with fasting
Type II <i>Pompe, early onset</i>	1:400,000	Lysosomal acid glucosidase (acid maltase)	Growth delay, developmental delay, hepatomegaly, macroglossia, progressive hypotonia, death <1 yr of age	Markedly elevated creatinine kinase (CK) levels, elevated AST/ALT, LDH	Progressive cardiac, respiratory, skeletal muscle weakness	Massive cardiomegaly, concentric LV hypertrophy, outflow tract obstruction, cardiomyopathy, CHF, SVT, VT, VF, cardiorespiratory arrest with anesthesia
Type II <i>Pompe, late onset</i>	1:400,000	Lysosomal acid glucosidase (acid maltase)	Onset in second to seventh decade of life, progressive respiratory failure	Markedly elevated CK levels, elevated AST/ALT, LDH	Slowly progressive myopathy	None
Type IIIa1 <i>Forbes Cori's</i>	1:400,000	Amylo-1,6-glucosidase (glycogen debrancher)	Childhood-onset muscle weakness, hepatic dysfunction	Fasting hypoglycemia, mildly to moderately elevated ALT/AST, elevated CK, hyperlipidemia	Slowly progressive muscle weakness, gross motor delay	Concentric LV hypertrophy, rare cardiac dysfunction or arrhythmias
Type IIIa2 <i>Forbes</i>	1:400,000	Amylo-1,6-glucosidase (glycogen debrancher)	Hepatic dysfunction with onset in childhood and persistence in adulthood, adult-onset muscle weakness	Fasting hypoglycemia, mildly to moderately elevated ALT/AST, elevated CK, hyperlipidemia	Slowly progressive muscle weakness, gross motor delay	Concentric LV hypertrophy, rare cardiac dysfunction or arrhythmias
Type IIIa3 <i>Forbes</i>	1:400,000	Amylo-1,6-glucosidase (glycogen debrancher)	Hepatic dysfunction with onset in childhood and resolution in adulthood, adult-onset muscle weakness	Fasting hypoglycemia, mildly to moderately elevated ALT/AST, elevated CK, hyperlipidemia	Slowly progressive muscle weakness, gross motor delay	Concentric LV hypertrophy, rare cardiac dysfunction or arrhythmias
Type IIIa4 <i>Forbes</i>	1:400,000	Amylo-1,6-glucosidase (glycogen debrancher)	Adult-onset skeletal muscle symptoms	Fasting hypoglycemia, mildly to moderately elevated ALT/AST, elevated CK, hyperlipidemia	Slowly progressive muscle weakness, gross motor delay	Concentric LV hypertrophy, rare cardiac dysfunction or arrhythmias
Type IIIb <i>Forbes</i>	1:400,000	Amylo-1,6-glucosidase (glycogen debrancher)	Hepatic dysfunction	Fasting hypoglycemia, mildly to moderately elevated ALT/AST, elevated CK, hyperlipidemia	None	Rare cardiac dysfunction or arrhythmias

Type IV <i>Andersen</i>		Glycogen branching enzyme	Failure to thrive, hepatosplenomegaly, hypotonia, esophageal varices, portal hypertension, late hepatic cirrhosis/failure, neuropathy	Elevation of CK, moderate elevation of AST/ALT Myopathy, muscle weakness, exercise intolerance, exertional dyspnea, neuronal involvement	Two forms: stable and progressive	Dilated cardiomyopathy, CHF
Type V <i>McArdle</i>	1:100,000	Muscle glycogen phosphorylase	Muscle glycogenoses, exercise intolerance, <i>no</i> hepatic involvement	Episodic myoglobinuria	Muscle cramps	None
Type VI <i>Hers</i>	Very rare	Hepatic glycogen phosphorylase	Mild symptoms, short stature, hepatomegaly	Fasting ketotic hypoglycemia, mild hyperlipidemia, myoglobinuria, elevated AST/ALT, proximal renal tubular acidosis (rarely)	Hypotonia, muscle cramps	Usually none, rare cardiac failure with enzyme variant
Type VII <i>Tarui's</i>	Very rare	Muscle phosphofructokinase	Muscle glycogenoses, exercise intolerance, <i>no</i> hepatic involvement	Episodic myoglobinuria, hemolytic anemia	Muscle cramps	None
Type IX	Very rare	Glycogen phosphorylase kinase	Mild symptoms, short stature, hepatomegaly of X-linked variant	Fasting ketotic hypoglycemia, mild hyperlipidemia, myoglobinuria, elevated AST/ALT, proximal renal tubular acidosis (rarely)	Hypotonia, muscle cramps	Usually none, rare cardiac failure with enzyme variant
Type XI <i>Fanconi-Bickel</i>	Very rare	Glucose transporter	Hepatic glycogenosis, Fanconi renal syndrome	Short stature, hepatic glycogenosis, Fanconi renal syndrome	None	None
Type 0	Unknown	Hepatic glycogen synthase	Short stature, developmental delay (22%), seizures	Postprandial hyperglycemia and hyperlactatemia, recurring ketotic hypoglycemia, metabolic acidosis, fasting ketonuria	No skeletal muscle involvement	None

Fanconi-Bickel syndrome: the original patient and his natural history, historical steps leading to the primary defect, and a review of the literature. *Eur J Pediatr*. 1998;157:783–797.

### **Type IV (Andersen Disease, Amylopectinosis)**

This is a very rare disorder caused by a deficiency of glycogen-branching enzyme (GBE). This leads to an accumulation of glycogen in liver, muscle, nerves, and cardiac muscle. Clinical manifestations are diverse depending on the affected tissues.<sup>69</sup> The severest form of the disease presents in infancy with hepatosplenomegaly, failure to thrive, and hypotonia. Esophageal varices, portal hypertension, and cirrhosis are common by 2 years of age. Muscle weakness with exercise intolerance and exertional dyspnea occur. Cardiac effects include dilated cardiomyopathy and congestive heart failure. The only effective treatment is liver transplantation. A neuromuscular variant presents in adults with sensory loss in the legs, gait disturbances, difficulty with urination, and cognitive dysfunction.

### **Type V (McArdle Disease)**

McArdle disease is an autosomal recessive disorder due to a deficiency of glycogen phosphorylase in muscle. Skeletal muscle is unable to mobilize glycogen stores for sustained exercise and cramping with exercise is characteristic of this disorder. GSD type V is a multisystem disease that presents in adolescence with progressive muscle weakness, myalgia, and lack of endurance. Episodes of myoglobinuria with overexertion are due to rhabdomyolysis and may occur after administration of succinylcholine. Acute renal failure with rhabdomyolysis has been reported after cardiac surgery.<sup>70</sup> Tourniquets should not be used and frequent automated measurements of blood pressure should be done with caution. Whether patients with McArdle

disease are susceptible to MH is controversial.<sup>71</sup> Dantrolene may, however, have a beneficial effect on non-MH rhabdomyolysis. Cardiac muscle is typically not affected in patients with McArdle disease.

#### *Type VI (Hers Disease)*

This relatively benign disorder is caused by a deficiency in a regulatory enzyme that controls hepatic glycogen phosphorylase. Symptoms include hepatomegaly, mild hypoglycemia, hyperlipidemia, and ketosis. A mild cardiomyopathy may develop with aging.<sup>72</sup> Lactic acidosis and hyperuricemia do not occur. Symptoms usually improve with age. Fever and acidosis after an anesthetic with ketamine, halothane, and succinylcholine have been reported. Liver transplantation has been performed in patients with more severe forms of Hers disease.

#### *Type VII (Tarui Disease)*

Tarui disease is caused by a deficiency of muscle phosphofructokinase. It is similar to McArdle disease and is characterized by muscle cramping. Patients with Tarui disease present with exercise intolerance and episodic myoglobinuria. There is usually no cardiac or hepatic involvement. The same enzyme defect in erythrocytes causes chronic hemolytic anemia. There are four forms of the disease: classic, late-onset, infantile (usually fatal), and hemolytic.<sup>73</sup>

#### *Type IX*

GSD type IX is caused by a deficiency of hepatic glycogen phosphorylase kinase and is clinically similar to Hers disease (type VI). There are several isoforms of the enzyme controlled by many genes. The clinical presentation can be very heterogeneous. Most patients have short stature, hypotonia, muscle cramps, exertional myoglobinuria, and hyperlipidemia.

#### *Type XI (Fanconi–Bickel Syndrome)*

Fanconi–Bickel syndrome is a rare autosomal recessive disorder caused by mutations of the glucose-transporting enzyme (Glut-2). These patients have short stature, hepatomegaly, glucose and galactose intolerance, fasting hypoglycemia, and a characteristic proximal renal tubular acidosis. They usually survive to adulthood.<sup>74</sup>

#### *Type 0*

Type 0 GSD is caused by a deficiency of the hepatic form of glycogen synthase that causes a decrease in liver glycogen. Hepatomegaly, consequently, does not occur. Clinical features include fasting ketotic

hypoglycemia, short stature, and osteopenia. Many patients are asymptomatic and the disease is often diagnosed by the unsuspected discovery of hypoglycemia.<sup>75</sup> As preoperative fasting may cause hypoglycemia, intravenous administration of a glucose-containing solution may be necessary.

## **Mucopolysaccharidoses**

The mucopolysaccharidoses (MPS) are rare familial diseases inherited as autosomal recessive disorders. The disorders are a result of a deficiency of a specific lysosomal enzyme that cleaves mucopolysaccharides. The result is an accumulation of mucopolysaccharides in the brain, heart, bone, liver, cornea, and tracheobronchial tree.<sup>76</sup>

There are eight types of MPS and several subtypes (Table 24-16). All forms of MPS are characterized by progressive craniofacial deformities, joint and skeletal anomalies, cardiac involvement, and early death from pulmonary infection or cardiac failure. The upper airway is characterized by a depressed nasal bridge, short neck, macroglossia, and tongue protrusion secondary to infiltration of mucopolysaccharides. Chronic rhinitis, enlarged tonsils and adenoids, and obstructive sleep apnea are typical. Clinical phenotypes within each MPS type range from severe to attenuated variants with longer life expectancy.

Hunter and Hurler syndromes are the best known of the MPS diseases. Respiratory infection and cardiac disease (valvular and ischemic) lead to death at an early age. MPS type IV (Morquio syndrome) is associated with the most significant skeletal deformities. Respiratory insufficiency with marked chest wall deformity is common. Severe dysplasia or absence of the odontoid process frequently leads to chronic or acute myelopathy. Neurologic manifestations such as developmental delay and hydrocephalus are due to MPS depositions in the CNS. Cardiac involvement occurs in most forms of MPS except the Sanfilippo variants (Type III). MPS infiltration of the myocardium, cardiac valves, and conducting system often lead to myocardial ischemia, cardiomyopathy, and dysrhythmias.

Patients with MPS develop coarse facial features (gargoylism), lumbar lordosis, stiff joints, chest deformities, small stature, corneal opacities, hepatomegaly, and splenomegaly. The diagnosis of MPS is based on detection of urinary glycosaminoglycans and measurement of enzyme activity in the serum, leukocytes, and fibroblasts. No definitive therapy exists for MPS. Depending on the specific enzyme defect, however, ERT may lessen the effects of the disease. ERT, however, does little to ameliorate the cardiac or neurologic effects of MPS.<sup>77</sup> The role of human stem cell transplantation (HSCT) for the treatment of MPS is controversial.

**Table 24-16 Mucopolysaccharidoses**

Type Eponym	Main Clinical Features	Prevalence	Enzyme Defect	Urinary Mucopolysaccharides	Progressive Craniofacial Deformities	Progressive Joint or Skeletal Deformities	Progressive Cardiac Involvement
Type I(H) <i>Hurler</i>	Severe Hurler phenotype, mental retardation, corneal clouding, death <14 yrs	1:100,000	$\alpha$ -L-Iduronidase	Dermatan sulfate Heparan sulfate	Macrocephaly, coarse facies, macroglossia, hydrocephalus	Stiff joints, thoracolumbar kyphosis, possible odontoid hypoplasia, short neck, short stature	Coronary intimal and valvular thickening, mitral regurgitation, cardiomegaly
Type I(S) <i>Scheie</i>	Corneal clouding, normal intelligence Survival to adulthood	1:500,000	$\alpha$ -L-Iduronidase	Dermatan sulfate	Mild to coarse facies, macroglossia, prognathia	Short neck, normal stature	Aortic regurgitation
Type I(H/S) <i>Hurler-Scheie</i>	Intermediate phenotype	1:111,000	$\alpha$ -L-Iduronidase	Dermatan sulfate Heparan sulfate	Macrocephaly, coarse facies, macroglossia, micrognathia	Diffuse joint limitation, short neck, short stature	Mitral and aortic valvular thickening or regurgitation
Type II <i>Hunter</i>	Variable course: severe to mild Survival to adulthood, possible mental retardation	1:162,000	Iduronidate-2-sulfatase	Dermatan sulfate	Macrocephaly, coarse facies, hydrocephalus	Diffuse joint limitation, short neck, short stature	Coronary intimal thickening, ischemic cardiomyopathy
Type IIIA <i>Sanfilippo</i>	Behavioral problems, aggression	1:114,000	Heparan-N-sulfatase	Heparan sulfate	Mildly coarse facies	Mildly stiff joints, lumbar vertebral dysplasia, short stature	Minimal to none
Type IIIB <i>Sanfilippo</i>	Progressive dementia, seizures Survival: 2nd to 3rd decade	1:211,000	$\alpha$ -N-acetylglucosaminidase	Heparan sulfate	Mildly coarse facies	Stiff joints that may not extend fully, ambulation difficulties	Minimal to none
Type IIIC <i>Sanfilippo</i>	Intrafamilial variability, mild dysmorphism	1:1,407,000	$\alpha$ -N-acetylglucosaminidase N-acetyltransferase	Heparan sulfate	Mildly coarse facies	Stiff joints that may not extend fully, walking problems	Minimal to none
Type IIID <i>Sanfilippo</i>	Coarse hair, clear cornea Normal height	1:1,056,000	N-acetylglucosamine-6-sulfatase	Heparan sulfate	Mildly coarse facies	Stiff joints that may not extend fully, walking problems	Minimal to none
Type IVA <i>Morquio</i>	Short trunk type of dwarfism, fine corneal opacities, skeletal dysplasia spondyloepiphyseal dysplasia, final height <125 cm	1:1, 201,000	N-acetylgalactosamine-6-sulfatase	Keratan sulfate	Mildly coarse facies	Joint laxity, severe kyphoscoliosis, odontoid hypoplasia, short neck, C1-C2 subluxation possible, short stature	Aortic regurgitation
Type IVB <i>Morquio</i>	Same as MPS IVA but milder, final height >120 cm	1:248,000	$\beta$ -Galactosidase	Keratan sulfate	Mildly coarse facies	Joint laxity, severe kyphoscoliosis, odontoid hypoplasia, short neck, C1-C2 subluxation possible, short stature	Aortic regurgitation
Type VI <i>Maroteaux-Lamy</i>	Hurler phenotype with marked corneal clouding, normal intelligence	1:100,000	N-acetylgalactosamine-4-sulfatase	Dermatan sulfate	Macrocephaly, coarse facies, macroglossia	Mild joint stiffness, kyphoscoliosis, odontoid hypoplasia, short stature	Mitral and valvular thickening or regurgitation
Type VII <i>Sly</i>	Highly variable; dense inclusion in granulocytes	1:2,111,000	$\beta$ -Glucuronidase	Dermatan sulfate	Macrocephaly, coarse facies	Mild joint stiffness, kyphoscoliosis, odontoid hypoplasia, short stature	Mitral and valvular thickening or regurgitation, aortic dissection

Prevalence of lysosomal storage diseases. *JAMA*. 2011;281:249-254.

## Management of Anesthesia

MPS patients have significant deformities of the upper airway and cardiorespiratory dysfunction and the risks of perioperative management must not be underestimated. The variability of clinical abnormalities in patients with MPS requires individualized treatment for each patient. Some types of MPS produce severe airway and cardiac effects, whereas other types

have mild dysfunction.

Airway management can be extremely challenging. All options for airway management, including oropharyngeal airways, supraglottic airways, video laryngoscopes, and flexible fiberscopes should be readily available prior to induction of anesthesia. Careful positioning of the head and neck is required to minimize the risk of spinal cord damage. A slow, controlled inhalation induction with sevoflurane in oxygen is preferred. Mask ventilation, however, can become difficult and a supraglottic airway may be helpful during induction. Laryngoscopy is complicated by thick, noncompressible tissue of the upper airway, macroglossia, copious airway secretions, and bony deformities of the head and neck. Muscle relaxants should be avoided until the airway has been secured.<sup>78,79</sup> Postoperative respiratory complications are common.<sup>80</sup>

Careful preoperative evaluation with echocardiography is indicated for some types of MPS (e.g., Hurler syndrome). The presence of cardiac dysfunction will certainly influence the type of anesthesia and intraoperative monitoring.

### *Osteogenesis Imperfecta*

Osteogenesis imperfecta (OI) is a heterogeneous group of diseases characterized by susceptibility to bone fractures due to a defect in collagen type I (Table 24-17). Type I collagen is the primary component of the extracellular matrix of bone and skin. Inheritance is autosomal dominant for most forms (type VI, autosomal recessive) and the incidence is 1 in 20,000 to 50,000 live births. OI is a multisystem disease characterized by brittle bones, osteoporosis, joint laxity, tendon weakness, cardiac anomalies, blue sclera, platelet dysfunction, abnormal airway anatomy, and abnormal dentition. Pectus deformities of the chest and kyphoscoliosis may lead to restrictive pulmonary disease and respiratory failure.<sup>81</sup>

**Table 24-17 Anesthetic Considerations in Osteogenesis Imperfecta**

Type	Clinical Severity	Inheritance	Mutant Gene	Manifestations	Anesthetic Considerations	Lifespan
I	Mild, nondeforming	Autosomal dominant	Col1A/2	Increased frequency of fractures; short stature; blue sclera; progressive hearing impairment	A: Normal dentition B: Dentinogenesis imperfecta	Long-term survival <sup>a</sup>
II	Perinatally lethal	Autosomal dominant	COL1A/2	Multiple fractures in utero; micromelia; bowed LEs; small thorax; respiratory failure		Death in utero or within first month of life
III	Progressively deforming	Autosomal dominant	COL1A/2	Growth retardation; multiple fractures; progressive kyphoscoliosis; vertebral compression; blue sclera; dentinogenesis imperfecta	Airway anomalies	Death in second to fourth decade
IV	Moderately deforming	Autosomal dominant	COL1A/2	In utero fractures; fractures with minor trauma; bowing of LEs with weight bearing	A: Normal dentition B: Dentinogenesis imperfecta; midface or mandibular deformity	Long-term survival <sup>a</sup>
V	Moderately deforming	Autosomal dominant	Unknown	In utero fractures; fractures with minor trauma; bowing of LEs with weight bearing	Potential for midface or mandibular deformity	Long-term survival <sup>a</sup>
VI	Moderately to severely deforming	Autosomal recessive	Unknown	In utero fractures; fractures with minor trauma; bowing of LEs with weight bearing	Potential for midface or mandibular deformity	Long-term survival <sup>a</sup>

<sup>a</sup>With appropriate medical care.

LEs, lower extremities.

Adapted from: Van Dijk FS, Pals G, Van Rijn RR, et al. Classification of osteogenesis imperfecta revisited. *Eur J Med Genet.* 2010;53(1):1–5; and Stynnowick GA, Tobias JD. Perioperative care of the patient with osteogenesis imperfect. *Orthopedics.* 2007;30(12):1043–1049.

The most common cardiac lesion is aortic insufficiency. Aortic root dilation may lead to aortic dissection. Mitral valve prolapse and insufficiency can occur.<sup>82</sup> Central nervous manifestations include craniovertebral instability and atlantoaxial subluxation that can lead to quadriparesis. Hydrocephalus is common.

## Management of Anesthesia

Patients with OI need to be carefully and gently positioned as minor trauma can cause fractures. The upper airway should be carefully examined and cervical range of motion determined. Megalocephaly and a short neck can make direct laryngoscopy difficult and alternative intubation techniques may be required. A preoperative echocardiogram may be beneficial if there is a history of valvular heart disease. Induction of anesthesia can be performed with inhalation or intravenous techniques. Regional anesthesia is generally

avoided because of the risk of trauma to the spine and the potential for coagulopathy from platelet dysfunction. Caudal analgesia, however, has been used in selected patients.<sup>83</sup> Mild intraoperative temperature elevation can occur in patients with OI. There is no evidence that OI patients are at increased risk for MH.<sup>84</sup>

## ANEMIAS

Anemia is a common finding among patients undergoing anesthesia. The absolute or relative deficiency of red blood cells (RBCs) is commonly due to blood loss, but can be due to inherited or acquired disorders of RBC production (Table 24-18). Several physiologic responses compensate for anemia. These responses include increased cardiac output, increased plasma volume, decreased blood viscosity, and increased levels of 2,3-diphosphoglycerate (Table 24-19).

It is estimated that one third of blood transfusions are administered for postoperative anemia. Many institutions have implemented some form of preoperative blood management that includes identification of preoperative anemia. The goal of these programs is to identify specific causes of anemia and institute appropriate therapy prior to elective surgery in order to reduce the need for perioperative blood transfusion.<sup>85</sup>

**Table 24-18** Types of Anemia

<b><i>Nutritional Deficiency</i></b>
Iron
Vitamin B <sub>12</sub>
Folate
Anemia of chronic illness
<b><i>Hemolytic</i></b>
Spherocytosis
Glucose-6-phosphate dehydrogenase deficiency
Pyruvate kinase deficiency
Immune mediated
Drug-induced ABO incompatibility
<b><i>Hemoglobinopathies</i></b>
Hemoglobin S (sickle cell)
Thalassemia major (Cooley anemia)
Thalassemia intermedia
Thalassemia minor

## Table 24-19 Compensatory Mechanisms to Increase Oxygen Delivery with Chronic Anemia

Increased cardiac output  
Increased RBC 2,3-diphosphoglycerate  
Increased P-50  
Increased plasma volume  
Decreased blood viscosity

### Nutritional Deficiency Anemias

Deficiencies of iron, vitamin B<sub>12</sub>, or folate (vitamin B<sub>9</sub>) produce characteristic anemias. Nutritional anemia can be a result of decreased intake or the inability to absorb vital nutrients. Chronically ill patients may suffer a combination of these deficiencies with the added burden of a systemic inflammatory response that impairs the patient's ability to process nutrients and causes an *anemia of chronic illness*.

*Iron deficiency anemia* typically occurs because of a diet low in iron or chronic, slow blood loss. The hemogram of a person with iron deficiency anemia shows a low total hemoglobin, low mean corpuscular volume (MCV) (microcytosis), and a low mean corpuscular hemoglobin (MCH) (hypochromia).

*Megaloblastic anemia* is caused by a deficiency of vitamin B<sub>12</sub> or folate. A critical deficiency of these vitamins inhibits cell division and maturation in the bone marrow. Vitamin B<sub>12</sub> deficiency can be due to inadequate intake or poor absorption (pernicious anemia). Although the deficiency of either vitamin B<sub>12</sub> or folate can cause megaloblastic anemia, neurologic deficits are associated with B<sub>12</sub> deficiency. The neurologic changes are a result of patchy cerebral and spinal cord demyelination. The neurologic deficits may improve with vitamin B<sub>12</sub> therapy. Regional anesthesia is relatively contraindicated if neurologic dysfunction is present. The administration of nitrous oxide is controversial. Nitrous oxide inactivates methionine synthetase, a B<sub>12</sub>-based enzyme that catalyzes the conversion of homocysteine to methionine. Methionine synthetase deficiency causes megaloblastic cellular changes and neurologic deficits. The short exposure to nitrous oxide that occurs during a routine anesthetic is unlikely to have detrimental effects.<sup>86</sup> Prolonged or frequent exposure to nitrous oxide has caused confirmed instances of adverse hematologic and neurologic effects.

Folate deficiency is most frequently associated with alcoholism, pregnancy, or malabsorption.

### Hemolytic Anemias

The normal lifespan of an RBC is 120 days and any cause of premature RBC destruction can cause anemia. The causes of premature RBC destruction can be due to fragility of the RBC cytoskeleton, immune mediated destruction, or a deficiency in a cytoplasmic enzyme.

## Hereditary Spherocytosis

Hereditary spherocytosis and hereditary elliptocytosis are inherited conditions that cause misshapen and fragile RBCs. The abnormally shaped RBCs are removed from the circulation by the spleen and the severity of the anemia can be subclinical, mild, or severe. Other effects of premature RBC destruction include cholelithiasis, splenomegaly, and jaundice. Moderate to severe disease usually presents in infancy with hyperbilirubinemia. Splenectomy can be performed to alleviate the anemia.<sup>87,88</sup> Splenectomy is avoided in young children, if possible, as loss of the spleen can cause an overwhelming postsplenectomy infection (OPSI). OPSI is usually caused by encapsulated bacterial pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Cholecystectomy due to cholelithiasis is commonly performed.

## Glucose-6-Phosphate Dehydrogenase Deficiency

 Glucose-6-phosphate dehydrogenase (G6PD) is the most common human enzymopathy. G6PD catalyzes the first step in the pentose phosphate shunt. NADPH is produced in this step and is deficient in the RBCs of affected individuals. NADPH deficiency increases the vulnerability of RBCs to oxidative stressors. Oxidative stress can result from the consumption of fava beans, exposure to drugs, infections, and metabolic derangements (e.g., diabetic ketoacidosis). The mechanism by which the “stressed” RBCs hemolyze is unknown. Many drugs and chemicals can cause hemolysis in patients with G6PD deficiency. Although anesthetic drugs are not likely to cause hemolysis, many common drugs can and should be avoided in the perioperative period ([Table 24-20](#)). Drugs that promote the formation of methemoglobin (prilocaine, nitroprusside) should also be avoided.<sup>89</sup>

## Pyruvate Kinase Deficiency

Pyruvate kinase converts phosphoenolpyruvate to pyruvate and produces nearly half of the ATP in the RBCs. PK deficiency dramatically reduces the amount of ATP available to RBCs and shortens their lifespan. Clinical presentation is highly variable and may present in infancy with anemia and hyperbilirubinemia. Patients with PK deficiency can develop iron overload with or without blood transfusion and monitoring for signs of iron overload is

necessary. Splenectomy may increase RBC lifespan. Pregnancy may be associated with increased hemolysis. Anesthesia care is directed at the degree of anemia and potential comorbidities.<sup>90</sup>

### Immune Hemolytic Anemias

Immune hemolytic anemia may be classified as autoimmune, drug-induced, or alloimmune. Autoimmune hemolytic anemia occurs when autoantibodies are formed that attack antigens on the RBC. RBCs that are bound by the autoantibodies are damaged by activation of the complement cascade. The spectrum of illness caused by autoimmune hemolysis is broad. The autoantibodies may be further characterized as cold, warm, or mixed based on their range of activity at different temperatures. Autoimmune hemolytic anemia can be associated with infection, malignancy, lymphoma, organ transplantation, and connective tissue diseases.<sup>91</sup> Cold autoimmune hemolytic anemia is triggered in the perioperative period when a patient is exposed to a cold environment or receives cold intravenous solutions. Cooling during cardiopulmonary bypass could precipitate severe hemolysis unless a preoperative exchange transfusion is performed.

Drugs can act as haptens that bind to proteins on the RBC membrane forming a protein-hapten antigen that stimulates antibody production. The antibodies attack the antigen and lyse the RBC. Drugs that are frequently implicated in drug-induced hemolysis include penicillin, cephalosporins, and  $\alpha$ -methyl dopa. Anesthetic drugs have not been shown to induce hemolysis by this mechanism.<sup>92</sup>

Alloimmune hemolytic anemia occurs when a patient is transfused with incompatible donor blood. Hemolytic disease of the newborn is an example of this type of reaction. In this instance, appropriate pre-existing antibodies damage or destroy targeted “nonself” RBCs.

**Table 24-20** Drugs That Can Produce Hemolysis in Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

Aspirin (high doses)	Penicillin
Chloramphenicol	Phenacetin
Dapsone	Phenazopyridine
Doxorubicin	Phenazopyridine
Furazolidone	Primaquine
Isoniazid	Quinidine
Methylene blue	Quinine
Nalidixic acid	Streptomycin
Naphthalene	Sulfacetamide
Niridazole	Sulfanilamide
Nitrofurantoin	Sulfapyridine

## Hemoglobinopathies

Hemoglobinopathies occur when there is a genetic miscoding in the amino acid sequence of the hemoglobin. The end result is anemia and multisystem injury that can be severe. Normal hemoglobin (hemoglobin A) is comprised of four molecular subunits: two alpha ( $\alpha$ -) globins, two beta ( $\beta$ -) globins, and ferrous iron. Normal and variant hemoglobins are listed in [Table 24-21](#). Hemoglobinopathies are commonly found in areas of the world that are endemic for malaria. Individuals who are heterozygous for the hemoglobinopathy may have a resistance to malaria. Individuals who are homozygous for the hemoglobinopathy, however, have a broad spectrum of illnesses due to anemia, accumulation of excessive iron and hemoglobin precursors, immunocompromise, tissue ischemia, and inflammation. The most common hemoglobinopathies are sickle cell disease (SCD) and thalassemia. Together, these two hemoglobinopathies are the most severe genetic disorders in the world.

### Sickle Cell Disease

SCD is transmitted as an autosomal recessive trait with an asymptomatic carrier state. In the United States, 1 in 600 African-Americans have SCD and 8% to 10% of the African-American population carries the trait.

**Table 24-21** Hemoglobin Variants

Hemoglobin	Globin Chains	Type
A	$\alpha_2\beta_2$	Normal adult
A2	$\alpha_2\delta_2$	Normal adult (minor)
F	$\alpha_2\gamma_2$	Normal fetal
S	$\alpha_2\beta_5\delta_2$	Sickle (HbS)
C	$\alpha_2\beta\gamma\delta_2$	HbC (clinical illness)
E	$\alpha_2\beta\epsilon_2$	HbE (clinical illness)
Bart's	$\gamma_4$	$\alpha$ -Thalassemia (fetal demise)
H	$\beta_4$	$\alpha$ -Thalassemia major

**Table 24-22** Mechanisms of Cellular and Tissue Injury in Sickle Cell Disease

Capillary obstruction with tissue ischemia
RBC and platelet adhesion to the endothelium
Activation of coagulation with thrombosis and/or embolism
Reperfusion injury
Hemolysis and release of free hemoglobin
Leukocytosis and immune system activation
Free radical injury due to leukocyte superoxide release
Nitric oxide depletion due to superoxide release and uptake by free Hgb
Release of cytokines and inflammatory mediators
Endothelial injury
Iron accumulation

SCD is caused by a single amino acid substitution in the  $\beta$ -globin molecule. Valine is substituted for glutamine at the sixth amino acid position. The valine changes the physical characteristics of the affected hemoglobin under conditions of oxygen desaturation. When exposed to low oxygen tension, HbS polymerizes into fiber-like chains that distort the normal biconcave shape into the crescent or “sickle cell” shape. Sickled RBCs are relatively inflexible and have difficulty moving through capillaries. The spleen removes these abnormal cells from the circulation, reducing their lifespan to 12 to 17 days (normal = 120 days). The pathophysiology of SCD occurs because of microvascular obstruction, tissue ischemia, and chronic anemia. Less evident and insidious mechanisms cause other detrimental effects ([Table 24-22](#)).

Patients with SCD display a remarkable variability in the severity of the disease. Some patients experience severe complications and death at an early age whereas others have only mild symptoms. The severity of the symptoms has been correlated with the amount of fetal hemoglobin (HbF) that persists beyond the neonatal period. A higher concentration of HbF reduces symptoms and complications. The clinical manifestations of SCD affect almost all systems ([Table 24-23](#)).

**Table 24-23** Complications of Sickle Cell Disease

<b>Hematologic:</b> hemolytic anemia, aplastic anemia, leukocytosis
<b>Spleen:</b> autoinfarction, hyposplenism, splenic sequestration
<b>Central nervous system:</b> stroke, hemorrhage, aneurysm, meningitis
<b>Musculoskeletal:</b> painful crisis, bone marrow hyperplasia, avascular necrosis, osteomyelitis, bone infarction, skeletal deformity, growth retardation, cutaneous ulceration
<b>Cardiac:</b> cardiomegaly, pulmonary hypertension, cor pulmonale, diastolic dysfunction, cardiomyopathy
<b>Pulmonary:</b> acute chest syndrome, asthma, fibrosis, pulmonary infarction, sleep apnea, pneumonia, hypoxemia, thromboembolism
<b>Renal:</b> papillary necrosis, glomerular sclerosis, renal failure
<b>Genitourinary:</b> priapism, infection
<b>Hepatobiliary:</b> jaundice, hepatitis, cirrhosis, cholelithiasis, cholestasis
<b>Eye:</b> retinopathy, hemorrhage, visual loss
<b>Immune:</b> immunosuppression, leukocytosis
<b>Psychosocial:</b> depression, anxiety, substance abuse, narcotic dependence

Several recurrent problems that cause significant morbidity and mortality afflict SCD patients. *Vaso-occlusive crisis (VOC)* is often the first and most frequent manifestation of SCD and is secondary to musculoskeletal ischemia. The pain of VOC ranges from mild to excruciating. Mild cases can be managed with oral analgesics, rest, and hydration. Severe VOC requires hospitalization, parenteral narcotics, intravenous hydration, supplemental oxygen, RBC transfusion, and in some cases regional analgesia. The incidence of VOC in the perioperative period is 10%. *Acute chest syndrome (ACS)* has a mortality of 1% to 20% and represents the single greatest threat to patients with SCD. Clinical manifestations of ACS are chest pain, dyspnea, cough, wheezing, hypoxemia, and chest infiltrates (radiography). ACS may be caused by thrombosis, embolism (clot, fat), and infection. The incidence of ACS is higher in children and may be due to infection. The treatment of ACS is supplemental oxygen, hydration, analgesia, and respiratory support. Antibiotics may be empirically administered pending the results of sputum culture. Severe ACS or ACS unresponsive to usual therapies may require RBC transfusion. The incidence of ACS after abdominal surgery is 10% to 20%. Factors that may contribute to postoperative ACS are pain, splinting, narcotics, and hypoventilation. The risk of postoperative ACS can be reduced by preoperative RBC transfusion and postoperative incentive spirometry. *Sequestration crisis* occurs when the splenic rate of RBC removal exceeds the rate of RBC production. Severe anemia and hemodynamic instability can occur rapidly. Sequestration may be an indication for splenectomy. Patients with SCD require a high and continuous rate of RBC production. Mild bone marrow suppression triggered by a viral infection (parvovirus B19) can precipitate an *aplastic crisis*. *Asthma* occurs in 50% of SCD patients and

*pulmonary hypertension* occurs in 10% of SCD patients. Mortality is increased when either condition is present.<sup>93</sup>

Preventive treatment of SCD patients includes oral hydroxyurea to increase HbF production, pneumococcal vaccination to reduce the risk of sepsis, and daily penicillin in children less than 5 years of age. Transfusion of RBCs is performed when anemia is severe or as a preventive measure to reduce the amount of HbS. Bone marrow transplantation can be curative and is an option for severe SCD. Removal and genetic manipulation of the SCD patient's own bone marrow to increase HbF production is currently being investigated.<sup>94</sup>

### *Management of Anesthesia*

Patients with SCD frequently require anesthesia and surgery. Patients enrolled in comprehensive sickle cell clinics are likely to have current surveillance evaluations by experienced hematologists. The clinic notes may provide important information. Preoperative evaluation is directed at identification of underlying organ dysfunction. Patients with a history of respiratory dysfunction, ECG abnormalities, functional limitations, or indicators of cor pulmonale should have a preoperative echocardiogram. Common echocardiographic findings include left ventricular hypertrophy, right ventricular dilation, atrial enlargement, and pulmonary hypertension.

Preoperative RBC transfusion to achieve a hemoglobin level of 10 g/dL can be performed and may reduce the likelihood of sickle cell complications (ACS, VOC). In most cases, a simple transfusion is preferable to an exchange transfusion. Exchange transfusion is indicated when preparing patients for cardiopulmonary bypass. There is a high incidence of alloimmunization among SCD patients and obtaining cross-matched RBCs can be time consuming.

Active measures to maintain normothermia and normovolemia should be employed in the perioperative period. Extremity tourniquets can be used in situations where the success of the surgery is dependent on their use. The complication rate after tourniquet use is 12%.

Administration of narcotics has been implicated as a cause of postoperative ACS. The use of regional analgesia and nonnarcotic analgesics to reduce the need for narcotics are encouraged. Spinal anesthesia for Cesarean section has been shown to decrease perioperative blood loss and reduce the need for postoperative narcotics.<sup>95</sup> If narcotics are required, careful monitoring of oxygenation and sedation should be performed. Early recognition of developing ACS and aggressive therapy may be critical to successful treatment.<sup>96,97</sup>

## **Thalassemia**

Thalassemia is the result of deficient production of either the  $\alpha$ - or  $\beta$ -globin components of hemoglobin.  $\alpha$ -Thalassemia is caused by underproduction of  $\alpha$ -globin and  $\beta$ -thalassemia from a deficit of  $\beta$ -globin. Anemia is caused by an inadequate amount of normal hemoglobin. The underproduction of one of the globin chains is not balanced by underproduction of the other globin chain. The globin that can be produced in normal amounts is overproduced. These excess globin chains are ineffective as they are not paired with the correct globin to form a functional tetramer. The excess unpaired globin chains cause cellular and tissue injury. Ineffective erythropoiesis causes severe bone marrow hyperplasia, skeletal deformity, and skeletal fragility. Multisystem injury is caused by many of the mechanisms that cause systemic injury in SCD.

The terms thalassemia major, intermedia, and minor are a reflection of the severity of the anemia that correlates with underproduction of the globin chain. Many patients with thalassemia minor do not require RBC transfusion. Routine transfusion of RBCs maintains an adequate hemoglobin level, suppresses bone marrow hyperplasia and extramedullary erythropoiesis. Routine transfusion, however, inevitably results in iron overload. Iron overload causes cardiac, hepatic, immune, and endocrine system dysfunction. Chelation therapy may reduce the amount of iron overload. Bone marrow transplantation may be considered for severely affected individuals.

### *Management of Anesthesia*

Patients with thalassemia often require anesthesia for cholecystectomy, splenectomy, vascular access, and correction of skeletal abnormalities. The preoperative evaluation should include measurement of the hemoglobin and the search for evidence of cardiac, hepatic, and endocrine dysfunction from iron overload. There is a high incidence of alloimmunization and cross-matching blood can require considerable time.

Facial dysmorphism can cause difficulties with airway management.<sup>98</sup> Spontaneous hemorrhage from extramedullary bone marrow deposits has been reported. Although spinal anesthesia has been successfully used for Cesarean section, bone marrow deposits in the spinal canal can be considered to be a relative contraindication to neuraxial anesthesia.

## **Connective Tissue Diseases**

The four most common connective tissues diseases are rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), systemic sclerosis (SSc, scleroderma), and the inflammatory myopathies (dermatomyositis [DM]/polymyositis [PM]). Although many patients have well-defined diseases, many others have overlap syndromes with features of different

connective tissue diseases. The etiologies of the connective tissue diseases are unknown, although the immune system is clearly involved in the cascade of pathologic events that cause the clinical manifestations. Each of these diseases has effects on joints and diffuse systemic effects.

## **Rheumatoid Arthritis**

RA is a chronic, autoimmune, and inflammatory disease characterized by symmetric polyarthropathy and diverse systemic effects. Although the etiology is unknown, research continues to unravel the pathogenesis. There are interactions between environmental factors and genetic susceptibility that initiates the process that causes RA. Smoking, exposure to silica, infection, and periodontal disease are associated with an increased risk of RA. Activated endothelial cells attract adhesion molecules that stimulate T cells and B lymphocytes. The release of cytokines (tumor necrosis factor [TNF], interleukins) accelerates the inflammatory cascade. B lymphocytes produce autoantibodies (rheumatoid factor) that further increase cytokine production.<sup>99</sup> Seventy-five percent of RA patients have measurable levels of rheumatoid factor. The pathologic effects of RA begin with cellular hyperplasia of the synovium followed by invasion of lymphocytes, plasma cells, macrophages, and fibroblasts. Cartilage and articular surfaces are ultimately destroyed.

The metacarpophalangeal and interphalangeal joints of the hands are involved first. The knee is the most frequently involved joint of the leg. The upper cervical spine is affected in 85% of patients with RA. Atlantoaxial and subaxial instability can lead to compression of the spinal cord. Plain radiography and CT of the cervical spine will demonstrate the bony changes. MRI is better suited to study the effects on the spinal cord. The degree of cord compression, however, may not correlate with symptoms. Although a very rare event, spinal cord damage after laryngoscopy and tracheal intubation has been reported.<sup>100</sup> Intradural cord compression secondary to rheumatoid nodules or pannus formation can occur. RA commonly affects the joints of the larynx, resulting in limitation of vocal cord movement and edema of the laryngeal mucosa that can progress to airway obstruction. The laryngeal effects and arthritic changes in the temporomandibular joint can complicate laryngoscopy and tracheal intubation.

Extra-articular and systemic effects of RA are diverse (Table 24-24). Cardiovascular disease is a common cause of mortality and there is a high incidence of subclinical cardiac dysfunction. Pericarditis occurs in 20% to 50% of RA patients and can produce restrictive pericarditis and cardiac tamponade. Other cardiovascular manifestations include coronary artery disease, myocarditis, aortitis (aortic root dilation, aortic valve insufficiency),

diastolic dysfunction, dysrhythmias, and pulmonary hypertension.<sup>101</sup> Pulmonary changes include interstitial lung disease, reduced oxygen diffusing capacity, obstructive and restrictive lung disease, pulmonary nodules, and pleural effusions. Several of the antirheumatic drugs can cause or accentuate pulmonary damage.<sup>102</sup> Renal disease as a direct result of RA is uncommon, but glomerulonephritis and amyloidosis can cause kidney failure. Mild anemia is present in almost all patients with RA. The anemia may be secondary to decreased erythropoiesis or a side effect of drug therapy.

Neurologic complications of RA include peripheral nerve compression from joint destruction and noncompressive neuropathies (mononeuritis multiplex) secondary to vasculitis of the blood vessels supplying affected nerves (vasa nervorum). Cervical myelopathy may be secondary to cervical spine compression. Rheumatoid vasculitis can affect cerebral blood vessels resulting in headache, hemiparesis, aphasia, and confusion.

**Table 24-24** Extra-articular Manifestations of Rheumatoid Arthritis

<b>Skin</b>	<b>Peripheral Nervous System</b>
Raynaud phenomenon	Compression syndromes
Digital necrosis	Mononeuritis
<b>Eyes</b>	<b>Central Nervous System</b>
Scleritis	Dural nodules
Corneal ulceration	Necrotizing vasculitis
<b>Lung</b>	<b>Liver</b>
Pleural effusions	Hepatitis
Pulmonary fibrosis	<b>Blood</b>
<b>Heart</b>	Anemia
Pericarditis	Leukopenia
Cardiac tamponade	
Coronary arteritis	
Aortic insufficiency	
<b>Kidney</b>	
Interstitial fibrosis	
Glomerulonephritis	
Amyloid deposition	

The disease process of immunoinflammatory modulation that causes RA is complex and monotherapy is unlikely to be completely successful. There are four groups of antirheumatic drugs: nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, disease-modifying antirheumatic drugs (DMARDs), and biologic DMARD drugs. NSAIDs reduce pain and inflammation, but do little to affect the ultimate course of the disease. Corticosteroids are effective, but the side effects associated with long-term use limit their usefulness. DMARDs target T and B cells. Of the DMARDs, methotrexate has proven to be very effective and is often the initial drug of choice. Biologics target inflammatory mediators such as TNF, and interleukins. Potential side effects

of biologic DMARDs are increased susceptibility to infection and cancer (Table 24-25).<sup>103</sup> Surgical procedures such as synovectomy, tenolysis, and joint replacement are performed to relieve pain and restore joint function.

## Management of Anesthesia

RA is a multisystem disease with diverse clinical manifestations. Although the joint disabilities may be obvious, less evident are the effects of RA on the heart, lung, liver, CNS, and kidneys. The type and severity of systemic dysfunction must be considered when planning an anesthetic for the patient with RA.<sup>104</sup>

Arthritic changes in the temporomandibular joints, cricoarytenoid joints, and the cervical spine can complicate rigid, direct laryngoscopy, and tracheal intubation. The incidence of atlantoaxial subluxation may exceed 40% in RA patients and flexion of the neck can compress the spinal cord. Many patients with RA are asymptomatic with respect to cervical spine disease (Fig. 24-6). Preoperative imaging studies (radiography, CT, MRI) may be indicated if the degree of cervical involvement is unknown. An intubation technique that minimizes cervical movement is recommended. Awake intubation, video laryngoscopy, or flexible, fiberscope-assisted tracheal intubation should be considered. Cricoarytenoid arthritis produces edema of the larynx and may decrease the size of the glottis inlet, necessitating the use of a smaller than predicted tracheal tube.

**Table 24-25** Adverse Effects of Drugs Used to Treat Connective Tissue Diseases

<b>Class of Drugs</b>	<b>Adverse Effects</b>
Corticosteroids	Hypertension, osteoporosis, hyperglycemia
<b><i>Immunosuppressants</i></b>	
Methotrexate	Hepatotoxicity, anemia, leucopenia
Azathioprine	Biliary stasis, leucopenia
Cyclosporine	Nephrotoxicity, hypertension, hypomagnesemia
Cyclophosphamide	Hemorrhagic cystitis, cholinesterase inhibition
Leflunomide	Hepatotoxicity, weight loss, hypertension
Mycophenolate mofetil	Nausea, emesis, diarrhea
<b><i>TNF Antagonists</i></b>	
Etanercept	Infections, tuberculosis
Infliximab	Lymphoma, heart failure
Adalimumab	Infection, T-cell lymphoma, fatigue
Golimumab	Infection, lymphoma
Certolizumab	Infection, lymphoma
<b><i>Interleukin-1 Antagonists</i></b>	
Anakinra	Infection, skin irritation
<b><i>Interleukin-6 Antagonists</i></b>	
Tocilizumab	Infection, headache, stomatitis, fever

<b><i>T-cell Inhibitors</i></b>	
Abatacept	Infection
<b><i>CD20 Monoclonal Antibody</i></b>	
Rituximab	Infection, infusion reaction
<b><i>Janus Kinase Inhibitors</i></b>	
Tofacitinib	Infection, anemia, leucopenia
<b><i>Antimalarials</i></b>	
Hydroxychloroquine	Myopathy, retinopathy
<b><i>Antibiotics</i></b>	
Sulfasalazine	Nausea, neutropenia, hepatotoxicity
<b><i>Heavy Metal Chelators</i></b>	
Penicillamine	Autoimmune dermatoses, glomerulonephritis
<b><i>Aspirin</i></b>	
	Platelet dysfunction, peptic ulcers, sensitivity
<b><i>NSAIDs</i></b>	
	Peptic ulcer, leucopenia, coronary artery disease
<b><i>COX-2 Inhibitors</i></b>	
	Nephrotoxicity, cardiovascular dysfunction

**Figure 24-6** Magnetic resonance imaging of a cervical spine in a patient with rheumatoid arthritis. Although the patient had no neurologic symptoms, there was severe spinal stenosis in the upper cervical spine.

The degree of cardiopulmonary involvement by the rheumatoid process will influence the selection of anesthetics and level of intraoperative monitoring. The need for postoperative ventilatory support should be anticipated if severe pulmonary disease is present.

RA patients receiving corticosteroids may require corticosteroid supplementation during the perioperative period. Aspirin and other anti-inflammatory drugs interfere with platelet function and clotting may be abnormal. RA drugs that alter immune function can increase the risk of postoperative infection. Although methotrexate does not seem to increase the risk of infection, it is recommended that anti-TNF biologics be withheld before surgery.<sup>105</sup>

Restriction of joint mobility necessitates careful positioning of the patient during surgery. The extremities should be positioned to minimize the risk of neurovascular compression and further joint injury. Preoperative examination of joint motion will help determine how the extremities and head should be positioned. Regional anesthesia should be considered, but must be individualized. Factors such as technical impediments to nerve identification from joint deformity, potential for platelet dysfunction, and the patient's ability to tolerate positioning for a period of time must be factored into the decision for regional anesthesia.<sup>106</sup>

## **Systemic Lupus Erythematosus**

SLE is a multisystem disease caused by complex interactions between genetic susceptibility, environmental factors, and alterations in innate and adaptive immunity. Deficiencies in the complement cascade, B-cell immunity, T-cell signaling, and apoptotic clearance have also been implicated. Anti-DNA antibodies, antiphospholipid antibodies, anticardiolipin antibodies, and lupus anticoagulant may be detected in many patients with SLE. The diverse clinical manifestations of SLE are undoubtedly secondary to many genes that influence the immune system.<sup>107</sup> Environmental influences include ultraviolet light exposure, vitamin D deficiency, and infection. Numerous drugs have been associated with lupus including clonidine, enalapril, captopril, hydralazine, methyldopa, isoniazid, and procainamide.

The clinical manifestations of SLE are varied and many can be life-threatening. The most common presenting features are polyarthritis and dermatitis. The arthritis is migratory and can involve any joint, including the cervical spine. The classic malar rash occurs in one third of SLE patients. Renal disease is present in 60% of SLE patients and is a common cause of morbidity. Lupus nephritis causes proteinuria, decreased creatinine clearance, and hypertension. Dialysis or renal transplantation is required for 10% to 20% of lupus patients. CNS manifestations of lupus are caused by vasculitis and include seizures, stroke, dementia, psychosis, myelitis, and peripheral neuropathy.

Cardiovascular manifestations of SLE include pericarditis, accelerated atherosclerosis, noninfectious endocarditis (Libman–Sacks), ventricular dysfunction, and dysrhythmias. Although pericardial effusions are common, cardiac tamponade is unusual. The pulmonary effects of SLE include serositis, interstitial disease, pulmonary embolism, pulmonary hemorrhage, and pulmonary hypertension. Pulmonary function studies typically reveal a restrictive disease pattern and a decreased diffusion capacity.<sup>108</sup>

Hoarseness, stridor, and upper airway obstruction can be caused by cricoarytenoiditis. Gastrointestinal manifestations of SLE include esophageal dysmotility, peritonitis, pancreatitis, hepatitis, and bowel ischemia.

Despite the diverse effects of SLE and the lack of specific therapy, survival of SLE patients has significantly improved. The antimalarials hydroxychloroquine and chloroquine suppress production of cytokines and TNF- $\alpha$  and increase long-term survival. IVIG may induce remission in selected patients. Lupus nephritis has been treated with many drugs including corticosteroids, cyclophosphamide, azathioprine, tacrolimus, and methotrexate. More recently, monoclonal antibodies such as rituximab, belimumab, and epratuzumab have proven to be effective. The potential for side effects from any of the SLE drugs is significant (Table 24-25).<sup>109</sup>

## Management of Anesthesia

Careful preoperative evaluation of the SLE patient is necessary because of the diverse effects of the disease.<sup>110,111</sup> Preoperative chest radiography, pulmonary function testing, and echocardiography may be indicated if the clinical history suggests cardiopulmonary dysfunction. Preoperative quantitation of renal function may be necessary. Although minor changes in hepatic function are common, these effects are generally not significant. Patients with SLE are at increased risk for infection.

Arthritic involvement of the cervical spine is unusual and tracheal intubation is generally not difficult. The potential for laryngeal involvement and upper airway obstruction does, however, require clinical evaluation of laryngeal function. Should postextubation laryngeal edema or stridor occur, intravenous corticosteroids are effective.

Drugs for the treatment of SLE will influence the choice of anesthetics. Patients receiving corticosteroids will usually require the administration of perioperative corticosteroids. Cyclophosphamide inhibits cholinesterase and may prolong the response to succinylcholine. Azathioprine can increase dose requirements for nondepolarizing muscle relaxants.

### **Systemic Sclerosis (Scleroderma)**

SSc is characterized by changes in the microvasculature that cause inflammation and fibrosis of the skin, blood vessels, and internal organs. It appears that an environmental trigger when applied to genetically susceptible individuals initiates an autoimmune response that releases inflammatory mediators that cause edema and accelerated fibrosis of tissues.<sup>112</sup>

The skin becomes swollen and thickened and eventually becomes fibrotic and taut leading to joint immobility. Raynaud phenomenon occurs in 85% of SSc patients and may be the presenting symptom.

More than 80% of SSc patients develop interstitial lung disease that progresses to pulmonary fibrosis and pulmonary hypertension. The leading cause of death in patients with SSc is pulmonary hypertension and right ventricular failure.<sup>113</sup> Cardiac manifestations of SSc include myocardial fibrosis, fibrosis of the conduction system, and pericarditis. Echocardiography may reveal reduced systolic function and diastolic dysfunction.<sup>114</sup>

Renal dysfunction is common and secondary to renal vasculopathy. Five percent of SSc patients develop a scleroderma renal crisis with hypertension, retinopathy, and a rapid deterioration in renal function.<sup>115</sup> Gastrointestinal motility is decreased and frequent episodes of gastroesophageal reflux and aspiration pneumonitis exacerbate pulmonary dysfunction. Decreased small intestine and colonic motility can cause pseudo-obstruction.

Therapy is directed at immunomodulation with immunosuppressants such

as cyclophosphamide, mycophenolate mofetil, azathioprine, and methotrexate. ACE inhibitors are commonly used to treat hypertension. Monoclonal antibodies directed at B-cells and cytokines are being investigated. Stem cell transplantation is effective in selected patients.<sup>116</sup>

## Management of Anesthesia

SSC, like other connective tissue diseases is a multisystem disease with diverse manifestations. The type of anesthesia must be guided by the presence and severity of organ dysfunction.

Tracheal intubation can be quite difficult. Fibrotic and taut skin markedly reduces active and passive motion of the temporomandibular joint. Awake, fiberoptic-assisted tracheal intubation may be required. On some occasions, an awake tracheostomy may be necessary. Orotracheal intubation is preferred as fragility of the nasal mucosa increases the risk of severe nasal hemorrhage from nasotracheal intubation.

Esophageal dysmotility and gastroesophageal reflux increase the risk of aspiration pneumonitis during anesthesia. Chronic hypoxemia is common and is secondary to interstitial lung disease and pulmonary hypertension. Compromised myocardial function and coronary arteriosclerosis may necessitate invasive cardiovascular monitors and echocardiography during surgery. Venous access can be challenging and central venous cannulation may be required. Myopathy is present in most patients with SSC and an increased sensitivity to muscle relaxants can occur.

Regional anesthesia may be a suitable alternative to general anesthesia. The response to local anesthetics may be prolonged.<sup>117</sup> Anesthesiologists are frequently consulted for treatment of Raynaud phenomenon.

## *Inflammatory Myopathies (Dermatomyositis/Polymyositis)*

Five diseases comprise the inflammatory myopathies: DM, PM, necrotizing autoimmune myositis (NAM), inclusion-body myositis (IBM), and overlap myositis. Although the clinical features of the five diseases are diverse, severe muscle weakness and noninfectious muscle inflammation are present in all five. Circulating autoantibodies are common.<sup>118</sup>

DM is the most common of the five and is the result of antibody-induced complement activation that causes muscle necrosis. Presenting features of DM are proximal muscle weakness and a characteristic skin rash. The skin rash consists of a purplish discoloration of the eyelids (heliotrope rash), periorbital edema, and scaly erythematous lesions on the knuckles (Gottron papules). DM occurs in children and adults. The presenting symptoms of PM are muscle pain and proximal muscle weakness that occur in the second decade of life.

Fifty percent of patients with DM and PM have pulmonary disease. The pulmonary manifestations are interstitial pneumonitis, alveolitis, and bronchopneumonia. Aspiration pneumonia is very common.<sup>119</sup> Myocardial fibrosis can cause congestive heart failure and dysrhythmias.

Patients with NAM typically have an acute onset of severe proximal muscle weakness. IBM is characterized by the slow onset of proximal muscle weakness and frequent falls.

The treatment of DM, PM, and NAM is initially with corticosteroids, followed by immunosuppressants (azathioprine, methotrexate, cyclosporine, mycophenolate). IVIG and rituximab have also been used with success. No drugs have been shown to be effective for the treatment of IBM.

## Management of Anesthesia

The reported experience with anesthesia in patients with inflammatory myopathies is very limited. Patients with DM have limited motion of the temporomandibular joint and decreased mouth opening. Rigid, direct laryngoscopy is usually difficult and alternative intubation techniques are often required. Tracheal intubation of patients with PM is generally not difficult. Dysphagia and gastroesophageal reflux are common and there is an increased risk of aspiration pneumonitis. Gastrointestinal perforations that require surgical intervention are common in patients with PM. Cardiac dysfunction may be subclinical and preoperative echocardiography may be informative.

It should be anticipated that the response to muscle relaxants will be varied. It would be prudent to avoid the use of succinylcholine as hyperkalemia may occur. Short-acting nondepolarizing muscle relaxants are preferred. Postoperative mechanical ventilation may be required for patients with significant muscle weakness and interstitial lung disease.

## Skin Disorders

Most diseases of the skin are localized and cause few systemic effects or complications during the administration of anesthesia. Epidermolysis bullosa (EB) and pemphigus, two blistering skin diseases, can result in perioperative complications.

### *Epidermolysis Bullosa*

EB is a rare skin disease that can be inherited or acquired. Patients with heritable forms have abnormalities in the anchoring systems of skin layers. The acquired forms are autoimmune disorders in which autoantibodies

are produced that destroy the basement membrane of the skin and mucosa. The end result is the loss of normal intercellular bridges and separation of skin layers, intradermal fluid accumulation, and bullae formation (Fig. 24-7). Many gene mutations that contribute to abnormal skin structure have been identified and there may be as many as 30 subtypes of EB. For clinical purposes there are four types depending on where skin separation occurs: epidermolysis simplex (EBS), separation within the epidermis; junctional epidermolysis (JEB), separation at the lamina lucida; epidermolysis bullosa dystrophica (DEB), separation beneath the lamina densa; and Kindler syndrome (mixed EB), separation at different levels.<sup>120</sup>

**Figure 24-7** The ultrastructure of the zones of the skin. The diagram demonstrates where skin separation occurs in different types of epidermolysis bullosa (EB). (Adapted from Uitto J, Christiano AM. Molecular genetics of the cutaneous basement membrane zone. *J Clin Invest.* 1992;90:687–692.)

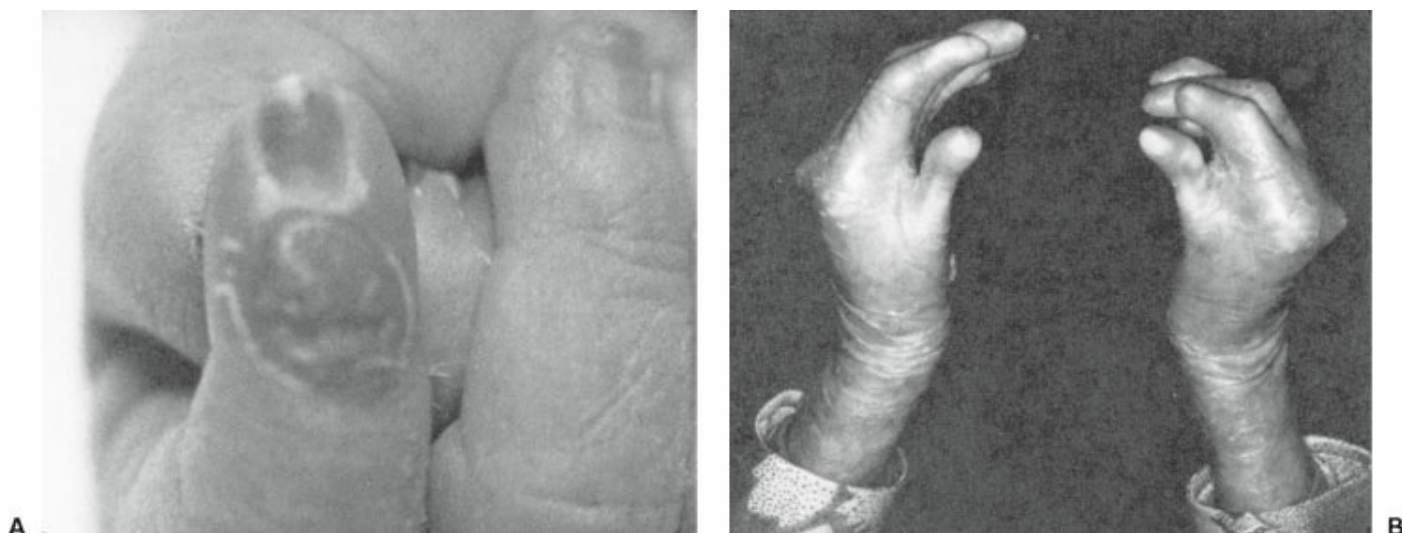

EBS is generally benign. Some types of JEB have marked involvement of the airway and are lethal by one year of age.<sup>121</sup>

DEB is caused by a defect in type VII collagen. Progressive blistering and scarring causes severe deformities of the fingers and toes with pseudosyndactyly formation (Fig. 24-8). Secondary infection and malignant degeneration of the skin are common. The esophagus is involved with resultant dysphagia, esophageal strictures, and poor nutrition. Dilated cardiomyopathy with ventricular dysfunction, aortic root dilation, and intracardiac thrombi can develop.<sup>122</sup> Anemia secondary to poor nutrition and recurrent infection is common. Streptococcal infection-induced glomerulonephritis with albuminuria occurs. Hypoplasia of tooth enamel often necessitates extensive dental restorations. Patients with DEB rarely survive beyond the third decade of life.

Medical therapy for DEB has not been very successful. Gene therapy, injection of fibroblasts, and bone marrow stem cell transplantation are under investigation. Surgical therapy is directed at improvement of hand function and improved nutrition.

### Management of Anesthesia

Preoperative presence of an unrecognized cardiomyopathy should be considered as it will certainly influence the selection of anesthesia and monitoring. Many patients with DEB have decreased physical activity from limb deformities and their history of exercise tolerance may not be an accurate reflection of cardiac function. Preoperative echocardiography may provide the best evaluation of cardiac function.

**Figure 24-8** Epidermolysis bullosa. **A:** Bullous lesion of the finger in a neonate with epidermolysis bullosa. **B:** Hands of an older child with epidermolysis progression to produce severe scarring and pseudosyndactyly. (Courtesy of James E. Bennett, MD, Division of Plastic Surgery, Indiana University School of Medicine, Indianapolis, IN.)

It is critical that trauma to the skin and mucous membrane be minimized during the intraoperative period. Movement should be minimized as much as possible. Lateral shearing forces applied to the tissue are especially damaging, whereas pressure applied perpendicular to the skin is not as hazardous. Gel pads (defibrillation pads) can be used for ECG monitoring. The blood pressure cuff can be padded with loose cotton dressings or PVC film. Intravenous lines can be secured with a nonadhesive material or sutured in place.

Despite the myriad of potential risks, anesthesia is generally well tolerated when care is rendered at centers with expertise in management of DEB patients. Surgical procedures that are commonly performed include hand reconstruction, dental restorations, esophageal dilation, and gastrostomy. Intravenous and inhalation induction have been used successfully in patients

with DEB. Trauma from the face mask should be minimized with the use of a lubricated material. Frictional trauma to the oropharynx can cause large intraoral bullae and hemorrhage. All airway instruments must be well lubricated. Tracheal intubation is generally safe for patients with DEB; however, scarring of the oral cavity with microstomia and tongue immobility increases the difficulty of tracheal intubation. Fiberoptic-assisted tracheal intubation may be required. Nasotracheal intubation has been performed but its use is controversial. The laryngeal mask airway has been used for patients with DEB.<sup>123</sup>

Ketamine may be useful for superficial extremity procedures as it provides good analgesia and may not require supplementation with inhaled anesthetics. Regional anesthesia, including spinal, epidural, and brachial plexus block has been used successfully in patients with DEB.

## **Pemphigus**

Pemphigus is an autoimmune blistering disease that involves extensive areas of the skin and mucous membranes. IgG autoantibodies attack desmosomal proteins, desmoglein 3 and desmoglein 1, leading to loss of cell adhesion and separation of epithelial layers. There are five types of pemphigus: pemphigus vulgaris (PV), pemphigus foliaceus, pemphigus erythematosus, drug-induced pemphigus, and paraneoplastic pemphigus. More than 50 drugs have been implicated as causes of pemphigus.<sup>124</sup>

PV is the most common type and is of most importance to the anesthesiologist because of the occurrence of oral lesions. Oral lesions develop in 50% to 70% of patients with PV. Oropharyngeal lesions can make eating so painful that malnutrition develops. Lesions of the pharynx, larynx, esophagus, urethra, conjunctiva, cervix, and anus can develop. Skin denudation and blister formation cause significant losses of fluid and protein and pose the risk of secondary infection.<sup>125</sup> As with EB, lateral shearing force is more likely to produce bullae than pressure applied perpendicularly to the skin. Systemic corticosteroids are the treatment of choice for pemphigus. Improvement may be seen within days of corticosteroid therapy. Immunosuppressants, immunomodulators, and IVIG can be used to reduce corticosteroid dosage.

Paraneoplastic pemphigus is associated with several malignant tumors, especially lymphomas and leukemias. IgG antibodies are produced that react to desmoglein 3 and desmoglein 1. Oral and cutaneous lesions occur. Obstructive respiratory failure may result from inflammation and sloughing of tracheal tissue.

## **Management of Anesthesia**

Preoperative drug therapy and the extreme fragility of the mucous membranes are primary concerns for management of anesthesia. Corticosteroid supplementation will be necessary during the perioperative period for patients receiving chronic steroid therapy. Management of the airway and tracheal intubation should be performed as described for patients with DEB.<sup>126</sup>

There are no specific contraindications to the use of any intravenous or inhaled anesthetic. Regional anesthesia has been used for PV patients. Methotrexate may produce hepatorenal dysfunction and bone marrow suppression. Cyclophosphamide can prolong the action of succinylcholine by inhibition of cholinesterase.

## **Additional Notes**

## **KEY POINTS**

- 1 The most important (but often overlooked) item in the preuse checkout of the anesthesia workstation is to have immediately available a functioning self-inflating resuscitation bag (SIRB) and a full auxiliary tank of oxygen.
- 2 The low-pressure circuit (LPC) is the “vulnerable area” of the anesthesia workstation because it is most subject to breakage and leaks. The LPC is located downstream from all anesthesia machine safety features except the oxygen analyzer (or, in some cases, the ratio controller), and it is the portion of the machine where a leak is most likely to go unrecognized if an inappropriate LPC leak test is performed. Leaks in the LPC can cause

- delivery of a hypoxic or subanesthetic mixture, leading to patient hypoxic injury or awareness during anesthesia.
- 3 Because some GE Healthcare/Datex-Ohmeda anesthesia machines have a one-way check valve in the LPC, a negative-pressure leak test is required to detect leaks in the LPC. A positive-pressure leak test will not detect leaks in the LPC of a machine with an outlet check valve.
  - 4 Before administering an anesthetic, the circle breathing system must be checked for leaks and for correct flow. To test for leaks, the circle system is pressurized to 30-cm water pressure, and the circle system airway pressure gauge is observed (static test). To check for appropriate flow to rule out obstructions and faulty valves, the ventilator and a test lung (breathing bag) are used (dynamic test). In addition, the manual/bag circuit must be actuated by compressing the reservoir bag, in order to rule out obstructions to flow in the manual/bag mode.
  - 5 Internal vaporizer leaks can only be detected with the vaporizer turned to the “on” position. In the “off” position the vaporizer is excluded from the LPC.
  - 6 Many new anesthesia workstation self-tests do not detect internal vaporizer leaks unless each vaporizer is individually turned on during repeated self-tests.
  - 7 The oxygen failure cutoff valves (also known previously as “fail-safe” valves, “hypoxic guards,” or “proportioning systems”) help minimize the likelihood of delivery of a hypoxic gas mixture, but they are not foolproof. Delivery of a hypoxic mixture may still result from (1) the wrong supply gas, either in the cylinder or in the main pipeline; (2) a defective or broken safety device; (3) leaks downstream from the safety devices; (4) inert gas administration (e.g., helium); and (5) dilution of the inspired oxygen concentration by high concentrations of inhaled anesthetics.
  - 8 In the event of a gas pipeline crossover, two actions must be taken. The backup oxygen cylinder must be turned on (since the tank valve should always be turned off when not in use), and the wall/pipeline supply sources must be disconnected.
  - 9 Because of desflurane’s low boiling point (22.8°C) and high vapor pressure (669 mmHg at 20°C), delivery of desflurane requires specially designed vaporizers, such as the GE Healthcare/Datex-Ohmeda Tec 6, the Dräger D-Vapor, and the GE Healthcare Aladin cassette vaporizing system.
  - 10 Erroneous filling of an empty variable bypass vaporizer with desflurane could theoretically be catastrophic, resulting in delivery of a hypoxic mixture and a massive overdose of inhaled desflurane.
  - 11 Inhaled anesthetics can interact with CO<sub>2</sub> absorbents and produce toxic

compounds. During sevoflurane (only) anesthesia, compound A can be formed, particularly at low fresh gas flow (FGF) rates. Carbon monoxide may be produced when volatile anesthetics are utilized, particularly with desiccated absorbents.

- 12 Desiccated strong base absorbents (particularly barium hydroxide lime, Baralyme) can react with sevoflurane, producing extremely high absorber temperatures and combustible decomposition products. These, in combination with the oxygen- or nitrous oxide-enriched environment of the circle system, have produced very high temperatures and fires within the breathing system. For this reason, Baralyme is no longer available in the United States. Lithium-based absorbents are nonreactive.
- 13 Anesthesia ventilators with ascending bellows (bellows that ascend during the expiratory phase) were initially thought to be safer than descending bellows. This is because a breathing system disconnection would be obvious since the ascending bellows would not refill/rise during exhalation. Contemporary machines with descending bellows, however, have been carefully redesigned to address the initial limitations. Current descending bellows ventilators have featherlight bellows, an electric eye at the bottom of the bellows housing to detect bellows movement, and the bellows housing is subjected to PEEP, such that in case of a disconnect, the bellows would actually rise and stay up.
- 14 With older design machines, use of the oxygen flush valve during the inspiratory phase of mechanical ventilation could cause barotrauma, particularly in pediatric patients. The newer workstations have fresh-gas decouplers or peak-inspiratory pressure limiters that were designed to prevent these complications. Ventilators that use fresh gas decoupling (FGD) technology virtually eliminate the possibility of barotrauma by oxygen flushing during the inspiratory phase because FGF and oxygen flush flow are diverted to the reservoir bag. However, if the reservoir bag has a large leak or is absent altogether, patient awareness under anesthesia and delivery of a lower-than-expected oxygen concentration could occur due to entrainment of room air.
- 15 With newer GE Healthcare/Datex-Ohmeda anesthesia ventilators such as the 7900 series SmartVent, both the patient circuit gas and the drive gas are scavenged, resulting in substantially increased volumes of scavenged gas. Thus, the scavenging system flow removal must be set appropriately high to accommodate the increased volume; otherwise, undesired PEEP and contamination of the operating room environment could result.
- 16 Modern ventilators compensate for the changes in FGF, respiratory rate, and I:E ratio so that the delivered tidal volume does not change from that set to be delivered. This compensation is achieved either by “fresh gas decoupling” (in Dräger Fabius, Tiro, and Apollo workstations) or by

“fresh gas compensation” (in GE Healthcare/Datex-Ohmeda workstations).

The anesthesia machine is, conceptually, a pump for delivering medical gases and inhalation agents to the patient’s lungs. The function of the anesthesia machine is to (1) receive gases from the central supply and cylinders, (2) meter them and add anesthetic vapors, and finally, (3) deliver them to the patient breathing circuit.<sup>1</sup> The machine has evolved over the past 160 years from a rather simple ether inhaler to a complex device of valves, pistons, vaporizers, monitors, and electronic circuitry.

The “pump” in the modern anesthesia machine is either a mechanical ventilator or the lungs of the spontaneously breathing patient, or perhaps, a combination of the two. The anesthesia pump has a supply system: medical gases from either a pipeline supply or a gas cylinder, alongside vaporizers delivering potent inhaled anesthetic agents that are mixed with the medical gases. The anesthesia pump also has an exhaust system, the waste gas scavenging system, which removes excess gases from the patient’s breathing circuit. The breathing circuit is a series of hoses, valves, filters, switches, and regulators that interconnect the supply system, the patient, and the exhaust system.

Modern anesthesia machines (Figs. 25-1 to 25-4) are now more properly referred to as *anesthesia workstations*. The anesthesia workstation, as defined by the International Standards Organization, is a system for administering anesthetics to patients consisting of *an anesthesia gas delivery system, an anesthetic breathing system and any required monitoring equipment, alarm systems, and protection devices*.<sup>2</sup> The protection device is designed to prevent the patient from hazardous output due to incorrect delivery of energy or substances; for example, the adjustable pressure-limiting (APL) valve prevents barotrauma.

**Figure 25-1** A: Dräger Apollo Workstation. B: Dräger Perseus A500 Workstation.

In this chapter, the anesthesia workstation is examined piece by piece. The normal operation, function, and integration of major anesthesia workstation subsystems are described. More importantly, the potential problems and hazards associated with the various components of the anesthesia delivery system, and the appropriate preoperative checks that may help to detect and prevent such problems, are illustrated.

## Anesthesia Workstation Standards and Preuse Procedures

Years ago, a fundamental knowledge of the basic anesthesia machine pneumatics would have sufficed for most anesthesia providers. Today, a detailed understanding of pneumatics, electronics, and even computer science is necessary to fully understand the capabilities and complexities of the anesthesia workstation. Along with the changes in the composition of the anesthesia workstation to include more complex ventilation systems and integrated monitoring, recently there has also been increasing divergence between anesthesia workstation designs from different manufacturers. In 1993, a joint effort between the American Society of Anesthesiologists (ASA) and the U.S. Food and Drug Administration (FDA) produced the 1993 FDA Anesthesia Apparatus Preuse Checkout Recommendations (Appendix A). This preuse checklist was versatile and could be applied to most commonly available anesthesia machines equally well and did not require users to vary the preuse procedure significantly from machine to machine.

A

B

**Figure 25-2** A: Dräger Fabius GS Workstation. B: Mindray A7 Workstation.

A

B

**Figure 25-3** A: GE Aisys CS<sup>2</sup> Workstation. B: GE Aestiva Workstation. (Courtesy of GE Healthcare.)

**A** **Figure 25-4** **A:** Spacelabs Healthcare ARKON workstation (courtesy Spacelabs Healthcare, Snoqualmie, Washington). **B:** Maquet FLOW-i C30 Workstation. **B**

Today, because of variations in fundamental anesthesia workstation design, the 1993 FDA preuse checklist is no longer applicable to many contemporary workstations. Anesthesia providers must be aware of this limitation, and the original equipment manufacturer's recommended preuse checklist should be followed. Some of the newer workstations have computer-assisted self-tests that automatically perform a part of the preuse machine checkout procedure. The availability of such automated checkout features further adds to the complexity of constructing a uniform preuse checklist such as the one utilized in the recent past. Ultimately the responsibility for performing an adequate preuse checkout of the anesthesia workstation falls to the individual operator, regardless of the level of his or her training and the quality of technical support. Each anesthesia care provider has the ultimate responsibility for proper function of all anesthesia delivery equipment that he or she uses. This includes an awareness of which anesthesia workstation components are checked out by automated self-tests and which ones are not. Because of the number of workstations currently available and the variability among their self-testing procedures, the following discussion will be limited to general topics related to these systems.

## Standards for Anesthesia Machines and Workstations

The International Organization for Standards (ISO) and the American National Standards Institute (ANSI) have defined standards for anesthesia machines and workstations, and provided guidelines to manufacturers regarding their minimum performance, design characteristics, and safety requirements. The current standard in the United States is ISO 80601-2-13:2011/Amd1:2015, Particular Requirements for Basic Safety Essential Performance of and Anaesthetic Workstation (outside of the United States, other countries may have modified versions of ISO 80602-2-13). In addition to the ISO standards, International Electrotechnical Commission (IEC) document IEC 60601-1 is a series of standards that govern medical device design. Part 1 describes general standards for safety and performance. Newly manufactured workstations must have monitors that measure the following parameters: continuous breathing system pressure, exhaled tidal volume, ventilatory CO<sub>2</sub> concentration, anesthetic vapor concentration, inspired oxygen concentration, oxygen supply pressure, arterial hemoglobin oxygen saturation, arterial blood pressure, and continuous electrocardiogram. The anesthesia workstation must have a prioritized alarm system that groups the alarms into three categories: high, medium, and low priority. These monitors and alarms may be enabled automatically and made to function by turning on the anesthesia workstation, or the monitors and alarms can be enabled manually and made functional by following a preuse checklist.<sup>2,3</sup>

Perhaps just as important as the specifications for new anesthesia machines and workstations that are introduced into clinical care are the characteristics that render older machines obsolete. This is not an inconsequential issue, since the financial investment for replacing older machines is significant. The ASA document (dated June 22, 2004), “Guidelines for Determining Anesthesia Machine Obsolescence,” addresses some of the absolute as well as relative criteria that can help institutions make a decision on when even otherwise functioning equipment should be replaced.<sup>4</sup>

## Failure of Anesthesia Equipment

An 11-year study of 1,000 anesthesia incidents in the United Kingdom revealed that the most common failure was due to an equipment leak (61/1,000).<sup>5</sup> The authors stated the most likely underlying cause of system leaks was due to “design weakness”; for example, push-on tapers in breathing circuits that can easily become disconnected. Poor equipment maintenance and setup were the second most common underlying causes of equipment failure. The authors found that the pulse oximeter alarm was the most common principal monitor alerting the anesthesiologist to an equipment

problem.<sup>5</sup> Equipment failure due to entrapped cables may result in the inability to ventilate (thus warranting careful attention to organization and tidiness of the anesthesia workstation environment).<sup>6–8</sup> In a 1997 review of the ASA “Closed Claims” database, Caplan et al.<sup>9</sup> found that although claims related to the medical gas-delivery system were rare, when they occurred they were usually severe, with 76% resulting in death or permanent brain injury. The most common malfunction in that review was the breathing circuit (39%), followed by vaporizers (21%), ventilators (17%), gas tanks or gas lines (11%), and the anesthesia machine itself (7%). Use error was judged to be the cause in 75% of the 72 gas delivery equipment claims reviewed, whereas pure failure of equipment was considered the cause in the remainder.<sup>9</sup> In 2013, Mehta et al.<sup>10</sup> published an update of the 1997 study. They reviewed the 40 most recent claims in the database (for incidents between 1990 and 2011) and concluded that provider error occurred in 68%, equipment failure only in 13%, and both in 18%. Of the 40 incidents, 35% were considered to have been avoidable if a proper preanesthesia checkout had been performed.

## Safety Features of Newer Anesthesia Workstations

Older conventional anesthesia machines have design limitations that limit their safety. For example, some machines may lack features to prevent barotrauma during oxygen flush, lack automated preuse checkout, have multiple external connections, and have gas-driven ventilator bellows that do not fully empty and that may allow “breath stacking” as well as inaccurate tidal volume delivery.<sup>11</sup>

Modern workstations have designs that incorporate additional safety features such as fresh gas decoupling (FGD) to prevent barotrauma during oxygen flush, have integrated, software-driven self-checkout routines, have limited external connections, and have electronic, piston-driven ventilators that deliver accurate tidal volumes. [Table 25-1](#) summarizes relevant safety features of newer anesthesia workstations.

**Table 25-1** Comparison of Anesthesia Workstation Functions

Function	Narkomed AV2+	Ohmeda 7800	Dräger Narkomed 6400	Dräger Julian <sup>a</sup>	Dräger Fabius GS 1.3	GE/Datex-Ohmeda Aestiva/5	GE/Datex-Ohmeda ADU	GE/Datex-Ohmeda Aisys	GE/Datex-Ohmeda Avance CS <sup>2</sup>	Dräger Apollo	Mindray A3/A5	Spacelabs ARKON

## Checkout of the Anesthesia Workstation

 A complete anesthesia apparatus checkout procedure must be performed each day prior to the first use of the anesthesia workstation. An abbreviated checkout procedure should be performed before each subsequent case. The 1993 FDA Anesthesia Apparatus Checkout Recommendations (reproduced in Appendix A) remain applicable to the majority of older anesthesia machines in use worldwide.<sup>12–16</sup>

In 2008, the ASA published recommendations for preanesthesia checkout of machines, taking into consideration newer workstations that perform automated checkout.<sup>17</sup> Since the design of newer workstations varies considerably, no single preuse procedure is applicable. These guidelines present a template for individual departments and practitioners to design preanesthesia checkout procedures specific to their needs and equipment

(Appendix B). Sample checkout procedures are published on the ASA web site ([www.asahq.org](http://www.asahq.org)), and they encompass adult as well as pediatric equipment from major equipment manufacturers in the United States. The reader is strongly encouraged to review the checkout procedures reproduced in Appendices A and B at the end of this chapter and to understand the rationale for, and importance of, each step.

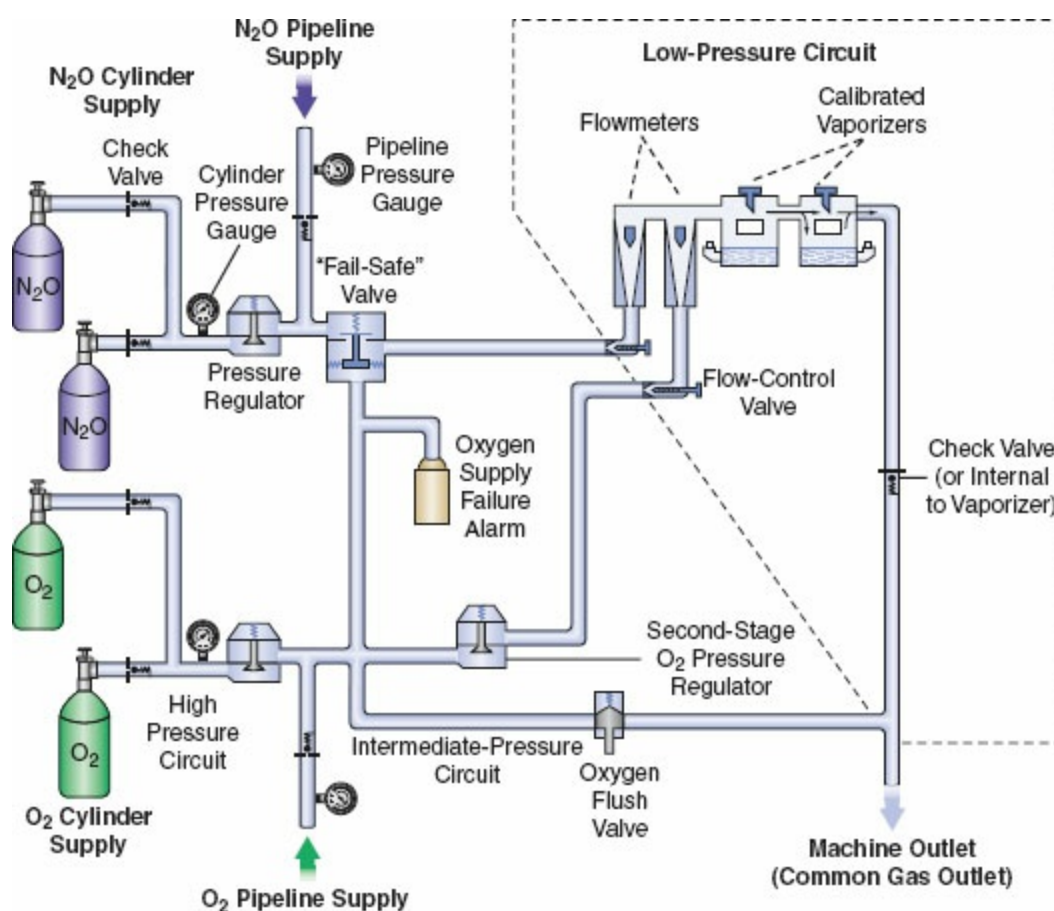

Perhaps the most important but often overlooked item in the preuse checkout of the anesthesia workstation is to have immediately available a functioning (tested) self-inflating resuscitation bag (SIRB) (Fig. 25-5) and a full auxiliary tank of oxygen. This is “plan B”—the backup plan. Many of the adverse outcomes associated with anesthesia equipment mishaps could have been averted if the SIRB had been used or used sooner. The SIRB is an item frequently missed in the preanesthesia setup.<sup>18</sup>

The next three most important preoperative checks are (1) oxygen analyzer calibration, (2) the low-pressure circuit (LPC) leak test, and (3) the circle system test. These are discussed in the following sections. Additional details regarding these systems are presented briefly in subsequent sections describing the anatomy of the anesthesia workstation; for a more comprehensive review, the reader is encouraged to consult the operator’s manual of their own equipment manufacturer. For a simplified diagram of a two-gas anesthesia machine and the components described in the following discussion, please refer to Figure 25-6. A comprehensive discussion of Figure 25-6 can also be found in the Anesthesia Workstation Pneumatics section.

### *Oxygen Analyzer Calibration*

The oxygen analyzer is one of the most important monitors on the anesthesia workstation. It is the only machine safety device that evaluates the integrity of the LPC in an ongoing fashion. Other machine safety devices, such as the oxygen supply pressure failure cutoff (“fail-safe”) valve, the oxygen supply pressure failure alarm, and the N<sub>2</sub>O/O<sub>2</sub> proportioning system, are all upstream from the flow control valves. The only monitor that detects problems downstream from the flow control valves is the oxygen analyzer. Calibration of this monitor is described in Step 9 of Appendix A (Anesthesia Apparatus Checkout Recommendations, 1993). The actual procedure for calibrating the oxygen analyzer has remained reasonably similar over the recent generations of the anesthesia workstations (Guideline for Designing Preanesthesia Checkout Procedures, 2008, Item 10 in Appendix B). Generally, the oxygen concentration-sensing element (usually a fuel cell on traditional machines) must be exposed to room air (at sea level) for calibration to 21%. This may require manually setting a dial on older machines, but on newer ones, it usually only involves temporarily removing the sensor, selecting and

then confirming that the oxygen calibration is to be performed from a set of menus on the workstation's display screen, and finally reinstalling the sensor. The function of the low oxygen concentration alarm should be verified by setting the alarm to trigger above the current oxygen reading. Some newer workstations use a side-stream sampling multigas monitoring module that incorporates a paramagnetic (fast) oxygen analyzer. These analyzers undergo automatic periodic oxygen calibration.<sup>19</sup> It should be noted that both the fuel cell and the paramagnetic oxygen analyzers actually measure PO<sub>2</sub> and express it as a percentage of 1 atmosphere at sea level. Thus, if a fuel cell were calibrated to 21% O<sub>2</sub> at sea level and then used at an altitude where the total air pressure is reduced, it would read less than 21% even though the composition of the atmosphere is unchanged (21%).

### Low-Pressure Circuit Leak Test

- 2** The LPC leak test checks the integrity of the anesthesia machine from the flow control valves to the common gas outlet. It evaluates the portion of the machine that is downstream from all safety devices except the oxygen

analyzer. The components located within this area are precisely the ones most subject to breakage and leaks. Leaks in the LPC can cause hypoxia or patient awareness.<sup>20,21</sup> Flow tubes, the most delicate pneumatic component of the machine, can crack or break. A typical three-gas anesthesia machine has 16 O-rings in the LPC. Leaks can occur at the interface between the glass flow tubes<sup>22</sup> and the manifold, and at the O-ring junctions between the vaporizer and its manifold. Loose filler caps on vaporizers are a common source of leaks, and these leaks can lead to delivery of subanesthetic doses of inhaled agents, causing patient awareness during general anesthesia.<sup>23</sup>

Several different methods have been used to check the LPC for leaks. They include the oxygen flush test, the common gas outlet occlusion test, the traditional positive-pressure leak test, the North American Dräger positive-pressure leak test, internal positive-pressure leak test, the GE Datex-Ohmeda negative-pressure leak test, the 1993 FDA universal negative-pressure leak test, and others. One reason for the large number of methods is that the internal design of various machines differs considerably. The most notable example is that many GE Healthcare/Datex-Ohmeda (hereafter frequently referred to as GE) machines/workstations have a check valve near the common gas outlet, whereas Dräger Medical workstations do not. The presence or absence of the outlet check valve profoundly influences which preuse check is indicated.

**3** Several mishaps have resulted from application of the wrong leak test to the wrong machine.<sup>24–27</sup> Therefore, it is mandatory to perform the appropriate low-pressure system leak test each day. To do this, it is essential to understand the exact location and operating principles of the Datex-Ohmeda check valve. Many Datex-Ohmeda anesthesia workstations have a machine outlet check valve located in the LPC (Table 25-1). The check valve is located downstream from the vaporizers and upstream from the oxygen flush valve (Fig. 25-6). It is open in the absence of back pressure. Gas flow from the manifold moves the rubber flapper valve off its seat and allows gas to proceed freely to the common gas outlet. The valve closes when back pressure is exerted.<sup>28</sup> Back pressure sufficient to close the check valve may occur with the following conditions: use of the oxygen flush, peak breathing circuit pressures generated during positive-pressure ventilation, or use of a positive-pressure leak test.

Generally speaking, the LPC of anesthesia workstations without an outlet check valve can be tested using a positive-pressure leak test, and machines with outlet check valves must be tested using a negative-pressure leak test. When performing a positive-pressure leak test, the operator generates positive pressure in the LPC using flow from the anesthesia machine or from a positive-pressure squeeze bulb to detect a leak. When performing a negative-pressure leak test, the operator creates negative pressure in the LPC using a

suction bulb to detect leaks. Two different LPC leak tests are described below.

### **Oxygen Flush Positive-Pressure Leak Test**

Historically, older anesthesia machines did not have check valves in the LPC. Therefore, it was common practice to pressurize the breathing circuit and the LPC with the oxygen flush valve to test for internal anesthesia machine leaks by observing the breathing system pressure gauge. Because some modern GE-Datex-Ohmeda machines have check valves in the LPC, application of a positive-pressure leak test to these machines can be misleading or even dangerous (Fig. 25-7). Inappropriate use of the oxygen flush valve or the presence of a leaking flush valve may lead to inadequate evaluation of the LPC for leaks. In turn, this can lead the workstation user into a false sense of security despite the presence of large leaks.<sup>29,30</sup> Positive pressure from the breathing circuit results in closure of the outlet check valve, and the value on the breathing system pressure gauge will fail to decrease. The system appears to be gas-tight, but in actuality, only the circuitry downstream from the outlet check valve is leak-free.<sup>31</sup> Thus, a vulnerable area exists from the check valve back to the flow control valves because this area is not tested by a positive-pressure leak test.

### **Verifying the Integrity of the Gas Supply Lines between the Flowmeters and the Common Gas Outlet**

The 1993 FDA Universal negative-pressure leak test (Appendix A, Step 5) was named “universal” because at that time it could be used to check all contemporary anesthesia machines regardless of the presence or absence of an outlet check valve in the LPC. It remains applicable for many older anesthesia machines, but for many newer machines this “universal” test is not applicable. Table 25-1 describes how newer workstations are tested for LPC and vaporizer leaks. Leaks in the gas supply lines between the flowmeters and the common gas outlet should be checked daily or whenever a vaporizer is changed (Appendix B, Item 8). The most thorough technique to check each vaporizer individually is by turning it on and then evaluating the low-4 pressure system for leaks. It is important to note that automated checkout procedures may not necessarily detect leaks at the vaporizer if the vaporizer is turned off during testing. In addition, vaporizers should be adequately filled and filler ports should be tightly closed (Appendix B, Item 7). As mentioned previously, the ASA now recommends that individual institutions develop internal guidelines specific to their own equipment and needs.<sup>17</sup>

**Figure 25-7** Inappropriate use of the oxygen flush valve to check the low-pressure circuit of a Datex-Ohmeda machine equipped with a check valve. The area within the rectangle is not checked by the inappropriate use of the oxygen flush valve. The components located within this area are precisely the ones most subject to breakage and leaks. Positive pressure within the patient circuit closes the check valve, and the value on the airway pressure gauge does not decrease despite leaks in the low-pressure circuit.

The 1993 FDA low-pressure system leak check is based on the Datex-Ohmeda negative-pressure leak test (Fig. 25-8). It is performed using a negative-pressure leak testing device, which is a simple suction 15-cc volume bulb that when evacuated generates a negative pressure of 65 mmHg. The machine main ON/OFF switch, the flow control valves, and the vaporizers are all turned off. The suction bulb is connected to the common gas outlet and squeezed repeatedly until it is fully collapsed. This action creates a vacuum in the low-pressure system circuitry. The machine is considered leak-free if the suction bulb remains collapsed for at least 10 seconds. A leak is present if the bulb reinflates during this period. The test is repeated with each vaporizer individually turned to the "on" position because internal vaporizer leaks can be detected only when the vaporizer is turned on and becomes part of the low-pressure system. Again, if the bulb reinflates in less than 10 seconds, a leak is present somewhere in the LPC. 5

### Evaluation of the Circle System

The circle system tests (Appendix B, Items 12 and 13) evaluate the integrity

of the circle breathing system, which spans from the machine common gas outlet to the Y-piece (Fig. 25-9). The test has two components: (1) breathing system pressure and leak testing and (2) verification that gas flows properly through the breathing circuit during both inspiration and exhalation. To thoroughly check the circle system for leaks, valve integrity, and obstruction, both tests must be performed preoperatively. The ASA 2008 recommendations call for performing the breathing system test and leak test before starting each case, such that pressure can be developed in the system during both manual/bag and automatic/mechanical ventilation.<sup>17</sup> Automated leak testing routines are implemented in modern workstations; system compliance is also calculated and used to adjust volume delivery during mechanical ventilation (Appendix B, Item 12). Because pressure and leak testing cannot identify all obstructions in the breathing circuit or confirm the function of the inspiratory and expiratory unidirectional valves, a test lung or second reservoir bag connected at the Y-piece can be used to confirm circuit integrity and function.<sup>32,33</sup> Visual inspection of the unidirectional valves should be performed daily, although subtle damage to these valves may be difficult to determine. Older 1993 FDA checkout procedures to identify valve incompetence that may not be visually obvious can be implemented, but are typically too complex for daily testing (Appendix B, Item 13).<sup>34,35</sup>

In the 1993 FDA Anesthesia Apparatus Checkout Recommendations, a *leak test* is performed by closing the APL (or pop-off) valve, occluding the Y-piece, and pressurizing the circuit to 30 cm H<sub>2</sub>O pressure using the oxygen flush valve. The value on the pressure gauge will not decrease if the circle system is leak-free, but this does not assure unidirectional valve integrity or function. The value on the pressure gauge will read 30 cm H<sub>2</sub>O even if the unidirectional valves are stuck shut or are incompetent. In addition, a *flow test* checks the integrity of the unidirectional valves, and it detects obstruction in the circle system. It can be performed by removing the Y-piece from the circle system and breathing through the two corrugated hoses individually. The unidirectional valve leaflets should be present and should move appropriately. The operator should be able to inhale but not be able to exhale through the inspiratory limb. The operator should be able to exhale but not inhale through the expiratory limb. Needless to say, before performing this test, the operator must ensure there is no anesthetic gas in the circuit! The flow test can also be performed by using the ventilator and a reservoir bag connected to the “Y” piece as described in the 1993 FDA Anesthesia Apparatus Checkout Recommendations (Appendix A, Steps 11 and 12).<sup>15</sup>

**Figure 25-8** FDA negative-pressure leak test. A negative-pressure leak testing device is attached directly to the machine common gas outlet. Squeezing the bulb creates a vacuum in the low-pressure circuit and opens the check valve (*left*). When a leak is present in the low-pressure circuit, room air is entrained through the leak and the suction bulb inflates (*right*). (Adapted from Andrews JJ. Understanding anesthesia machines. In: 1988 Review Course Lectures, p. 78. Cleveland: International Anesthesia Research Society, 1988.)

Inhaled anesthetic delivery systems. In: Miller RD, ed. *Anesthesia*. 6th ed. Philadelphia, PA: Churchill Livingstone; 2004:295.)

## Workstation Self-tests

Many new anesthesia workstations now incorporate technology that allows the machine to either automatically or manually guide the user through a series of self-tests to check for functionality of electronic, mechanical, and pneumatic components. Tested components commonly include the gas supply system, flow control valves, the circle system, ventilator, and integrated vaporizers. The comprehensiveness of these self-diagnostic tests varies from

one model and manufacturer to another. If these tests are to be employed, users must be certain to read and strictly follow all manufacturer recommendations. Although a thorough understanding of what the particular workstation's self-tests include is very helpful, this information may be difficult to obtain and may vary greatly among devices. None of the preuse checkouts are fully automated; therefore, the user must perform certain functions for the checkout to be complete. It is important for the user to know what is in the automated checkout and even more important to know what is not. Figures 25-10 and 25-11 show screen shots from the Dräger Apollo workstation checkout procedures, manual and automated.

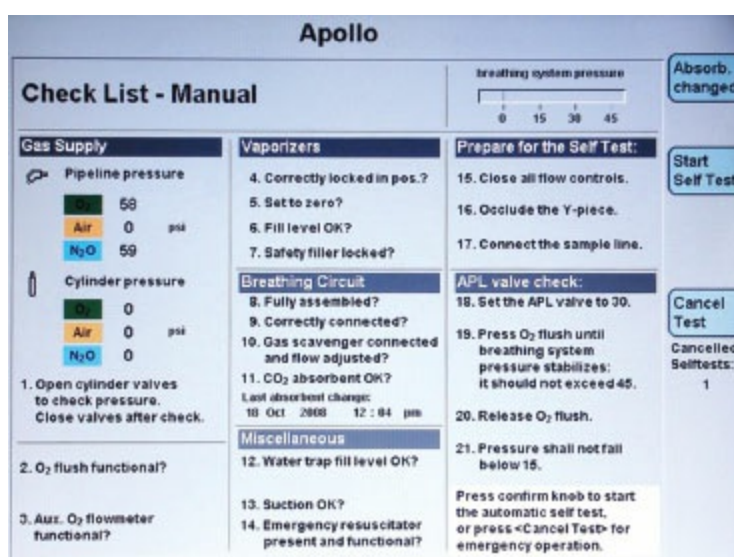

Figure 25-10 Apollo manual checklist screen.

One particularly important point of caution with self-tests should be noted on systems with manifold-mounted vaporizers such as the Dräger Apollo and Dräger Fabius GS workstations. A manifold-mounted vaporizer does not become a part of an anesthesia workstation's low-pressure system until its concentration control dial is turned to the "on" position. Therefore, to detect internal vaporizer leaks in this type of a system, the "leak test" portion of the self-diagnostic must be repeated with each individual vaporizer turned to the "on" position. If this precaution is not taken, large leaks that could potentially result in patient awareness, such as those from a loose filler cap or cracked fill indicator, could go undetected.

A successful automated machine checkout does not necessarily preclude machine failure. In one example, a leak in an APL bypass valve of a Dräger Fabius GS Premium workstation was not detected by an automated checkout, resulting in a ventilator failure alarm. The authors concluded that a *functional test* of the ventilator and breathing circuit should be added to the checkout procedure. This may be performed by connecting a breathing bag to the circuit elbow. Activating the oxygen flush to inflate the bag will allow the bag

to act as a model lung. The ventilator is now activated. Circuit pressure, tidal volume delivery, and bag inflation and deflation of the “lung” should be observed for proper function.<sup>36</sup>

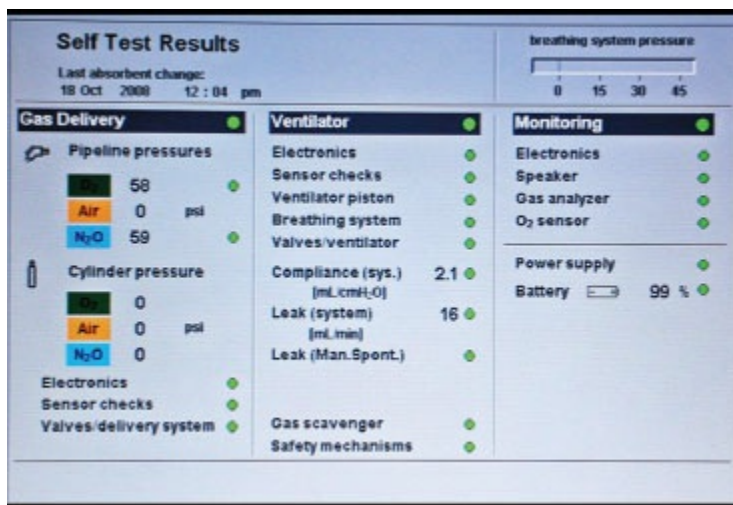

Figure 25-11 Apollo automated self-test screen.

## Anesthesia Workstation Pneumatics

### The Anatomy of an Anesthesia Workstation

A simplified diagram of a generic two-gas anesthesia machine is shown in Figure 25-6. The pressures within the anesthesia workstation can be divided into three circuits: a high-pressure, an intermediate-pressure, and an LPC. The *high-pressure circuit* is confined to the cylinders and the cylinder primary pressure regulators. For oxygen, the pressure range of the high-pressure circuit extends from a high of 2,200 pounds per square inch gauge (psig) to 45 psig, which is the regulated cylinder pressure.\* For nitrous oxide in the high-pressure circuit, pressures range from a high of 750 psig in the cylinder to a low of 45 psig. The *intermediate-pressure circuit* begins at the regulated cylinder supply sources at a pressure of 45 psig, includes the pipeline sources at 50 to 55 psig and extends to the flow control valves. Depending on the manufacturer and specific machine design, second-stage pressure regulators may be used to decrease the pipeline supply pressures to the flow control valves to even lower pressures such as 14 psig or 26 psig within the intermediate-pressure circuit.<sup>37,38</sup> Finally, the LPC extends from the flow control valves to the common gas outlet. Therefore, the LPC includes the flow tubes, vaporizer manifold, vaporizers, and the one-way outlet check valve on most GE Healthcare/Datex-Ohmeda machines.

Both oxygen and nitrous oxide are supplied to the workstation from two sources: a pipeline supply source and a cylinder supply source. The pipeline supply source is the primary gas source for the anesthesia workstation. The  hospital pipeline supply system provides gases to the machine at

approximately 50 psig, which is the normal working pressure of most machines. The cylinder supply source serves as a backup if the pipeline supply fails or acts as the primary supply if the anesthesia workstation is being used in a location without the availability of pipeline supplied gases. As previously described, the oxygen cylinder source is regulated from 2,200 psig to approximately 45 psig, and the nitrous oxide cylinder source is regulated from 745 psig to approximately 45 psig.<sup>39</sup>

A safety device traditionally referred to as the *fail-safe* valve (and currently more appropriately termed the “*oxygen failure cutoff valve*”) is located downstream from the nitrous oxide supply source. It serves as an interface between the oxygen and nitrous oxide supply sources. This valve shuts off, or proportionally decreases, the supply of nitrous oxide (and other gases) if the oxygen supply pressure decreases. Contemporary machines have an alarm device to monitor the oxygen supply pressure. A high-priority alarm is actuated when a decreasing oxygen supply pressure reaches a predetermined threshold, such as 30 psig.

Many GE Healthcare/Datex-Ohmeda machines have a second-stage pressure regulator for oxygen that is located downstream from the oxygen supply source in the intermediate-pressure circuit. It is adjusted to a precise pressure level, such as 14 psig. This regulator supplies a constant pressure to the oxygen flow control valve regardless of fluctuating oxygen pipeline pressures. The flow from the oxygen flow control valve will be constant provided that its oxygen supply pressure is more than 14 psig.

The flow control valves represent an important anatomic landmark within the anesthesia workstation because they separate the intermediate-pressure circuit from the LPC. The LPC is that part of the machine that lies downstream from the flow control valves. The operator regulates flow entering the LPC by adjusting the flow control valves. The oxygen and nitrous oxide flow control valves are linked mechanically or pneumatically by a proportioning system to help prevent unintended delivery of a hypoxic mixture. After leaving the flow tubes, the mixture of gases travels 7 through a common manifold and may be directed to a concentration-calibrated vaporizer. Precise amounts of potent inhaled volatile anesthetic can be added, depending on vaporizer concentration control dial setting. The total FGF plus the anesthetic vapor then flow toward the common gas outlet.<sup>40</sup>

Some GE Datex-Ohmeda anesthesia machines have a one-way check valve located between the vaporizers and the common gas outlet in the mixed-gas line. Its purpose is to prevent back flow into the vaporizer during positive-pressure ventilation, therefore minimizing the effects of downstream intermittent pressure fluctuations on inhaled anesthetic concentration (see Vaporizers: Intermittent Back Pressure section). The presence or absence of this check valve *profoundly* influences which preoperative leak test is

indicated (see Checking Your Anesthesia Workstation). The oxygen flush connection joins the mixed-gas line between the one-way check valve (when present) and the machine common gas outlet. Thus, when the oxygen flush valve is activated the pipeline oxygen flows directly to the common gas outlet at a rate of 35 to 75 L/min and potentially at a pressure of 55 psig.

## Pipeline Supply Source

Most hospitals today have a central piping system to deliver medical gases including oxygen, nitrous oxide, air, and carbon dioxide to outlets in the operating room. The central piping system must supply the correct gases at the appropriate pressure for the anesthesia workstation to function properly. Unfortunately, this does not always occur. Even as recently as 2002, a large medical center with a huge cryogenic bulk oxygen storage system was not immune to component failures that contributed to a critical oxygen pipeline supply failure.<sup>41</sup> In this case, a faulty joint ruptured at the bottom of the primary cryogenic oxygen storage tank, releasing 8,000 gallons of liquid oxygen to flood the streets in the surrounding area and compromised oxygen delivery to the medical center.

In a 1976 survey of approximately 200 hospitals, 31% reported difficulties with pipeline systems.<sup>42</sup> The most common problem was inadequate oxygen pressure, followed by excessive pipeline pressures. The most devastating reported hazard, however, was accidental crossing of oxygen and nitrous oxide pipelines, which has led to many deaths. This problem caused 23 deaths in a newly constructed wing of a general hospital in Sudbury, Ontario, during a 5-month period.<sup>43</sup> In 2002, two hypoxic deaths were reported in New Haven, Connecticut. These resulted from a medical gas system failure in which an altered oxygen flowmeter was connected to a wall supply source for nitrous oxide.<sup>44</sup>

In the event that a pipeline crossover is suspected, the workstation user must immediately take two corrective actions. First, the backup oxygen cylinder should be turned on. Then, the pipeline supply must be disconnected. This second step is mandatory because the machine will preferentially use the (potentially) inappropriate 50 psig pipeline supply source instead of the lower-pressure (45 psig) oxygen cylinder source if the wall supply is not disconnected. Recent publications suggest that many anesthesia providers may not appreciate the importance of or reasons for these actions.<sup>45,46</sup>

The wall outlet connections for pipeline gases are gas-specific. If they are “quick connect” fittings then they are gas-specific within the same manufacturer. For example, a wall oxygen outlet made by Ohmeda will not accept an oxygen connector made by Chemetron, even though the gas is the

same. This can create problems if outlets and connectors by more than one manufacturer exist in the same facility.<sup>47</sup> Many institutions seeking to create uniformity are now using nationally standardized Diameter Index Safety System (DISS) threaded connections. The DISS provides threaded, noninterchangeable connections for medical gas lines, which minimizes the risk of misconnection. Regardless of which type of gas-specific connector (DISS or “quick connect”) exists at the wall end of the hose conducting gas to the anesthesia machine, the gas enters the anesthesia machine through DISS inlet connections (Fig. 25-14A; *arrows*). A pressure gauge measures the pipeline gas pressure when the machine is connected to a pipeline supply. A check valve is located downstream from the inlet. It prevents reverse flow of gases from the machine to the pipeline or the atmosphere.

### Cylinder Supply Source

Anesthesia workstations have E-cylinders for use when a pipeline supply source is not available or if the pipeline system fails. Anesthesia providers can easily become complacent and falsely assume that backup gas cylinders are, in fact, present on the anesthesia workstation, and further, if present, that they contain an adequate supply of compressed gas. The preuse checklist should contain steps that confirm both.

Medical gases supplied in E-cylinders are attached to the anesthesia machine via the hanger yoke assembly. The hanger yoke assembly orients and supports the cylinder, provides a gas-tight seal (using a washer called a Bodok seal between tank and hanger yoke), and ensures a unidirectional flow of gases into the machine. Each hanger yoke is equipped with the Pin Index Safety System (PISS). The PISS is a safeguard introduced to eliminate cylinder interchanging and the possibility of accidentally placing the incorrect gas on a yoke designed to accommodate another gas. Two metal pins on the yoke assembly are arranged so that they project into corresponding holes in the cylinder valve (Fig. 25-12E). Each gas or combination of gases has a specific and unique pin arrangement.<sup>48,49</sup> It is generally assumed that in the United States all oxygen tanks are green in color and that the medical gas pin index system (PISS) will ensure that only an oxygen tank can be mounted in the hanger yoke for oxygen. In fact, there is no FDA standard for cylinder colors, so it is important to read the tank label.<sup>50</sup> A failure of the pin index system, and medical staff to properly identify E-cylinder contents, was the cause of an intraoperative fire during laparoscopy.<sup>51</sup> A mixture of CO<sub>2</sub> (14%) and oxygen (86%) was utilized rather than 100% CO<sub>2</sub>. The wrong tank was able to be connected despite the PISS because all tanks containing more than 7% CO<sub>2</sub> have the same pin configuration.

Once the cylinders are turned on, compressed gases may pass from their

respective high-pressure cylinder sources into the anesthesia machine (Fig. 25-6). A check valve is located downstream from each cylinder if a double-yoke assembly is used. This check valve serves several functions. First, it minimizes gas transfer from a cylinder at high pressure to one with a lower pressure. Second, it allows an empty cylinder to be exchanged for a full one while gas flow continues from the other cylinder into the machine with minimal loss of gas or supply pressure. Third, it minimizes leakage from an open cylinder to the atmosphere if one cylinder is absent. A cylinder supply pressure gauge is located downstream from the check valves. The gauge will indicate the pressure in the cylinder having the higher pressure when two reserve cylinders of the same gas are opened at the same time. In some electronic workstations, gas pressures are measured by transducers and displayed on the checkout screen (Fig. 25-10).

Each cylinder supply source has a pressure-reducing valve known as the cylinder pressure regulator. It reduces the high and variable storage pressure present in a cylinder to a lower, more constant pressure suitable for use in the anesthesia machine. The oxygen cylinder pressure regulator reduces the oxygen cylinder pressure from a high of 2,200 psig to approximately 45 psig. The nitrous oxide cylinder pressure regulator receives pressure of up to 745 psig and reduces it to approximately 45 psig.

The gas supply cylinder valves should be turned off when not in use, except during the preoperative machine pressure checkout. If the cylinder supply valves are left open, the reserve cylinder supply can be silently depleted whenever the pressure inside the machine decreases to a value lower than the regulated cylinder pressure. For example, oxygen pressure within the machine can decrease below 45 psig with oxygen flushing or possibly even during the use of a pneumatically driven ventilator, particularly at high inspiratory flow rates. In addition, the pipeline supply pressures of all gases can fall to less than 45 psig if problems exist in the central piping system. If the cylinders are left open when this occurs, they will eventually become depleted and no reserve supply may be available if a complete central pipeline failure were to occur.

The amount of time that an anesthesia machine can operate from the E-cylinder supply is important knowledge. This is particularly true now that anesthesia is being provided more frequently in office-based and in remote (outside the OR) hospital settings where pipeline oxygen may not be available. Oxygen can exist only in gaseous form at room temperature, and it obeys Boyle's law which states that for a fixed mass of gas at constant temperature, the product of pressure times volume is constant ( $P_1 \times V_1 = P_2 \times V_2$ ).<sup>52</sup> The volume of oxygen available from the cylinder is directly proportional to the cylinder pressure.

An E-cylinder has an internal volume of 4.8 L and when "full" is

pressurized to approximately 2,000 psig. Since psig is the pressure measured in excess of atmospheric pressure (14.7 psia, pounds per square inch absolute pressure), the cylinder pressure is 2,014.7 psia. Applying Boyle's Law:

$$2014.7 \times 4.8 = 14.7 \times V_2.$$

Therefore,  $V_2$ , the volume of oxygen in a "full" E-cylinder at 1 atm is:

$$(2014.7 \times 4.8)/14.7 = 658 \text{ L.}$$

The following equation has been proposed to help estimate the remaining time that oxygen can be delivered at a given flow rate<sup>53</sup>:

$$\text{Approx. remaining time (hrs)} = \frac{\text{Oxygen cylinder pressure (psig)}}{(200 \times \text{oxygen flow rate [L/min]})}$$

For example, an E-cylinder of oxygen with a pressure of 1,000 psig, used at an oxygen flow rate of 5 L/min would be depleted in

$$[1000/(200 \times 5)] \approx 1 \text{ hour}$$

It should be noted that this calculation will provide only a gross estimate of remaining time and may not be exact. Furthermore, users should be cautioned that use of a pneumatically driven mechanical ventilator will dramatically increase oxygen utilization rates and decrease the remaining time until the cylinder is depleted.<sup>54,55</sup> Use of spontaneous or manual ventilation, with low FGF rates in a circle system with CO<sub>2</sub> absorption, will significantly reduce oxygen consumption from an E-cylinder if this is the only source of oxygen available. Because electrically powered piston-type anesthesia ventilators, such as found in the Dräger Fabius GS and Apollo workstations, do not impact oxygen usage rates they may be preferable to conventional gas-driven ventilators in practice settings where the supply of compressed gas cylinders may be limited.

**Figure 25-12** 3,000 psig E-cylinder with Linde Integrated Valve, LIV (A). Linde Gas North America LLC that permits adjustable flows of ¼ to 25 L/min from the low-pressure nozzle (arrow) (B). There is also a high-pressure regulator that can supply oxygen at 50 psig via a DISS connector. Standard E-cylinder (C) showing pin-index safety system (D) and mating yoke (E).

An integrated valve and regulator for E-cylinders of oxygen is available that permits controlled delivery of oxygen via a nozzle at flows of 25 L/min or less for patient transport (Figs. 25-12 and 25-13). The tank regulator also permits delivery of oxygen at 50 psig from a DISS connection (Fig. 25-12B). If the oxygen hose from the anesthesia machine is connected to a central source (e.g., at the wall) via a DISS connector, and that central source becomes unavailable, then the machine hose can be easily connected to the tank's DISS connector and provide a backup supply of oxygen (Fig. 25-13). A conventional E cylinder with pin index safety system is shown in Figure 25-14.

### Nitrous Oxide

Nitrous oxide (N<sub>2</sub>O) can be supplied to the anesthesia machine from the pipeline system at a pressure of approximately 50 psig or from a backup E-cylinder in the N<sub>2</sub>O hanger yoke. N<sub>2</sub>O has a molecular weight of 44 atomic mass units (AMU) and a boiling point of -88°C at 760 mmHg (14.7 psia) pressure.<sup>56</sup> The critical temperature (CT) is the highest temperature at which

a gas can exist in liquid form. The CT of N<sub>2</sub>O is 36.5°C (critical pressure: 1,054 psig); therefore, N<sub>2</sub>O can exist as a liquid at room temperature (20°C). E-cylinders of N<sub>2</sub>O are factory-filled to 90% to 95% capacity with liquid N<sub>2</sub>O. Above the liquid in the tank is N<sub>2</sub>O vapor. Because the liquid agent is in equilibrium with its vapor or gas phase, the pressure exerted by the gaseous N<sub>2</sub>O is its saturated vapor pressure (SVP) at the ambient temperature. At 20°C, the SVP of N<sub>2</sub>O is 750 psig.

A full E-tank of N<sub>2</sub>O generates approximately 1,600 L of gas at 1 atm pressure at sea level (14.7 psia). As long as some liquid N<sub>2</sub>O is present in the tank and the ambient temperature remains at 20°C, the pressure in the N<sub>2</sub>O tank will remain at 750 psig, which is the SVP of N<sub>2</sub>O at 20°C. The volume of N<sub>2</sub>O gas available from a tank therefore *cannot* be determined by reference to the N<sub>2</sub>O tank pressure gauge. It is determined by weighing the tank and subtracting the weight of the empty tank (tare weight) to determine the weight of the contained N<sub>2</sub>O. Once all the liquid N<sub>2</sub>O has been used and the tank contains only vapor, the pressure in the tank will begin to decrease as nitrous oxide is used. However, because N<sub>2</sub>O is a vapor and not a gas, it does not obey Boyle's law and the volume of nitrous oxide remaining in the tank cannot be calculated from the tank pressure gauge. When the last drop of liquid N<sub>2</sub>O has just evaporated, nearly one-quarter of the full cylinder remains (i.e., ~400 L) in an E cylinder.<sup>57</sup> From then on, as N<sub>2</sub>O continues to be utilized, the value on the tank pressure gauge will fall.

Nitrous oxide from the tank supply enters the N<sub>2</sub>O hanger yoke at pressures of up to 750 psig (at 20°C) and then passes through a regulator that reduces this pressure to 40 to 45 psig (Fig. 25-6). The PISS is designed to ensure that only an N<sub>2</sub>O tank may hang in an N<sub>2</sub>O hanger yoke. As with oxygen, a check valve in each yoke prevents the back leakage of N<sub>2</sub>O if no tank is hanging in the yoke.

The N<sub>2</sub>O pipeline is supplied from a bulk storage container of liquid N<sub>2</sub>O or from banks of large N<sub>2</sub>O tanks, usually H-cylinders. (Each H-cylinder of N<sub>2</sub>O evolves 16,000 L of gas at atmospheric pressure.) The pressure in the N<sub>2</sub>O pipeline is regulated to approximately 50 psig to supply the outlets in the operating room. Having entered the anesthesia machine intermediate-pressure system, N<sub>2</sub>O must flow past the "fail-safe" valve to reach the N<sub>2</sub>O flow control.

**Figure 25-13** 3,000 psig E-cylinder valve showing 50 psig DISS connection (arrow) (A) that could be connected to the machine oxygen hose if wall oxygen supply fails (B).

### *Machine Intermediate-Pressure System*

Having entered the anesthesia machine's intermediate-pressure system from the pipeline supply at approximately 50 psig, or from the tank supply at 45 psig, oxygen can take several paths:

1. To the DISS auxiliary oxygen takeoff, to which a Sanders type jet ventilating system can be connected
2. To supply a pneumatically powered bellows ventilator
3. Via a regulator and an auxiliary oxygen flowmeter to be connected to a nasal cannula, SIRB, and so forth
4. To the oxygen low-pressure alarm sensor
5. To the pressure sensitive shutoff ("fail-safe") valve
6. To the oxygen flush control valve
7. To the oxygen flowmeter (in some machines via a second-stage regulator)

### *Oxygen Supply Pressure Failure Safety Devices*

The 2000 ASTM F1850–00 standard stated, "The anesthesia gas supply device shall be designed so that whenever oxygen supply pressure is reduced to below the manufacturer specified minimum, the delivered oxygen concentration shall not decrease below 19% at the common gas outlet." Contemporary anesthesia machines have a number of safety devices that act together in a cascade manner to minimize the risk of delivery of a hypoxic gas mixture as oxygen pressure decreases. Several of these devices are described

in the following sections.

**Figure 25-14** A: DISS connector. B: PISS connector.

### **Pneumatic and Electronic Alarm Devices**

Many older anesthesia machines have a pneumatic alarm device that provides an audible warning when the oxygen supply pressure decreases to a predetermined threshold value such as 30 psig. The 2000 ASTM F1850–00 standard mandated that a medium priority alarm be activated within 5 seconds when the oxygen pressure decreases below a manufacturer-specific pressure threshold. Electronic alarm devices are now used to meet this requirement.

### **Oxygen Failure Cutoff (“Fail-Safe”) Valves**

An oxygen failure cutoff valve is present in the gas line supplying each of the flowmeters except oxygen. Controlled by oxygen supply pressure, the valve shuts off (or proportionally decreases) the supply pressure of all other gases (nitrous oxide, CO<sub>2</sub>, helium, and in some machines, air) as the oxygen supply pressure decreases. Unfortunately, the misnomer “fail-safe” has led to the misconception that the valve prevents administration of a hypoxic mixture. This is not the case. Machines that are either not equipped with an N<sub>2</sub>O/O<sub>2</sub> flow proportioning system (see Proportioning Systems section) or whose system may be disabled by the user can deliver a hypoxic mixture under normal working conditions. On such a system, the oxygen flow control valve can be closed intentionally or accidentally. Normal oxygen pressure will keep other gas lines open so that a hypoxic mixture could result.

Many GE-Datex-Ohmeda machines are equipped with a fail-safe valve known as the pressure-sensor shutoff valve. On older machines, this valve operates in a threshold manner and is either open or closed. Oxygen supply pressure opens the valve, and the valve return spring closes the valve. [Figure 25-15](#) shows a nitrous oxide pressure-sensor shutoff valve with a threshold

pressure of 20 psig. In [Figure 25-15A](#), an oxygen supply pressure greater than 20 psig is exerted on the mobile diaphragm. This pressure moves the piston and pin upward and the valve opens. Nitrous oxide flows freely to the nitrous oxide flow control valve. In [Figure 25-15B](#), the oxygen supply pressure is less than 20 psig, and the force of the valve return spring completely closes the valve. Nitrous oxide flow stops at the closed fail-safe valve, and it does not advance to the nitrous oxide flow control valve.

In the GE Datex Aestiva/5, which is a more recent model machine, the “fail-safe” valve is not of an “open or closed” design, rather it is a variable valve in a balance regulator. The balance regulator works as follows. The second-stage pressure regulator for oxygen reduces the pressure to about 30 psig in the intermediate-pressure system. The oxygen pressure is then piloted to the balance regulator where it is applied to the oxygen side of the regulated diaphragm. If the pressure of oxygen is sufficient, the diaphragm pushes against a mechanism that opens the flow pathway for nitrous oxide. If the oxygen piloting pressure decreases, the mechanism begins to close off the pathway for nitrous oxide in proportion to the decrease in piloted oxygen pressure. The balance regulator for nitrous oxide closes completely when the pressure of oxygen falls to 0.5 psig. Balance regulators for heliox and CO<sub>2</sub> interrupt the flows of these gases when the piloted oxygen pressure falls below 10 psig.

Dräger Medical uses a different fail-safe valve known as the Oxygen Failure Protection Device (OFPD) to interface the oxygen pressure with that of other gases, such as nitrous oxide or inert gases. Similar in principle to the balance regulator described in the previous paragraph, the OFPD is based on a proportioning principle rather than a threshold principle. The pressure of all gases controlled by the OFPD will decrease in proportion with the oxygen pressure. The OFPD consists of a seat–nozzle assembly connected to a spring-loaded piston ([Fig. 25-16](#)). The oxygen supply pressure in the left panel is 50 psig. This pressure pushes the piston upward, forcing the nozzle away from the valve seat. Nitrous oxide and/or other gases advance toward the flow control valve at 50 psig. The oxygen pressure in the right panel is 0 psig. The spring is expanded and forces the nozzle against the seat, preventing flow through the device. Finally, the center panel shows an intermediate oxygen pressure of 25 psig. The force of the spring partially closes the valve. The nitrous oxide pressure delivered to the flow control valve is 25 psig. There is a continuum of intermediate configurations between the extremes (0 to 50 psig) of oxygen supply pressure. These intermediate valve configurations are responsible for the proportional nature of the OFPD. An important concept to be understood with these particular fail-safe devices is that the older Datex-Ohmeda Pressure Sensor Shutoff Valve is threshold in nature (all-or-nothing), whereas the GE balance regulator and Dräger OFPD are variable flow type

proportioning systems. It is important to recognize that the “fail-safe” valve is pressure sensitive and not flow sensitive. As long as the pressure in the intermediate pressure system for oxygen is adequate, nitrous oxide can flow to its flow control valve (Fig. 25-17).

### Second-stage Oxygen Pressure Regulator

Most contemporary GE Datex-Ohmeda workstations have a second-stage oxygen pressure regulator set at a specific value, ranging from 12 to 19 psig. Output from the oxygen flowmeter is constant when the oxygen supply pressure exceeds the threshold (minimal) value. The pressure-sensor shutoff valve of older Datex-Ohmeda machines is set at a higher threshold value (20 to 30 psig) to ensure that oxygen is the last gas flowing if oxygen pressure failure occurs.

**Figure 25-15** Pressure-sensor shutoff valve. **A:** The valve is open because the oxygen supply pressure is greater than the threshold value of 20 psig. **B:** The valve is closed because of inadequate oxygen pressure. (Adapted from Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI, Ohmeda, a division of BOC Healthcare, Inc., 1985.)

**Figure 25-16** Oxygen Failure Protection Device/Sensitive Oxygen Ratio Controller

(OFPD/S-ORC), which responds proportionally to changes in oxygen supply pressure. (Adapted from Narkomed 2A *Anesthesia System: Technical Service Manual*. 6th ed. Telford, PA: North American Dräger; 1985.)

## Flowmeter Assemblies

The flowmeter assembly (Fig. 25-18) precisely controls and measures gas flow to the common gas outlet. With traditional glass flowmeter assemblies, the flow control needle valve regulates the amount of flow that enters a tapered, transparent flow tube known as a Thorpe tube. The tube is tapered such that it has a small cross-sectional area at its lower (low flow) end, and a larger cross-sectional area at its upper (high flow) end. A mobile indicator float inside the flow tube indicates the amount of flow passing through the associated flow control valve. The quantity of flow is indicated on a scale associated with the flow tube. Some newer anesthesia workstations have now replaced the conventional glass flow tubes with electronic flow sensors that measure the flow of the individual gases. The flow rate data are then presented in numerical format, graphical format, or a combination of the two on the workstation screen. The integration of these “electronic flowmeters” is an essential step in the evolution of the anesthesia workstation if it is to become fully integrated with anesthesia data-capturing systems, such as computerized anesthesia record keepers (or anesthesia information management systems, AIMS).

**Figure 25-17** Failure of fail-safe valve to prevent a hypoxic mixture.

**Figure 25-18** Oxygen flowmeter assembly. The oxygen flowmeter assembly is composed of the flow control valve assembly plus the flowmeter subassembly. Note that this is a GE Datex-Ohmeda design because in this figure oxygen is supplied to the flowmeter at 16 psig from a second-stage regulator. (Adapted from Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding*. Madison, WI: Ohmeda, a division of BOC Healthcare, Inc., 1985.)

**Figure 25-19** The annular space. The clearance between the head of the float and the flow tube is known as the annular space. It can be considered equivalent to a circular channel of the same cross-sectional area. (Adapted from Macintosh R, Mushin WW, Epstein HG. *Physics for the Anaesthetist*. 3rd ed. Oxford: Blackwell Scientific Publications; 1963.)

## Operating Principles of Conventional Flowmeters

Opening the flow control needle valve allows gas to travel through the space between the float and the flow tube. This space is known as the annular space (Fig. 25-19). The indicator float hovers freely in an equilibrium position where the upward force resulting from gas flow equals the downward force on the float resulting from gravity at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flowmeters are commonly referred to as *constant pressure variable orifice* flowmeters because the pressure decrease across the float remains constant for all positions in the tube.<sup>58,59</sup>

Flow tubes are tapered, with the smallest diameter at the bottom of the tube and the largest diameter at the top. The term *variable orifice* designates this type of unit because the annular space between the float and the inner wall of the flow tube varies with the position of the float. Flow through the constriction created by the float can be laminar or turbulent, depending on the flow rate (Fig. 25-20). The characteristics of a gas that influence its flow rate through a given constriction are viscosity (laminar flow) and density (turbulent flow). Because the annular space is tubular, at low flow rates laminar flow is present and *viscosity* determines the gas flow rate. The annular space simulates an orifice at high flow rates, and turbulent gas flow then depends predominantly on the *density* of the gas.

## Components of the Flowmeter Assembly

### *Flow Control Valve Assembly*

The flow control valve assembly (Fig. 25-18) consists of a flow control knob, a needle valve, a valve seat, and a pair of valve stops. The assembly can receive its pneumatic input either directly from the pipeline source (50 psig) or from a second-stage pressure regulator. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Extreme clockwise rotation may result in damage to the needle valve and valve seat. Therefore, flow control valves are equipped with valve “stops” to prevent this occurrence.

**Safety Features.** Flow control valve assemblies have numerous safety features. The oxygen flow control knob is physically distinguishable from other gas knobs. It is distinctively fluted, projects beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases. All knobs are color coded for the appropriate gas, and the chemical formula or name of the gas is permanently marked on each. Flow control knobs are recessed or protected with a shield or barrier to minimize

accidental change from a preset position. If a single gas has two flow tubes, the tubes are arranged in series and are controlled by a single flow control valve.

**Figure 25-20** Flow tube constriction. The lower half of illustration represents the lower portion of a flow tube. The clearance between the head of the float and the flow tube is narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining gas flow rate through this tubular constriction. The upper half of illustration represents the upper portion of a flow tube. The equivalent channel is orificial because its length is less than its width. Density is dominant in determining gas flow rate through this orificial constriction. (Adapted from Macintosh R, Mushin WW, Epstein HG. *Physics for the Anaesthetist*. 3rd ed. Oxford: Blackwell Scientific Publications;1963.)

In many of the new anesthesia workstations, the flowmeters have been replaced by electronic control panels that contain “soft keys.” To adjust any gas flow, the operator must perform the following steps: (1) select and press the “soft key” to identify the gas and anesthetic agent selected; (2) turn the selector knob to adjust the desired flow level; and (3) press the selector knob again to confirm the selected flow level and anesthetic agent (see Electronic Flowmeters section).

### *Flowmeter Subassembly*

The flowmeter subassembly (Fig. 25-18) consists of the flow tube, the indicator float with float stops, and the indicator scale.

**Flow Tubes.** Contemporary flow tubes are made of glass. Most have a single taper in which the inner diameter of the flow tube increases uniformly from bottom to top. Manufacturers provide double flow tubes for oxygen and

nitrous oxide to provide better visual discrimination at low flow rates. A fine flow tube indicates flow from approximately 200 mL/min to 1 L/min, and a coarse flow tube indicates flow from approximately 1 mL/min to 10 or 12 L/min. The two tubes are connected in series and supplied from a single flow control valve.

**Indicator Floats and Float Stops.** Anesthesia machines with traditional flowmeters use several different types of bobbins or floats, including plumb-bob floats, rotating skirted floats, and ball floats. Flow is read at the top of plumb-bob and skirted floats and at the center of the ball on the ball-type floats. Flow tubes are equipped with float stops at the top and bottom of the tube. The upper stop prevents the float from ascending to the top of the tube and plugging the outlet. It also ensures that the float will be visible at maximum flows instead of being hidden in the manifold. The bottom float stop provides a central foundation for the indicator when the flow control valve is turned off.

**Scale.** The flowmeter scale can be marked directly on the flow tube or located to the right of the tube. Gradations corresponding to equal increments in flow rate are closer together at the top of the scale because the annular space increases more rapidly than does the internal diameter from bottom to top of the tube. Rib guides are used in some flow tubes with ball-type indicators to minimize this compression effect. They are tapered glass ridges that run the length of the tube. There are usually three rib guides that are equally spaced around the inner circumference of the tube. In the presence of rib guides, the annular space from the bottom to the top of the tube increases almost proportionally with the internal diameter. This results in a nearly linear scale. Rib guides are employed on many Dräger Medical flow tubes.

**Safety Features.** The flowmeter subassemblies for each gas on the GE-Datex-Ohmeda and Aestiva models are housed in independent, color-coded, pin-specific modules. The flow tubes are adjacent to a gas-specific, color-coded backing. The flow scale and the chemical formula (or name of the gas) is permanently etched on the backing to the right of the flow tube. Flowmeter scales are individually hand-calibrated to provide a high degree of accuracy. The tube, float, and scale make an inseparable unit. The entire set must be replaced if any component is damaged.

Dräger Medical does not use a modular system for the flowmeter subassembly. The flow scale, the chemical symbol, and the gas-specific color codes are etched directly onto the flow tube.

## **Problems with Flowmeters**

## Leaks

Flowmeter leaks are a significant hazard because the flowmeters are located downstream from all machine safety devices except the oxygen analyzer.<sup>60</sup> Leaks can occur at the O-ring junctions between the glass flow tubes and the metal manifold or in cracked or broken glass flow tubes, the most fragile pneumatic component of the anesthesia machine. Even though gross damage to conventional glass flow tubes is usually apparent, subtle cracks and chips may be overlooked, resulting in errors of delivered flows.<sup>61</sup> The use of electronic flowmeters and the removal of conventional glass flow tubes from some newer anesthesia workstations (e.g., GE-Datex-Ohmeda S/5 ADU and the Dräger Fabius) may help to eliminate these potential sources of leaks (see Electronic Flowmeters section).

Eger et al.<sup>62</sup> demonstrated that, in the presence of a flowmeter leak, a hypoxic mixture is less likely to occur if the oxygen flowmeter is located downstream from all other flowmeters. [Figure 25-21](#) is an updated version of the figure in Eger's original publication. The unused air flow tube has a large leak. Nitrous oxide and oxygen flow rates are set at a ratio of 3:1. A potentially dangerous arrangement is shown in [Figure 25-21A](#) and [B](#) because the nitrous oxide flowmeter is located in the downstream position. A hypoxic mixture can result because a substantial portion of oxygen flow passes through the leak, and all nitrous oxide is directed to the common gas outlet. Safer configurations are shown in [Figure 25-21C](#) and [D](#), where the oxygen flowmeter is located in the downstream position.

**Figure 25-21** Flowmeter sequence—a potential cause of hypoxia. In the event of a flowmeter leak (in this example, air), a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (**A**, **B**). The safest configuration exists when oxygen is located in the downstream position (**C**, **D**). See text for details. (Adapted from Eger EI 2nd, Hylton RR, Irwin RH, et al. Anesthetic flowmeter sequence—a cause for hypoxia. *Anesthesiology*. 1963;24:396.)

The above, preferred, arrangement is not infallible. A leak in the oxygen flow tube may result in creation of a hypoxic mixture even when oxygen is located in the downstream position ([Fig. 25-22](#)). Oxygen escapes through the

leak and nitrous oxide continues to flow toward the common outlet, particularly at high ratios of nitrous oxide to oxygen flow.

### *Inaccuracy*

Flow measurement error can occur even when flowmeters are assembled properly with appropriate components. Dirt or static electricity can cause a float to stick, and the actual flow may be higher or lower than that indicated. Sticking of the indicator float is more common in the low flow ranges because the annular space is smaller. A damaged float can cause inaccurate readings because the precise relationship between the float and the flow tube is altered. Back pressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flowmeters are not aligned properly in the vertical position (plumb), readings can be inaccurate because tilting distorts the annular space.

### *Ambiguous Scale*

Before the standardization of flowmeter scales and the widespread use of oxygen analyzers, at least two deaths resulted from confusion created by ambiguous scales.<sup>63</sup> The operator read the float position beside an adjacent but erroneous scale in both cases. Today this error is less likely to occur because contemporary flowmeter scales are marked either directly onto the flow tube or immediately to the right of it.

**Figure 25-22** Oxygen flow tube leak. An oxygen flow tube leak can produce a hypoxic mixture regardless of flow tube arrangement. (Adapted from Brockwell RC. Inhaled anesthetic delivery systems. In: Miller RD, ed. *Anesthesia*. 6th ed. Philadelphia, PA: Churchill Livingstone; 2004:281.)

**Figure 25-23** Datex S5/ADU. Note mechanical needle valve controls for the gas flows but electronic display of virtual flowmeter and digital readout.

### **Electronic Flowmeters**

Many of the newer anesthesia workstations (e.g., the Dräger Apollo, Dräger Fabius GS, Spacelabs Healthcare’s ARKON, and Datex S5/ADU; [Figs. 25-23](#) and [25-1A](#), [25-2A](#), [25-4A](#)) have conventional flow control knobs and flow control valves, but have electronic flow sensors and digital displays rather than glass flow tubes. The output from the flow control valve is represented graphically and/or numerically in liters per minute on the workstation’s integrated user interface. These systems are dependent on electrical power to provide a precise display of gas flows. However, even when electrical power is totally interrupted, since the flow control valves themselves are mechanical (i.e., nonelectronic), the set gas flows will continue uninterrupted. Since these machines do not have individual flow tubes that physically quantify the flow of each gas, a small conventional pneumatic “fresh gas” or “total flow” indicator is also provided that gives the user an estimate of the total quantity of fresh gas flowing from all gas flow control valves to the anesthesia workstation’s common gas outlet, and is functional even in the event of a total power failure ([Fig. 25-24](#)).

**Figure 25-24** Dräger Fabius GS. Note needle valve controls, graphical and digital flow displays. The total gas flow rotameter continues to function if electrical power is lost.

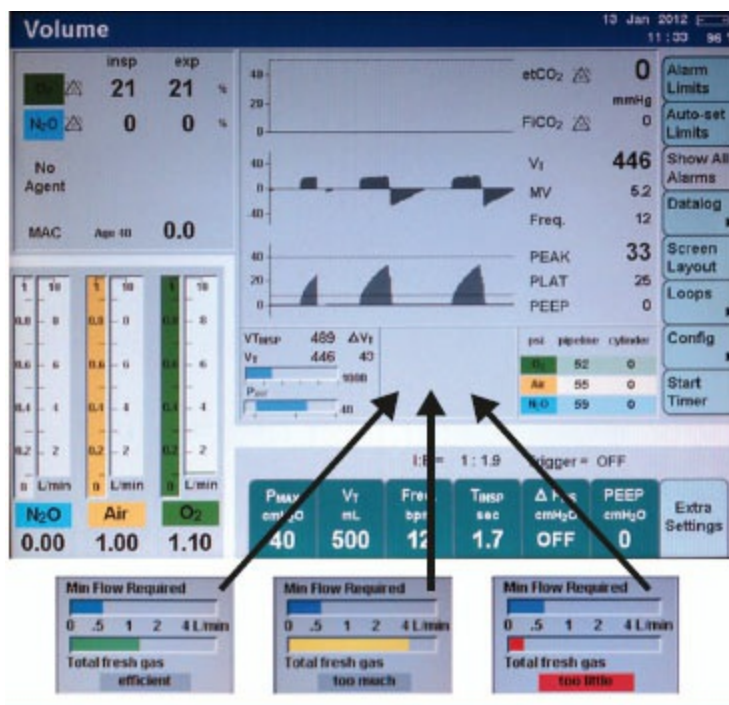

In the GE Aisys Carestation (Fig. 25-3A), the traditional needle valve gas flow controls and color-coded control knobs are replaced by an electronic control system that uses a gas mixer. In this model, the second gas, either N<sub>2</sub>O or air is first selected, followed by the desired inspired oxygen concentration (FIO<sub>2</sub>) and total FGF. Total flow and FIO<sub>2</sub> selections are made by pressing soft keys on the control panel, adjusting the settings using a “com wheel,” and then pressing the com wheel to “confirm.”

In the GE Aisys Carestation (Fig. 25-3A), the controls to increase or decrease flows (or agent concentration) represent a departure from the traditional. The traditional needle valve gas flow controls were designed by mechanical engineers so that one turns the flow control knob counterclockwise to increase flow (by opening the valve wider). The same applies to increasing agent concentration on a variable bypass vaporizer. The Aisys Carestation controls are designed by electrical engineers where the standard is to increase the output by rotating the dial (com wheel) in a clockwise direction. Thus, when learning to use the Aisys Carestation workstation, the operator must adapt to “clockwise to increase” and remember to confirm new settings; otherwise they are not implemented. In the event the gas mixer fails, the Aisys Carestation will switch to a backup system that permits delivery of oxygen to the breathing system via an alternate oxygen flowmeter, which is a traditional mechanical needle valve and rotameter flow tube.

## Automated Fresh Gas Flow Optimization by Workstation Software

Anesthetic gas cost and environmental impact of excessive waste anesthetic gas are increasing concerns. The Dräger Apollo anesthesia workstation has an FGF optimization tool called the Low Flow Wizard (LFW). The LFW gives the user an indication of whether there is too much, too little, or the correct amount of FGF. It is important to understand how this tool works and to understand its limitations. [Figure 25-25](#) shows the three possible recommendations from the LFW.

The LFW determines minimum FGF by calculating the difference between inspiratory and expiratory minute volume. In addition, anesthetic uptake is calculated using inspired and expired anesthetic gas concentrations as well as N<sub>2</sub>O and CO<sub>2</sub> concentrations. This algorithm is designed to err on the side of overestimation of uptake. Oxygen uptake is calculated using CO<sub>2</sub> uptake because the gas analysis system is able to determine CO<sub>2</sub> concentrations with greater precision than oxygen concentrations. During laparoscopic surgery with CO<sub>2</sub> insufflation, if end-tidal CO<sub>2</sub> is increased, the calculated oxygen uptake will increase, thus the LFW will recommend higher FGF. In addition, application or removal of PEEP will transiently affect LFW calculations until gas flow dynamics reach a state of equilibrium.<sup>64</sup> A simulator-based study demonstrated that use of the LFW reduced isoflurane consumption by 53% during the maintenance phase of anesthesia.<sup>65</sup>

**Figure 25-25** Low flow wizard of the Dräger Apollo workstation.

GE-Datex-Ohmeda has developed an optional software tool, called “ecoFLOW” to determine approximate minimum flow of O<sub>2</sub> required to maintain a preset FiO<sub>2</sub>. This system (available on the Aisys CS<sup>2</sup> and Avance

CS<sup>2</sup> models) also shows approximate amount of agent used and cost per hour. The minimum O<sub>2</sub> flow is calculated using patient O<sub>2</sub> uptake, the dilution effect of the delivered anesthetic agent, and the effects of the circle breathing system.<sup>66</sup>

## Proportioning Systems

Manufacturers equip anesthesia workstations with N<sub>2</sub>O/O<sub>2</sub> proportioning systems designed to prevent creation and delivery of a hypoxic mixture when nitrous oxide is administered. Nitrous oxide and oxygen are interfaced mechanically and/or pneumatically, or electronically (on the GE Aisys Carestation), so that the minimum oxygen concentration at the common gas outlet is between 23% and 25% depending on the manufacturer.

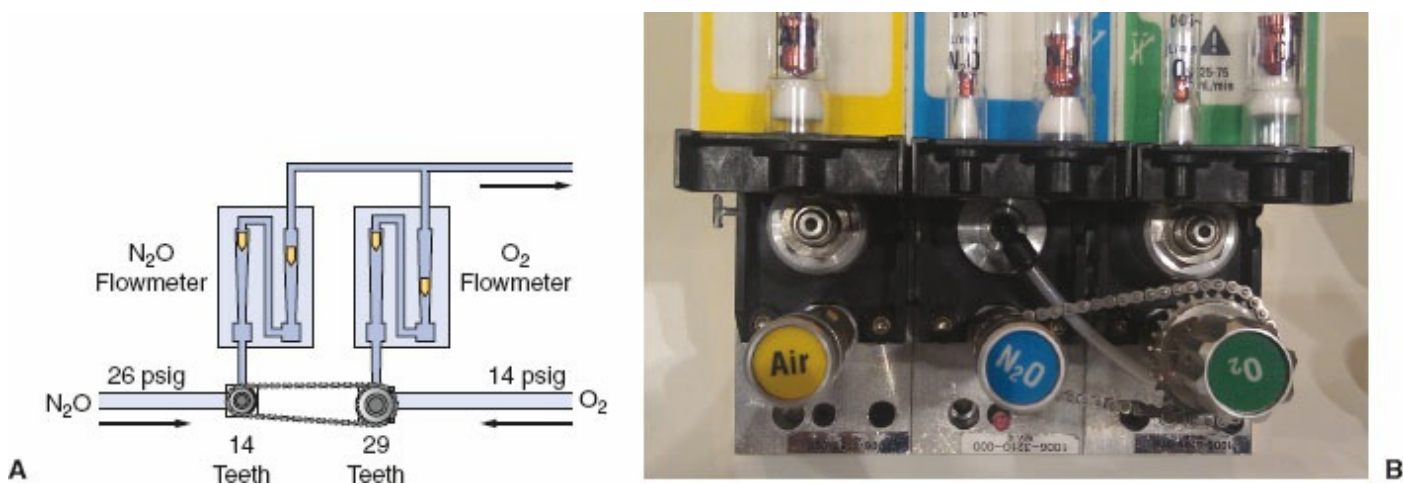

### GE-Datex-Ohmeda Link-25 Proportion-Limiting Control System

Traditional GE-Datex-Ohmeda machines use the Link-25 System. The heart of the system is the mechanical integration of the nitrous oxide and oxygen flow control valves. It allows independent adjustment of either valve, yet automatically intercedes to maintain a minimum 25% oxygen concentration with a maximum nitrous oxide–oxygen flow ratio of 3:1. The Link-25 automatically increases oxygen flow to prevent delivery of a hypoxic mixture.

Figure 25-26 illustrates the GE-Datex-Ohmeda Link-25 System. A 14-tooth sprocket is attached to the nitrous oxide flow control valve, and a 29-tooth sprocket is attached to the oxygen flow control valve. A stainless steel chain physically links the sprockets. When the nitrous oxide flow control valve is turned through 2.09 revolutions the oxygen flow control valve will revolve once because of the gear ratio. The final 3:1 flow ratio results because the nitrous oxide flow control valve is supplied with nitrous oxide at a pressure of approximately 26 psig from a second-stage N<sub>2</sub>O regulator, whereas the oxygen flow control valve is supplied by a second-stage regulator at 14 psig. The combination of the mechanical and pneumatic aspects of the system yields the final minimum 25% oxygen concentration. The GE-Datex-Ohmeda Link-25 proportioning system increases oxygen flow when nitrous oxide flow would be excessive by opening the O<sub>2</sub> needle valve more. Conversely, if the oxygen flow is decreased such that the nitrous oxide flow would be excessive, it acts to decrease the flow of N<sub>2</sub>O by physically decreasing the opening of the nitrous oxide needle valve.

Several reports have described failures of the Link-25 system.<sup>67–70</sup> The authors of these reports describe failures that either resulted in inability to administer oxygen without nitrous oxide or allowed creation of a hypoxic

mixture.

**Figure 25-26** Schematic (A) and photo (B) of Ohmeda Link-25 Proportion-Limiting Control System. See text for details.

### Dräger Oxygen Ratio Monitor Controller/Sensitive Oxygen Ratio Controller System

The Oxygen Ratio Monitor Controller (ORMC) is the nitrous oxide:oxygen proportioning system used on older model North American Dräger anesthesia machines (e.g., Narkomed models 2B, 2C, 3, and 4). In the more recent model Dräger anesthesia workstations (e.g., Fabius GS, Apollo) the same ORMC is renamed the Sensitive Oxygen Ratio Controller (S-ORC). The ORMC/S-ORC is a pneumatic oxygen–nitrous oxide interlock system designed to maintain a fresh gas oxygen concentration of at least  $25 \pm 3\%$  when nitrous oxide is used. It controls the fresh gas oxygen concentration to levels substantially greater than 25% when the oxygen flow rate is less than 1 L/min. The ORMC/S-ORC limits nitrous oxide flow to prevent delivery of a hypoxic mixture by decreasing the supply pressure of nitrous oxide to its flow control needle valve. This is unlike the GE-Datex-Ohmeda Link-25 system, in which the gas supply pressure to the nitrous oxide needle valve is held constant (by the second-stage regulator) and gas flow changes are made by physically changing the size of the needle valve opening.

A schematic of the ORMC/S-ORC is shown in [Figure 25-27](#). It consists of an oxygen chamber, a nitrous oxide chamber, and a nitrous oxide slave control valve. All are interconnected by a mobile horizontal shaft. The pneumatic input into the device is from the oxygen and the nitrous oxide flowmeters. These flowmeters are unique because they have specific resistors located downstream from the flow control valves. When nitrous oxide and oxygen are flowing, these resistors create back pressures directed to the oxygen and nitrous oxide chambers. The value of the oxygen flow tube resistor is three to four times that of the nitrous oxide flow tube resistor, and

the relative value of these resistors determines the value of the controlled fresh gas oxygen concentration. The back pressures in the oxygen and nitrous oxide chambers are applied against rubber diaphragms attached to the mobile horizontal shaft. Movement of the shaft adjusts the opening of the nitrous oxide slave control valve, which in turn adjusts the feed pressure to the nitrous oxide flow control needle valve.

If the oxygen flow, and therefore back pressure, is proportionally higher than the nitrous oxide back pressure, the nitrous oxide slave control valve opens more widely, increasing the pressure of nitrous oxide upstream of the nitrous oxide flow control needle valve, which results in an increase in nitrous oxide flow. As the nitrous oxide flow is increased manually, the nitrous oxide back pressure forces the shaft rightward toward the oxygen chamber. The nitrous oxide slave control valve opening becomes more restrictive and limits the nitrous oxide feed pressure to the flowmeter, which decreases the nitrous oxide flow. When the oxygen flow is less than 200 mL/min, the slave control valve closes completely, preventing any flow of nitrous oxide.

Figure 25-27 illustrates the action of a single ORMC/S-ORC under different sets of circumstances. The back pressure exerted on the oxygen diaphragm in the upper configuration is greater than that exerted on the nitrous oxide diaphragm. This causes the horizontal shaft to move to the left, opening the nitrous oxide slave control valve. Nitrous oxide is then able to proceed to its flow control valve and out through the flowmeter. In the lower configuration, the nitrous oxide slave control valve is closed because of inadequate oxygen back pressure. To summarize, in contrast to the GE-Datex-Ohmeda Link-25 System, which actively increases oxygen flow to maintain a fresh gas oxygen concentration 25% or higher, the Dräger ORMC/S-ORC are systems that limit nitrous oxide flow to prevent delivery of a fresh gas mixture with an oxygen concentration no higher than 25%.

## Limitations

N<sub>2</sub>O/O<sub>2</sub> proportioning systems are not foolproof. Workstations equipped with these systems can still deliver a hypoxic mixture under certain conditions. The following is a description of some of the situations in which this may occur.

### *Wrong Supply Gas*

Both the GE-Datex-Ohmeda Link-25 and the Dräger S-ORC will be defeated if a gas other than oxygen is present in the oxygen pipeline and will allow delivery of hypoxic gas mixtures. In the Link-25 System, the nitrous oxide and oxygen flow control valves will continue to be mechanically linked. Nevertheless, a hypoxic mixture can proceed to the common gas outlet. In the case of the Dräger S-ORC, the rubber diaphragm for oxygen will reflect adequate supply pressure on the oxygen side even though the incorrect gas is present, and flow of both the wrong gas plus nitrous oxide will result. The oxygen analyzer is the only workstation monitor besides an integrated multigas analyzer that would detect this condition in either system.

### *Defective Pneumatics or Mechanics*

Normal operation of the Datex-Ohmeda Link-25 and the Dräger/S-ORC is contingent on pneumatic and mechanical integrity.<sup>71</sup> Pneumatic integrity in the Datex-Ohmeda system requires properly functioning second-stage regulators. A nitrous oxide:oxygen ratio other than 3:1 may result if the regulators are not precise. The chain connecting the two sprockets must be intact—if the chain is cut or broken, a 97% nitrous oxide concentration can result.<sup>72</sup> In the Dräger System, a functional OFPD is necessary to supply appropriate pressure to the S-ORC. The mechanical aspects of the S-ORC, such as the rubber diaphragms, the flow tube resistors, and the nitrous oxide slave control valve, must likewise be intact.

### *Leaks Downstream*

The S-ORC and the Link-25 function at the level of the flow control valves. A leak downstream from these devices, such as a broken oxygen flow tube (Fig. 25-22), can result in delivery of a hypoxic mixture to the common gas outlet. In this situation, oxygen escapes through the leak and the predominant gas delivered is nitrous oxide. The oxygen monitor and/or integrated multigas analyzer are the only machine safety devices that can detect this problem. For the majority of anesthesia workstations a preuse positive or negative-pressure

leak test (depending on the manufacturer) is recommended to detect such a leak (see Checking Your Anesthesia Workstation section).

### *Inert Gas Administration*

Administration of a third inert gas, such as helium, nitrogen, or carbon dioxide, can cause a hypoxic mixture because contemporary proportioning systems link only nitrous oxide and oxygen.<sup>73</sup> Use of an oxygen analyzer to monitor the inspired oxygen concentration is mandatory (or a multigas analyzer when available) if the operator uses a third gas.

### *Dilution of Inspired Oxygen Concentration by Potent Inhaled Volatile Anesthetics*

Volatile inhaled anesthetics are added to the mixed gases downstream from both the flowmeters and the proportioning system. High concentrations of less-potent inhaled anesthetics such as desflurane (MAC ~7%) may inadvertently be added downstream of the proportioning system, with a resulting gas/vapor mixture that may contain an inspired oxygen concentration that is below 21%. Awareness of this possibility, particularly when high concentrations of desflurane are used, is essential.

### *Oxygen Flush Valve*

The oxygen flush valve allows direct communication between the oxygen intermediate-pressure circuit and the LPC (Fig. 25-6). Flow from the oxygen flush valve enters the LPC downstream from the vaporizers and, most importantly, downstream from any outlet check valve, if present. The spring-loaded oxygen flush valve remains closed until the operator opens it by depressing the oxygen flush button. Actuation of the valve delivers 100% oxygen at a flow of 35 to 75 L/min to the breathing circuit.

The oxygen flush valve can provide a “high pressure” oxygen source that might be used for jet ventilation under the following circumstances: (1) the anesthesia machine is equipped with a one-way check valve positioned between the vaporizers and the oxygen flush valve; and (2) when a positive-pressure relief valve exists downstream from the vaporizers. The pressure relief valve must be upstream of the outlet check valve. For example, because the Ohmeda Modulus II has such a one-way check valve and its low-pressure system positive-pressure relief valve is upstream from the outlet check valve, the entire oxygen flow of 35 to 75 L/min is delivered to the common gas outlet at a pressure of 45 to 50 psig. On the other hand, the Ohmeda Modulus II Plus and some GE-Datex-Ohmeda Excel machines are not capable of functioning as an appropriate oxygen source for jet ventilation. The Ohmeda

Modulus II Plus, which does not have the check valve, provides only 7 psig at the common gas outlet because much of the oxygen flows retrograde into the LPC and out to atmosphere through an internal relief valve located upstream from the oxygen flush valve. The Ohmeda Excel 210, which does have a one-way check valve, also has a positive-pressure relief valve downstream from the check valve and therefore is unsuitable for jet ventilation. Older North American Dräger machines such as the Narkomed 2A (which also does not have the outlet check valve) produce a pressure of 18 psig at the common gas outlet because oxygen is vented to atmosphere through a pressure relief valve located in the Dräger Vapor vaporizers.<sup>74</sup>

It must be emphasized that use of the oxygen flush to drive a jet ventilation system connected at the machine's common gas outlet is an "off label" use of the machine, and is not recommended by the machine manufacturers. If jet ventilation is required, a purpose-built Sanders type system should be used, connected to a 50 psig oxygen source.

Several hazards have been reported with use of the oxygen flush valve. A defective or damaged valve can stick in the fully, or partially, open position, resulting in barotrauma,<sup>75</sup> or patient awareness during general anesthesia due to high oxygen flow diluting the inhaled anesthetic. Overzealous intraoperative oxygen flushing can also dilute inhaled anesthetics. Oxygen flushing during the inspiratory phase of positive-pressure ventilation can produce barotrauma in patients if the anesthesia machine does not incorporate fresh gas decoupling (FGD) or an appropriately adjusted inspiratory pressure limiter. Anesthesia systems, such as the Dräger Narkomed 6000 series, Julian, Fabius GS, or Apollo, use FGD which minimizes the chance of producing barotrauma from inappropriate oxygen flush valve use (see Fresh Gas Decoupling section).

With traditional anesthesia breathing circuits, excess volume cannot be vented during the inspiratory phase of mechanical ventilation because the ventilator pressure relief valve is closed and the APL valve is either out-of-circuit or closed. An alternative solution to this problem is used in the GE-Datex-Ohmeda S/5 ADU and GE-Aestiva. The breathing systems on these machines utilize an integrated adjustable pressure limiter. If this device is properly adjusted, it functions like the APL (or pop-off) valve to limit the maximum airway pressure to a safe level, thereby reducing the possibility of barotrauma.

## **Web-based Anesthesia Software Simulation, the Virtual Anesthesia Machine**

The advances in web-based application technology, as well as trends to incorporate simulation into anesthesia training and education, have generated

development of online anesthesia simulation resources. The Virtual Anesthesia Machine (VAM) is a web-based anesthesia simulation environment (Fig. 25-28) that provides information on the function of anesthesia machines along with tutorials and operational scenarios, including failure modes of new and traditional anesthesia workstations.<sup>76</sup> It is available for use free of charge but may not be available indefinitely due to limited funding. The authors of the VAM, in collaboration with the Anesthesia Patient Safety Foundation (APSF), have created the Anesthesia Machine Workbook (AMW). The AMW provides additional information and tutorials covering six anesthesia machine subsystems: the high-pressure system, the low-pressure system, the breathing circuit, manual ventilation, mechanical ventilation, and the scavenging system.<sup>1</sup> Some workstation manufacturers offer web-based interactive product trainers.<sup>77-80</sup>

## Vaporizers

As dramatic as the evolution of the anesthesia workstation has been in recent years, vaporizers have also changed from rudimentary ether inhalers and the “Copper Kettle” to the temperature-compensated, computer-controlled, and flow-sensing devices in use today. In 1993, with the introduction into clinical use of desflurane, an even more sophisticated vaporizer was introduced to handle the unique physical properties of this agent. Now, a new generation of anesthesia vaporizers blending traditional technology and “new” computerized control technology has emerged in the GE-Datex Aladin cassette vaporizer system. Before proceeding with a discussion of variable bypass vaporizers, the Datex-Ohmeda Tec 6 desflurane vaporizer and the GE-Datex-Ohmeda Aladin cassette vaporizer, it is important to review certain physical principles to facilitate understanding of the operating principles, construction, and design of contemporary volatile anesthetic vaporizers.

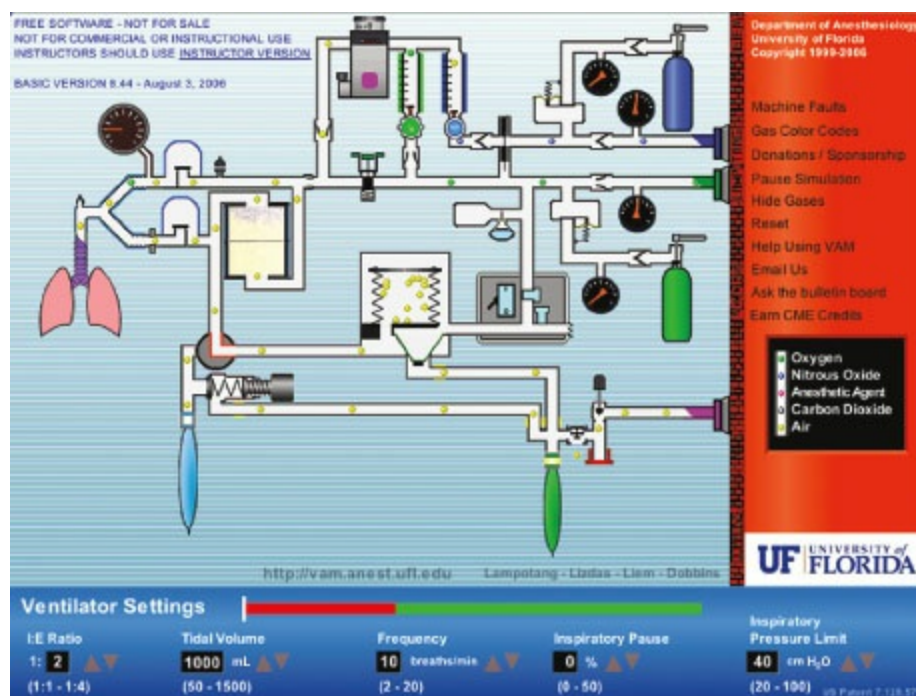

### *Physics*

The physical properties of potent inhaled volatile anesthetic agents that are pertinent to a discussion of vaporizers and vaporization are shown in Table 25-2.

### **Vapor Pressure**

Contemporary inhaled volatile anesthetics exist in the liquid state at temperatures below 20°C. When a volatile liquid is in a closed container, molecules escape from the liquid phase to the vapor phase until the number of molecules in the vapor phase is constant. These molecules in the vapor phase

bombard the wall of the container and create a pressure known as the *SVP*. As the temperature increases, more molecules enter the vapor phase, and the vapor pressure increases (Fig. 25-29). Vapor pressure is independent of atmospheric pressure and is dependent only on the temperature and physical characteristics of the liquid. The *boiling point* of a liquid is defined as that temperature at which the vapor pressure equals atmospheric pressure. At 760 mmHg, the boiling points for desflurane, isoflurane, halothane, enflurane, and sevoflurane are approximately 22.8°C, 48.5°C, 50.2°C, 56.5°C, and 58.5°C, respectively. Unlike other contemporary inhaled anesthetics, desflurane boils at temperatures that may be encountered in particularly warm clinical settings such as pediatric and burn operating rooms. This unique physical characteristic alone mandates a special vaporizer design to control the delivery of desflurane. If agent-specific vaporizers are accidentally filled with incorrect liquid anesthetic agents, the resulting mixtures of volatile agents may demonstrate properties that differ from those of the individual component agents and may alter the anticipated output of the vaporizer (see section on Variable Bypass Vaporizers: Misfilling).<sup>81</sup>

## Latent Heat of Vaporization

When a molecule is converted from a liquid to the gaseous phase, energy is consumed because the molecules of a liquid tend to cohere. The amount of energy that is consumed by a given liquid as it is converted to a vapor is referred to as the *latent heat of vaporization*. It is more precisely defined as the number of calories required to change 1 g of liquid into vapor without a temperature change. The thermal energy for vaporization must be derived from the liquid itself or from an external source. The temperature of the liquid itself will decrease during vaporization in the absence of an external energy source. This energy loss can lead to significant decreases in temperature of the remaining liquid and can greatly decrease subsequent vaporization.<sup>82</sup>

**Figure 25-29** Saturated vapor pressure versus temperature curves for desflurane, isoflurane, halothane, enflurane, and sevoflurane. The vapor pressure curve for desflurane is both steeper and shifted to higher vapor pressures when compared with the curves for other contemporary inhaled anesthetics. (Adapted from inhaled anesthetic package insert equations and from Susay SR, Smith MA, Lockwood GG. The saturated vapor pressure of desflurane at various temperatures. *Anesth Analg*.

## Specific Heat

The *specific heat* of a substance is the number of calories required to increase the temperature of 1 g of a substance by 1°C. The substance can be a solid, liquid, or gas. The concept of specific heat is important to the design, operation, and construction of vaporizers because it is applicable in two ways. First, the specific heat value for an inhaled anesthetic is important because it indicates how much heat must be supplied to the liquid to maintain a constant temperature when heat is being lost during vaporization. Second, manufacturers select vaporizer component materials that have a high specific heat to minimize temperature changes associated with vaporization.

## Thermal Conductivity

*Thermal conductivity* is a measure of the rate at which heat flows through a substance. The higher the thermal conductivity, the better the substance conducts heat. Vaporizers are constructed of metals that have relatively high thermal conductivity, thus maintaining a uniform internal temperature.

## Ambient Pressure Effects

These are discussed in the section titled GE-Datex-Ohmeda Tec 6 and Dräger D-Vapor Vaporizers for Desflurane: Factors that Influence Vaporizer Output: Varied Altitudes.

## Variable Bypass Vaporizers

The GE-Datex-Ohmeda Tec 4, Tec 5, and Tec 7, as well as the Dräger Vapor 19.n, 2000, and 3000 series, vaporizers are classified as variable bypass, flow-over, temperature-compensated, agent-specific, out-of-breathing circuit vaporizers. *Variable bypass* refers to the method for regulating the anesthetic agent concentration output from the vaporizer. As fresh gas from the machine flowmeters enters the vaporizer inlet, the concentration control dial setting determines the ratio of incoming gas that flows through the bypass chamber to that entering the vaporizing chamber (sump). The gas channeled through the vaporizing chamber flows over a wick system saturated with the liquid anesthetic and subsequently also becomes saturated with vapor. Thus, *flow-over* refers to the method of vaporization and is in contrast to a *bubble-through* system that is used in now-obsolete measured flow vaporizers (e.g., Copper Kettle, Verni-Trol). The GE-Ohmeda Tec 4, Tec 5, and Tec 7, and the Dräger Vapor 19.n and Vapor 2000 and 3000 series are further classified as

*temperature compensated*. Each is equipped with an automated temperature-compensating device that helps maintain a constant vapor concentration output for a given concentration dial setting, and over a wide range of operating temperatures. These vaporizers are *agent specific* because each is designed to accommodate a single anesthetic agent, and are *out-of-circuit*, that is, physically located outside of the breathing circuit. Variable bypass vaporizers are used to deliver halothane, enflurane, isoflurane, and sevoflurane, but not desflurane.

## Basic Operating Principles

A diagram of a generic, variable bypass vaporizer is shown in [Figure 25-30](#). In principle, it creates a saturated vapor concentration of the liquid agent in the vaporizing chamber and dilutes this to clinically usable concentrations by mixing it with fresh gas from the vaporizer bypass. For example, the SVP of sevoflurane is 160 mmHg at 20°C, at sea level. This corresponds to a vapor concentration of  $160 \text{ mmHg} / 760 \text{ mmHg} \times 100 = 21\%$ , which is too high for clinical use. Therefore, the vaporizer must dilute this 21% concentration to a clinically desirable value indicated on the vaporizer dial. Vaporizer components include the concentration control dial, the bypass chamber, the vaporizing chamber, the filler port, and the filler cap. Using the filler port, the operator fills the vaporizing chamber with liquid anesthetic. The maximum safe fill level is predetermined by the position of the filler port, which is designed to minimize the likelihood of overfilling. If a vaporizer is overfilled or tilted, liquid anesthetic can spill into the bypass via the inlet and outlet chambers. If this were to happen, both the vaporizing chamber flow and the bypass flow could potentially be carrying saturated anesthetic vapor, and an overdose would result. The concentration control dial is a variable restrictor, which controls gas flow through the bypass and through the outlet of the vaporizing chamber.<sup>83</sup>

FGF from the machine's flowmeters enters the inlet of the vaporizer. Most of the flow passes straight through the bypass chamber to the vaporizer outlet. A smaller fraction of the fresh gas inflow is diverted to the vaporizing chamber. Depending on the temperature and vapor pressure of the particular inhaled anesthetic, the fresh gas entering the vaporizing chamber entrains a specific flow of the anesthetic agent saturated vapor. The mixture that exits the vaporizer outlet comprises flow through the bypass chamber, flow through the vaporizing chamber, and flow of entrained anesthetic vapor. The final concentration of inhaled anesthetic (in volumes percent) is the ratio of the flow of the entrained anesthetic vapor to the total gas flow.<sup>84</sup> The quantity (mL) of liquid volatile anesthetic agent used by a typical vaporizer is proportional to the FGF rate and the concentration set on the dial. It can be

approximated from the following formula<sup>85</sup>:

**Figure 25-30** Generic variable bypass vaporizer. See text for details.

$$3 \times \text{FGF (L/min)} \times \text{vol\%} = \text{mL liquid volatile anesthetic/hr}$$

Figure 25-30 shows that the agent concentration emerging from the vaporizer is controlled by proportioning the vaporizing chamber outflow to the bypass flow. For example, assume that the vaporizing chamber outflow is 100 mL/min. The SVP of sevoflurane is 160 mmHg at 20°C (Table 25-2), the saturated vapor concentration of sevoflurane is 21% (i.e., 160/760); therefore, each 100 mL of gas exiting the vaporizing chamber contains 21 mL of sevoflurane vapor, the other 79 mL being the gas entering the vaporizing chamber. If the vaporizer dial is set to deliver 1% sevoflurane, the bypass flow will be 2,000 mL/min because 21 mL of sevoflurane vapor will be diluted in a total volume of 2,100 mL (21 + 79 + 2,000); 21/2,100 = 1% by volume. To achieve this the vaporizer concentration dial has created a flow ratio of 2,000:100 or 20:1 between the bypass flow and the flow exiting the vaporizing chamber. When the dial is set to deliver 2% sevoflurane, the vaporizer concentration dial creates a ratio of 950:100, or 9.5:1; i.e., 21 mL of sevoflurane vapor are diluted in a total volume of (21 + 79 + 950) 1,050 mL (21/1,050 = 2%).

In the case of an isoflurane vaporizer set to deliver 1% isoflurane, the concentration of isoflurane vapor in the vaporizing chamber will be 238/760 = 31% at 20°C (Table 25-2). Each 100 mL of gas leaving the vaporizing chamber will contain 31 mL of isoflurane vapor, the other 69 mL being the gas that entered the vaporizing chamber. The bypass flow must be 3,000 mL because now 31 mL of isoflurane vapor is diluted in a total volume of 3,100 (31 + 69 + 3,000). The vaporizer concentration dial has created a flow ratio

of 30:1 between the bypass flow and the flow exiting the vaporizing chamber. For 2% isoflurane the flow ratio would be 14.5:1 (i.e., 31 mL isoflurane vapor diluted in a total volume of (31 + 69 + 1,450) 1,550 mL). These examples demonstrate why variable bypass vaporizers are agent-specific.

The SVP of a potent volatile anesthetic depends on the ambient temperature (Fig. 25-29). For example, at 20°C the SVP of isoflurane is 238 mmHg, whereas at 35°C the SVP is almost double (450 mmHg). Variable bypass vaporizers incorporate a mechanism to compensate for variations in ambient temperature. The temperature-compensating valve of the GE-Datex-Ohmeda Tec-type vaporizers is shown in Figure 25-31. At relatively high ambient temperatures, such as those commonly seen in operating rooms designated for the care of pediatric or burn patients, the SVP in the vaporizing chamber is high. To compensate for this, the bimetallic strip of the temperature-compensating valve leans to the right, decreasing the resistance to gas flow through the bypass chamber. This allows more flow to pass through the bypass chamber and less flow to pass through the vaporizing chamber. In contrast, in a cold environment, the SVP of the agent in the vaporizing chamber is decreased. To compensate for this decrease in SVP, the bimetallic strip leans to the left. This increases the resistance to flow through the bypass chamber, causing relatively more flow to pass through the vaporizing chamber and less flow to pass through the bypass chamber. The net effect in both situations is maintenance of relatively constant vapor output concentration despite large swings in ambient temperature.

**Figure 25-31** Simplified schematic of the GE-Ohmeda Tec Type Vaporizer. Note bimetallic strip temperature-compensating mechanism in the bypass chamber. See text for details.

### Factors That Influence Vaporizer Output

If an ideal vaporizer existed, for a given concentration dial setting, its output would be constant regardless of changes in FGF rate, temperature, back

pressure, and fresh gas mixture composition and ambient pressure. Designing such a vaporizer is difficult because as ambient conditions change, the physical properties of gases and of the vaporizers themselves can change. Contemporary vaporizers approach ideal but still have some limitations. Even though some of the most sophisticated vaporizing systems now available use computer-controlled components and multiple sensors, they have yet to become significantly more accurate than conventional mechanical flow-splitting (variable bypass) vaporizers. Several factors that affect vaporizer performance in general are described below.

### *Fresh Gas Flow Rate*

With a fixed dial setting, vaporizer output can vary with the rate of gas flowing through the vaporizer. This variation is particularly notable at extremes of flow rates. The output of all variable bypass vaporizers is less than the dial setting at low flow rates (< 250 mL/min). This results from the relatively high density of volatile inhaled anesthetic vapors. At low flow rates, insufficient turbulence is generated in the vaporizing chamber to advance the vapor molecules upwardly. At extremely high flow rates, such as 15 L/min, the output of most variable bypass vaporizers is less than that set on the dial. This discrepancy is attributed to incomplete mixing and failure to saturate the carrier gas in the vaporizing chamber. In addition, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases.

### *Temperature*

Because of improvements in design, the output of contemporary temperature-compensated vaporizers is almost linear over a wide range of temperatures. Automatic temperature-compensating mechanisms in the bypass chamber maintain a constant vaporizer output with varying temperatures. As previously described, a bimetallic strip (Fig. 25-31) or in Dräger Vapor vaporizers, an expansion element (Fig. 25-32), directs a greater proportion of gas flow through the bypass chamber as temperature increases. In addition, the wick systems are placed in direct contact with the metal wall of the vaporizer to help replace energy (heat) consumed during vaporization.

**Figure 25-32** Simplified schematic of the Dräger Vapor 19.1 vaporizer. Here an expansion element performs the same function as the bimetallic strip in the previous figure. See text for details.

The materials from which vaporizers are constructed are chosen because they have a relatively high specific heat and high thermal conductivity. These factors help minimize the effect of cooling of the liquid anesthetic during vaporization. In addition, they should not react chemically with the liquid anesthetic agent.<sup>86</sup>

### *Intermittent Back Pressure*

Intermittent back pressure that results from either positive-pressure ventilation or use of the oxygen flush valve may result in higher-than-expected vaporizer output. This phenomenon, known as the *pumping effect*, is more pronounced at low FGF rates, low concentration dial settings, and low levels of liquid anesthetic in the vaporizing chamber.<sup>87,88</sup> In addition, the pumping effect is increased by rapid respiratory rates, high peak inspired pressures, and rapid decreases in pressure during exhalation.<sup>89</sup> Modern variable bypass vaporizers are relatively immune from the pumping effect. One proposed mechanism for the pumping effect is dependent on retrograde pressure transmission from the patient circuit to the vaporizer during the inspiratory phase of positive-pressure ventilation. Gas molecules are compressed in both the bypass and vaporizing chambers. When the back pressure is suddenly released during the expiratory phase of positive-pressure ventilation, vapor exits the vaporizing chamber via both the vaporizing chamber outlet and retrograde through the vaporizing chamber inlet.

To decrease the pumping effect, the vaporizing chambers of contemporary variable bypass systems are smaller than those of older model vaporizers. Consequently, no substantial volumes of vapor can be discharged from the vaporizing chamber into the bypass chamber during the expiratory phase of ventilation. The Dräger Vapor 19.1 and 20.n (Fig. 25-32) have a long spiral

tube that serves as the inlet to the vaporizing chamber. When the pressure in the vaporizing chamber is released, some of the vapor enters this tube but does not enter the bypass chamber because of the tube's length. The Tec 4 (Fig. 25-31) has an extensive baffle system in the vaporizing chamber, and a one-way check valve has been inserted at the common gas outlet (outlet check valve) to minimize the pumping effect. This check valve attenuates, but does not eliminate, the pressure increase because gas still flows from the flowmeters to the vaporizer during the inspiratory phase of positive-pressure ventilation.<sup>90</sup>

### *Fresh Gas Composition*

Vaporizer output is influenced by the composition of the gas that flows through the vaporizer.<sup>91</sup> During experimental conditions, when the carrier gas is rapidly changed from 100% oxygen to 100% nitrous oxide, a sudden transient decrease in vaporizer output occurs, followed by a slow increase to a new steady-state value.<sup>92</sup> Because nitrous oxide is more soluble than oxygen in the anesthetic liquid in the vaporizer sump, when this change occurs the output from the vaporizing chamber is transiently decreased.<sup>93</sup> Once the anesthetic liquid is totally saturated with nitrous oxide, vaporizing chamber output increases somewhat, and a new steady state is established.

The explanation for the new steady-state output value is less well understood.<sup>94,95</sup> With contemporary vaporizers such as the Dräger Vapor 19.n and 20.n and the GE Tec-type vaporizers, the steady-state output value is less when nitrous oxide rather than oxygen is the carrier gas (Fig. 25-33). Conversely, the output of some older vaporizers is increased when nitrous oxide is the carrier gas instead of oxygen.<sup>96,97</sup> Factors that contribute to the characteristic steady-state response resulting when various carrier gases are used include the viscosity and density of the carrier gas (i.e., whether the flow is laminar or turbulent), the relative solubilities of the carrier gas in the anesthetic liquid, the flow-splitting characteristics of the specific vaporizer, and the concentration control dial setting.

### **Safety Features**

Contemporary vaporizers (e.g., Dräger Vapor 19.n and Vapor 2000 series, and the GE-Datex-Ohmeda Tec 5, and Tec 7) have built-in safety features that have minimized or eliminated many of the hazards once associated with variable bypass vaporizers. Agent-specific, keyed filling devices help prevent filling a vaporizer with the wrong agent. Overfilling of vaporizers is minimized because the filler port is located at the maximum safe liquid level. Vaporizers are firmly secured to a vaporizer manifold on the anesthesia workstation and have antispill protection designs (e.g., “Transport” setting on

Dräger Vapor 2000 series vaporizers) so that problems associated with vaporizer tipping are prevented. Contemporary interlock systems prevent simultaneous administration of more than one inhaled volatile anesthetic. 

**Figure 25-33** Influence of gas composition on delivered anesthetic concentration. A Dräger Vapor 2000 vaporizer is initially set at 1 vol% and 100% air. The concentration falls by 10% (not more than 0.4 vol%) of the set value after switching to a mixture of 30% O<sub>2</sub> and 70% N<sub>2</sub>O. When 100% O<sub>2</sub> is used, the concentration rises by 10% of the set value (not more than 0.4 vol%). (Adapted from Schreiber P. *Anaesthetic Equipment: Performance, Classification, and Safety*. New York, NY: Springer; 1972.)

## Hazards

Despite many safety features, some hazards continue to be associated with contemporary variable bypass vaporizers.

### Misfilling

Vaporizers not equipped with keyed fillers have been occasionally misfilled with the wrong anesthetic liquid. A potential for misfilling exists even on contemporary vaporizers equipped with keyed fillers.<sup>98-100</sup> When a vaporizer misfilling occurs, patients can be rendered inadequately, or excessively, anesthetized depending on which “incorrect” agent is in the vaporizer.<sup>101</sup> The use of an anesthetic agent analyzer should alert the user to such a problem. In principle, if a vaporizer designed for an agent with a relatively low SVP (e.g., sevoflurane-160 mmHg at 20°C) is erroneously filled with an agent that has a relatively high SVP (e.g., isoflurane-238 mmHg at 20°C) the output concentration of isoflurane (in vol%) will be greater than that set on the concentration dial of the sevoflurane vaporizer. Conversely, an isoflurane vaporizer misfilled with sevoflurane will deliver a lower concentration of sevoflurane than that set on the concentration dial. In addition to considering the agent concentration output of a misfilled vaporizer, one must also

consider the potency output. Thus, a sevoflurane vaporizer set to deliver 2% sevoflurane (1 MAC) that is misfilled with isoflurane will deliver about 3% isoflurane which would be more than double the potency (MAC multiple) expected!

Understanding the principles of operation of a variable bypass vaporizer (i.e., how gas flows are split between bypass and vaporizing chamber) makes it possible to predict the output of an erroneously filled vaporizer so that in certain situations (e.g., remote locations, impoverished countries) deliberate mismatch has been safely used.<sup>102</sup> But caution is required. Mismatching of inhaled agent and vaporizer is a dangerous practice and should not be performed unless it is absolutely necessary.

Contamination of anesthetic vaporizer contents has occurred by filling an isoflurane vaporizer with a contaminated bottle of isoflurane. A potentially serious incident was avoided because the operator detected an abnormal acrid odor.<sup>103</sup>

### *Tipping*

Tipping of a vaporizer can occur when they are incorrectly “switched out” or moved. However, tipping is unlikely when a vaporizer is secured to the anesthesia workstation manifold short of the entire machine being turned over. Excessive tipping can cause the liquid agent to enter the bypass chamber and can cause an output with extremely high agent vapor concentration.<sup>104</sup>

One milliliter of liquid anesthetic produces approximately 200 mL of anesthetic vapor at 20°C and 1 atm pressure so that even a small quantity of liquid anesthetic in the bypass can produce a large amount of vapor (Table 25-2). If a vaporizer has been tipped, it should not be used clinically until it has been purged for 20 to 30 minutes using a high FGF rate from the machine’s flowmeters. During this procedure, the vaporizer concentration control dial should be set at a high concentration which maximizes bypass chamber flow as well as vaporizing chamber inlet and outlet flows. Purging should continue until all spilled liquid anesthetic has been cleared. Following this procedure the accuracy of the vaporizer output must be confirmed using an agent analyzer before placing the vaporizer back into clinical service. As mentioned above, the Dräger Vapor 2000 and 3000 series vaporizers have a transport (“T”) dial setting that prevents tipping-related problems. When the dial is set to this position, the vaporizer sump is isolated from the bypass chamber, thereby reducing the likelihood of spillage (and a possible accidental overdose). In order to remove a Vapor 2000 or 3000 from the anesthesia workstation, the control dial must be set to the “T” position.

The design of the GE-Datex-Ohmeda Tec 6 and the Aladin cassette vaporizer systems has essentially eliminated the dangers of tipping. Since the Aladin vaporizer’s bypass chamber is physically separated from the “cassette,”

and permanently resides in the anesthesia workstation, the possibility of tipping is virtually eliminated. Tipping of the Aladin cassettes themselves when they are not installed in the vaporizer is not problematic. Similarly, Dräger's D-Vapor (desflurane) vaporizer is hermetically tight and can be transported in any position before draining.

### *Improper Filling*

Overfilling of a vaporizer combined with failure of the vaporizer sight glass can cause an anesthetic overdose. When liquid anesthetic enters the bypass chamber, up to 10 times the intended vapor concentration can be delivered to the common gas outlet.<sup>105,106</sup> Most modern vaporizers are now relatively immune to overfilling because of side-fill rather than top-fill designs.

Just as with overfilling, underfilling of anesthetic vaporizers may also be problematic. When a Tec 5 sevoflurane vaporizer is in a low-fill state and used under conditions of high FGF rates ( $>7.5$  L/min) and high dial setting (such as seen during inhalational inductions), the vaporizer output may abruptly decrease to less than 2%. The causes of this problem are likely multifactorial. However, the combination of low vaporizer fill state ( $<25\%$  full) in combination with the high vaporizing chamber flow can result in a clinically significant and reproducible decrease in vapor output.<sup>107</sup>

### *Simultaneous Inhaled Anesthetic Administration*

Some older anesthesia machines, such as the Datex-Ohmeda with the Select-a-Tec three-vaporizer manifold, do not utilize a vapor-interlock system. Thus, two inhaled anesthetics potentially can be administered simultaneously. Newer anesthesia workstations have a built-in vapor-interlock or vapor-exclusion device that prevents this problem.

### *Leaks*

Vaporizer leaks do occur frequently and can potentially result in patient awareness during anesthesia<sup>108</sup> or in contamination of the operating room environment. A loose filler cap is the most common source of vaporizer leaks. Leaks can also occur at the O-ring junctions between the vaporizer and its manifold. To detect a leak within a vaporizer, the concentration control dial must be in the "on" position. Even though vaporizer leaks in Dräger anesthesia systems can potentially be detected with a conventional positive-pressure low-pressure system leak test (because of the absence of an outlet check valve), a negative-pressure leak test is probably more sensitive. GE-Datex-Ohmeda recommends a negative-pressure leak testing device (suction bulb) to detect vaporizer leaks in the Modulus I, Modulus II, Excel, and the Aestiva workstations because of the check valve located just upstream of each

machine's fresh gas outlet (see Checking Your Anesthesia Workstation section).

Many newer anesthesia workstations are capable of performing self-testing procedures that, in some cases, may eliminate the need for the conventional negative-pressure leak testing. However, it is of vital importance that anesthesia providers understand that these self-tests may not detect internal vaporizer leaks in systems with add-on vaporizers. For the self-tests to determine if an internal vaporizer leak is present, the leak test must be repeated for each vaporizer sequentially, while its concentration control dial is turned to the "on" position. Recall that when a vaporizer's concentration control dial is set in the "off" position, it may not be possible to detect even major internal leaks such as an absent or loose filler cap.

### *Vaporizers in the MRI Suite*

The presence of a powerful magnetic field, the significant noise pollution, and limited access to the patient during an MRI procedure all complicate care in this setting. It is imperative that only nonferrous (MRI compatible) equipment be used. Some anesthesia vaporizers, although they may appear nonferrous by testing with a horseshoe magnet, may indeed contain substantial internal ferrous components. Inappropriate use of such a device in an MRI suite may potentially turn it into a dangerous missile if left unsecured.<sup>109</sup>

### *The Tec 6 and D-Vapor Vaporizers for Desflurane*

Because of its unique physical characteristics, the controlled vaporization of desflurane requires a novel approach to vaporizer design. Ohmeda  developed the Tec 6 vaporizer, the first such system, and introduced it into clinical use in the early 1990s. The Tec 6 vaporizer is an electrically heated, pressurized device specifically designed to deliver desflurane.<sup>110,111</sup> The vapor pressure of desflurane is three to four times that of other contemporary inhaled anesthetics, and it boils at 22.8°C which is slightly above normal room temperature (Fig. 25-29). Desflurane has a minimum alveolar anesthetic concentration (MAC) value of 6% to 7%.<sup>112</sup> It is valuable because it has a low blood:gas partition coefficient of 0.45 at 37°C, and recovery from anesthesia is more rapid than from other potent inhaled anesthetics. In 2004, Dräger Medical received FDA approval for its own version of the Tec 6 desflurane vaporizer, the D-Vapor. The operating principles described in the following discussion are applicable to both vaporizers, although reference is made to the Tec 6 specifically.

### **Unsuitability of Contemporary Variable Bypass Vaporizers for Controlled**

## Vaporization of Desflurane

Desflurane's high volatility and moderate potency preclude its use with contemporary variable bypass vaporizers such as GE-Datex-Ohmeda Tec 4, Tec 5, and Tec 7, or the Dräger Vapor 19.n or 20.n for two primary reasons (Table 25-2):

1. At 20°C the SVP of desflurane is 669 mmHg (almost 1 atm pressure at sea level). The vapor pressures of sevoflurane, enflurane, isoflurane, halothane, and desflurane at 20°C are 160, 172, 240, 244, and 669 mmHg, respectively (Fig. 25-29; Table 25-2). Equal amounts of flow through a traditional vaporizer would vaporize many more volumes of desflurane than any other of these agents. For example, at 1 atm and 20°C, 100 mL/min passing through the vaporizing chamber would entrain 735 mL/min desflurane versus 25, 29, 46, and 47 mL/min of sevoflurane, enflurane, isoflurane, and halothane, respectively.<sup>98</sup> In addition, at temperatures of 22.8°C or higher at 1 atm, desflurane will boil. The amount of vapor produced would be uncontrolled and limited only by the heat energy available from the vaporizer.<sup>98</sup>
2. Contemporary variable bypass vaporizers lack an external heat source. The latent heat of vaporization for desflurane is approximately equal to those of the other potent agents but its MAC is four to nine times higher. Thus, the absolute amount of desflurane liquid vaporized over a given time period is considerably greater than that of the other anesthetic agents. To deliver desflurane via a conventional vaporizer in higher (equivalent MAC) concentrations would lead to excessive cooling of the vaporizer and would significantly reduce its output. In the absence of an external heat source, temperature compensation using traditional mechanical devices would be almost impossible. Because of the broad range of temperatures seen in the clinical setting, and because of desflurane's steep SVP versus temperature curve (Fig. 25-29), the delivery of desflurane in a conventional anesthetic vaporizer would be unpredictable.<sup>113</sup>

## Operating Principles of the Tec 6 and D-Vapor

The physical appearance and operation of the Tec 6 are similar to other vaporizers, but some aspects of the internal design and operating principles are radically different. Functionally, the Tec 6's operation is more accurately described as a dual-gas blender than as a vaporizer. A simplified schematic of the Tec 6 is shown in Figure 25-34. The vaporizer has two independent gas circuits arranged in parallel. The fresh gas circuit is shown in darker gray, and the vapor circuit in light gray. The FGF from the machine's flowmeters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the

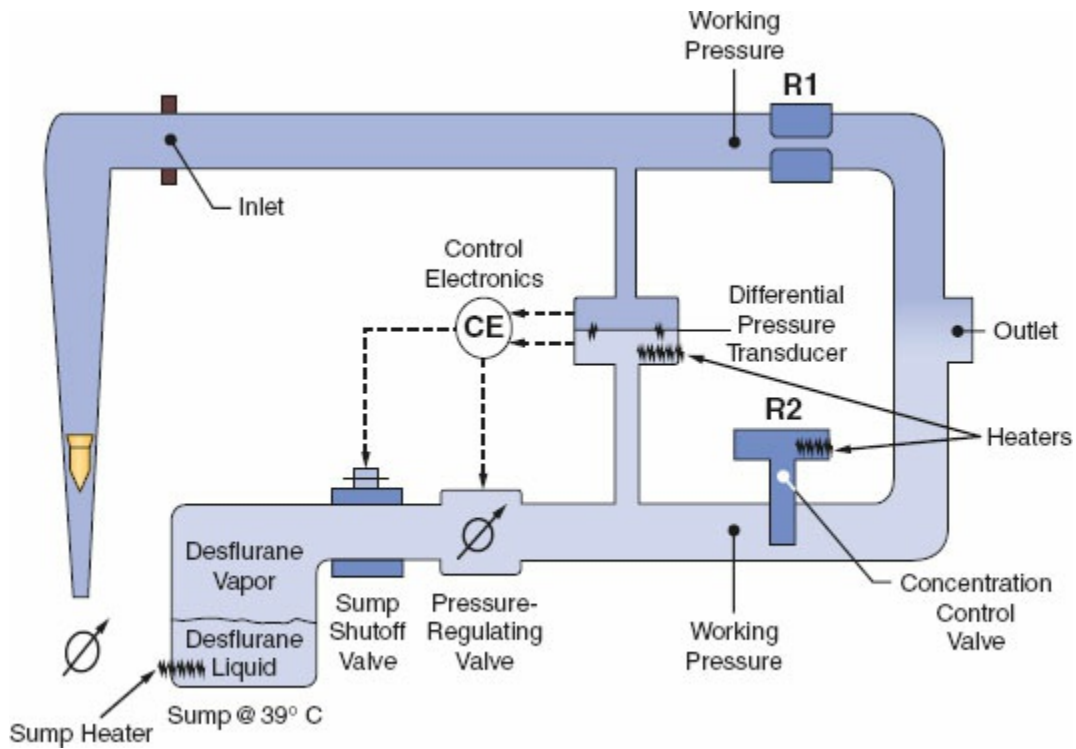

vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is electrically heated and thermostatically controlled to 39°C, a temperature well above desflurane's boiling point at 1 atm. The heated sump assembly creates a reservoir of desflurane vapor. At 39°C, the vapor pressure in the sump is approximately 1,500 mmHg, or 2 atm absolute (Fig. 25-29). Just downstream from the sump is the shutoff valve. After the vaporizer has warmed up to working temperature, the shutoff valve fully opens when the concentration control valve is turned to the "on" position. A pressure-regulating valve located downstream from the shutoff valve regulates downward the pressure to approximately 1.1 atm absolute (74 mmHg gauge) at an FGF rate of 10 L/min. The operator controls desflurane output by adjusting the concentration control valve (R2), which is a variable restrictor. The vapor flow through R2 joins the FGF through R1 at a point downstream from the restrictors. Until this point, the two circuits are physically separated. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When a constant FGF encounters the fixed restrictor, R1, a specific back pressure, proportional to the FGF rate, pushes against the diaphragm of the control differential pressure transducer. The differential pressure transducer conveys the pressure difference between the fresh gas circuit and the vapor circuit to the control electronics system. The control electronics system regulates the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, and the working pressure is constant at a fixed FGF rate. If the operator increases the FGF rate, more back pressure is exerted upon the diaphragm of the control pressure transducer, and the working pressure of the vaporizer increases.

Table 25-3 shows the approximate correlation between FGF rate and working pressure for a typical vaporizer. At an FGF rate of 1 L/min, the working pressure is 10 millibars, or 7.4 mmHg gauge. At an FGF rate of 10 L/min, the working pressure is 100 millibars, or 74 mmHg gauge. Therefore, there is a linear relationship between FGF rate and working pressure. When the FGF rate is increased 10-fold, the working pressure increases 10-fold.<sup>110</sup>

The following are two examples to demonstrate the operating principles of the Tec 6 (and D-Vapor). Example A: Constant FGF rate of 1 L/min, with an increase in the dial setting.

With an FGF rate of 1 L/min, the working pressure of the vaporizer is 7.4 mmHg. That is, the pressure supplying R1 and R2 is 7.4 mmHg. As the operator increases the dial setting, the opening at R2 becomes larger, allowing more vapor to pass through R2. Specific vapor flow rates at different dial settings are shown in Table 25-4.

**Figure 25-34** Simplified schematic of the Tec 6 desflurane vaporizer. (Modified from Andrews JJ. *Operating Principles of the Ohmeda Tec 6 Desflurane Vaporizer: A Collection of Twelve Color Illustrations*. Washington, DC: Library of Congress, Copyright 1996.)

**Table 25-3** Fresh Gas Flow Rate versus Working Pressure

Fresh Gas Flow Rate (L/min)	Working Pressure at R1 and R2 (Gauge) (Gas Inlet Pressure)		
	mbar	cm Water	mmHg
1	10	10.2	7.4
5	50	51.0	37.0
10	100	102.0	74.0

Reprinted with permission from: Andrews JJ, Johnston RV Jr. The new Tec 6 desflurane vaporizer. *Anesth Analg*. 1993;76:1338.

Example B: Constant dial setting with an increase in FGF from 1 to 10 L/min.

At an FGF rate of 1 L/min, the working pressure is 7.4 mmHg, and at a dial setting of 6% the vapor flow rate through R2 is 64 mL/min (Tables 25-3 and 25-4). With a 10-fold increase in the FGF rate, there is a concomitant 10-fold increase in the working pressure to 74 mmHg. The ratio of resistances of R2 to R1 is constant at a fixed dial setting of 6%. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases 10-fold to 640 mL/min. Vaporizer output in volumes percent is constant because both the FGF and the vapor flow increase proportionally.

## Altitude Can Influence Vaporizer Output

Changes in ambient pressure may significantly affect the output of older Tec-type vaporizers (i.e., those in which gas flow splitting occurs at the entrance to the vaporizing chamber rather than at the exit) in terms of volumes percent (i.e., concentration), but the effect on anesthetic potency (i.e., partial pressure of agent) is minimal. This effect is illustrated using the example of isoflurane shown in Table 25-5. With a constant dial setting of 0.89%, at 1 atm (760 mmHg), if perfectly calibrated, the volumes percent delivered would be 0.89% and the partial pressure of isoflurane would be 6.8 mmHg. Maintaining the same dial setting and lowering ambient pressure to 0.66 atm (roughly equivalent to 10,000 ft elevation) would result in an increase in the concentration output to 1.75% (almost double), but the partial pressure only increases to 8.77 mmHg (a 29% increase) because of the proportionate decrease in ambient pressure (Fig. 25-35).

**Table 25-4** Dial Setting versus Flow through Restrictor R2

Dial Setting (vol%) <sup>a</sup>	Fresh Gas Flow Rate (L/min)	Approximate Vapor Flow Rate Through R2 (mL/min)
1	1	10
6	1	64
12	1	136
18	1	220

Reprinted with permission from: Andrews JJ, Johnston RV Jr. The new Tec 6 desflurane vaporizer. *Anesth Analg.* 1993;76:1338.  
<sup>a</sup>vol% = [(vapor flow rate)/(fresh gas flow rate + vapor flow rate)] × 100%.

It is generally considered that the partial pressure of the anesthetic agent in the central nervous system, not its concentration in volumes percent, is responsible for the anesthetic effect. To obtain a consistent depth of anesthesia when gross changes in barometric pressure occur, the concentration in volumes percent must be changed in inverse proportion to the barometric pressure.

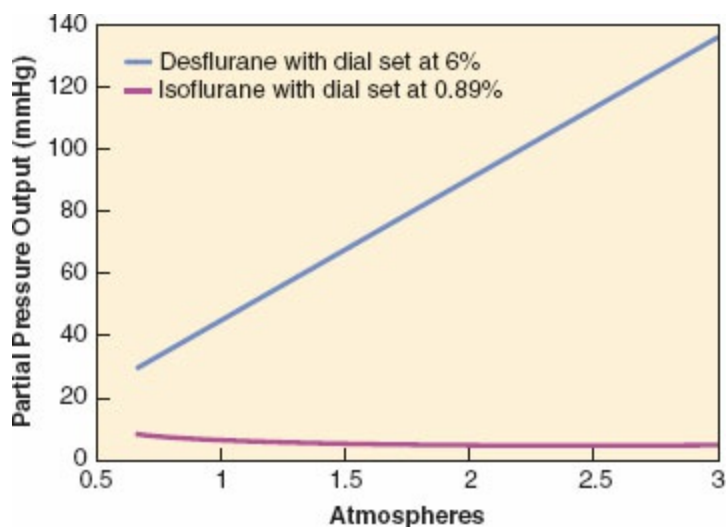

In contemporary variable bypass vaporizers (e.g., GE Tec 5, Tec 7, Dräger Vapor 19.1 and Vapor 2000) the flow proportioning occurs as gas leaves the vaporizing chamber, so that for any given dial setting and FGF, the volume of gas saturated with vapor that leaves the vaporizing chamber remains constant, to be diluted by the bypass flow. Assume that gas leaves the vaporizing chamber of an isoflurane vaporizer at 100 mL/min. At 1 atm (760 mmHg) that gas would be 31.3% isoflurane by volume (238/760) and the partial pressure would be 31.3% × 760 = 238 mmHg. At a barometric pressure of 500 mmHg, the gas exiting the vaporizing chamber would be 47.6% isoflurane by volume (238/500) and the partial pressure would be

47.6% × 500 = 238 mmHg. By proportioning flow as gas leaves the vaporizing chamber, these vaporizers essentially become ambient pressure compensated.

**Table 25-5** Performance of OLDER<sup>a</sup> Tec Type Vaporizers versus the Tec 6 Desflurane Vaporizer at Varying Ambient Pressures

Atmospheres	Ambient Pressure (mmHg)	Isoflurane Vaporizer with a Dial Setting of 0.89%			Tec 6 Desflurane Vaporizer with a Dial Setting of 6%
		Isoflurane Vapor Entrained by 100 cc O <sub>2</sub>	Output Concentration (%)	Partial Pressure Output (mmHg)	Partial Pressure Output of Desflurane (mmHg)
0.66 (2/3)	500 (10,000 ft)	91	1.753	8.77	30
0.74	560	74	1.429	8.0	33.6
0.80	608 (6,564 ft)	64.32	1.25	7.6	36.5
1.0	760	46	0.89	6.8	45.6
1.5	1,140	26.4	0.515	5.87	68.4
2	1,520	19	0.36	5.5	91.2
3	2,280	11.65	0.228	5.198	136

The following were assumed: 5,000 cc bypass chamber flow, 100 cc vaporizing chamber flow—equivalent to an isoflurane dial setting of 0.89%.  
<sup>a</sup>Variable bypass vaporizers in which the incoming gas flow is split before gas enters the vaporizing chamber.

**Figure 25-35** Performance of Tec type vaporizer versus the Tec 6 desflurane vaporizer at varying ambient atmospheric pressures (1 atm = 760 mmHg).

The above examples should be considered in stark contrast to the response of the Tec 6 desflurane vaporizer at varied altitudes (Fig. 25-35 and Table 25-5). One must remember this device is more accurately described as a dual gas “blender” than a vaporizer. Regardless of the ambient pressure, the Tec 6 will maintain a constant concentration of vapor output (in vol%), not a constant partial pressure. This means that at high altitudes, the partial pressure of desflurane for any given dial setting will be decreased in proportion to the atmospheric pressure divided by the calibration pressure (normally 760 mmHg) according to the following formula:

Required dial setting = normal dial setting (v/v × 760 mmHg)/ambient pressure (mmHg)

Consider a Tec 6 vaporizer that is set to deliver 10% desflurane at 1 atmosphere. The partial pressure of desflurane delivered from the vaporizer (Pdes) is 76 mmHg (i.e., 10% × 760). If used at an altitude at which the ambient pressure is 500 mmHg, the Tec 6 dial setting must be increased to 15% to maintain the same anesthetic potency (15% × 500 = Pdes 75 mmHg). Conversely, the Tec 6's maintenance of a constant vol% output under hyperbaric conditions could produce significant increases in partial pressure output and, if not accounted for, the potential for anesthetic overdose. Therefore, in hyperbaric situations the Tec 6 dial setting would need to be decreased to maintain the desired partial pressure output of desflurane.

### Carrier Gas Composition Can Influence Vaporizer Output

Vaporizer output approximates the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated by the manufacturer using 100% oxygen. At low flow rates when a carrier gas other than 100% oxygen is used, however, a clear trend toward reduction in vaporizer output emerges. This reduction parallels the proportional decrease in viscosity of the carrier gas. Nitrous oxide has a lower viscosity than oxygen, so the back pressure generated by resistor R1 (Fig. 25-34) is less when nitrous oxide is the carrier gas, and the working pressure is reduced. At low flow rates using nitrous oxide as the carrier gas, vaporizer output is approximately 20% less than the dial setting. This suggests that, at clinically useful FGF rates, the gas flow across resistor R1 is laminar, and the working pressure is proportional to both the FGF rate and the viscosity of the carrier gas.<sup>114</sup>

### Safety Features

Because desflurane's SVP at room temperature is near 1 atm, misfilling contemporary vaporizers with desflurane could theoretically result in both desflurane overdose and creation of a hypoxic gas mixture.<sup>115</sup> GE-Datex-Ohmeda has introduced a unique, anesthetic-specific filling system to minimize occurrence of this potential hazard. The agent-specific filler of the desflurane bottle known as the "Saf-T-Fill" adapter is intended to prevent its use with traditional vaporizers. The filling system also minimizes spillage of liquid or vapor anesthetic by maintaining a "closed system" during the filling process. Each desflurane bottle has a spring-loaded filler cap with an O-ring on the tip. The spring seals the bottle until it is engaged in the filler port of the vaporizer. Thus, this anesthetic-specific filling system interlocks the vaporizer and the dispensing bottle, preventing loss of anesthetic to the

atmosphere. Despite these safety features designed to minimize filling errors, a case report described the misfilling of a Tec 6 desflurane vaporizer with sevoflurane. This error was possible because of similarities between a new type of keyed filler for sevoflurane and the desflurane Saf-T-Fill adapter. In this case, however, the desflurane vaporizer detected this error and automatically shut itself off.<sup>98</sup> Major vaporizer faults cause the shutoff valve located just downstream from the desflurane sump (Fig. 25-34) to close, producing a no-output situation. The valve is closed and a “no-output” alarm is activated immediately if any of the following conditions occur: (1) the anesthetic level decreases to <20 mL; (2) the vaporizer is tilted; (3) a power failure occurs; or (4) there is a disparity between the pressure in the vapor circuit versus the pressure in the fresh gas circuit exceeding a specified tolerance. Note the alarm panel on the front of the Tec 6 vaporizer (Fig. 25-36A) showing “No Output,” “Low Agent,” “Warm Up,” and “Alarm Battery Low” indicators.

The Dräger D-Vapor vaporizer has similar alarms (Fig. 25-36B). The “No Output” alarm (flashes red) indicates that the vaporizer is unable to deliver anesthetic (i.e., the vaporizer is warming up) or there is a device failure. The “Delivery Low” alarm (flashes red) triggers when the vaporizer is unable to supply the output set by the concentration dial (only with FGF > 1.5 L/min), the reservoir is empty, or if there is an apparatus fault. The “Fill Up” alarm (glows amber) indicates the reservoir level has dropped below the refill mark (the reservoir contains <40 mL). The “Battery” alarm will indicate (1) *amber glow* if the vaporizer is not able to operate without power, (2) *amber flashing* if the vaporizer is currently operating on battery backup, (3) *flashing amber plus “No Output” flashing red* if the vaporizer battery is depleted after operating on battery backup and another method of anesthesia is required. The vaporizer will also provide an audible alarm along with visual alarms. Medium priority alarms (amber glowing and flashing) may be silenced; high-priority alarms (red flashing) cannot be silenced.<sup>113</sup>

### **The GE-Datex-Ohmeda Aladin Cassette Vaporizer**

The vaporizer system used in the GE-Datex-Ohmeda S/5 ADU and GE Aisys Carestation is unique in that the single electronically controlled vaporizer is designed to deliver five different inhaled anesthetics including halothane, isoflurane, enflurane, sevoflurane, and desflurane (Figs. 25-37 and 25-38). The vaporizer consists of a permanent internal control unit housed within the workstation and an interchangeable Aladin agent-specific cassette that contains anesthetic liquid. The Aladin agent cassettes are color coded for each anesthetic agent, and they are also magnetically coded so that the workstation can identify which anesthetic cassette has been inserted. The cassettes are

filled using agent-specific fillers.

**Figure 25-36** A: Tec 6 desflurane vaporizer alarm indicators. B: Dräger D-Vapor desflurane alarm indicators.

Though very different in external appearance, the functional anatomy of the Aladin cassette vaporizer (Fig. 25-39) is very similar to that of the traditional variable bypass vaporizers because it is also made up of a bypass chamber and vaporizing chamber. A fixed restrictor is located in the bypass chamber, and flow measurement sensors are located both in the bypass chamber and in the outlet of the vaporizing chamber. The heart of the Aladin vaporizer is the electronically regulated flow control valve located in the vaporizing chamber outlet. This valve is controlled by a central processing unit (CPU). The CPU receives input from multiple sources including the concentration control dial, a pressure sensor located inside the vaporizing chamber (cassette), a temperature sensor located inside the vaporizing chamber, a flow measurement unit located in the bypass chamber, and a flow measurement unit located in the outlet of the vaporizing chamber. The CPU also receives input from the machine's flowmeters regarding the composition of the carrier gas. Using data from these multiple sources, the CPU is able to precisely regulate the flow control valve to attain the desired vapor concentration output. Appropriate electronic control of the flow control valve is essential to the proper function of this vaporizer.<sup>116</sup>

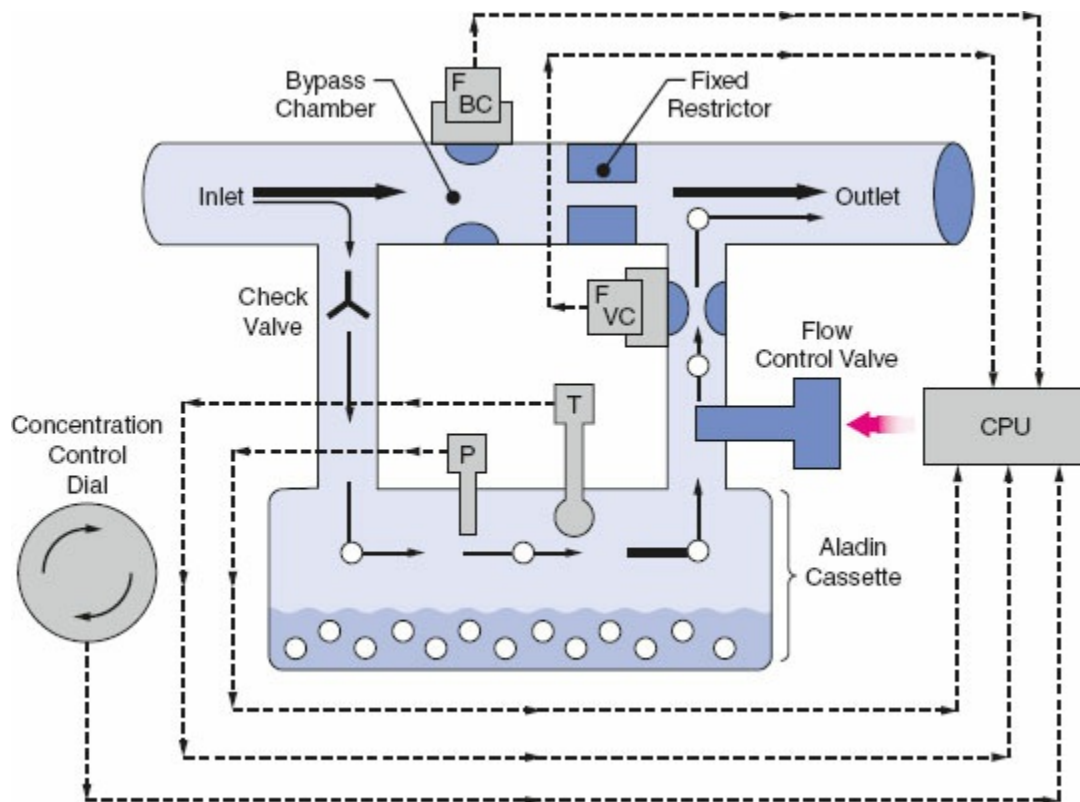

**Figure 25-37** Aladin vaporizer sevoflurane cassette (courtesy of GE Healthcare).

**Figure 25-38** Aladin cassette vaporizers (*arrows*) on a GE Datex-Ohmeda Aisys Carestation. Upper cassette is in use, lower cassettes are stored on workstation.

**Figure 25-39** Simplified schematic of GE-Datex-Ohmeda Aladin Cassette Vaporizer. The *black arrows* represent flow from the flowmeters, and the *white circles* represent anesthetic vapor. The heart of the vaporizer is the electronically controlled flow control valve located in the outlet of the vaporizing chamber. CPU, central processing unit; FBC, flow measurement unit, which measures flow through the bypass chamber; FVC, flow measurement unit, which measures flow through the vaporizing chamber; P, pressure sensor; T, temperature sensor. (Modified from Andrews JJ. *Operating Principles of the Datex-Ohmeda Aladin Cassette Vaporizer: A Collection of Color Illustrations*. Washington, DC: Library of Congress; 2000.)

A fixed restrictor is located in the bypass chamber, and it causes flow from the vaporizer inlet to be split into two flow streams (Fig. 25-39). One stream passes through the bypass chamber, and the other portion enters the inlet of the vaporizing chamber and passes through a one-way check valve. The presence of this check valve is unique to the Aladin system. This one-way valve prevents retrograde flow of the anesthetic vapor back into the bypass chamber, and its presence is crucial when delivering desflurane if the room temperature is greater than the boiling point for desflurane (22.8°C). A precise amount of vapor-saturated carrier gas passes through the flow control valve, which is regulated by the CPU. This flow then joins the bypass flow and is directed to the outlet of the vaporizer.

As mentioned during the discussion of the Tec 6, the controlled vaporization of desflurane presents a unique challenge, particularly when the room temperature is greater than the boiling point of desflurane (22.8°C). At higher temperatures, the pressure inside the vaporizer sump increases, and

the sump becomes pressurized. When the sump pressure exceeds the pressure in the bypass chamber, the one-way check valve located in the vaporizing chamber inlet closes preventing carrier gas from entering the vaporizing chamber. At this point, the carrier gas passes straight through the bypass chamber and its flow sensor. Under these conditions, the electronically regulated flow control valve simply meters in the appropriate flow of pure desflurane vapor needed to achieve the desired final concentration selected by the user.

During operating conditions in which high FGF rates and/or high dial settings are used, large quantities of anesthetic liquid are rapidly vaporized. The temperature of the remaining liquid anesthetic and the vaporizer itself decreases as a result of energy consumption of the latent heat of vaporization. To offset this cooling effect, the workstation (GE ADU and Aisys) is equipped with a fan that forces warmed air from an “agent heating resistor” across the cassette (vaporizer sump) to raise its temperature when necessary. The fan is activated during two common clinical scenarios: (1) desflurane induction and maintenance and (2) sevoflurane induction. A summary of the characteristics of various vaporizer models currently in use is found in [Table 25-6](#).

**Table 25-6** Vaporizer Models and Characteristics

Type of Vaporizer	Tec 4, Tec 5, SevoTec, Vapor 19.n, Vapor 2000, Aladin	Tec 6 (Desflurane), D-Vapor (Desflurane)
Carrier gas flow	Variable bypass	Dual circuit
Vaporization method	Flow-over	Gas/vapor blender
Temperature compensation	Automatic	Thermostatically controlled at 39°C
Calibration	Agent specific	Agent specific
Position	Out of circuit	Out of circuit
Fill capacity	Tec 4: 125 mL Tec 5: 300 mL Vapor 19.n: 200 mL Vapor 2000: 360 mL (dry wick) Aladin: 250 mL	Tec 6: 425 mL D-Vapor: 300 mL

### *Maquet FLOW-i Electronic Injector Vaporizer*

The ability to calculate volume of vapor produced per mL of liquid agent ([Table 25-2](#)) is applied in the vaporizing system of the Maquet FLOW-i workstation ([Fig. 25-4B](#)). In principle, and somewhat analogous to fuel injection in an automobile engine, measured amounts of liquid anesthetic are injected into the FGF stream. An electronically controlled valve in the injector controls the amount of anesthetic that is delivered. The fresh gas flows through a chamber in which the anesthetic is injected. Various electronic controls and feedback mechanisms as well as continuous gas analysis ensure that the desired concentration of inhaled anesthetic is delivered in the fresh

gas flowing to the patient.

## Anesthesia Breathing Circuits

As the prescribed mixture of gases from the flowmeters and vaporizer exits the anesthesia workstation at the common gas outlet, it then enters an anesthetic breathing circuit. The function of the anesthesia breathing circuit is not only to deliver oxygen and anesthetic gases to the patient but also to eliminate CO<sub>2</sub>. Carbon dioxide can be removed either by washout with adequate fresh gas inflow or by the use of CO<sub>2</sub> absorbent media (e.g., soda lime absorption).

### Mapleson Systems

In 1954, Mapleson described and analyzed five different semiclosed anesthetic systems; these are now classically referred to as the Mapleson systems and are designated with letters A through E (Fig. 25-40).<sup>117</sup> Subsequently in 1975, Willis et al.<sup>118</sup> described the F system that was added to the original five. The Mapleson systems consist of several common components. These components commonly include a facemask, a spring-loaded pop-off valve, reservoir tubing, fresh gas inflow tubing, and a reservoir bag. Within the Mapleson systems, three distinct functional groups can be seen. They include the A; the B, C; and the D, E, F groups. The Mapleson A, also known as the Magill attachment, has a spring-loaded pop-off valve located near the facemask, and the FGF enters the opposite end of the circuit near the reservoir bag. In the B and C systems, the spring-loaded pop-off valve is located near the facemask, but the fresh gas inlet tubing is located near the patient. The reservoir tubing and reservoir bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson D, E, F group, or “T-piece” group, the fresh gas enters near the patient, and excess gas is released at the opposite end of the circuit.

Although the components and component arrangements are simple, functional analysis of the Mapleson systems can be complex. The amount of CO<sub>2</sub> rebreathing associated with each system is multifactorial, and variables that dictate the ultimate CO<sub>2</sub> concentration include (1) the fresh gas inflow rate, (2) the patient’s minute ventilation, (3) the mode of ventilation (spontaneous or controlled), (4) the tidal volume, (5) the respiratory rate, (6) the I:E ratio, (7) the duration of the expiratory pause, (8) the peak inspiratory flow rate, (9) the volume of the reservoir tube, (10) the volume of the breathing bag, (11) ventilation by mask, (12) ventilation through an endotracheal tube, and (13) the CO<sub>2</sub> sampling site.

The performance of the Mapleson systems is best understood by studying

the expiratory phase of the respiratory cycle.<sup>119</sup> Illustrations of the various Mapleson system component arrangements are shown in [Figure 25-40](#). During spontaneous ventilation, the Mapleson A has the best efficiency of the six systems requiring a fresh gas inflow rate of only one time the patient's minute ventilation to prevent rebreathing of exhaled CO<sub>2</sub>. However, it has the least efficiency during controlled ventilation, requiring an FGF as high as 20 L/min to prevent rebreathing. Systems D, E, and F are slightly more efficient than systems B and C. To prevent rebreathing of CO<sub>2</sub>, the D, E, and F systems require an FGF rate of approximately 2.5 times the minute ventilation, whereas the FGF rates required for B and C systems are somewhat higher.<sup>120</sup>

The Mapleson A, B, and C systems are rarely used today, but the D, E, F systems are still commonly employed. In the United States, the most popular representative from the D, E, F group is the Bain circuit.

**Figure 25-40** Mapleson breathing systems (A–F). (Adapted from Willis BA, Pender JW, Mapleson WW. Rebreathing in a T-piece: volunteer and theoretical studies of the Jackson-Rees modification of Ayre's T-piece during spontaneous respiration. *Br J*

## Bain Circuit

The Bain circuit is a coaxial circuit and a modification of the Mapleson D system. The fresh gas flows through a narrow inner tube within the outer corrugated tubing. The inner fresh gas tubing enters the outer corrugated hose near the reservoir bag, but the fresh gas actually empties into the circuit at the patient end (Fig. 25-41). Exhaled gases enter the corrugated tubing and are vented through the expiratory valve near the reservoir bag. The Bain circuit may be used for both spontaneous and controlled ventilation. The fresh gas inflow rate necessary to prevent rebreathing is 2.5 times the patient's minute ventilation.

**Figure 25-41** The Bain Circuit (Coaxial version of Mapleson D). (Adapted from Bain JA, Spoerel WE. A streamlined anaesthetic system. *Can Anaesth Soc J.* 1972;19(4):426–435.)

The Bain circuit has many advantages over other systems. It is lightweight, convenient, and disposable. Scavenging of the waste gases from the “pop-off” valve is facilitated because the valve is located away from the patient. Exhaled gases in the outer reservoir tubing add warmth by countercurrent heat exchange to inspired fresh gases. The main hazards related to the use of the Bain circuit are either an unrecognized disconnection or kinking of the inner fresh gas hose. These problems can cause hypercarbia from inadequate gas flow or increased respiratory resistance. As with other circuits, an obstructed antimicrobial filter positioned between the Bain circuit and the tracheal tube can result in increased resistance in the circuit and may mimic the signs and symptoms of severe bronchospasm.<sup>121</sup>

The outer corrugated tube is transparent to allow ongoing inspection of the inner tube. The integrity of the inner tube can be assessed as described by Pethick.<sup>122</sup> With his technique, high-flow oxygen is fed into the circuit while the patient end is occluded until the reservoir bag is filled. The patient end is opened, and oxygen is flushed into the circuit. If the inner tube is intact, the Venturi effect occurs at the patient end. This causes a decrease in pressure

within the circuit, and as a result, the reservoir bag deflates. Conversely, a leak in the inner tube allows the fresh gas to escape into the expiratory limb, and the reservoir bag will remain inflated. This test is recommended as a part of the preanesthesia check if a Bain circuit is used.

## Circle Breathing Systems

For many years, the overall design of the circle breathing system has undergone few changes. The individual components and the order in which they appear in the circle system were consistent across major platforms. More recently, however, with the increasing technologic complexity of the anesthesia workstation, the circle system has gone through some major changes as well. These changes have resulted in part from an effort to improve patient safety (as in the integration of Fresh Gas Decoupling and Inspiratory Pressure Limiters), but have also allowed the deployment of new technologic advances. Examples of major new technologies include (1) a return to the application of single-circuit piston-type ventilators and (2) use of new spirometry devices that are located at the Y-connector instead of at the traditional location in the expiratory limb of the circuit. The following discussion first focuses on the traditional circle breathing system, and then is followed by a brief discussion of some variations in the designs of newer circle systems.

### The Traditional Circle Breathing System

The circle system remains the most popular breathing system in the United States. It is so named because its components are arranged in a circular manner (Fig. 25-9). A coaxial version of the traditional circle system, referred to as either a “Universal F” (King Systems, Noblesville, IN) or a “single limb circuit,” has increased in popularity over recent years. Although these systems appear very different externally, they have the same overall functional layout as the traditional circle system and the following discussion is applicable to both the traditional circle system and the coaxial Universal F system.

The circle system prevents rebreathing of CO<sub>2</sub> by use of CO<sub>2</sub> absorbents, but allows partial rebreathing of other exhaled gases. The extent of rebreathing of the other exhaled gases depends on breathing circuit component arrangement and the FGF rate. A circle system can be semiopen, semiclosed, or closed, depending on the amount of FGF.<sup>123</sup> A *semiopen* system has no rebreathing and requires a very high FGF. A *semiclosed* system is associated with some rebreathing of exhaled gases and is the system that is most commonly used in the United States. A *closed* system is one in which the FGF exactly matches that being taken up, or consumed, by the patient. In a

closed system, there is complete rebreathing of exhaled gases after absorption of CO<sub>2</sub>, and the overflow (pop-off or APL) valve or ventilator pressure relief valve remains closed.

The circle system (Fig. 25-9) consists of seven primary components: (1) a fresh gas inflow source; (2) inspiratory and expiratory unidirectional valves; (3) inspiratory and expiratory corrugated tubes; (4) a Y-piece connector; (5) an overflow or pop-off valve, referred to as the APL valve; (6) a reservoir bag; and (7) a canister containing CO<sub>2</sub> absorbent. The inspiratory and expiratory valves that are placed in the system to ensure gas flow through the corrugated hoses remains unidirectional. The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine.

Numerous variations of the circle arrangement are possible, depending on the relative positions of the unidirectional valves, the APL valve, the reservoir bag, the CO<sub>2</sub> absorber, and the site of fresh gas entry. However, to prevent rebreathing of CO<sub>2</sub> in a traditional circle system, three rules must be followed<sup>124</sup>:

1. A unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and the expiratory limbs of the circuit.
2. The fresh gas inflow cannot enter the circuit between the expiratory valve and the patient.
3. The overflow (pop-off) valve cannot be located between the patient and the inspiratory valve.

If these rules are followed, any arrangement of the other components will prevent rebreathing of CO<sub>2</sub>. Some newer anesthesia workstations now employ less traditional circle breathing systems. Two of these systems (the Datex-Ohmeda S/5 ADU breathing system and the Dräger Apollo and Fabius GS workstations breathing system) are discussed in greater detail (see the Anesthesia Workstation Variations section).

The most efficient circle system arrangement with the highest conservation of fresh gases is one in which the unidirectional valves are near the patient and the pop-off valve is located just downstream from the expiratory valve. This arrangement minimizes dead space gas and preferentially eliminates exhaled alveolar gases. A more practical arrangement, the one used on most conventional anesthesia machines (Fig. 25-9), is somewhat less efficient because it allows alveolar and dead space gases to mix before they are vented.<sup>125</sup>

The main advantages of the circle system over other breathing systems include its (1) maintenance of relatively stable inspired gas concentrations; (2) conservation of respiratory moisture and heat; and (3) prevention of operating room atmosphere contamination by waste gases. In addition, the circle system can be used as a semiclosed system or as a closed system with

very low FGFs. The major disadvantage of the circle system stems from its complex design. Commonly, the circle system may have 10 or more different connections. These multiple connection sites set the stage for misconnections, disconnections, obstructions, and leaks. In the 1997 ASA closed claims analysis of adverse anesthetic outcomes arising from gas delivery equipment, more than one-third (25/72) of malpractice claims resulted from breathing circuit misconnections or disconnections.<sup>9</sup> Malfunction of the circle system's unidirectional valves can result in life-threatening problems. Rebreathing can occur if the valves stick in the open position, and total occlusion of the circuit can occur if they are stuck shut. If the expiratory valve is stuck in the closed position, breath-stacking and barotrauma or volutrauma can result. Obstructed filters located in the expiratory limb of the circle breathing system have caused increased airway pressures, hemodynamic collapse, and bilateral tension pneumothorax. Causes of circle system obstruction and failure include manufacturing defects, debris, patient secretions, and particulate obstruction from other odd sources such as albuterol nebulization.<sup>126–129</sup> Some systems, such as the GE Datex-Ohmeda 7900 SmartVent, use flow transducers located on both the inspiratory and the expiratory limbs of the circle system. In one report, cracks in the flow transducer tubing used by this system produced a leak in the circle system that was difficult to detect.<sup>130</sup>

## CO<sub>2</sub> Absorbents

In the early 2000s, there were several reports of adverse chemical reactions between CO<sub>2</sub> absorbent materials and anesthetic agents. Some of these undesirable interactions were quite dramatic, such as sevoflurane interacting with desiccated Baralyme, resulting in fires within the breathing system and severe patient injury.<sup>131,132</sup> Although other sources of ignition and fire in the breathing system continue to be described, the Baralyme-sevoflurane problem is somewhat unique in that nothing “unusual” is added to or removed from the breathing system for this to occur.<sup>133</sup> In August 2004, the manufacturer of Baralyme (Allied Healthcare Products) discontinued the sale of this absorbent. Other reactions between agents such as desflurane or sevoflurane and desiccated strong base absorbents can produce more insidious patient morbidity and potentially even death from the release of byproducts such as carbon monoxide or compound A.<sup>134</sup> Although absorbent materials may be problematic, they still represent an important component of the circle breathing system.

Different anesthesia breathing systems eliminate CO<sub>2</sub> with varying degrees of efficiency. The closed and semiclosed circle systems both *require* that CO<sub>2</sub> be absorbed from the exhaled gases to avoid hypercapnia. If one could design an ideal CO<sub>2</sub> absorbent, its characteristics would include lack of reactivity

with common anesthetics, lack of toxicity, low resistance to gas flow, low cost, ease of handling, and efficiency in CO<sub>2</sub> absorption.

### *The Absorber Canister*

On many anesthesia machines, the absorber canister (Fig. 25-9) is composed of two clear plastic canisters arranged in series. The canisters can be filled either with loose bulk absorbent or with absorbent supplied by the factory in prefilled plastic disposable cartridges called prepacks. Free granules from bulk absorbent can create a clinically significant leak if they lodge between the clear plastic canister and the O-ring gasket of the absorber, or between other joints in the circuit.<sup>135</sup> Leaks have also been caused by defective prepacks, which were larger than factory specifications.<sup>136</sup> Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed prior to use.<sup>137</sup> Contemporary workstations from GE Healthcare and Dräger use proprietary CO<sub>2</sub> absorbent canisters that allow exchange of the canisters while maintaining the breathing circuit integrity.

### *Chemistry of Absorbents*

Several formulations of CO<sub>2</sub> absorbents are available today, including soda lime, and calcium hydroxide lime (Amsorb). Of these agents, the most commonly used is soda lime.<sup>138</sup> All serve to remove CO<sub>2</sub> from the breathing circuit with varying degrees of efficiency.

By weight, the approximate composition of “high moisture” soda lime is 80% calcium hydroxide, 15% water, 4% sodium hydroxide, and 1% potassium hydroxide (an activator). Small amounts of silica are added to produce calcium and sodium silicate. This addition produces a harder and more stable pellet and thereby reduces dust formation. The efficiency of the soda lime absorption varies inversely with the hardness; therefore, little silicate is used in contemporary soda lime.<sup>139,140</sup> Sodium hydroxide is the catalyst for the CO<sub>2</sub> absorptive properties of soda lime. Calcium hydroxide lime is one of the newest clinically available CO<sub>2</sub> absorbents. It consists primarily of calcium hydroxide and calcium chloride and contains two setting agents: calcium sulfate and polyvinylpyrrolidone. The latter two agents serve to enhance the hardness and porosity of the agent.<sup>141</sup> The most significant advantage of calcium hydroxide lime over other agents is its lack of the strong bases, sodium and potassium hydroxide. The absence of these chemicals eliminates the undesirable production of carbon monoxide, the potentially nephrotoxic substance known as compound A, and may reduce or eliminate the possibility of a fire in the breathing circuit.<sup>142</sup> The most significant disadvantages of calcium hydroxide lime are less absorptive capacity, about 50% less than

strong-base containing absorbents, and generally higher cost per unit than other absorbents.<sup>143,144</sup>

The size of the actual absorptive granules has been determined over time by trial and error. The current size particles represent a compromise between resistance to gas flow and absorptive efficiency. The smaller the granule size, the greater the surface area that is available for absorption. However, as particle size decreases, resistance to gas flow increases. The granular size of soda lime used in clinical practice is between 4 and 8 mesh, a size at which absorptive surface area and resistance to flow are optimized. Mesh size refers to the number of openings per linear inch in a sieve through which the granular particles can pass. The absorption of CO<sub>2</sub> by absorbents such as soda lime occurs by a series of chemical reactions; it is not a physical process like soaking water into a sponge. CO<sub>2</sub> combines with water to form carbonic acid. Carbonic acid reacts with the hydroxides to form sodium (or potassium) carbonate and water. Calcium hydroxide accepts the carbonate to form calcium carbonate and sodium (or potassium) hydroxide. The equations for the reactions are as follows:

1.  $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$
2.  $\text{H}_2\text{CO}_3 + 2\text{NaOH}(\text{KOH}) \rightleftharpoons \text{Na}_2\text{CO}_3(\text{K}_2\text{CO}_3) + 2\text{H}_2\text{O} + \text{Heat}$
3.  $\text{Na}_2\text{CO}_3(\text{K}_2\text{CO}_3) + \text{Ca}(\text{OH})_2 \rightleftharpoons \text{CaCO}_3 + 2\text{NaOH}(\text{KOH})$

Some CO<sub>2</sub> may react directly with Ca(OH)<sub>2</sub>, but this reaction is much slower.

### **Absorptive Capacity**

The maximum amount of CO<sub>2</sub> that can be absorbed by soda lime is 26 L of CO<sub>2</sub> per 100 g of absorbent. The absorptive capacity of calcium hydroxide lime is significantly less and has been reported at 10.2 L per 100 g of absorbent. However, as previously mentioned, absorptive capacity is the product of both available chemical reactivity and physical (granule) availability. As the absorbent granules stack up in the absorber canisters, small passageways inevitably form. These small passages channel gases preferentially through low resistance areas. Because of this phenomenon, functional absorptive capacity of either soda lime or calcium hydroxide lime may be substantially decreased.<sup>145</sup>

### **Indicators**

Ethyl violet is the pH indicator added to soda lime to help assess the functional integrity of the absorbent. This compound is a substituted

triphenylmethane dye with a critical pH of 10.3.<sup>142</sup> Ethyl violet changes from colorless to violet in color when the pH of the absorbent decreases as a result of CO<sub>2</sub> absorption. When the absorbent is fresh, the pH exceeds the critical pH of the indicator dye, and it exists in its colorless form. However, as absorbent becomes exhausted, the pH decreases below 10.3, and ethyl violet changes to its violet form because of alcohol dehydration. This change in color indicates that the absorptive capacity of the material has been consumed. Unfortunately, in some circumstances ethyl violet may not always be a reliable indicator of the functional status of absorbent. For example, prolonged exposure of ethyl violet to fluorescent lights can produce photodeactivation of this dye.<sup>146</sup> When this occurs, the absorbent appears white even though it may have a reduced pH and its absorptive capacity has been exhausted. Even in the absence of color changes, clinical signs that the CO<sub>2</sub> absorbent is exhausted include:

1. Increased spontaneous respiratory rate (requires that no neuromuscular blocking drug be used)
2. Initial increase in blood pressure and heart rate, followed later by a decrease in both
3. Increased sympathetic drive: skin flushing, sweating, tachydysrhythmia, hypermetabolic state (increased CO<sub>2</sub> production; must rule out malignant hyperthermia)
4. Respiratory acidosis as evidenced by arterial blood gas analysis
5. Increased surgical bleeding—due to both hypertension and coagulopathy

**10** Although a diagnosis of depletion of CO<sub>2</sub> absorbent capability can be made by observation of clinical signs, the most sensitive indicator of this problem is capnography. If the end-expiratory level of exhaled CO<sub>2</sub> is increased, and the inspiratory level is greater than zero, then exhaustion of the CO<sub>2</sub> absorbent must be pursued as a possible cause.

### *Interactions of Inhaled Anesthetics with Absorbents*

It is important and desirable to have CO<sub>2</sub> absorbents that neither release **11** toxic particles or fumes nor produce toxic compounds when exposed to common anesthetics. Soda lime and Amsorb generally fit this description, but inhaled anesthetics do interact with all absorbents to some extent.

Sevoflurane has been shown to produce degradation products upon interaction with CO<sub>2</sub> absorbents.<sup>147,148</sup> The major degradation product produced is an olefin compound known as fluoromethyl-2, 2-difluoro-1-(trifluoromethyl) vinyl ether, or compound A. During sevoflurane anesthesia, factors apparently leading to an increase in the concentration of compound A include (1) low flow or closed circuit anesthetic techniques; (2) the use of

Baralyme (now no longer available); (3) higher concentrations of sevoflurane in the anesthetic circuit; (4) higher absorbent temperatures; and (5) fresh absorbent.<sup>149,150</sup> Interestingly, the dehydration of Baralyme increased the concentration of compound A, but the dehydration of soda lime decreases the concentration of compound A.<sup>151,152</sup> Apparently, the degradation products released during clinical conditions do not commonly result in adverse effects in humans even during low flow anesthesia.<sup>153–155</sup> Hepatorenal function biomarkers using sevoflurane are unchanged in patients during low flow anesthesia when compared to high flow anesthesia.<sup>156</sup> Desiccated strong-base absorbents can also degrade contemporary inhaled anesthetics to clinically significant concentrations of carbon monoxide (CO) as well as trifluoromethane, which can interfere with anesthetic gas monitoring. Under certain conditions, this process can produce very high carboxyhemoglobin concentrations, reaching 35% or more.<sup>157</sup> Higher levels of carbon monoxide are more likely after prolonged contact between absorbent and anesthetics, and after disuse of an absorber for at least 2 days, especially over a weekend.<sup>158</sup> Thus, case reports describing carbon monoxide poisoning have been most common in patients anesthetized on Monday morning, presumably because continuous flow from the unused anesthesia machine desiccated the absorbents over the weekend. FGF rates of 5 L/min or more through the breathing system and absorbent (without a patient connected) are sufficient to cause critical drying of the absorbent material. This is even worse when the reservoir bag is left off the breathing circuit. Absence of the reservoir bag facilitates retrograde flow through the circle system (Fig. 25-9).

Several factors appear to increase the production of carbon monoxide and result in increased carboxyhemoglobin levels. They include (1) the inhaled anesthetic used (for a given MAC multiple, the magnitude of CO production from greatest to least is desflurane  $\geq$  enflurane  $>$  isoflurane  $>>$  halothane = sevoflurane); (2) the absorbent dryness (completely dry absorbent produces more CO than hydrated absorbent); (3) the type of absorbent (at a given water content, Baralyme produced more CO than does soda lime); (4) the temperature (increased temperature increases CO production); (5) the anesthetic concentration (more CO is produced from higher anesthetic concentrations)<sup>151</sup>; (6) low FGF rates; and (7) reduced experimental animal (patient) size per 100 g of absorbent.<sup>159</sup>

Several interventions have been suggested to reduce the incidence of carbon monoxide exposure in patients undergoing general anesthesia. These interventions include (1) educating anesthesia personnel regarding the etiology of CO production; (2) turning off the anesthesia machine at the conclusion of the last case of the day to eliminate FGF that dries the absorbent; (3) changing CO<sub>2</sub> absorbent if fresh gas was found flowing during the morning machine preuse check; (4) rehydrating desiccated absorbent by

adding water; (5) changing the chemical composition of soda lime to reduce or eliminate potassium hydroxide (such products now available include Drägerorb 800 plus, Sofnolime, and Spherasorb); and (6) using absorbent materials such as calcium hydroxide lime that are free of both sodium and potassium hydroxides. The elimination of sodium and potassium hydroxides from desiccated soda lime diminishes or eliminates degradation of desflurane to carbon monoxide and sevoflurane to compound A, but does not compromise CO<sub>2</sub> absorption.<sup>160</sup>

As a result of the increasing evidence that exposure of volatile anesthetics to desiccated CO<sub>2</sub> absorbents could be hazardous (Table 25-7), the Anesthesia Patient Safety Foundation convened in 2005 a conference on CO<sub>2</sub> absorption safety considerations. The conference experts agreed with the following recommendations<sup>138</sup>:

1. Turn off all gas flow when the machine is not in use
2. Change absorbents regularly (on Monday mornings, since the absorbent may have become desiccated over the weekend)
3. Change absorbent whenever the color change indicates exhaustion
4. Change BOTH canisters in a two-canister system
5. Change absorbent whenever the FGF has been left on for an extensive or indeterminate period of time
6. If compact canisters are used, consider changing them more frequently

**12** One extremely rare but potentially life-threatening complication related to CO<sub>2</sub> absorbent use is the development of fires within the breathing system. Specifically, this can occur as the result of interactions between the strong-base absorbents (particularly with the now obsolete Baralyme) and the inhaled anesthetic, sevoflurane. When desiccated strong-base absorbents are exposed to sevoflurane, absorber temperatures of several hundred degrees may result from their interaction. The build-up of very high temperatures, the formation of combustible degradation by-products (formaldehyde, methanol, and formic acid), plus the oxygen- or nitrous oxide-enriched environment provide all the substrates necessary for a fire to occur.

New CO<sub>2</sub> absorbents that incorporate lithium have become available.<sup>161</sup> One example is Litholyme (Allied Healthcare, St. Louis, MO), which consists of calcium hydroxide, lithium chloride, and ethyl violet indicator. It is supplied as pellets (similar to soda lime granules). Litholyme contains a lithium catalyst to facilitate CO<sub>2</sub> absorption and does not use strong bases (NaOH or KOH). The lithium catalyst does not react with common inhaled anesthetic agents and therefore eliminates the potential for generation of CO or Compound A. Absorption of CO<sub>2</sub> is minimally exothermic. The indicator color change from off-white to violet is permanent and profound, indicating both exhaustion and/or desiccation and eliminating the possibility for unintentional use of expended absorbent.

Another absorbent that uses lithium is SpiraLith (Micropore Inc., Elkton, MD). It is supplied on a polymer matrix base and rolled up as a fixed spiral in a cylinder. It does not use an indicator to show exhaustion so that the anesthesiologist must monitor inspired CO<sub>2</sub>. An advantage is that the exhausted absorbent can be recycled by the manufacturer.

**Table 25-7** Absorbent Comparisons<sup>138a</sup>

## Anesthesia Ventilators

The ventilator on the modern anesthesia workstation serves as a mechanized substitute for the manual squeezing of the reservoir bag of the circle system, the Bain circuit, or another breathing system. As recently as the late 1980s, anesthesia ventilators were mere adjuncts to the anesthesia machine. Today, in newer anesthesia workstations, they have attained a prominent central role. In addition to the near ubiquitous role of the anesthesia ventilator in today's anesthesia workstation, many advanced ICU-style ventilation features have also been integrated into anesthesia ventilators (Fig. 25-42). Although many similarities exist between today's anesthesia ventilator and ICU ventilator, some fundamental differences in ventilation parameters and control systems remain.

### Classification

Ventilators can be classified according to their power source, drive mechanism, cycling mechanism, and bellows type.<sup>162,163</sup>

## Power Source

The power source required to operate a mechanical ventilator is provided by compressed gas, electricity, or both. Older pneumatic ventilators required only a pneumatic power source to function properly. Contemporary electronic ventilators from Dräger Medical, GE Datex-Ohmeda, and others require either an electrical only or both an electrical and a pneumatic power source.

## Drive Mechanism and Circuit Designation

Double-circuit ventilators (in which one circuit contains patient gas and the other circuit contains drive gas) are used most commonly in modern anesthesia workstations. Generally, these conventional ventilators are pneumatically driven. In a double-circuit ventilator, a driving force—pressurized gas—compresses a component analogous to the reservoir bag known as the ventilator bellows. The bellows then in turn delivers ventilation to the patient. The driving gas in the GE-Datex-Ohmeda ventilators is 100% oxygen. In the Dräger AV-E and AV-2+, a Venturi device mixes oxygen and air. Some newer pneumatic anesthesia workstations have the ability for the user to select whether compressed air or oxygen is used as the driving gas.

**Figure 25-42** Dräger Fabius GS ventilator.

More recently, with the introduction of circle breathing systems that integrate fresh gas decoupling (FGD, as described in more detail below), resurgence has been seen in the utilization of mechanically driven anesthesia ventilators. These “piston”-type ventilators use a computer-controlled stepper motor instead of compressed drive gas to actuate gas movement in the

breathing system. In these systems, rather than having dual circuits, a single patient gas circuit is present. Thus, they are classified as piston-driven, single-circuit ventilators. The piston operates much like the plunger of a syringe to deliver the desired tidal volume or airway pressure to the patient breathing circuit. Sophisticated computerized controls are able to provide advanced types of ventilatory support such as synchronized intermittent mandatory ventilation (S-IMV), pressure-controlled ventilation (PCV), and pressure support–assisted ventilation, in addition to the conventional volume and pressure control. Since the patient’s mechanical breath is delivered without the use of compressed gas to actuate a bellows, these systems consume dramatically less compressed gas during ventilator operation than traditional pneumatic ventilators. This improvement in efficiency may have clinical significance when the anesthesia workstation is used in a setting where no pipeline gas supply is available (e.g., remote locations or office-based anesthesia practices).

## Cycling Mechanism

Most anesthesia machine ventilators are time cycled and provide ventilator support in the control mode. Inspiratory phase is initiated by a timing device. Older pneumatic ventilators use a fluidic (fluid logic) timing device. Contemporary electronic ventilators use a solid-state electronic timing device and are thus classified as time cycled and electronically controlled. More advanced ventilation modes such as S-IMV, PCV, and modes that utilize a pressure-support option have an adjustable threshold pressure trigger as well. In these modes, pressure sensors provide feedback to the ventilator control system to allow it to determine when to initiate and/or terminate the respiratory cycle.

## Bellows Classification

The direction of bellows movement during the expiratory phase determines the bellows classification. *Ascending (standing) bellows* ascend during the expiratory phase (Fig. 25-43B), whereas *descending (hanging) bellows* descend during the expiratory phase. Of the two configurations, the ascending bellows is generally thought to be safer. An ascending bellows will not fill if a total disconnection occurs. However, the bellows of a descending bellows ventilator will continue its upward and downward movement despite a patient disconnection. The driving gas pushes the bellows upward during the inspiratory phase. During the expiratory phase, room air is entrained into the breathing system at the site of the disconnection because gravity acts on the weighted bellows. The disconnection pressure monitor and the volume monitor may be fooled even

if a disconnection is complete (see Problems and Hazards section). Some contemporary anesthesia workstation designs have returned to the descending bellows to integrate FGD (e.g., Mindray Anestar). An essential safety feature on any anesthesia workstation that utilizes a descending bellows is an integrated CO<sub>2</sub> apnea alarm that cannot be disabled while the ventilator is in use.

### ***Operating Principles of Ascending Bellows Pneumatically Powered Ventilators***

Contemporary examples of ascending bellows, double-circuit, electronic ventilators include the Dräger Medical AV-E, AV-2+, the GE-Datex-Ohmeda 7000, 7800, and 7900 series. A generic ascending bellows ventilator is illustrated in [Figure 25-43](#). It may be viewed as a reservoir bag (bellows) located within a clear plastic box. The bellows physically separates the driving gas circuit from the patient gas circuit. The driving gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During the inspiratory phase ([Fig. 25-43A](#)) the driving gas enters the bellows chamber, causing the pressure within it to increase. This increase in pressure is responsible for two events. First, the ventilator relief valve closes, preventing anesthetic gas from escaping into the scavenging system. Second, the bellows is compressed, and the anesthetic gas within the bellows is delivered to the patient's lungs. This compression action is analogous to the hand of the anesthesiologist squeezing the breathing bag.

During the expiratory phase ([Fig. 25-43B](#)), the driving gas exits the bellows housing. This produces a decrease to atmospheric pressure within both the bellows housing and the pilot line to the ventilator relief valve. The decrease in pressure to the ventilator relief valve causes the "mushroom valve" portion of the assembly to open. Exhaled patient gases refill the bellows before any scavenging can begin. The bellows refill first because a weighted ball (like those used in ball-type positive end-expiratory pressure [PEEP] valves) or similar device is incorporated into the base of the ventilator relief valve. This ball produces 2 to 3 cm H<sub>2</sub>O of back pressure; therefore, flow to scavenging occurs only after the bellows fills completely and the pressure inside the bellows exceeds the pressure threshold of the "ball valve." This design causes all ascending bellows ventilators to produce 2 to 3 cm water pressure of PEEP within the breathing circuit when the ventilator is in use. Scavenging occurs only during the expiratory phase, as the ventilator relief valve is open only during expiration.

**Figure 25-43** Inspiratory (**A**) and expiratory (**B**) phases of gas flow in a traditional circle system with an ascending bellows ventilator. The bellows physically separates the driving-gas circuit from the patient gas circuit. The driving-gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During inspiratory phase (**A**), the driving gas enters the bellows chamber, causing the pressure within it to increase. This causes the ventilator relief valve to close, preventing anesthetic gas from escaping into the scavenging system, and the bellows to compress, delivering anesthetic gas within the bellows to the patient's lungs. During expiratory phase (**B**), pressure within the bellows chamber and the pilot line decreases to zero, causing the mushroom portion of the ventilator relief valve to open. Gas exhaled by the patient refills the bellows before any scavenging occurs, because a weighted ball is incorporated into the base of the ventilator relief valve. Scavenging occurs only during the expiratory phase, because the ventilator relief valve is only open during expiration. (Adapted from

Andrews JJ. *The Circle System. A Collection of 30 Color Illustrations*. Washington, DC: Library of Congress; 1998.)

It is important to understand that on most older anesthesia workstations, gas flow from the anesthesia machine into the breathing circuit is continuous and independent of ventilator activity. During the inspiratory phase of mechanical ventilation, the ventilator relief valve is closed (Fig. 25-43A), and the breathing system's APL (pop-off) valve is most commonly out of circuit. Therefore, the patient's lungs receive the volume from the bellows plus that entering the circuit from the flowmeters during the inspiratory phase. Factors that influence the relationship between set tidal volume and exhaled tidal volume include the FGF settings, the inspiratory time, the compliance of the breathing circuit, external leakage, and the location of the tidal volume sensor. Usually, the volume gained from the flowmeters during inspiration is counteracted by the volume lost to compliance of the breathing circuit, and 14 set tidal volume generally approximates the exhaled tidal volume.

However, certain conditions such as inappropriate activation of the oxygen flush valve during the inspiratory phase can result in barotrauma and/or volutrauma to the patient's lungs because excess pressure and volume may not be able to be vented from the circle system.<sup>164</sup>

## **Problems and Hazards**

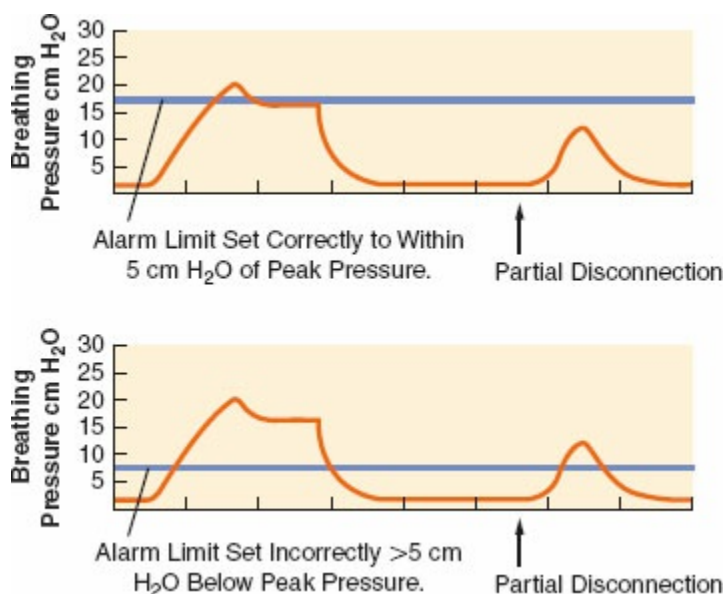

Numerous hazards are associated with anesthesia ventilators. These include problems with the breathing circuit, the bellows assembly, and the control assembly.

### **Traditional Circle System Problems**

Breathing circuit misconnections and disconnection are a leading cause of critical incidents in anesthesia.<sup>165</sup> The most common disconnection site is at the Y-piece. Disconnections can be complete or partial (leaks). In the past, a common source of leaks with older absorbers was failure to close the APL (or pop-off) valve upon initiation of mechanical ventilation. On contemporary anesthesia workstations, the bag/ventilator selector switch has virtually eliminated this problem, as the APL valve is usually out of circuit when the ventilator mode is selected. Preexisting undetected leaks can exist in compressed, corrugated, disposable anesthetic circuits. To detect such a leak preoperatively, the circuit must be fully expanded before it is checked for leaks.<sup>166</sup> As previously mentioned, disconnections and leaks are made more obvious with the ascending bellows ventilator systems because they result in a situation in which the bellows will not refill.

Several breathing system disconnection monitors exist, although none should replace the anesthesia provider's vigilance. Observation of chest wall excursion and/or monitoring of breath sounds should continue despite use of both mechanical (spirometers and pressure sensors) and physiologic monitors.

Pneumatic and electronic pressure monitors are helpful in detecting disconnections. Factors that influence monitor effectiveness include the disconnection site, the pressure sensor location, the threshold pressure alarm limit, the inspiratory flow rate, and the resistance of the disconnected breathing circuit.<sup>167-169</sup> Various anesthesia workstations and ventilators have different locations for the airway pressure sensor and different values for the threshold pressure alarm limit. The threshold pressure alarm limit may be preset at the factory or adjustable. An audible or visual alarm is actuated if the peak inspiratory pressure of the breathing circuit does not exceed the threshold pressure alarm limit. When an adjustable threshold pressure alarm limit is available, such as on many workstations from Dräger Medical and GE Healthcare, the operator should set the pressure alarm limit to within 5 cm water of the peak inspiratory pressure. On systems that have an "autoset" feature, when activated, the threshold limit is automatically set at 3 to 5 cm H<sub>2</sub>O below the current peak inspiratory pressure. On such systems, failure to reset the threshold pressure alarm limit may result in either an "Apnea Pressure" or "Threshold Low" alert. [Figure 25-44](#) illustrates how a partial disconnection (leak) may be unrecognized by the low-pressure monitor if the threshold pressure alarm limit is set too low or if the factory preset value is relatively low.

**Figure 25-44** Threshold pressure alarm limit. **Top:** The threshold pressure alarm limit (*dotted line*) has been set appropriately. An alarm is actuated when a partial disconnection occurs (*arrow*) because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. **Bottom:** A partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has

been set too low. (Adapted from Baromed Breathing Pressure Monitor: Operator's Instruction Manual. Telford, PA: North American Dräger; 1986.)

Respiratory volume monitors are useful in detecting disconnections. Volume monitors may sense exhaled tidal volume, inhaled tidal volume, minute volume, or all three. The user should bracket the high and low threshold volumes slightly above and below the exhaled volumes. For example, if the exhaled minute volume of a patient is 10 L/min, reasonable alarm limits would be 8 to 12 L/min. Many of the older Datex-Ohmeda ventilators are equipped with volume monitor sensors that use infrared light/turbine technology. These volume sensors are usually located in the expiratory limb of the breathing circuit and thus measure exhaled tidal volume. In the case of the Datex-Ohmeda S/5 ADU, a special attachment known as the D-Lite spirometry connector is placed in the breathing circuit between the Y-piece and the patient's airway (i.e., tracheal tube connector, LMA). This device permits measurement of both inhaled and exhaled volumes and pressures (see Anesthesia Workstation Variations section). With the older infrared type sensors, exposure to a direct beam of light from the overhead surgical lighting could cause erroneous volume readings as the surgical beam interfered with the infrared sensor. Other types of expiratory volume sensors can be seen in systems such as the GE Datex Aestiva, Aespire, and other workstations that incorporate the 7100 ventilator or 7900 SmartVent. These systems generally utilize differential pressure transduction technology to determine inhaled and exhaled volumes and to measure airway pressures. Some Dräger workstations use an ultrasonic flow sensor located in the expiratory limb. Other systems from Dräger measure exhaled volume using "hot wire" sensor technology. With this type of sensor, a tiny array of two platinum wires is electrically heated to a high temperature. As gas flows past the heated wires, they tend to be cooled. The amount of energy required to maintain the temperature of the wire is proportional to the volume of gas flowing past it. This system, however, has been associated in at least one report of accidental fire in the breathing circuit.

Capnographs (CO<sub>2</sub> monitors) are probably the best devices for revealing circuit disconnections. CO<sub>2</sub> concentration is measured near the Y-piece either directly (mainstream) or by continuous aspiration of a gas sample to the analyzer instrument (sidestream). Either a sudden change in the differences between the inspiratory and end-tidal CO<sub>2</sub> concentrations or the acute absence of measured CO<sub>2</sub> indicates a disconnection, a nonventilated patient, or other problems. Importantly, an absence of exhaled CO<sub>2</sub> can also be an indication of low (or no) cardiac output rather than a mechanical equipment problem.

Misconnections of the breathing system are unfortunately relatively common. Despite the efforts of standards committees to eliminate this

problem by assigning different diameters to various hoses and hose terminals, they continue to occur. Anesthesia workstations, breathing systems, ventilators, and scavenging systems incorporate many of these diameter-specific connections. The “ability” of anesthesia providers to outwit these “foolproof” systems has led to various hoses being cleverly adapted or forcefully fitted to inappropriate terminals and even to various other solid cylindrically shaped protrusions of the anesthesia machine.

Occlusion (obstruction) of the breathing circuit may occur. Tracheal tubes can become kinked. Hoses throughout the breathing circuit are subject to occlusion by internal obstruction or external mechanical forces, which can impinge on flow and have severe consequences. For example, blockage of a bacterial filter in the expiratory limb of the circle system has resulted in bilateral tension pneumothorax.<sup>127</sup> Incorrect insertion of flow direction-sensitive components can result in a no-flow state. Examples of these components include some PEEP valves and cascade humidifiers. Depending on the location of the occlusion relative to the pressure sensor, a high-pressure alarm may (or may not) alert the practitioner to the problem.

Excess inflow to the breathing circuit from the anesthesia machine during the inspiratory phase can cause barotrauma. The best example of this phenomenon is oxygen flushing. Excess volume cannot be vented from the system during inspiration because the ventilator relief valve is closed and the APL valve is out of circuit. A high-pressure alarm, if present, may be activated when the pressure becomes excessive. With many Dräger Medical systems, both audible and visual alarms are actuated when the high-pressure threshold is exceeded. The GE ventilators automatically switch from the inspiratory to the expiratory phase when the adjustable peak pressure threshold is exceeded.

On workstations equipped with adjustable inspiratory pressure limiters (such as the GE-Datex-Ohmeda S/5 ADU, Aestiva and Aisys, and Dräger Medical’s Narkomed series, 2B, 2C, GS, Fabius GS, and Apollo) the maximal inspiratory pressure may be set by the user to a desired peak airway pressure. An adjustable pressure relief valve will open when the predetermined user-selected pressure threshold is exceeded. This should prevent generation of excessive airway pressure. Unfortunately, this feature is dependent on the user having preset the appropriate “pop-off” pressure. If the setting is too low, insufficient pressure for ventilation may be generated, resulting in inadequate minute ventilation; if set too high, the excessive airway pressure may still occur, resulting in barotrauma. The piston-driven ventilator in the Dräger Fabius GS and Apollo, as well as others may also include a factory preset peak inspiratory pressure safety valve that opens at a preset airway pressure such as 75 cm H<sub>2</sub>O to minimize the risk of barotrauma.

## **Bellows Assembly Problems**

Leaks can occur in the bellows assembly. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas leaks to the atmosphere. A hole in the bellows can lead to alveolar hyperinflation and possibly barotrauma in some ventilators because high-pressure driving gas can enter the patient circuit. The oxygen concentration of the patient gas may increase when the driving gas is 100% oxygen, or it may decrease if the driving gas is composed of an air–oxygen mixture.<sup>170</sup>

The ventilator relief valve can cause problems. Hypoventilation occurs if the valve is incompetent because the anesthetic gases are delivered to the scavenging system instead of to the patient during the inspiratory phase. Gas molecules preferentially exit into the scavenging system because it represents the path of least resistance, and the pressure within the scavenging system can be subatmospheric. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or from a damaged flapper valve.<sup>171,172</sup> A ventilator relief valve stuck in the closed or partially closed position can produce either barotrauma or undesired PEEP.<sup>173</sup> Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases. In this case, breathing circuit pressure increases because excess anesthetic gas cannot be vented. It is worthwhile to note that during the expiratory phase, some newer machines from GE-Datex-Ohmeda (S/5 ADU, 7100 and 7900 SmartVent) scavenge both excess patient gases and the exhausted ventilator drive gas. That is, when the ventilator relief valve opens, and waste anesthetic gases are vented from the breathing circuit, the drive gas from the bellows housing joins with it to enter the scavenging system. Under certain conditions, the large volume of exhausted gases could overwhelm the scavenging system, resulting in contamination of the operating room atmosphere with waste anesthetic gases (see Scavenging Systems section). Other mechanical problems that can occur include leaks within the system, faulty pressure regulators, and faulty valves. Unlikely problems such as an occluded muffler on the Dräger AV-E ventilator can result in barotrauma. In this case, obstruction of driving gas outflow closes the ventilator relief valve, and excess patient gas cannot be vented.<sup>174</sup>

## **Control Assembly and Power Supply Problems**

The control assembly can be the source of both electrical and mechanical problems. Electrical failure can be total or partial; the former is the more obvious. As anesthesia workstations are becoming increasingly dependent on integrated computer-controlled systems, power supply interruptions become more significant. Battery backup systems are designed to continue operation of essential electronics during brief outages. However, even with these

systems, in the event of a failure, significant time may be required to reboot a computerized system after an electrical outage has occurred. During this time, the availability of certain workstation features such as manual or mechanical ventilation can be variable. One cluster of electrical failures that could have potentially resulted in operating room fires was attributed to the workstation's power supply printed circuit boards. This prompted a corrective recall action by the equipment manufacturer.<sup>175</sup>

## Anesthesia Workstation Variations

With the introduction of new technology, often comes the need for adaptation of current technology to successfully allow its integration into existing systems. Otherwise, a more comprehensive redesign of an entire anesthesia system “from the ground up” could be necessary. One such example of adaptation in the anesthesia workstation can be seen with two new design variations of the circle breathing system. The first of these is found on the GE-Datex-Ohmeda S/5 ADU, and the second is incorporated into the Dräger Fabius GS and Apollo workstations. Since use of the circle system is fundamental to the day-to-day practice for most anesthesiologists, a comprehensive understanding of these new systems is crucial for their safe use.

### *Datex-Ohmeda S/5 ADU and GE Healthcare Aisys Carestation*

**15** The Datex-Ohmeda S/5 ADU debuted as the AS/3 ADU in 1998 (Fig. 25-45A). Along with its more comprehensive safety features and integrated design that eliminated glass flow tubes and conventional anesthesia vaporizers in exchange for a computer screen with digital FGF scales and the built-in Aladin Cassette vaporizer system, the machine had a radically different appearance in general. It is not until closer inspection that the other unique properties of the ADU begin to stand out. The principal difference in the ADU's circle system lies in the incorporation of the patented “D-Lite” flow and pressure transducer (Fig. 25-45B) inserted into the circle at the level of the Y-connector. The D-Lite spirometry module was redesigned to accommodate low-flow anesthesia and is currently an optional feature of the GE Healthcare Aisys workstation. On most traditional circle systems, exhaled tidal volume is measured by a spirometry sensor located in proximity to the expiratory unidirectional valve. The placement of the D-Lite fitting at the Y-connector provides a better location to perform exhaled volume measurement and allows airway gas composition and pressure monitoring to be done with a single adapter instead of with multiple fittings added to the breathing circuit. In addition, it provides the ability to assess both inspiratory and expiratory

gas flows and therefore generation of complete flow-volume spirometry. The relocation of the spirometer sensor to the Y-connector also makes it necessary to move the location of the fresh gas inlet to the “patient” side of the inspiratory unidirectional valve without adversely affecting accuracy of exhaled tidal volume measurement. On the other hand, placement of the D-Lite sensor near the patient adds bulk and weight to the breathing circuit and may interfere with mask ventilation.

This atypical circle system arrangement with the fresh gas entering on the patient side of the inspiratory valve is advantageous for several reasons. It is likely to be more efficient in delivering fresh gas to the patient, while preferentially eliminating exhaled gases. It is also less likely to cause desiccation of the CO<sub>2</sub> absorbent (see Interactions of Inhaled Anesthetics with Absorbents section). Other notable changes on the S/5 ADU circle system include a compact proprietary CO<sub>2</sub> absorbent canister design that can be changed during ventilation without loss of circle system integrity, and the reorientation of the inspiratory and expiratory unidirectional valves from a horizontal position to a vertical position on the “compact block” assembly just below the absorbent canister. The reorientation of the unidirectional valves reduces the breathing circuit resistance encountered by a spontaneously breathing patient. The vertically oriented unidirectional valves only have to be tipped away from the vertical position to be opened, unlike conventional horizontal valve discs, which have to be physically lifted off from the valve seat against gravity to be opened.

**Figure 25-45** **A:** The GE Datex-Ohmeda AS/3 ADU workstation. **B:** D-Lite sensor. (Courtesy of GE Healthcare.)

In the newest GE workstations (e.g., Aisys, Aespire, Avance) that use the Advanced Breathing System, the inspiratory and expiratory check valves are oriented horizontally and the circle system arrangement is such that fresh gas enters the circuit upstream from the inspiratory unidirectional valve.

The GE SmartVent 7900 is an electronically controlled, pneumatically driven ventilator. Sensors in the breathing circuit allow the ventilator to compensate for compression losses, fresh gas contribution, and small leaks. Delivered tidal volume is determined by differential pressure, variable orifice flow sensors on both the inspiratory and expiratory sides of the breathing circuit. The inspiratory flow sensor is located downstream of the gas system inspiratory check valve. Feedback from this sensor is used to calculate and supply tidal volume corrections for FGF and circuit compression losses. The expiratory flow sensor is located at the input to the gas system expiratory check valve. Breathing rate and expiratory tidal volume are determined by this sensor. Excess fresh gas from the bellows and ventilator drive gas is transferred to the scavenging system.

## *The Dräger Medical Narkomed 6000 Series, Fabius GS, and Apollo Workstations*

Several important differences exist between the traditional circle breathing systems and those utilized in the more recent Dräger products. At first glance, the most notable difference lies in the appearance and design of the ventilators used with these systems. From the inconspicuous horizontally mounted Divan piston ventilator of the Dräger Narkomed 6000/6400 to the vertically mounted and visible piston ventilator of the Dräger Fabius GS with its electronic FGF indicators (virtual flowmeters displayed on the screen), these systems appear drastically different from traditional anesthesia systems. The piston ventilators of the Dräger Narkomed 6000 (Divan ventilator) and Dräger Fabius series (E-Vent ventilator) anesthesia systems are classified as electrically powered, piston driven, single circuit, electronically controlled with fresh gas decoupling (FGD). The ventilator found on the Dräger Apollo workstation, the E-Vent plus, is an electrically driven and electronically controlled, fresh gas decoupled, high-speed piston ventilator that requires no drive gas (unlike the traditional bellows ventilators). The E-Vent plus ventilator offers modes of ventilation previously found only on intensive care unit ventilators, including synchronized volume mode with adjustable flow trigger and pressure support.

The circle breathing systems utilized by these Dräger workstations incorporate a feature known as FGD. The incorporation of this patient safety enhancing technology has required a significant redesign of the traditional circle system. A functional schematic of a circle system similar to the one used by the Dräger Fabius GS series mechanical ventilation can be seen in [Figure 25-46](#). To understand the operating principles of FGD, it is important to have a good understanding of gas flows in a traditional circle system both during inspiratory and expiratory phases of mechanical ventilation. A complete discussion of this was presented earlier in the section titled Operating Principles of Ascending Bellows Ventilators. 16

The key concept of the FGD breathing system can be illustrated during the inspiratory phase of mechanical ventilation. With the traditional circle system, several events are occurring: (1) continuous FGF from the flowmeters and/or the oxygen flush valve is entering the circle system at the fresh gas inlet; (2) the ventilator is delivering the prescribed tidal volume to the patient's lungs; and (3) the ventilator relief valve (ventilator exhaust valve) is closed, so no gas is escaping the circle system except into the patient's lungs.<sup>176</sup> In a traditional circle system, when these events coincide and fresh gas inflow is coupled directly into the circle system, the total volume delivered to the patient's lungs is the sum of the volume delivered by the

ventilator, plus the volume of gas that enters the circle via the fresh gas inlet minus the volume lost to breathing system compliance (usually 2 to 3 mL/cm H<sub>2</sub>O pressure). In contrast, when FDG is used, during the inspiratory phase (Fig. 25-46) the fresh gas coming from the anesthesia workstation flowmeters via the fresh gas inlet is diverted into the reservoir bag by a decoupling valve that is located between the fresh gas source and the ventilator circuit. The reservoir (breathing) bag serves as an accumulator for fresh gas until the expiratory phase begins. During expiratory phase, the decoupling valve opens, allowing the accumulated fresh gas in the reservoir bag to be drawn into the circle system to refill the piston ventilator chamber (or descending bellows in the Mindray Anestar). Since the ventilator exhaust valve also opens during the expiratory phase, excess fresh gas and exhaled patient gases are allowed to escape to the scavenging system.

**Figure 25-46** Dräger Fabius GS fresh gas decoupled (FDG) breathing system during inspiratory phase of mechanical ventilation. The figure demonstrates the path of fresh gas (and O<sub>2</sub> flush) into the reservoir bag during upstroke of the ventilator piston. Note the requirement here for a mechanical decoupling valve and electronic exhalation/PEEP/Plimit valve. A man./spont. valve is electronically opened during CMV, so that excess gas can escape through the low-pressure scavenger valve, which also allows preferential filling of the reservoir bag during the inspiratory phase. (Adapted from Olympio MA. Modern anesthesia machines offer new safety features. *APSF Newsletter*. 2003;18:17.)

Contemporary fresh gas decoupled systems are designed with either piston-type (Dräger) or descending bellows-type ventilators. Since the

bellows in either of these types of systems refills under slight negative pressure, it allows the accumulated fresh gas from the reservoir bag to be drawn into the ventilator for delivery to the patient during the next ventilator cycle.

The claimed advantages of circle systems using FGD include more accurate delivery of the set tidal volume and decreased risk of barotrauma and volutrauma. With a traditional circle system, increases in FGF from the flowmeters or from inappropriate use of the oxygen flush valve may contribute directly to tidal volume, which if excessive, may result in pneumothorax or other injuries. Since systems with FGD isolate fresh gas coming into the system from the patient while the ventilator exhaust valve is closed, the risk of barotrauma is greatly reduced.

Possibly the greatest disadvantage to the new anesthesia circle systems that utilize FGD is the possibility of entraining room air into the patient gas circuit. As previously discussed, in a fresh gas decoupled system the bellows or piston refills under slight negative pressure. If the volume of gas contained in the reservoir bag plus the returning volume of gas exhaled from the patient's lungs is inadequate to refill the bellows or piston chamber, negative patient airway pressures could develop. To prevent this, a negative-pressure relief valve is incorporated into the breathing system. If breathing system pressure falls below a preset value such as  $-2$  cm H<sub>2</sub>O, then the relief valve opens and ambient air is entrained into the patient gas circuit. If this goes undetected, the entrained atmospheric gases could lead to dilution of the inhaled anesthetic agents, the enriched oxygen mixture (resulting in a lowering of the enriched oxygen concentration toward 21%), or both. If unnoticed, this dilution of patient gases could lead to intraoperative patient awareness or hypoxia. High-priority alarms with both audible and visual alerts should notify the user that FGF is inadequate and room air is being entrained.

Another potential problem with an FGD system is its reliance on the reservoir bag to accumulate the incoming fresh gas. If the reservoir bag is removed during mechanical ventilation, or if it has a significant leak from poor fit on the bag mount or a perforation, room air may enter the breathing circuit as the ventilator piston unit refills during expiratory phase.<sup>177</sup> This may also result in dilution of the inhaled anesthetic agents, the enriched oxygen mixture, or both. Furthermore, this type of a disruption could lead to significant contamination of the operating room atmosphere with anesthetic gases as fresh gases would be allowed to escape into the atmosphere. Incompetence of the FGD valve leads to inability to ventilate the patient's lungs using the ventilator, but ability to ventilate using the reservoir bag in the circuit.<sup>178</sup> If there is a leak in the low pressure system of the workstation that permits air entry, mechanical ventilation is possible but not manual. The

piston ventilator will continue to deliver the tidal volume as air. If the expiratory unidirectional valve is missing or incompetent, mechanical ventilation is possible but manual is not.<sup>179</sup>

### Maquet FLOW-i Workstation

The Maquet FLOW-i workstation uses a novel breathing system that dispenses with the need for a bellows or piston to provide positive-pressure ventilation (Fig. 25-47).<sup>180</sup> The system incorporates a volume reflector (a 3.6-m-long plastic coil of internal volume 1.2 L) located between the circle system, and the reservoir bag and APL/PEEP valve (Fig. 25-48). Also connected directly to the volume reflector is the reflector oxygen module that provides oxygen as the drive gas during positive-pressure ventilation. During exhalation, the patient exhales through the volume reflector. During positive-pressure inspiration, the APL/PEEP valve closes and the computer controlled reflector gas module delivers oxygen into the reflector, forcing the gas in the reflector back into the circle system through the absorber, past the inspiratory unidirectional valve to the patient's airway. FGF is added to the circuit during positive-pressure inspiration, combining with the reflector gas module oxygen flow to achieve the set  $FiO_2$  and anesthetic agent concentration. The gas flows are electronically controlled using pressure and flow sensors to provide the set ventilation parameters (e.g., TV, MV, ventilator patterns). During exhalation, reflector gas module and FGFs cease, the PEEP valve (that was closed during positive-pressure inspiration) opens to the set PEEP, and exhaled gas flows via the volume reflector and on to the waste gas scavenging system.

**Figure 25-47** Maquet FLOW-i breathing and ventilator circuit during positive-pressure

inspiration. For details, see text.

**Figure 25-48** Maquet FLOW-i volume reflector.

The FLOW-i is purported to be more economical than bellows or piston ventilators during controlled ventilation because fresh gas enters the circuit only during inspiration. In the other systems described FGF enters the circuit continuously throughout the respiratory cycle. During spontaneous or manually assisted ventilation, however, the FLOW-i's economy is the same as other systems because in this mode FGF is continuous and the FLOW-i functions as a conventional circle breathing system.

## Waste Gas Scavenging Systems

Scavenging is the collection and the subsequent removal of waste anesthetic gases from the operating room.<sup>181</sup> In most cases, the amount of gas used to **14** anesthetize a patient for a given anesthetic far exceeds the minimal amount needed. Therefore, scavenging minimizes operating room contamination by removing this excess of gases. In 1977, the National Institute for Occupational Safety and Health (NIOSH) published a document entitled "Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors."<sup>182</sup> Although a minimum safe level of exposure could not be defined, NIOSH made the recommendations shown in [Table 25-8](#). The recommended ceiling for volatile anesthetics was established before desflurane and sevoflurane were introduced into clinical practice. However, this limit is likely to be similarly applicable for the newer volatile anesthetics.<sup>183</sup> The NIOSH recommendations have never promulgated into law and therefore are not enforceable. (For a more in-depth discussion of this topic, refer to the chapter on Occupational Health.)

In 1991, the ASTM released the ASTM F1343–91 standard titled "Standard Specification for Anesthetic Equipment—Scavenging Systems for Anesthetic Gases."<sup>184</sup> The document provided guidelines for devices that safely and

effectively scavenge waste anesthetic gases to reduce contamination in anesthetizing areas. Because of lack of safety data on exposure to the newer halogenated anesthetic agents, in 2006 NIOSH requested comments and information relevant to the evaluation of health risks associated with occupational exposure to these agents in order to establish recommended maximum exposure levels (REL).<sup>185</sup> The ASA Task Force on Trace Anesthetic Gases developed a booklet entitled “Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit.” This ASA publication addresses analysis of the literature, the role of regulatory agencies, scavenging and monitoring equipment, and recommendations.<sup>186</sup>

**Table 25-8** NIOSH Recommendations for Maximum Levels for Exposure of Personnel to Trace Anesthesia Gases and Vapors

Anesthetic Gas	Maximum TWA <sup>a</sup> Concentration (ppm)
Halogenated agent alone	2
Nitrous oxide	25
Combination of halogenated agent plus nitrous oxide	—
Halogenated agent	0.5
Nitrous oxide	25
Dental facilities (nitrous oxide alone)	50

Reprinted from US Department of Health, Education, and Welfare.

Criteria for a recommended standard: occupational exposure to waste anesthetic gases and vapors. March ed., Washington, DC; 1977.

Note: Despite being in clinical use for more than 15 years, isoflurane, desflurane, and sevoflurane have not been tested for maximum recommended trace gas levels.

<sup>a</sup>TWA, time-weighted average. Time-weighted average sampling, also known as time-integrated sampling, is a sampling method that evaluates the average concentration of anesthetic gas over a prolonged period of time, such as 1 to 8 hours.

The two major causes of waste gas contamination in the operating room are the anesthetic technique employed and equipment issues.<sup>186</sup> Regarding the anesthetic technique, the following factors cause operating room atmosphere contamination: (1) failure to turn off gas flow control valves at the end of an anesthetic; (2) poorly fitting masks; (3) flushing the circuit; (4) filling anesthetic vaporizers; (5) use of uncuffed tracheal tubes; and (6) use of breathing circuits such as the Jackson-Rees (modification of Ayre’s T-piece/Mapleson E rebreathing circuit), which are difficult to scavenge. Equipment failure or lack of understanding of proper equipment use can also contribute to operating room contamination. Leaks can occur in the high-pressure hoses, the nitrous oxide tank mounting, the high-pressure circuit and LPC of the anesthesia machine, or in the circle system, particularly at the CO<sub>2</sub> absorber assembly. The anesthesia provider must be certain that the scavenging system is operational and adjusted properly to ensure adequate

scavenging. If sidestream CO<sub>2</sub> or multigas analyzers are used, the analyzed gas (withdrawn from the circuit at a rate of 50 to 250 cc/min) must be directed to the scavenging system or returned to the breathing system to prevent contamination of the operating room atmosphere.

## Components

Scavenging systems generally consist of five components (Fig. 25-49): (1) the gas-collecting assembly, (2) the transfer means, (3) the scavenging interface, (4) the gas-disposal assembly tubing, and (5) an active or passive gas-disposal assembly. An “active system” uses a central evacuation (vacuum) system to remove waste gases. The “weight” or pressure of the waste gas itself produces flow through a “passive system.”

**Figure 25-49** Components of a scavenging system. APL, adjustable pressure-limiting valve.

### Gas-Collecting Assembly

The gas-collecting assembly captures excess anesthetic gas and delivers it to the transfer tubing. Waste anesthetic gases are vented from the anesthesia system either through the APL valve or through the ventilator relief valve. All excess patient gas either is vented into the room (e.g., from a poor facemask fit or tracheal tube leak) or exits the breathing system through one of these valves. Gas passing through these valves accumulates in the gas-collecting assembly and is directed to the transfer means. In some newer GE Healthcare systems (e.g., S5/ADU workstation) and others that incorporate either the 7100 or 7900 ventilators, the ventilator drive gas is also exhausted into the

scavenging system. This is significant, because under conditions of high FGFs and high minute ventilation, the gases flowing into the scavenging interface may overwhelm the evacuation system. If this occurs, waste anesthetic gases may overflow the system via the positive-pressure relief valve (closed systems) or through the atmospheric vents (open systems) into the operating room atmosphere. In contrast, most other pneumatic ventilators from both Datex-Ohmeda and Dräger Narkomedes with AV-E ventilators exhaust their drive gas (oxygen or an oxygen/air mixture) into the operating room through a small vent on the back of the ventilator control housing.

## **Transfer Means**

The transfer means carries excess gas from the gas-collecting assembly to the scavenging interface. The tubing diameter must be either 19 or 30 mm, as specified by the ASTM F1343–91 standard.<sup>184</sup> The tubing should be sufficiently rigid to prevent kinking, and as short as possible to minimize the chance of occlusion. Some manufacturers color code the transfer tubing with yellow bands to distinguish it from 22-mm diameter breathing system tubing. Many machines have separate transfer tubes for the APL valve and for the ventilator relief valve. The two tubes usually merge into a single hose before they enter the scavenging interface. Occlusion of the transfer means can be particularly problematic since it is upstream from the pressure-buffering features of the scavenging interface. If the transfer means is occluded, baseline breathing circuit pressure will increase and barotrauma can occur.

## **Scavenging Interface**

The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressures. The interface should limit the pressures immediately downstream from the gas collecting assembly to between  $-0.5$  and  $+10$  cm H<sub>2</sub>O with normal working conditions. Positive-pressure relief is mandatory, irrespective of the type of disposal system used, to vent excess gas in case of occlusion downstream from the interface. If the disposal system is an “active system,” negative-pressure relief is necessary to protect the breathing circuit or ventilator from excessive subatmospheric pressure. A reservoir is highly desirable with active systems, since it stores waste gases until the evacuation system can remove them. Interfaces can be open or closed, depending on the method used to provide positive- and negative-pressure relief.

### *Open Interfaces*

An open interface contains no valves and is open to the atmosphere, allowing

both positive- and negative-pressure relief. Open interfaces should be used only with active disposal systems that use a central evacuation system. Open interfaces require a reservoir because waste gases are intermittently discharged in surges, whereas flow from the evacuation system is continuous.

Many contemporary anesthesia machines are equipped with open interfaces like those in [Figures 25-50A and B](#).<sup>187</sup> An open canister provides reservoir capacity. The canister volume should be large enough to accommodate a variety of waste gas flow rates. Gas enters the system at the top of the canister and travels through a narrow inner tube to the canister base. Gases are stored in the reservoir between breaths. Positive- and negative-pressure relief is provided by holes in the top of the canister. The open interface shown in [Figure 25-50A](#) differs somewhat from the one shown in [Figure 25-50B](#). The operator can regulate the vacuum by adjusting the vacuum control valve shown in [Figure 25-50B](#). The efficiency of an open interface depends on several factors. The vacuum flow rate per minute must equal or exceed the volume of excess gases to prevent spillage. The volume of the reservoir and the flow characteristics within the interface are important. Spillage will occur if the volume of a single exhaled breath exceeds the capacity of the reservoir. The flow characteristics of the system are important because gas leakage can occur long before the volume of waste gas equals the reservoir volume if significant turbulence occurs within the interface.<sup>188</sup>

**Figure 25-50 A, B:** Two open reservoir scavenging interfaces. Each requires an active disposal system. APL, adjustable pressure-limiting valve. See text for details. (Adapted from Dorsch JA, Dorsch SE. Controlling trace gas levels. In: Dorsch JA, Dorsch SE, eds. *Understanding Anesthesia Equipment*. 4th ed. Baltimore, MD: Williams & Wilkins; 1999:355.)

### Closed Interfaces

A closed interface communicates with the atmosphere through valves. All

closed interfaces must have a positive-pressure relief valve to vent excess system pressure if obstruction occurs downstream from the interface. A negative-pressure relief valve is mandatory to protect the breathing system from subatmospheric pressure if an active disposal system is used. Two types of closed interfaces are commercially available. One has positive-pressure relief only; the other has both positive- and negative-pressure relief. Each type is discussed in the following sections.

**Positive-Pressure Relief Only.** This interface (Fig. 25-51, left) has a single positive-pressure relief valve and is designed to be used only with passive disposal systems. Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the “weight” or pressure of the waste gas itself since a negative-pressure evacuation system is not used. The positive-pressure relief valve opens at a preset value such as 5 cm water if an obstruction between the interface and the disposal system occurs.<sup>189,190</sup> On this type of system, a reservoir bag is not required.

**Figure 25-51** Closed scavenging interfaces. **Left:** Interface used with a passive disposal system. (Adapted from *Scavenger Interface for Air Conditioning: Instruction Manual*. Telford, PA: North American Dräger; 1984.) **Right:** Interface used with an active system. See text for details. (Adapted from *Narkomed 2A Anesthesia System: Technical Service Manual*. Telford, PA: North American Dräger; 1985.)

**Figure 25-52** Dynamic Gas Scavenging System (DGSS). **A:** DGSS interface; **B:** Interface mounted on a GE anesthesia workstation. For details see text.

**Positive- and Negative-Pressure Relief.** This interface has a positive-pressure relief valve, and at least one negative-pressure relief valve, in addition to a reservoir bag. It is used with active disposal systems. [Figure 25-51](#) (right) is a schematic of Dräger Medical’s closed interface for suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir intermittently accumulates excess gas until the evacuation system eliminates it. The operator should adjust the vacuum control valve so that the reservoir bag is properly inflated (A), not over-distended (B), or completely deflated (C). Gas is vented to the atmosphere through the positive-pressure relief valve if the system pressure exceeds +5 cm water. Room air is entrained through the negative-pressure relief valve if the system pressure is more negative than  $-0.5$  cm H<sub>2</sub>O. On some systems, a backup negative-pressure relief valve opens at  $-1.8$  cm H<sub>2</sub>O if the primary negative-pressure relief valve becomes occluded.

The effectiveness of a closed system in preventing spillage depends on the rate of waste gas inflow, the evacuation flow rate, and the size of the reservoir. Leakage of waste gases into the atmosphere occurs only when the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive-pressure relief valve. In contrast, the effectiveness of an

open system to prevent spillage depends not only on the volume of the reservoir but also on the flow characteristics within the interface.

### **Gas-Disposal Assembly Conduit**

The gas-disposal assembly conduit, or disposal assembly tubing (Fig. 25-49), conducts waste gas from the scavenging interface to the gas-disposal assembly. It should be collapse-proof and should run overhead, if possible, to minimize the chances of accidental occlusion.

### **Gas-Disposal Assembly**

The gas-disposal assembly ultimately eliminates excess waste gas (Fig. 25-49). There are two types of disposal systems: active and passive.

The most common method of gas disposal is the active assembly, which uses a central evacuation system. A vacuum pump serves as the mechanical flow-inducing device that removes the waste gases usually to the outside of the building. An interface with a negative-pressure relief valve is mandatory because the pressure within the system is negative. A reservoir is very desirable, and the larger the reservoir, the lower the suction flow rate needed.

A passive disposal system does not use a mechanical flow-inducing device. Instead, the “weight” or pressure from the heavier-than-air anesthetic gases produces flow through the system. Positive-pressure relief is mandatory, but negative-pressure relief and a reservoir are unnecessary. Excess waste gases can be eliminated from the surgical suite in a number of ways. Some include venting through the wall, ceiling, floor, or to the room exhaust grill of a nonrecirculating air conditioning system.

### **Hazards**

Scavenging systems minimize operating room atmosphere contamination, yet they add complexity to the anesthesia system. A scavenging system functionally extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Obstruction of scavenging pathways can cause excessive positive pressure in the breathing circuit, and barotrauma can occur. Excessive vacuum applied to a scavenging system can result in undesirable negative pressures within the breathing system. For most contemporary anesthesia workstations, preuse checkout of the scavenging system is a function that must be performed manually by the operator according to the manufacturer’s instructions. In the Spacelabs Healthcare’s ARKON workstation

the scavenger test is a component of the automated checkout.<sup>191</sup>

Another unusual problem is a report of fires in engineering equipment rooms that house the vacuum pumps used for waste anesthetic gas evacuation.<sup>192</sup> It seems that in some hospitals, waste gases are not directly vented outside, but may be vented into machine rooms that have vents that open to the outside. Since some anesthesia machines are designed such that ventilator drive gas (oxygen) is also scavenged, the environment in these machine rooms into which the scavenged gas is vented may become highly enriched with oxygen. These sites may contain equipment or materials such as petroleum distillates (pumps/oil/grease) that in the presence of an oxygen-enriched atmosphere could be excessively combustible and present a severe fire hazard.

## Low-Flow Scavenging Systems

Active waste gas scavenging systems draw large volumes of gas—anesthetic waste plus entrained air in the range of 25 to 75 L/min—from each OR. This requires large and costly vacuum pumps that operate continuously, incurring a high-energy cost. In an effort to reduce the carbon footprint associated with running these pumps, a more efficient, low-flow scavenger interface has been designed and evaluated.<sup>193</sup> The Dynamic Gas Scavenging System (DGSS; Anesthetic Gas Reclamation, Nashville, TN) interface is a gas-tight metal container with a 3-L reservoir bag attached to ensure compliance with OSHA recommendations (Fig. 25-52). The design is such that scavenging outflow to the vacuum system remains closed until a pressure of 0.5 cm H<sub>2</sub>O from the anesthesia workstation exhaust, via the APL or ventilator pressure relief valve, is sensed in the interface enclosure by a sensitive pressure transducer. A solenoid valve then opens and remains open until the internal pressure reaches  $-0.5$  cm H<sub>2</sub>O, thus emptying the interface reservoir bag. In this way the flow to the vacuum system is continuously titrated according to needs. An additional benefit is that by producing a more concentrated flow of waste gases, technologies designed to recover potent inhaled anesthetic agents from the waste-gas flow are facilitated. Such technologies are likely to become more important because the inhaled anesthetics are greenhouse gases with the potential to increase global warming.<sup>194,195</sup>

# Appendix A

## *FDA 1993 Anesthesia Apparatus Checkout Recommendations*

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are only valid for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: Capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline that users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (Step 5).

### **Emergency Ventilation Equipment**

- 1. \*Verify Backup Ventilation Equipment is Available and Functioning**

#### *High-Pressure System*

- 2. \*Check Oxygen Cylinder Supply**
  - Open O<sub>2</sub> cylinder and verify at least half full (about 1,000 psi)
  - Close cylinder
- 3. \*Check Central Pipeline Supplies**
  - Check that hoses are connected and pipeline gauges read about 50 psi

#### *Low-Pressure System*

- 4. \*Check Initial Status of Low-pressure System**
  - Close flow control valves and turn vaporizers off
  - Check fill level and tighten vaporizers' filler caps
- 5. \*Perform Leak Check of Machine Low-pressure System**
  - Verify that the machine master switch and flow control valves are OFF
  - Attach "Suction Bulb" to common (fresh) gas outlet
  - Squeeze bulb repeatedly until fully collapsed
  - Verify bulb stays fully collapsed for at least 10 seconds
  - Open one vaporizer at a time and repeat "c" and "d" as above
  - Remove suction bulb and reconnect fresh gas hose
- 6. \*Turn on Machine Master Switch and all other necessary electrical equipment**

## **7. \*Test Flowmeters**

- a. Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flow tubes
- b. Attempt to create a hypoxic O<sub>2</sub>/N<sub>2</sub>O mixture and verify correct changes in flow and/or alarm

### ***Scavenging System***

## **8. \*Adjust and Check Scavenging System**

- a. Ensure proper connections between the scavenging system and both APL (pop-off) valve and ventilator relief valve
- b. Adjust waste gas vacuum (if possible)
- c. Fully open APL valve and occlude Y-piece
- d. With minimum O<sub>2</sub> flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero
- e. With the O<sub>2</sub> flush activated, allow the scavenger reservoir bag to distend fully and then verify that absorber pressure gauge reads < 10 cm H<sub>2</sub>O

### ***Breathing System***

## **9. \*Calibrate O<sub>2</sub> Monitor**

- a. Ensure monitor reads 21% in room air
- b. Verify low O<sub>2</sub> alarm is enabled and functioning
- c. Reinstall sensor in circuit and flush breathing system with O<sub>2</sub>
- d. Verify that monitor now reads greater than 90%

## **10. Check Initial Status of Breathing System**

- a. Set selector switch to “Bag” mode
- b. Check that breathing circuit is complete, undamaged, and unobstructed
- c. Verify that CO<sub>2</sub> absorbent is adequate
- d. Install the breathing circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case

## **11. Perform Leak Check of the Breathing System**

- a. Set all gas flows to zero (or minimum)
- b. Close APL (pop-off) valve and occlude Y-piece
- c. Pressurize breathing system to about 30 cm H<sub>2</sub>O with O<sub>2</sub> flush
- d. Ensure that pressure remains fixed for at least 10 seconds
- e. Open APL (pop-off) valve and ensure that pressure decreases

### ***Manual and Automatic Ventilation Systems***

## **12. Test Ventilation Systems and Unidirectional Valves**

- a. Place a second breathing bag on Y-piece
- b. Set appropriate ventilator parameters for next patient
- c. Switch to automatic ventilation (Ventilator) mode

- d. Turn ventilator ON and fill bellows and breathing bag with O<sub>2</sub> flush
- e. Set O<sub>2</sub> flow to minimum, other gas flows to zero
- f. Verify that during inspiration bellows deliver appropriate tidal volume and that during expiration bellows fill completely
- g. Set fresh gas flow to about 5 L/min
- h. Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end expiration
- i. Check for proper action of unidirectional valves
- j. Exercise breathing circuit accessories to ensure proper function
- k. Turn ventilator OFF and switch to manual ventilation (bag/APL) mode
- l. Ventilate manually and assure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance
- m. Remove second breathing bag from Y-piece

### ***Monitors***

#### **13. Check, Calibrate, and/or Set Alarm Limits of All Monitors**

- a. Capnometer
- b. Oxygen Analyzer
- c. Pressure monitor with High- and Low-airway Pressure Alarms
- d. Pulse Oximeter
- e. Respiratory Volume Monitor (Spirometer)

### ***Final Position***

#### **14. Check Final Status of Machine**

- a. Vaporizers off
- b. APL valve open
- c. Selector switch to "Bag"
- d. All flowmeters to zero (or minimum)
- e. Patient suction level adequate
- f. Breathing system ready to use

---

\*Gauge pressure is the pressure above atmospheric pressure. Atmospheric pressure at sea level is 14.7 pounds per square inch absolute (psia). Thus in absolute pressure terms 45 psig would be 59.7 psia.

---

## Appendix B

### *Recommendations for Preanesthesia Checkout Procedures (2008)*

### *Subcommittee of ASA Committee on Equipment and Facilities*

### *Guidelines for Preanesthesia Checkout (PAC) Procedures*

#### **Background**

Improperly checking anesthesia equipment prior to use can lead to patient injury and has also been associated with an increased risk of severe postoperative morbidity and mortality.<sup>1,2</sup> In 1993 a preanesthesia checkout (PAC) was developed and widely accepted to be an important step in the process of preparing to deliver anesthesia care.<sup>3</sup> Despite the accepted importance of the PAC, available evidence suggests that the current version is neither well understood nor reliably utilized by anesthesia providers.<sup>4-6</sup> Furthermore, anesthesia delivery systems have evolved to the point that one checkout procedure is not applicable to all anesthesia delivery systems currently on the market. For these reasons, a new approach to the PAC has been developed. The goal was to provide guidelines applicable to all anesthesia delivery systems so that individual departments can develop a PAC that can be performed consistently and expeditiously.

#### **General Considerations**

The following document is intended to serve not as a PAC itself, but rather as a template for developing checkout procedures that are appropriate for each individual anesthesia machine design. When using this template to develop a checkout procedure for systems that incorporate automated checkout features, items that are not evaluated by the automated checkout need to be identified, and supplemental manual checkout procedures included as needed.

Simply because an automated checkout procedure exists does not mean it can completely replace a manual checkout procedure or that it can be performed safely without adequate training and a thorough understanding of what the automated checkout accomplishes. An automated checkout procedure can be incomplete and/or misleading. For example, the leak test performed by some current automated checkouts does not test for leaks at the vaporizers. As a result, a loose vaporizer filler cap, or a leak at the vaporizer mount, could easily be missed.

Ideally automated checkout procedures should clearly reveal to the user the functions that are being checked, any deficient function that is found, and recommendations to correct the problem. Documentation of the automated

checkout process should preferably be in a manner that can be recorded on the anesthesia record.

Operator's manuals, which accompany anesthesia delivery systems, include extensive recommendations for equipment checkout. Although these recommendations are quite extensive and typically not utilized by anesthesia providers, they are nevertheless important references for developing machine-specific and institution-specific checkout procedures.

## **Personnel Performing the PAC**

The previously accepted Anesthesia Apparatus Checkout Recommendation placed all of the responsibility for preuse checkout on the anesthesia provider. Sole reliance on one individual to complete the checkout process may increase the likelihood that one or more steps will be omitted or performed improperly. This guideline identifies those aspects of the PAC that could be completed by a qualified anesthesia and/or biomedical technician. Utilizing technicians to perform some aspects of the PAC may improve compliance with the PAC. Steps completed by a technician may be part of the morning preuse check or part of a procedure performed at the end of each day. Critical checkout steps (e.g., availability of backup ventilation equipment) will benefit from intentional redundancy (i.e., having more than one individual responsible for checking the equipment). *Regardless of the level of training and support by technicians, the anesthesia care provider is ultimately responsible for proper function of all equipment used to provide anesthesia care.*

Adaptation of the PAC to local needs, assignment of responsibility for the checkout procedures, and training are the responsibilities of the individual anesthesia department. Training procedures should be documented. Proper documentation should include records of completed coursework (e.g., a manufacturer course) or for in-house training, a listing of the competency items taught and records of successful completion by trainees.

## **Objectives for a New PAC**

- Outline the essential items that need to be available and functioning properly prior to delivering every anesthetic.
- Identify the frequency with which each of the items needs to be checked.
- Suggest which items may be checked by a qualified anesthesia technician, biomedical technician, or a manufacturer-certified service technician.

## **Basic Principles**

- The anesthesia care provider is ultimately responsible for ensuring that the anesthesia equipment is safe and ready for use. This responsibility includes adequate familiarity with the equipment, following relevant local policies for performing and documenting the PAC and being knowledgeable about those procedures.
- Depending upon the staffing resources in a particular institution, anesthesia technicians and/or biomedical technicians can participate in the PAC. Biomedical technicians are often trained and certified by manufacturers to perform on-site maintenance of anesthesia delivery systems and therefore can be a useful resource for completing regular checkout procedures. Anesthesia technicians are not commonly trained to perform checkout procedures. Involving the anesthesia technicians is intended to enhance compliance with the PAC. Each department should decide whether the available technicians can or should be trained to assist with checkout procedures. Formal certification of anesthesia technicians by the American Society of Anesthesia Technicians and Technologists (ASATT) is encouraged but does not necessarily guarantee familiarity with checkout procedures.
- Critical items will benefit from redundant checks to avoid errors and omissions.
- When more than one person is responsible for checking an item, all parties should perform the check if intentional redundancy is deemed important, or either party may be acceptable, depending upon the available resources.
- Whoever conducts the PAC should provide documentation of successful performance. The anesthesia provider should include this documentation on the patient chart.
- Whenever an anesthesia machine is moved to a new location, a complete beginning-of-the-day checkout should be performed.
- Automated checks should clearly distinguish the components of the delivery system that are checked automatically from those which require manual checkout.
- Ideally, the date, time, and outcome of the most recent check(s) should be recorded and the information made accessible to the user.
- Specific procedures for preuse checkout cannot be prescribed in this document since they vary with the delivery systems. Clinicians must learn how to effectively perform the necessary preuse check for each piece of equipment they use.
- Each department or health-care facility should work with the manufacturer(s) of their equipment to develop preuse checkout procedures that satisfy both the following guidelines and the needs of the local department.

- Default settings for ventilators, monitors, and alarms should be checked to determine if they are appropriate
- These checkout recommendations are intended to replace the preexisting FDA-approved Anesthesia Apparatus Checkout Recommendations. They are not intended to be a replacement for required preventive maintenance.
- The PAC is essential to safe care but should not delay initiating care if the patient needs are so urgent that time taken to complete the PAC could worsen the patient's outcome.

### ***ASA 2008 Guidelines for Developing Institution-Specific Checkout Procedures Prior to Anesthesia Delivery***

These guidelines describe a basic approach to checkout procedures and rationale that will ensure that these priorities are satisfied. They should be used to develop institution-specific checkout procedures designed for the equipment and resources available. (Example of institution-specific procedures for current anesthesia delivery systems are published on the same web site as this document.)

#### **Requirements for Safe Delivery of Anesthesia Care**

- Reliable delivery of oxygen at any appropriate concentration up to 100%.
- Reliable means of positive-pressure ventilation.
- Backup ventilation equipment available and functioning.
- Controlled release of positive pressure from the breathing circuit.
- Anesthesia vapor delivery (if intended as part of the anesthetic plan).
- Adequate suction.
- Means to conform to standards for patient monitoring.<sup>7,8</sup>

#### **Specific Items**

The following items need to be checked as part of a complete PAC. The intent is to identify what to check, the recommended frequency of checking and the individual(s) who could be responsible for the item. For these guidelines, the responsible party would fall into one of four categories: Provider, Technician, Technician or Provider, or Technician and Provider. The designation "Technician and Provider" means that the provider must perform the check whether or not it has been completed by a technician. It is not intended to make the use of technician checks mandatory. The intent is not to specify how an item needs to be checked, as the specific checkout procedure will depend

upon the equipment being used.

**Item 1: Verify whether auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.**

**Frequency:** Daily

**Responsible Parties:** Provider and Technician

**Rationale:** Failure to be able to ventilate is a major cause of morbidity and mortality related to anesthesia care. Because equipment failure with resulting inability to ventilate the patient can occur at any time, a self-inflating manual ventilation device (e.g., AMBU bag) should be present at every anesthetizing location for every case and should be checked for proper function. In addition, a source of oxygen separate from the anesthesia machine and pipeline supply, specifically an oxygen cylinder with regulator and a means to open the cylinder valve, should be immediately available and checked. After checking the cylinder pressure, it is recommended that the main cylinder valve be closed to avoid inadvertent emptying of the cylinder through a leaky or open regulator.

**Item 2: Verify patient suction is adequate to clear the airway.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider and Technician

**Rationale:** Safe anesthetic care requires the immediate availability of suction to clear the airway if needed.

**Item 3: Turn on anesthesia delivery system and confirm that AC power is available.**

**Frequency:** Daily

**Responsible Parties:** Provider or Technician

**Rationale:** Anesthesia delivery systems typically function with backup battery power if AC power fails. Unless the presence of AC power is confirmed, the first obvious sign of power failure can be a complete system shutdown when the batteries can no longer power the system. Many anesthesia delivery systems have visual indicators of the power source showing the presence of both AC and battery power. These indicators should be checked and connection of the power cord to a functional AC power source should be confirmed.

Desflurane vaporizers require electrical power and recommendations for checking power to these vaporizers should also be followed.

**Item 4: Verify availability of required monitors and check alarms.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider or Technician

**Rationale:** Standards for patient monitoring during anesthesia are clearly defined.<sup>7,8</sup> The ability to conform to these standards should be confirmed for every anesthetic. The first step is to visually verify that the appropriate monitoring supplies (BP cuffs, oximetry probes, etc.) are available. All monitors should be turned on and proper completion of power-up self-tests confirmed. Given the importance of pulse oximetry and capnography to patient safety, verifying proper function of these devices before anesthetizing the patient is essential. Capnometer function can be verified by exhaling through the breathing circuit or gas sensor to generate a capnogram, or verifying that the patient's breathing efforts generate a capnogram before the patient is anesthetized. Visual and audible alarm signals should be generated when this is discontinued. Pulse oximeter function, including an audible alarm, can be verified by placing the sensor on a finger and observing for a proper recording. The pulse oximeter alarm can be tested by introducing motion artifact or removing the sensor.

Audible alarms have also been reconfirmed as essential to patient safety by the American Society of Anesthesiologists (ASA), American Association of Nurse Anesthetists (AANA), Anesthesia Patient Safety Foundation (APSF), and Joint Commission on the Accreditation of Healthcare Organizations (JCAHO). Proper monitor functioning includes visual and audible alarm signals that function as designed.

**Item 5: Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.**

**Frequency:** Daily

**Responsible Parties:** Provider and Technician

**Rationale:** Anesthesia delivery systems rely on a supply of oxygen for various machine functions. At a minimum, the oxygen supply is used to provide oxygen to the patient. Pneumatically powered ventilators also rely on a gas supply. Oxygen cylinder(s) should be mounted on the anesthesia delivery system and determined to have an acceptable minimum pressure. The acceptable pressure depends on the intended use, the design of the anesthesia delivery system and the availability of piped oxygen.

- Typically, an oxygen cylinder will be used if the central oxygen supply fails.
- If the cylinder is intended to be the primary source of oxygen (e.g., remote site anesthesia), then a cylinder supply sufficient to last for the entire anesthetic is required. If a pneumatically powered ventilator that uses oxygen as its driving gas will be

used, a full “E” oxygen cylinder may provide only 30 minutes of oxygen. In that case, the maximum duration of oxygen supply can be obtained from an oxygen cylinder if it is used only to provide fresh gas to the patient in conjunction with manual or spontaneous ventilation. Mechanical ventilators will consume the oxygen supply if pneumatically powered ventilators that require oxygen to power the ventilator are used. Electrically powered ventilators do not consume oxygen so that the duration of a cylinder supply will depend only on total fresh gas flow.

- The oxygen cylinder valve should be closed after it has been verified that adequate pressure is present, unless the cylinder is to be the primary source of oxygen (i.e., piped oxygen is not available). If the valve remains open and the pipeline supply should fail, the oxygen cylinder can become depleted while the anesthesia provider is unaware of the oxygen supply problem.

Other gas supply cylinders (e.g., Heliox, CO<sub>2</sub>, air, N<sub>2</sub>O) need to be checked only if that gas is required to provide anesthetic care.

**Item 6: Verify that piped gas pressures are 50 psig or higher.**

**Frequency:** Daily

**Responsible Parties:** Provider and Technician

**Rationale:** A minimum gas supply pressure is required for proper function of the anesthesia delivery system. Gas supplied from a central source can fail for a variety of reasons. Therefore, the pressure in the piped gas supply should be checked at least once daily.

**Item 7: Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider. Technician if redundancy desired.

**Rationale:** If anesthetic vapor delivery is planned, an adequate supply is essential to reduce the risk of light anesthesia or recall. This is especially true if an anesthetic agent monitor with a low agent alarm is not being used. Partially open filler ports are a common cause of leaks that may not be detected if the vaporizer control dial is not open when a leak test is performed. This leak source can be minimized by tightly closing filler ports. Newer vaporizer designs have filling systems that automatically close the filler port when filling is completed.

High and low anesthetic agent alarms are useful to help prevent over- or

underdosage of anesthetic vapor. Use of these alarms is encouraged and they should be set to the appropriate limits and enabled.

**Item 8: Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.**

**Frequency:** Daily and whenever a vaporizer is changed

**Responsible Parties:** Provider or Technician

**Rationale:** The gas supply in this part of the anesthesia delivery system passes through the anesthetic vaporizer(s) on most anesthesia delivery systems. In order to perform a thorough leak test, each vaporizer must be turned on individually to check for leaks at the vaporizer mount(s) or inside the vaporizer. Furthermore, some machines have a check valve between the flowmeters and the common gas outlet, requiring a negative-pressure test to adequately check for leaks. Automated checkout procedures typically include a leak test but may not evaluate leaks at the vaporizer especially if the vaporizer is not turned on during the leak test. When relying upon automated testing to evaluate the system for leaks, the automated leak test would need to be repeated for each vaporizer in place. This test should also be completed whenever a vaporizer is changed. The risk of a leak at the vaporizer depends upon the vaporizer design. Vaporizer designs where the filler port closes automatically after filling can reduce the risk of leaks.

Technicians can provide useful assistance with this aspect of the machine checkout since it can be time-consuming.

**Item 9: Test scavenging system function.**

**Frequency:** Daily

**Responsible Parties:** Provider or Technician

**Rationale:** A properly functioning scavenging system prevents room contamination by anesthetic gases. Proper function depends upon correct connections between the scavenging system and the anesthesia delivery system. These connections should be checked daily by a provider or technician. Depending upon the scavenging system design, proper function may also require that the vacuum level is adequate, which should also be confirmed daily. Some scavenging systems have mechanical positive- and negative-pressure relief valves. Positive- and negative-pressure relief is important to protect the patient circuit from pressure fluctuations related to the scavenging system. Proper checkout of the scavenging system should ensure that positive- and negative-pressure relief is functioning properly. Due to the complexity of checking for effective positive-

and negative-pressure relief, and the variations in scavenging system design, a properly trained technician can facilitate this aspect of the checkout process.

**Item 10: Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm.**

**Frequency:** Daily

**Responsible Parties:** Provider or Technician.

**Rationale:** Continuous monitoring of the inspired oxygen concentration is the last line of defense against delivering hypoxic gas concentrations to the patient. The oxygen monitor is essential for detecting adulteration of the oxygen supply. Most oxygen monitors require calibration once daily, although some are self-calibrating. For self-calibrating oxygen monitors, they should be verified to read 21% when sampling room air. This is a step that is easily completed by a trained technician. When more than one oxygen monitor is present, the primary sensor that will be relied upon for oxygen monitoring should be checked.

*The low oxygen concentration alarm should also be checked at this time by setting the alarm above the measured oxygen concentration and confirming that an audible alarm signal is generated.*

**Item 11: Verify carbon dioxide absorbent is not exhausted.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider or Technician

**Rationale:** Proper function of a circle anesthesia system relies on the absorbent to remove carbon dioxide from rebreathed gas. Exhausted absorbent as indicated by the characteristic color change should be replaced. It is possible for absorbent material to lose the ability to absorb CO<sub>2</sub> yet the characteristic color change may be absent or difficult to see. Some newer absorbents do change color when desiccated. Capnography should be utilized for every anesthetic and, when using a circle anesthesia system, rebreathing carbon dioxide as indicated by an inspired CO<sub>2</sub> concentration above 0 can also indicate exhausted absorbent. (See Additional Note 2, below.)

**Item 12: Breathing system pressure and leak testing.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider and Technician

**Rationale:** The breathing system pressure and leak test should be performed with the circuit configuration to be used during anesthetic delivery. If any components of the circuit are changed after this test

is completed, the test should be performed again. Although the anesthesia provider should perform this test before each use, anesthesia technicians who replace and assemble circuits can also perform this check and add redundancy to this important checkout procedure. Proper testing will demonstrate that pressure can be developed in the breathing system during both manual and mechanical ventilation and that pressure can be relieved during manual ventilation by opening the APL valve.

Automated testing is often implemented in the newer anesthesia delivery systems to evaluate the system for leaks and also to determine the compliance of the breathing system. The compliance value determined during this testing will be used to automatically adjust the volume delivered by the ventilator to maintain a constant volume delivery to the patient. It is important that the circuit configuration that is to be used be in place during the test.

**Item 13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider and Technician

**Rationale:** Pressure and leak testing does not identify all obstructions in the breathing circuit or confirm proper function of the inspiratory and expiratory unidirectional valves. A test lung or second reservoir bag can be used to confirm that flow through the circuit is unimpeded. Complete testing includes both manual and mechanical ventilation. The presence of the unidirectional valves can be assessed visually during the PAC. Proper function of these valves cannot be visually assessed since subtle valve incompetence may not be detected. Checkout procedures to identify valve incompetence that may not be visually obvious can be implemented but are typically too complex for daily testing. A trained technician can perform regular valve competence tests. (See Note 4 in Appendix.) Capnography should be used during every anesthetic and the presence of carbon dioxide in the inspired gases can help to detect an incompetent valve.

**Item 14: Document completion of checkout procedures.**

**Frequency:** Prior to each use

**Responsible Parties:** Provider and Technician

**Rationale:** Each individual responsible for checkout procedures should document completion of these procedures. Documentation gives credit for completing the job and can be helpful if an adverse event

should occur. Some automated checkout systems maintain an audit trail of completed checkout procedures that are dated and timed.

**Item 15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)**

**Frequency:** Immediately prior to initiating the anesthetic

**Responsible Parties:** Provider

**Rationale:** This step is intended to avoid errors due to production pressure or other sources of haste. The goal is to confirm that appropriate checks have been completed and that essential equipment is indeed available. The concept is analogous to the “time out” used to confirm patient identity and surgical site prior to incision. Improper ventilator settings can be harmful especially if a small patient is following a much larger patient or vice versa. Pressure limit settings (when available) should be used to prevent excessive volume delivery from improper ventilator settings.

**Items to check:**

- Monitors functional?
- Capnogram present?
- Oxygen saturation by pulse oximetry measured?
- Flowmeter and ventilator settings proper?
- Manual/ventilator switch set to manual?
- Vaporizer(s) adequately filled?

## Additional Notes

1. *Testing the flowmeters:* This step is present in the 1993 Checkout Recommendation and is intended to check the oxygen/nitrous oxide proportioning system. It has been eliminated from the Preanesthesia Checkout in these guidelines because proper function is verified during the preventive maintenance and failures of this system in a properly maintained delivery system are rare.
2. *Desiccated carbon dioxide absorbent:* Carbon dioxide absorbents which contain sodium, potassium, or barium hydroxide may become dangerous when desiccated, producing carbon monoxide and/or excessive heat leading to fires. Unfortunately, it is not possible to reliably identify when the absorbent material has been desiccated. Some departments elect to change all absorbent material on Monday morning to eliminate the possibility of using absorbent exposed to continuous fresh gas flow throughout the weekend. Other departments elect to use absorbent materials that do not pose a risk when desiccated. It is important to have a strategy to prevent the hazards

related to using absorbents containing the problematic hydroxides that have desiccated. There are no steps that could be included in the checkout recommendation that can reliably identify desiccated absorbent. If a department uses absorbent that may be hazardous when desiccated, it may be prudent to change the absorbent material whenever the duration of time exposure to high fresh gas flow cannot be determined and is likely to have been prolonged. A protocol for preventing absorbent hazards should be part of every department's risk management strategy.

3. *Anesthesia information systems and automated record keepers:* These systems are being adopted by an increasing number of anesthesia departments and are the mainstay of the recordkeeping process in those departments. Reliably functioning systems is therefore important to the conduct of an anesthetic, although not essential to patient safety in the same fashion as the anesthesia delivery system and patient monitors. For departments that rely upon these systems, it would be prudent to have a protocol for checking connections and the proper functioning of the associated computers, displays, and network function.
4. *Testing circle system valve competence:* As part of the test Item 13 (Verify that gas flows properly through the breathing circuit during both inspiration and exhalation), the inspiratory and expiratory valves are visually observed for proper cycling (opening and closing fully). Visual inspection will also detect a missing valve leaflet. Ascertaining full closure of the valve is subjective. Incompetence of the valve may also be detected during test Item 13 through spirometry at the expiratory limb. For expiratory valve malfunction, a spirometer with reverse flow detection will alarm when gas flows retrograde in the expiratory limb. For inspiratory valve malfunction, the measured exhaled tidal volume will be less than the expected value. Capnography may also help to detect incompetence of the unidirectional valves. Intraoperatively, an inspiratory valve malfunction may not be indicated by an elevation of the inspired CO<sub>2</sub> baseline. If the delivered tidal volume exceeds the volume of gas in the inspiratory limb containing CO<sub>2</sub>, rebreathing will appear on the capnogram as a gradual, instead of sharp, downstroke. An expiratory valve malfunction is indicated by an elevated CO<sub>2</sub> baseline as there is typically a large volume of exhaled gas containing CO<sub>2</sub> that can return to the patient.

## SUMMARY OF CHECKOUT RECOMMENDATIONS BY FREQUENCY AND RESPONSIBLE PARTY

To Be Completed Daily	
Item to Be Completed	Responsible Party
Item 1: Verify whether auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning.	Provider and Tech
Item 2: Verify patient suction is adequate to clear the airway.	Provider and Tech
Item 3: Turn on anesthesia delivery system and confirm that ac power is available.	Provider or Tech
Item 4: Verify availability of required monitors, including alarms.	Provider or Tech
Item 5: Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine.	Provider and Tech
Item 6: Verify that the piped gas pressures are $\geq 50$ psig.	Provider and Tech
Item 7: Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed.	Provider or Tech
Item 8: Verify that there are no leaks in the gas supply lines between the flowmeters and the common gas outlet.	Provider or Tech
Item 9: Test scavenging system function.	Provider or Tech
Item 10: Calibrate, or verify calibration of, the oxygen monitor and check the low oxygen alarm.	Provider or Tech
Item 11: Verify carbon dioxide absorbent is not exhausted.	Provider or Tech
Item 12: Breathing system pressure and leak testing.	Provider and Tech
Item 13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.	Provider and Tech
Item 14: Document completion of checkout procedures.	Provider and Tech
Item 15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)	Provider
To Be Completed Prior to Each Procedure	
Item to Be Completed	Responsible Party
Item 2: Verify patient suction is adequate to clear the airway.	Provider and Tech
Item 4: Verify availability of required monitors, including alarms.	Provider or Tech
Item 7: Verify that vaporizers are adequately filled and if applicable that the filler ports are tightly closed.	Provider
Item 11: Verify carbon dioxide absorbent is not exhausted	Provider or Tech
Item 12: Breathing system pressure and leak testing.	Provider and Tech
Item 13: Verify that gas flows properly through the breathing circuit during both inspiration and exhalation.	Provider and Tech
Item 14: Document completion of checkout procedures.	Provider and Tech
Item 15: Confirm ventilator settings and evaluate readiness to deliver anesthesia care. (ANESTHESIA TIME OUT)	Provider

## **KEY POINTS**

- 1 The purpose of monitoring equipment is to augment the situational awareness of the anesthesiologist by providing clinical data either more rapidly than can be achieved manually or more precisely than can be achieved by direct examination of the patient. The value of any particular monitoring technique lies in its ability to inform the anesthesiologist so that the patient's physiologic condition can be maintained within satisfactory parameters. No monitoring technique, however sophisticated, can substitute for the judgment of the

anesthesiologist.

- 2 It is mandatory to measure inspired oxygen concentration for patients receiving general anesthesia to prevent the inadvertent administration of a hypoxic gas mixture. However, inspired oxygen concentration monitoring cannot reliably detect disconnection of the circuit nor does it guarantee adequate arterial oxygenation.
- 3 Pulse oximetry provides a noninvasive means to detect the onset of hypoxemia rapidly. Modern pulse oximeters are noninvasive, continuous, autocalibrating, have quick response times, and are suitable for use during transport. However, pulse oximetry is a poor indicator of adequate ventilation; desaturation is a late sign of apnea or respiratory insufficiency.
- 4 Monitoring of expired carbon dioxide is now recommended for procedures involving moderate to deep sedation in addition to procedures performed under general anesthesia. Advances in infrared absorption spectroscopy have led to the production of conveniently portable devices for expired gas analysis.
- 5 During direct invasive arterial pressure monitoring, the fidelity of the system is optimized when the catheter and tubing are stiff, the mass of the fluid is small, and the length of the connecting tubing is not excessive.
- 6 Automated noninvasive blood pressure monitors use the oscillometric method to estimate arterial blood pressure. Pulsatile flow generates oscillations in the internal pressure of an inflated blood pressure cuff; these oscillations are greatest when the cuff is inflated to mean arterial pressure. During prolonged surgical cases, it may be prudent to relocate the blood pressure cuff every few hours to reduce the risk of neurapraxia or cutaneous injury.
- 7 On the basis of available evidence, it is difficult to draw meaningful conclusions regarding the effectiveness of pulmonary artery catheter (PAC) monitoring in reducing morbidity and mortality in critically ill patients. Expert opinion suggests that perioperative complications may be reduced if PACs are used in the appropriate patients and settings and if clinicians interpret and apply the data provided by the PAC correctly.
- 8 New noninvasive devices have been developed to generate similar cardiac output (CO) parameters to the PAC as well as potentially to be able to predict fluid responsiveness. However, certain common comorbidities can impair the accuracy of these devices; the PAC thermodilution technique remains the clinical gold standard for measuring CO.
- 9 Clinical studies have demonstrated that patients in whom intraoperative hypothermia develops are at a higher risk for development of

postoperative myocardial ischemia and wound infection compared with patients who are normothermic in the perioperative period. Although liquid crystal skin temperature strips are convenient to apply, they do not correlate well with core temperature measurements.

- 10 Although the algorithms used by processed electroencephalogram (EEG) monitors are proprietary, the general features of the EEG that they use are well described. Processed EEG monitors have not been demonstrated to be superior to end-tidal agent concentration monitoring in the prevention of awareness under anesthesia, although neither technique is sufficient to avoid awareness with complete reliability.
- 11 The advent of “smarter” and more technically sophisticated monitoring devices does not relieve anesthesiologists of their obligation to employ their clinical judgment wisely. On the contrary, it requires anesthesiologists to understand the operation of these devices intimately so that they can be used safely, accurately, and appropriately.

## Introduction

Historically, the foundation of anesthesia practice has been vigilance and ongoing clinical examination of the patient. The development of modern monitoring equipment does not replace these responsibilities. Automated monitoring equipment provides the anesthesiologist with the ability to acquire clinical information either more rapidly or more frequently than can be achieved through manual techniques or in a more quantitatively precise manner than can be achieved by physical examination alone. The purpose of **1** monitoring equipment, then, is to augment the situational awareness of the anesthesiologist so that clinical problems can be recognized and addressed in a timely manner and to guide treatment. The value of any particular monitoring technique lies in its ability to inform the practice of the anesthesiologist so that the patient's physiologic condition can be maintained within satisfactory parameters. The term itself is derived from *monere*, which in Latin means to warn, remind, or admonish.

This chapter discusses the methods and biomedical devices through which anesthesiologists monitor the physiologic state of the patient during anesthesia care. The principles of operation for each of these devices are explained. These explanations are, by necessity, simplified, as the actual design of a biomedical device involves significant engineering complexity. However, the explanations are intended to be sufficient to allow the anesthesiologist to understand how the device acquires its clinical data and how that process might be compromised and the data made erroneous as well as to understand how the device works and how it may fail. There is little high-grade evidence that electronic monitors, by themselves, reduce

morbidity and mortality. There is also controversy regarding the need for specific monitors in certain clinical situations, particularly in which use of the monitor in question may add significant cost or where the invasiveness of the monitoring technique may place the patient at risk of iatrogenic complications. Against these costs and risks, the anesthesiologist must balance the likely benefit from a particular monitoring technique when used and interpreted correctly. Therefore, alongside the science and engineering aspects of monitoring, there is also the clinical art of choosing how a patient should best be monitored intraoperatively. For each of the monitoring techniques, relative indications, contraindications, and common technical problems are discussed.

Standards for basic anesthetic monitoring have been established by the American Society of Anesthesiologists (ASA). Since 1986, these standards have emphasized the evolution of technology and practice. The current standards (which became effective on July 1, 2011) emphasize the importance of regular and frequent measurements, integration of clinical judgment and experience, and the potential for extenuating circumstances that can influence the applicability or accuracy of monitoring systems.<sup>1</sup>

Standard I requires qualified personnel to be present in the operating room during general anesthesia, regional anesthesia, and monitored anesthesia care to monitor the patient continuously and to modify anesthesia care based on clinical observations and the responses of the patient to dynamic changes resulting from surgery or drug therapy. Standard II focuses attention on continually evaluating the patient's oxygenation, ventilation, circulation, and temperature. Standard II specifically mandates the following:

1. Use of an inspired oxygen analyzer with a low concentration-limit alarm during general anesthesia.
2. Quantitative assessment of blood oxygenation during any anesthesia care.
3. Continuously ensuring the adequacy of ventilation by physical diagnostic techniques during all anesthesia care. Continual identification of expired carbon dioxide is performed unless precluded by the type of patient, procedure, or equipment.
4. Quantitative monitoring of tidal volume and capnography is strongly encouraged in patients undergoing general anesthesia.
5. When administering regional anesthesia or local anesthesia, ventilation sufficiency should be assessed by qualitative clinical signs. During moderate or deep sedation, ventilation shall be evaluated by continual evaluation of qualitative clinical signs as well as monitoring for the presence of exhaled carbon dioxide unless precluded by the type of patient, procedure, or equipment.
6. Ensuring correct placement of an endotracheal tube or laryngeal mask

airway requires clinical assessment and qualitative identification of carbon dioxide in the expired gas.

7. When using a mechanical ventilator, use of a device that is able to detect a disconnection of any part of the breathing system.
8. The adequacy of circulation should be monitored by the continuous display of the electrocardiogram, and by determining the arterial blood pressure and heart rate (HR) at least every 5 minutes. During general anesthesia, circulatory function is to be continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.
9. During all anesthetics, the means for continuously measuring the patient's temperature must be available. Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

## Monitoring of Inspired Oxygen Concentration

### *Principles of Operation*

Oxygen is a highly reactive chemical species, providing many chemical and physical opportunities to detect its presence. Three main types of oxygen analyzer are seen in clinical practice: paramagnetic oxygen analyzers, galvanic cell analyzers, and polarographic oxygen analyzers.

 Paramagnetic gases are attracted to magnetic energy because of unpaired electrons in their outer shell orbits. Oxygen is a highly paramagnetic gas. Differential paramagnetic oximetry has been incorporated into a variety of operating room monitors. These instruments detect the change in sample line pressure resulting from the attraction of oxygen by switched magnetic fields. Signal changes during electromagnetic switching correlate with the oxygen concentration in the sample line.<sup>2</sup>

Galvanic cell analyzers meet the performance criteria necessary for operative monitoring. These analyzers measure the current produced when oxygen diffuses across a membrane and is reduced to molecular oxygen at the anode of an electrical circuit.<sup>3</sup> The electron flow (current) is proportional to the partial pressure of oxygen in the fuel cell. Galvanic cell analyzers require regular replacement of the galvanic sensor capsule. In the sensor, the electric potential for the reduction of oxygen results from a chemical reaction. Over time, the reactants require replenishment.<sup>4</sup>

Polarographic oxygen analyzers are commonly used in anesthesia

monitoring. In this electrochemical system, oxygen diffuses through an oxygen-permeable polymeric membrane and participates in the following reaction:  $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$ . The current change is proportional to the number of oxygen molecules surrounding the electrode. Polarographic oxygen sensors are versatile and are important components of gas machine oxygen analyzers, blood gas analyzers, and transcutaneous oxygen analyzers.<sup>5</sup>

### *Proper Use and Interpretation*

The concentration of oxygen in the anesthetic circuit must be measured. Anesthesia machine manufacturers place oxygen sensors on the inspired limb of the anesthesia circuit to detect and alarm in the event that hypoxic gas mixtures are delivered to the patient. Carbon dioxide may reduce the usable lifetime of a galvanic oxygen sensor, so it is preferable to place the oxygen sensor on the inspired limb. Oxygen monitors require a fast response time (2 to 10 seconds), accuracy ( $\pm 2\%$  of the actual level), and stability when exposed to humidity and inhalation agents.

The removable external oxygen sensors seen commonly on anesthesia machines, such as the Dräger Narkomed and Dräger Fabius (Dräger, Inc., Telford, PA) are of the galvanic type. These devices should be calibrated against room air (21% FiO<sub>2</sub>) daily, and also after 8 hours of use. These devices may also infrequently require calibration against 100% FiO<sub>2</sub>. As part of the preoperative checkout of the anesthesia machine, the clinician must confirm that the alarm limits of the inspired oxygen analyzer are set appropriately to alert to the presence of hypoxic mixtures. Inspired oxygen alarms cannot be relied upon to detect disconnection of the circuit.

### *Indications*

According to the ASA Standards for Basic Anesthesia Monitoring,<sup>1</sup> Standard 2.2.1 states, “During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.”

The careful monitoring of the inspired oxygen concentration is of particular significance during low-flow anesthesia, in which the anesthesiologist attempts to minimize the fresh gas flow to the amount of oxygen necessary to replace the patient’s metabolic utilization. The gas mixture within the breathing circuit may become hypoxic if insufficient fresh gas flow is supplied, even if the fresh gas flow itself comprises pure oxygen.

## Contraindications

The requirement to monitor inspired oxygen concentration may be waived by the responsible anesthesiologist under extenuating circumstances. There are no clinical contraindications to monitoring inspired oxygen concentration.

## Common Problems and Limitations

Adequate inspiratory oxygen concentration does not guarantee adequate arterial oxygen concentration.<sup>6</sup> Consequently, ASA<sup>1</sup> Standard 2.2.2 mandates additional monitoring for blood oxygenation, including the provision of adequate lighting and exposure to assess the patient's color by direct observation. The practice of pediatric anesthesia merits additional vigilance to monitoring inspired oxygen concentration. Indications for altering inspired oxygen concentrations to facilitate anesthetics in children are common; for example, using a nitrous oxide–oxygen blend to facilitate inhalation inductions of anesthesia. Increased awareness of fire hazards in the operating room environment further reinforces the need for careful monitoring of  $\text{FiO}_2$  in pediatric anesthesia. Tonsillectomy and adenoidectomy, among the most common of surgical procedures in the pediatric anesthesia population, carry an increased risk of airway fire. In addition to using of cuffed endotracheal tubes, careful monitoring and maintenance of a decreased inspired oxygen concentration whenever electrosurgical equipment is in use may decrease airway fire risk in these patients.<sup>7,8</sup>

## Monitoring of Arterial Oxygenation by Pulse Oximetry

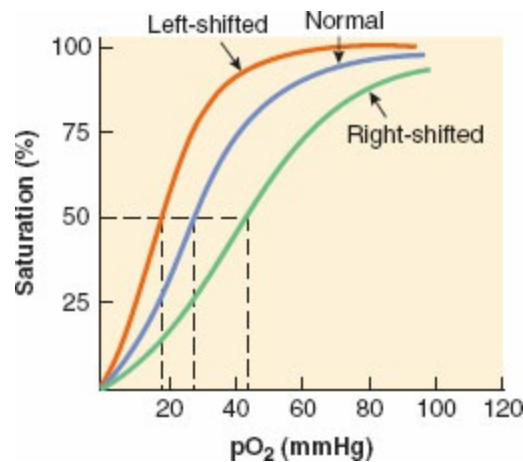

### Principles of Operation

 Pulse oximeters measure pulse rate and estimate the oxygen saturation of hemoglobin ( $\text{SPO}_2$ ) on a noninvasive, continuous basis.<sup>9</sup> The oxygen saturation ( $\text{SaO}_2$ ) of hemoglobin (as a percentage) is related to the oxygen tension (as a partial pressure, mmHg) by the oxyhemoglobin dissociation curve. On the steep part of the curve, a predictable correlation exists between  $\text{SaO}_2$  and partial pressure of oxygen ( $\text{PaO}_2$ ). In this range, the  $\text{SaO}_2$  is a good reflection of the extent of hypoxemia and the changing status of arterial oxygenation. For  $\text{PaO}_2$  greater than 75 mmHg, the  $\text{SaO}_2$  reaches a plateau and no longer reflects changes in  $\text{PaO}_2$ . Coexisting medical conditions, such as hypercapnia, acidosis, and hyperthermia, cause the oxyhemoglobin dissociation curve to shift to the right and decrease the affinity of hemoglobin for oxygen. This change favors the unloading of oxygen from hemoglobin to peripheral tissues, as shown in [Figure 26-1](#).

Pulse oximetry is based on the following premises:

1. The color of blood is a function of oxygen saturation.
2. The change in color results from the optical properties of hemoglobin and its interaction with oxygen.
3. The ratio of oxyhemoglobin (HbO<sub>2</sub>) and hemoglobin (Hb) can be determined by absorption spectrophotometry.

Oxygen saturation is determined by spectrophotometry, which is based on the Beer–Lambert law. At a constant light intensity and hemoglobin concentration, the intensity of light transmitted through a tissue is a logarithmic function of the oxygen saturation of Hb. Two wavelengths of light are required to distinguish HbO<sub>2</sub> from Hb. Light-emitting diodes in the pulse sensor emit red (660 nm) and near infrared (940 nm) light. The percentage of HbO<sub>2</sub> is determined by measuring the ratio of infrared and red light sensed by a photodetector. Pulse oximeters perform a plethysmographic analysis to differentiate the pulsatile “arterial” signal from the nonpulsatile signal resulting from “venous” absorption and other tissues, such as skin, muscle, and bone. The absence of a pulsatile waveform during extreme hypothermia or hypoperfusion can limit the ability of a pulse oximeter to calculate the SPO<sub>2</sub>.

**Figure 26-1** The oxyhemoglobin dissociation curve. The relationship between arterial saturation of hemoglobin and oxygen tension is represented by the sigmoid-shaped oxyhemoglobin dissociation curve. When the curve is left-shifted, the hemoglobin molecule binds oxygen more tightly. (Adapted from: Brown M, Vender JS. Noninvasive oxygen monitoring. *Crit Care Clin.* 1988;4:493–509.)

The SPO<sub>2</sub> measured by pulse oximetry is not the same as the arterial saturation (SaO<sub>2</sub>) measured by a laboratory co-oximeter. Pulse oximetry measures the “functional” saturation, which is defined by the following equation:

$$SPO_2 = \frac{HbO_2}{HbO_2 + Hb} \times 100\%$$

Laboratory co-oximeters use multiple wavelengths to distinguish other types of Hb, such as carboxyhemoglobin (COHb) and methemoglobin (MetHb) by their characteristic absorption. Co-oximeters measure the “fractional” saturation, which is defined by the following equation:

$$SaO_2 = \frac{HbO_2}{HbO_2 + Hb + COHb + MetHb} \times 100\%$$

In clinical circumstances in which other Hb moieties are present, the SPO<sub>2</sub> measurement may not correlate with the actual SaO<sub>2</sub> reported by the blood gas laboratory. For example, MetHb absorbs red and infrared wavelengths of light in a 1:1 ratio corresponding to a SPO<sub>2</sub> of approximately 85%. Therefore, increases in MetHb produce an underestimation when SPO<sub>2</sub> > 70% and an overestimation when SPO<sub>2</sub> < 70%. Similarly, COHb also produces artificially high and misleading results; one study showed that at 70% COHb, the SPO<sub>2</sub> still measured 90%. In most patients, MetHb and COHb are present in low concentrations so that the functional saturation approximates the fractional value.<sup>10</sup>

### *Proper Use and Interpretation*

The assessment of arterial oxygenation is an integral part of anesthesia practice. Early detection and prompt intervention may limit serious sequelae of hypoxemia. The clinical signs associated with hypoxemia (e.g., tachycardia, altered mental status, cyanosis) are often masked or difficult to appreciate during anesthesia.

The appropriate use of pulse oximetry necessitates an appreciation of both physiologic and technical limitations. Despite the numerous clinical benefits of pulse oximetry, other factors affect its accuracy and reliability. Factors that may be present during anesthesia care and that affect the accuracy and reliability of pulse oximetry include dyshemoglobins, dyes (methylene blue, indocyanine green, and indigo carmine), nail polish, ambient light, light-emitting diode variability, motion artifact, and background noise. Electrocautery can interfere with pulse oximetry if the radiofrequency emissions are sensed by the photodetector. Surgical stereotactic positioning systems that make use of infrared position sensors may interfere with the infrared signals used by the pulse oximeter. Reports of burns or pressure necrosis exist but are infrequent. Inspecting the digits during monitoring can reduce these complications.

Recent developments in pulse oximetry technology reportedly may permit more accurate measurements of SPO<sub>2</sub> during patient movement, low-perfusion conditions, and in the presence of dyshemoglobins. Some of these instruments

use complex signal processing of the two wavelengths of light to improve the signal-to-noise ratio and reject artifact. Studies in volunteers suggest that the performance of pulse oximeters incorporating this technology is superior to conventional oximetry during motion of the hand, hypoperfusion, and hypothermia.<sup>11,12</sup> Other pulse oximetry devices incorporate eight wavelengths of light to more accurately measure COHb and MetHb.<sup>10</sup>

## **Indications**

Pulse oximetry has been used in all patient age groups to detect and prevent hypoxemia. The clinical benefits of pulse oximetry are enhanced by its simplicity. Modern pulse oximeters are noninvasive, continuous, and autocalibrating. They have quick response times and their battery backup provides monitoring during transport. The clinical accuracy is typically reported to be within  $\pm 2\%$  to  $3\%$  at  $70\%$  to  $100\%$  saturation and  $\pm 3\%$  at  $50\%$  to  $70\%$  saturation. Published data from numerous investigations support accuracy and precision reported by instrument manufacturers. Quantitative assessment of arterial oxygen saturation is mandated by the ASA monitoring standards,<sup>1</sup> and the convenience and safety of pulse oximetry has supplanted earlier techniques such as heated transcutaneous pO<sub>2</sub> electrodes.<sup>13</sup>

Pulse oximetry has wide applicability in many hospital and nonhospital settings. However, there are no definitive data demonstrating a reduction in morbidity or mortality associated with the advent of pulse oximetry. An older large randomized trial did not detect a significant difference in postoperative complications when routine pulse oximetry was used.<sup>14</sup> However, a reduction of anesthesia mortality, as well as fewer malpractice claims from respiratory events, coincident with the introduction of pulse oximeters suggests that the routine use of these devices may have been a contributing factor.

## **Contraindications**

There are no clinical contraindications to monitoring arterial oxygen saturation with pulse oximetry.

## **Common Problems and Limitations**

Arterial oxygen monitors do not ensure adequacy of oxygen delivery to, or utilization by, peripheral tissues and should not be considered a replacement for arterial blood gas measurements or mixed central venous oxygen saturation when more definitive information regarding oxygen supply and utilization is required.

**3** Pulse oximetry is a poor indicator of adequate ventilation; patients who have been breathing supplemental oxygen may be apneic for several minutes before desaturation is detected by the pulse oximeter. Once the PaO<sub>2</sub> has fallen sufficiently to cause a detectable decrease in SPO<sub>2</sub>, further desaturation may occur precipitously once the steep part of the oxyhemoglobin dissociation curve is reached.

Placing and obtaining reliable data from blood pressure cuffs and electrocardiogram leads may be challenging in an awake and vigorous child prior to inhalation induction. Therefore, at a minimum, efforts should be made to place a pulse oximetry device on the child or infant prior to induction of anesthesia. Pulse oximetry has also been shown to be a more sensitive monitor than capnography for unrecognized main-stem/endobronchial intubation in pediatric anesthesia.<sup>15</sup> Respiratory events leading to inadequate ventilation and oxygenation represent the majority of perianesthetic morbidity in the pediatric anesthesia population. In conjunction with vigilant clinical assessment of the child's airway and oxygenation, the pulse oximeter usually provides the most important indicator of patient well-being during pediatric anesthesia.<sup>16</sup> Stress caused by hypoxemia and respiratory acidosis in infants and young children triggers a vagal response and subsequent systemic hypoperfusion. Infants cannot adequately increase their cardiac stroke volume (SV) in compensation and so, according to the cardiac output (CO) equation:

$$\text{Cardiac Output} = \text{Heart Rate} \times \text{Stroke Volume}$$

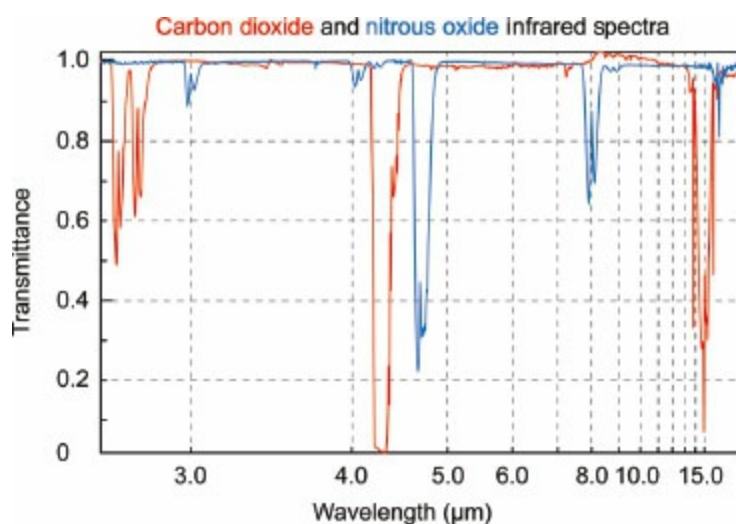

Therefore, in infants, CO must be maintained with an increase over their baseline HR. A decline in the pitch or rapidity of pulse oximetry tones may be the first signs of impending cardiovascular collapse.

## Monitoring of Expired Gases

### *Principles of Operation*

The patient's expired gas is likely to be composed of a mixture of oxygen (O<sub>2</sub>), nitrogen (NO<sub>2</sub>), carbon dioxide (CO<sub>2</sub>), and anesthetic gases such as nitrous oxide (N<sub>2</sub>O) and highly potent halogenated agents (sevoflurane, isoflurane, or desflurane). Anesthesiologists have long sought to measure the composition of expired gases noninvasively and in real time; these measurements can provide vital information regarding the patient's respiratory condition and assist in the titration of volatile anesthetic agents. Early anesthetic gas detectors were based simply on the change in elastance of rubber strips exposed to the circulating gas.<sup>17</sup> Later methods made use of Raman scattering<sup>18</sup> or multiplexed mass spectrometry.<sup>19</sup>

These techniques have now all been supplanted in clinical practice by infrared absorption spectrophotometry (IRAS). Asymmetric, polyatomic molecules like CO<sub>2</sub> absorb infrared light at specific wavelengths. By transmitting light through a pure sample of a known gas over the range of infrared frequencies, a unique infrared transmission spectrum (like a fingerprint) can be created for the gas. CO<sub>2</sub>, for example, strongly absorbs infrared light with a wavelength of 4.3 microns, as shown in Figure 26-2. At this wavelength, there is minimal interference from other gases that may also be present, such as water vapor, O<sub>2</sub>, N<sub>2</sub>O, and inhaled anesthetic agents. Infrared light at this wavelength can be passed through a sample of gas to an infrared detector. As the concentration of CO<sub>2</sub> increases, the intensity of the light that reaches the detector decreases in accordance with the Beer–Lambert law.

**Figure 26-2** Gaseous-phase infrared transmission spectrum for carbon dioxide and nitrous oxide. (Modified from the National Institute of Standards and Technology (<http://www.nist.gov>); and Craver CD, Coblenz Society. The Coblenz Society desk book of infrared spectra. 2nd ed. Kirwood, MO: The Society; 1982.)

IRAS devices have five components: a multiple-wavelength infrared light source, a gas sampler, an optical path, a detection system, and a signal processor. Operating room IRAS devices can detect CO<sub>2</sub>, N<sub>2</sub>O, and the potent inhaled anesthetic agents as mixed together in a sample of the patient's expired gas. The gas mixture is passed through the optical path of multiple infrared beams whose wavelengths are chosen to correspond to key features in the transmission spectra of the gases of interest. By analyzing the combination of absorption of infrared light at these wavelengths, the presence and concentrations of all of these gases can be determined simultaneously.<sup>20</sup> The use of multiple wavelengths allows the gases to be identified automatically. Older IRAS devices used a hot electrical element to generate radiant infrared light over a broad range of wavelengths. An optical filter

wheel was then used to cut out all but the desired wavelengths. **4** Contemporary devices make use of small lasers and filters, designed such that they emit only at the desired wavelengths. This approach consumes much less electrical power, is physically less heavy, and has led to the development of conveniently portable handheld gas analyzers.<sup>21</sup>

### Proper Use and Interpretation

Expired gas analysis allows the clinician to monitor inspired and expired concentrations of CO<sub>2</sub> and anesthetic gases simultaneously. These measurements require separate clinical interpretation. Critical events that can be detected by the analysis of respiratory gases and anesthetic vapors are listed in [Table 26-1](#).

### Interpretation of Inspired and Expired Carbon Dioxide Concentrations

Capnometry is the measurement and numeric representation of the CO<sub>2</sub> concentration during inspiration and expiration. A capnogram is a continuous concentration–time display of the CO<sub>2</sub> concentration sampled at a patient’s airway during ventilation. The capnogram is divided into four distinct phases, as shown in [Figure 26-3](#). 

**Table 26-1** Detection of Critical Events by Implementing Gas Analysis

Event	Gas Measured by Analyzer
Error in gas delivery	O <sub>2</sub> , N <sub>2</sub> , CO <sub>2</sub> , agent analysis
Anesthesia machine malfunction	O <sub>2</sub> , N <sub>2</sub> , CO <sub>2</sub> , agent
Disconnection	CO <sub>2</sub> , O <sub>2</sub> , agent analysis
Vaporizer malfunction or contamination	Agent analysis
Anesthesia circuit leaks	N <sub>2</sub> , CO <sub>2</sub> analysis
Endotracheal cuff leaks	N <sub>2</sub> , CO <sub>2</sub>
Poor mask or LMA fit	N <sub>2</sub> , CO <sub>2</sub>
Hypoventilation	CO <sub>2</sub> analysis
Malignant hyperthermia	CO <sub>2</sub>
Airway obstruction	CO <sub>2</sub>
Air embolism	CO <sub>2</sub> , N <sub>2</sub>
Circuit hypoxia	O <sub>2</sub> analysis
Vaporizer overdose	Agent analysis

LMA, laryngeal mask airway.

Modified from Knopes KD, Hecker BR. Monitoring anesthetic gases.

In: Lake CL, ed. *Clinical Monitoring*. Philadelphia, PA: WB Saunders; 1990:24, with permission.

**Figure 26-3** The normal capnogram. Point D delineates the end-tidal  $\text{CO}_2$  ( $\text{ETCO}_2$ ).  $\text{ETCO}_2$  is the best reflection of the alveolar  $\text{CO}_2$  partial pressure.

The first phase (A–B) represents the initial stage of expiration. Gas sampled during this phase occupies the anatomic dead space and is normally devoid of  $\text{CO}_2$ . At point B,  $\text{CO}_2$ -containing gas presents itself at the sampling site and a sharp upstroke (B–C) is seen in the capnogram. The slope of this upstroke is determined by the evenness of expiratory ventilation and alveolar emptying. Phase C–D represents the alveolar or expiratory plateau. At this phase of the capnogram, alveolar gas is being sampled. Normally, this part of the waveform is almost horizontal. However, when ventilation and perfusion are mismatched, Phase C–D may take an upward slope. Point D is the highest  $\text{CO}_2$  value and is called the end-tidal  $\text{CO}_2$  ( $\text{ETCO}_2$ ).  $\text{ETCO}_2$  is the best reflection of the alveolar  $\text{CO}_2$  ( $\text{PACO}_2$ ). As the patient begins to inspire, fresh gas is entrained and there is a steep downstroke (D–E) back to baseline. Unless rebreathing of  $\text{CO}_2$  occurs, the baseline approaches zero. If the  $\text{PACO}_2$ – $\text{PaCO}_2$  gradient is constant and small, capnography provides a noninvasive, continuous, real-time reflection of ventilation. The  $\text{ETCO}_2$ – $\text{PaCO}_2$  gradient typically is around 5 mmHg during routine general anesthesia in otherwise healthy supine patients.

The size and shape of the capnogram waveform can provide additional clinical information.<sup>22</sup> A slow rate of rise of the second phase (B–C) is suggestive of either chronic obstructive pulmonary disease or acute airway obstruction as from bronchoconstriction (asthma) secondary to mismatch in alveolar ventilation and alveolar perfusion. A normally shaped capnogram with an increase in  $\text{ETCO}_2$  suggests alveolar hypoventilation or an increase in  $\text{CO}_2$  production. Transient increases in  $\text{ETCO}_2$  are often observed during tourniquet release, aortic unclamping, or the administration of bicarbonate.

Capnography is an essential element in determining the appropriate placement of endotracheal tubes. The presence of a stable  $\text{ETCO}_2$  for three successive breaths indicates that the tube is not in the esophagus. A continuous stable  $\text{CO}_2$  waveform ensures the presence of alveolar ventilation but does not necessarily indicate that the endotracheal tube is properly positioned in the trachea. An endobronchial intubation, in which the tip of the tube is located in a main stem bronchus, cannot be ruled out until breath sounds are auscultated bilaterally. A continuous  $\text{CO}_2$  tracing also does not

guarantee that the endotracheal tube is placed securely; an endotracheal tube placed proximally to the vocal cords may still produce an otherwise satisfactory tracing until it becomes dislodged.

A sudden drop in  $\text{ETCO}_2$  to near zero followed by the absence of a  $\text{CO}_2$  waveform heralds a potentially life-threatening problem that could indicate malposition of an endotracheal tube into the pharynx or esophagus, sudden severe hypotension, massive pulmonary embolism, a cardiac arrest, or a disconnection or disruption of sampling lines. When a sudden drop of the  $\text{ETCO}_2$  occurs, it is essential to quickly verify that there is pulmonary ventilation and to identify physiologic and mechanical factors that might account for the  $\text{ETCO}_2$  of zero. During life-saving cardiopulmonary resuscitation, the generation of adequate circulation can be assessed by the restoration of the  $\text{CO}_2$  waveform.

Whereas abrupt decreases in the  $\text{ETCO}_2$  are often associated with an altered cardiopulmonary status (e.g., embolism or hypoperfusion), gradual reductions in  $\text{ETCO}_2$  more often reflect decreases in  $\text{PaCO}_2$  that occur when there exists an imbalance between minute ventilation and metabolic rate (i.e.,  $\text{CO}_2$  production), as commonly occurs during anesthesia at a fixed minute ventilation. Increases in  $\text{ETCO}_2$  can be expected when  $\text{CO}_2$  production exceeds ventilation, such as in hyperthermia or when an exogenous source of  $\text{CO}_2$  is present. Capnographic waveforms that do not return to zero during inspiration indicate rebreathing of  $\text{CO}_2$ . This nonzero inspiration phase can occur if the  $\text{CO}_2$  absorber in an anesthesia machine is chemically exhausted, if a valve in the ventilator circuit is not functioning properly, or if the flow of fresh gas is insufficient. An elevated baseline can also be seen if the device is calibrated incorrectly.

Alterations in ventilation,  $\text{CO}$ , distribution of pulmonary blood flow, and metabolic activity influence end-tidal  $\text{CO}_2$  concentration and the capnogram obtained during quantitative expired gas analysis. [Table 26-2](#) summarizes the common elements that may be reflected by changes in  $\text{ETCO}_2$  during anesthesia care.

## **Interpretation of Inspired and Expired Anesthetic Gas Concentrations**

Monitoring the concentration of expired anesthetic gases assists the anesthesiologist in titrating those gases to the clinical circumstances of the patient. At high fresh-gas flow rates, the concentration of an anesthetic gas in a circle breathing system will approximate the concentration set on the vaporizer. However, high fresh-gas flow rates lead to wasteful use of anesthetic vapor. As the fresh-gas flow rate is lowered, the concentration within the circuit and the concentration set at the vaporizer can become more decoupled. Inspired and expired gas concentration monitoring allows the

anesthesiologist to maintain satisfactory and well-controlled agent levels in the circuit even when extremely low fresh-gas flows are used. In an ideal, leak-free anesthesia system, the fresh-gas flow can be minimized to only the amount of pure oxygen necessary to replace the patient’s metabolic utilization—a practice known as “closed-circuit anesthesia.” This practice makes the most economic use of potent anesthetic vapor.<sup>23</sup>

**Table 26-2** Factors That May Change End-Tidal CO<sub>2</sub> (ETCO<sub>2</sub>) during Anesthesia

Increases in ETCO <sub>2</sub>	Decreases in ETCO <sub>2</sub>
<i>Elements that Change CO<sub>2</sub> Production</i>	
Increases in metabolic rate	Decreases in metabolic rate
Hyperthermia	Hypothermia
Sepsis	Hypothyroidism
Malignant hyperthermia	
Shivering	
Hyperthyroidism	
<i>Elements that Change CO<sub>2</sub> Elimination</i>	
Hypoventilation	Hyperventilation
Rebreathing	Hypoperfusion
	Pulmonary embolism

Anesthetic gases have differing potencies; thus, their concentrations are often normalized against the concentration of that agent required to produce a predetermined clinical end point. The most commonly used end point is the minimum alveolar concentration (MAC) value, defined as the end-tidal gas concentration that when maintained constant for 15 minutes at a pressure of one atmosphere, inhibits movement in response to a midline laparotomy incision in 50% of patients.<sup>24,25</sup> Historically, MAC is an acronym for *minimum alveolar concentration*, although it is more accurately a median constant end-tidal partial pressure. Monitoring of end-tidal gas concentrations performed with reference to MAC values helps to prevent the occurrence of intraoperative awareness and in some studies was superior to the use of processed electroencephalogram (EEG) monitors.<sup>26</sup>

### Indications

Monitoring of the partial pressure of expiratory CO<sub>2</sub> has evolved into an important physiologic and safety monitor. Capnography is the standard of care for monitoring the adequacy of ventilation in patients receiving general anesthesia. It is also now mandated for use in monitoring ventilation during procedures performed while the patient is under moderate or deep sedation.<sup>1</sup>

### Contraindications

There are no contraindications to the use of capnography, provided that the data obtained are evaluated in the context of the patient's clinical circumstances. It is generally safe to use capnography for the monitoring of all patients.

Monitoring of expired anesthetic gases is only informative if detectable gases are used to maintain anesthesia. Infrared spectroscopy cannot detect Xenon, and is not informative if anesthesia is maintained using a total intravenous technique.

### *Common Problems and Limitations*

The sampling lines or water traps of expired gas analyzers may become occluded with condensed water vapor during prolonged use.  Disconnecting the sampling line and flushing it with air from a syringe can sometimes clear it, but it may be necessary to replace these components. Elevating the sidestream sampling line above the ventilator circuit helps prevent the entry of condensed water. A humidity barrier is also useful, although this will increase the response time of the capnogram.

Although mass spectroscopy and Raman scattering are no longer seen in clinical practice, these technologies are able to detect the concentration of N<sub>2</sub> directly. Nitrogen monitoring provides quantification of washout during preoxygenation. A sudden rise in N<sub>2</sub> in the exhaled gas indicates either introduction of air from leaks in the anesthesia delivery system or venous air embolism. Infrared gas analyzers do not detect N<sub>2</sub> directly and its concentration must be inferred as the amount remaining after other measurable gases are accounted for.

Although capnography provides a quantitative measurement of ETCO<sub>2</sub>, it is not as accurate as blood gas analysis for the assessment of the partial pressure of arterial carbon dioxide. A gradient exists between the partial pressure of arterial carbon dioxide and ETCO<sub>2</sub>; this gradient increases as the dead-space volume increases. In disease states characterized by increased dead space and ventilation–perfusion mismatch, such as emphysema or pulmonary embolism, or in iatrogenic single-lung ventilation or in very low CO states, an arterial blood gas analysis is necessary for an accurate determination of the partial pressure of arterial carbon dioxide.

Younger children desaturate rapidly following apnea, largely due to increased oxygen consumption and a smaller ratio of functional residual capacity (FRC) to closing volume.<sup>27</sup> Hypoxemia may precipitate a hypoperfusing bradycardic state, especially in neonates. Capnography's role in early recognition of apnea via a sudden drop or newly absent CO<sub>2</sub> signal makes it particularly valuable in pediatric anesthesia. Endotracheally intubated neonates, particularly very-low-birthweight infants in neonatal

intensive care units, present unique challenges to accurate measurement of exhaled CO<sub>2</sub>. These infants are typically intubated with cuffless endotracheal tubes. A cuffless tube permits a larger internal diameter, which reduces resistance to flow and work-of-breathing, but also allows leakage of expired gases. Capnography measurements therefore become more likely to underestimate actual end-tidal CO<sub>2</sub> levels.<sup>28</sup>

Sidestream capnography systems are the most commonly utilized in the operating room. Sidestream sampling units suction up to 200 mL/min out of the breathing circuit, diverting this to a remote sensor where the gas is analyzed.<sup>29</sup> Given that the neonatal minute ventilation is normally 200 to 300 mL/kg/min, sidestream sampling rates can approach and even surpass the minute ventilation of premature infants. In neonates, sidestream capnography systems may report erroneously low end-tidal CO<sub>2</sub> levels since the capnography system may be sampling gas that never actually participated in ventilation.<sup>30</sup> The true end-tidal CO<sub>2</sub> has been erroneously diluted by fresh gas. Newer, low-flow sidestream capnography systems have since been developed to address this problem.<sup>31</sup> Because most anesthesia machines in the operating room are used with common higher-flow sidestream capnography devices, additional care must be taken when providing general endotracheal anesthesia for infants. In a neonate, an apparently normal ETCO<sub>2</sub> on the monitor may in fact represent inadequate ventilation, which would predispose the patient to respiratory acidemia.

## Invasive Monitoring of Systemic Blood Pressure

### *Principles of Operation*

 Indwelling arterial cannulation permits the opportunity to monitor arterial blood pressure continuously and to have vascular access for arterial blood sampling. Intra-arterial blood pressure monitoring uses fluid-filled tubing to transmit the force of the pressure pulse wave to a pressure transducer that converts the displacement of a silicon crystal into voltage changes. These electrical signals are amplified, filtered, and displayed as the arterial pressure trace. Intra-arterial pressure-transducing systems are subject to many potential errors based on the physical properties of fluid motion and the performance of the catheter–transducer–amplification system used to sense, process, and display the pressure pulse wave.

The behavior of transducers, fluid couplings, signal amplification, and display systems can be described by a complex second-order differential equation. Solving the equation predicts the output and characterizes the fidelity of the system's ability to faithfully display and estimate the arterial pressure over time. The fidelity of fluid-coupled transducing systems is

constrained by two properties: *damping* ( $\zeta$ ) and *natural frequency* ( $f_n$ ). Zeta ( $\zeta$ ) describes the tendency for fluid in the measuring system to extinguish motion and  $f_n$  describes the frequency at which the measuring system is most prone to resonance. The fidelity of the transduced pressure depends on optimizing  $\zeta$  and  $f_n$  so that the system can respond appropriately to the range of frequencies contained in the pressure pulse wave. Analysis of high-fidelity recordings of arterial blood pressure indicates that the pressure trace contains frequencies from 1 to 30 Hz. The “fast flush” test is a method used at the bedside to determine the natural frequency and damping characteristics of the transducing system. This test examines the characteristics of the resonant waves recorded after the release of a flush tail. Damping is estimated by the amplitude ratio of the first pair of resonant waves and the natural frequency is estimated by dividing the tracing speed by the interval cycle.<sup>32</sup>

### *Proper Use and Interpretation*

Multiple arteries can be used for direct measurement of blood pressure, including the radial, brachial, axillary, femoral, and dorsalis pedis arteries (Table 26-3). The radial artery remains the most popular site for cannulation because of its accessibility and the presence of a collateral blood supply. In the past, assessment of the patency of the ulnar circulation by performance of an Allen test has been recommended before cannulation. An Allen test is performed by compressing both radial and ulnar arteries while the patient tightens his or her fist. Releasing pressure on each respective artery determines the dominant vessel supplying blood to the hand. The prognostic value of the Allen test in assessing the adequacy of the collateral circulation has not been confirmed.<sup>33,34</sup>

Three techniques for cannulation are common: direct arterial puncture, guidewire-assisted cannulation (Seldinger technique), and the transfixion-withdrawal method.<sup>35</sup> A necessary condition for percutaneous placement is identification of the arterial pulse, which may be enhanced by a Doppler flow detection device in patients with poor peripheral pulses.<sup>36</sup>

 Ultrasound imaging with Doppler color flowmetry can provide valuable further assistance when the pulse is difficult to locate or the caliber of the vessel appears to be small.<sup>37</sup>

**Table 26-3** Arterial Cannulation and Direct Blood Pressure Monitoring

Arterial Cannulation Site	Clinical Points of Interest
Radial artery	Preferred site for monitoring Nontapered catheters preferred
Ulnar artery	Complication similar to radial Primary source of hand blood flow
Brachial artery	Insertion site medial to biceps tendon Median nerve damage is potential hazard Can accommodate 18-gauge cannula
Axillary artery	Insertion site at junction of pectoralis and deltoid muscles Specialized kits available
Femoral artery	Easy access in low-flow states Potential for local and retroperitoneal hemorrhage Longer catheters preferred
Dorsalis pedis artery	Collateral circulation = posterior tibial artery Higher systolic pressure estimates

Arterial blood pressure transduction systems must be “zeroed” before use.

 The transducer is positioned at the same level as the right atrium, the stopcock is opened to the atmosphere so that the pressure-sensing crystal senses only atmospheric pressure, and the “Zero Sensor” (or equivalent) option is selected on the monitoring equipment. This procedure establishes the calibration of the sensor and establishes the level of the right atrium as the datum reference point. For neurosurgical procedures in which the patient may be positioned in an upright or beach-chair position, it is common practice to zero the transducer at the level of the Circle of Willis so that the arterial pressure tracing provides a reading that is adjusted for the height of the fluid column between the heart and the brain; it represents the arterial pressure at the base of the brain.

Direct arterial pressure monitoring requires constant vigilance. The data displayed must correlate with clinical conditions before therapeutic interventions are initiated. Sudden increases in the transduced blood pressure may represent a hydrostatic error because the position of the transducer was not adjusted after change in the operating room table’s height. Sudden decreases often result from kinking of the catheter or tubing. Before initiating therapy, the transducer system should be examined quickly and the patency of the arterial cannula verified. This ensures the accuracy of the measurement and avoids the initiation of a potentially dangerous medication error.

Traumatic cannulation has been associated with hematoma formation,  thrombosis, and damage to adjacent nerves. Abnormal radial artery

blood flow after catheter removal occurs frequently. Studies suggest that blood flow normalizes in 3 to 70 days. Radial artery thrombosis can be minimized by using small catheters, avoiding polypropylene-tapered catheters, and reducing the duration of arterial cannulation. Flexible guidewires may reduce the potential trauma associated with catheters negotiating tortuous vessels. After arterial cannulation has been performed, the tissues that are perfused by that artery should be examined intermittently for signs of thromboembolism or ischemia. During cannula removal, the potential for thromboembolism may be diminished by compressing the proximal and distal arterial segment while aspirating the cannula during withdrawal.

## **Indications**

The standards for basic monitoring<sup>1</sup> stipulate that arterial blood pressure shall be determined and recorded at least every 5 minutes. This standard is usually met by intermittent, noninvasive blood pressure monitoring. However, continuous monitoring may be indicated by patient comorbidities or by the nature of the surgery to be performed.

Arterial catheters provide continuous monitoring of blood pressure and convenient vascular access to obtain blood samples for laboratory assays, including blood gas analysis to assess respiratory function. Placement of an arterial catheter can therefore be indicated by the need for any of these capabilities:

- 1. Rapid changes in blood pressure or extremes of blood pressure are anticipated.**

High-risk vascular surgeries, trauma surgeries, neurosurgical procedures, and intrathoracic and cardiac procedures are associated with the risk of sudden blood loss and rapid changes in blood pressure. These procedures may also involve periods of deliberate hypotension or hypertension.

- 2. The ability of the patient to tolerate hemodynamic instability is impaired.**

Patients with clinically significant cardiac disease, such as coronary artery disease, valvular disease, or heart failure, may require continuous monitoring in order to allow treatment for hypotension to be implemented rapidly and minimize the risk of coronary ischemia. Similar concerns apply to patients with a history of cerebrovascular disease. Procedures that involve potential compromise to the vascular supply of the spinal cord indicate the use of an arterial catheter to maintain adequate perfusion and decrease the risk of postoperative paraplegia from spinal cord infarction.<sup>38</sup>

Critically ill patients may already be hemodynamically unstable at the time of presentation, and require the administration of inotropes and vasopressors. Continuous blood pressure monitoring is indicated to manage the titration of these agents.

**3. Compromise of the patient's respiratory function, oxygenation, or ventilation is anticipated.**

Mismatch between pulmonary ventilation and perfusion will impair the ability of end-tidal CO<sub>2</sub> to predict P<sub>ACO<sub>2</sub></sub>. This variance may arise iatrogenically during procedures that require single-lung ventilation. Patients may present with pulmonary comorbidities, such as ARDS, pulmonary embolism, and pulmonary hypertension with consequent ventilation–perfusion mismatch and impaired alveolar diffusion. Arterial catheters provide a means to obtain arterial blood gas samples frequently to assess changes in respiratory function.

**4. Metabolic derangements are anticipated.**

Surgical procedures that are anticipated to produce large-volume fluid shifts may indicate the placement of an arterial catheter to enable laboratory samples to be drawn frequently and to allow electrolyte and acid–base disturbances to be detected and corrected.

## Contraindications

Arterial cannulation is regarded as an invasive procedure with documented morbidity. Ischemia after radial artery cannulation resulting from thrombosis, proximal emboli, or prolonged shock has been described.<sup>39</sup> Contributing factors include severe atherosclerosis, diabetes, low CO, and intense peripheral vasoconstriction. Ischemia, hemorrhage, thrombosis, embolism, cerebral air embolism (retrograde flow associated with flushing), aneurysm formation, arteriovenous fistula formation, skin necrosis, and infection have reportedly occurred as the direct result of arterial cannulation, arterial blood sampling, or high-pressure flushing. Patients with compromised collateral arterial supply, such as those with Reynaud phenomenon or thromboangiitis obliterans (Buerger disease), are at increased risk for ischemic complications.<sup>35</sup>

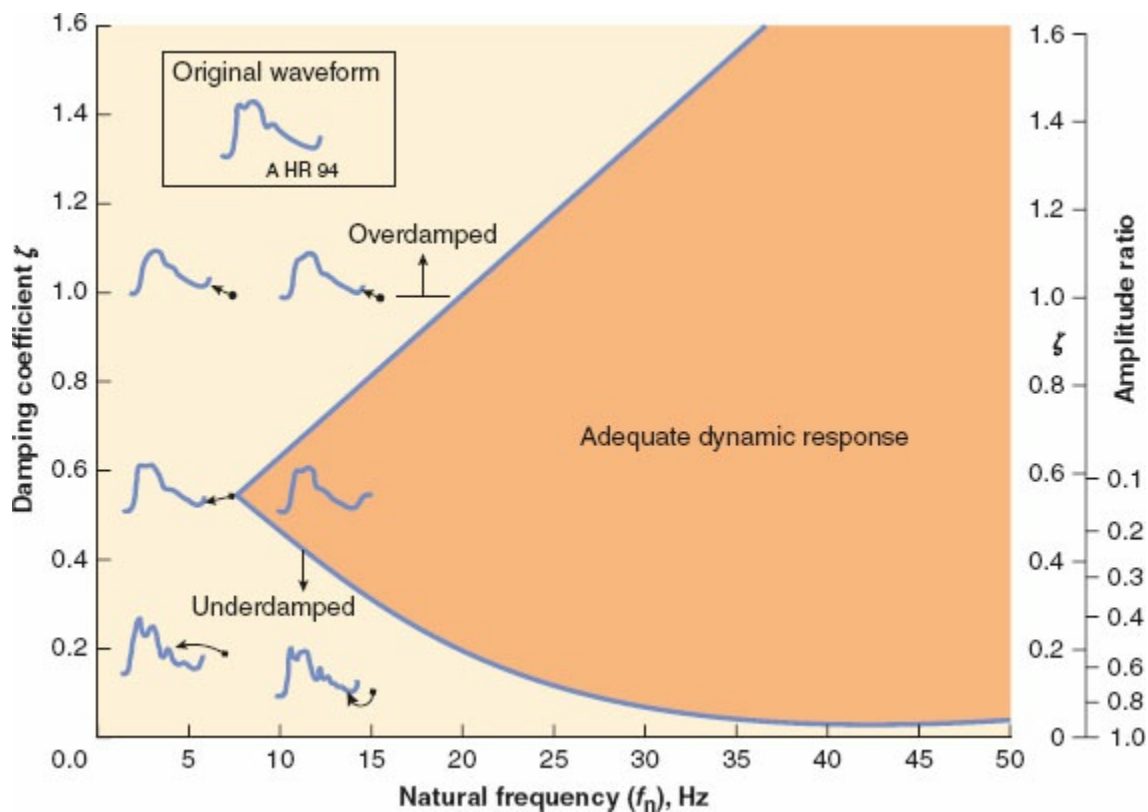

10

## Common Problems and Limitations

The fidelity of the transducer system is optimized when catheters and tubing are stiff, the mass of the fluid is small, the number of stopcocks is limited, and the connecting tubing is not excessive. **Figure 26-4** demonstrates the effect of damping on the character of the arterial pressure trace. In clinical practice, underdamped transducer systems tend to overestimate the

5

systolic pressure by 15 to 30 mmHg and amplify artifacts. Likewise, excessive increases in  $\zeta$  reduce fidelity and underestimate systolic pressure.

**Figure 26-4** The relationship between the frequency of fluid-filled transducing systems and damping. The shaded area represents the appropriate range of damping for a given natural frequency ( $f_n$ ). The size of the wedge also depends on the steepness of the arterial pressure trace and heart rate. (Adapted from Gardner RM. Direct blood pressure measurement—dynamic response requirements. *Anesthesiology*. 1981;54:227–236.)

Continuous-flush devices are incorporated into disposable transducer kits and infuse at 3 to 6 mL/hour. In neonates, the infusion volume may contribute to fluid overload. Continuous-flush devices have little effect on the blood pressure measurement. However, pressurized flush systems may serve as a source of an air embolism. Removing air from the pressurized infusion bag, stopcocks, and tubing minimizes the potential for air embolism.

A satisfactory Allen test does not rule out the possibility of formation of thrombus on the catheter and subsequent distal embolic complications. Although an intact palmar arch will provide some collateralization of arterial blood supply to the hand, this does not protect against emboli to the distal digital arteries.<sup>40</sup>

Invasive blood pressure monitoring in the pediatric population presents unique challenges for the anesthesiologist. Smaller-caliber arteries, lower circulating blood volume, and a closer anatomic proximity of peripheral vessels to the great vessels, the heart, and the cerebral circulation combine to

make line placement more technically difficult and make line maintenance more hazardous. Three of the more common sites of arterial blood pressure monitoring in pediatric and neonatal anesthesia are the umbilical artery, the radial artery, and the femoral artery.

In critically ill newborn infants, the umbilical artery represents a convenient site for catheterization in order to measure arterial blood pressure and for blood sampling for laboratory values. Attaining access may require a cutdown procedure on the umbilical arteries.<sup>41</sup> Arterial catheters at this site carry a risk of aortic thrombosis and have been implicated in the development of other aortic complications, including coarctation; thus, these should be removed as soon as they are no longer necessary for patient care.<sup>42,43</sup>

The use of smaller catheters (i.e., 22 g, or even 24 g) for radial arterial catheterization in pediatric patients has been established as safe for invasive blood pressure monitoring in young patients, including children under 1 year of age. Preemptive use of ultrasound in radial artery cannulation may increase first-pass success and decrease iatrogenic injury in children.<sup>44–46</sup>

Femoral arterial lines have also been used extensively in critically ill infants and children, with high rates of success and low complication rates.<sup>47</sup> Though rare, complications including hematoma, minor bleeding, and AV fistula formation may occur.<sup>48</sup> Young children (age <3 years) are at increased risk of pediatric groin line complications requiring surgical intervention.<sup>49</sup> Routine use of ultrasound guidance in pediatric groin line placement decreases these risks.<sup>50</sup>

Practices commonly accepted in arterial line management and maintenance in adults may prove hazardous in pediatric patients. Arterial line flushing should be kept to a minimum, particularly in the care of smaller children and infants, to reduce the risk of volume overload and inadvertent hemodilution. High-pressure flushing should not be attempted in efforts to restore function to an apparently occluded indwelling arterial catheter. It is best to clear the line by hand with a small syringe, using the minimum pressure and volume necessary, as even small-volume flushes (0.5 to 1 mL) injected into the radial arteries of small infants using automated pressurizing systems may cause retrograde flow into the cerebral vessels.<sup>51–55</sup> Due to heightened risk of thromboembolism, blood removed in the process of arterial line sampling should only be returned to the patient intravenously (not arterially). Meticulous care must be taken to ensure that all arterial line tubing is tightened securely to prevent hemorrhage from line disconnection.

## **Intermittent Noninvasive Monitoring of Systemic Blood Pressure**

### *Principles of Operation*

The simplest method of blood pressure determination estimates systolic blood pressure by palpating the return of an arterial pulse while a more proximal occluding cuff is deflated. Modifications of this technique include the observance of the return of Doppler sounds, the transduced arterial pressure trace, or a photoplethysmographic pulse wave as produced by a pulse oximeter.

Auscultation of the Korotkoff sounds permits estimation of both systolic (SP) and diastolic (DP) blood pressures. Korotkoff sounds result from turbulent flow within an artery created by the mechanical deformation from the blood pressure cuff. SP is signaled by the appearance of the first Korotkoff sound. Disappearance of the sound or a muffled tone signals the DP. The mean arterial pressure (MAP) can be calculated using an estimating equation:

$$\text{MAP} = \text{DP} + (\text{SP} - \text{DP})/3$$

In contemporary practice, automated noninvasive blood pressure monitors (also known as automated sphygmomanometers) employ the oscillometric method<sup>56</sup> to estimate the arterial blood pressure. The oscillometric method uses an occluding cuff to measure the pressure fluctuations that occur due to arterial pulsations. The SP is estimated using the maximum cuff pressure at which pressure oscillations can be perceived. The MAP is estimated by the **6** cuff pressure at which the amplitude of the oscillations is greatest. The DP is estimated using the minimum cuff pressure at which pressure fluctuations can be perceived. Some automated noninvasive blood pressure monitors refine these estimates using proprietary, empirical formulae<sup>57</sup>; thus, results may not be consistent from device to device.<sup>58</sup> The operation of automated blood pressure cuffs is covered by US<sup>59</sup> and international<sup>60</sup> standards.

### *Proper Use and Interpretation*

In the anesthetized patient, automated oscillometry is usually accurate and versatile. A variety of cuff sizes makes it possible to use oscillometry in all age groups. Different strategies of cuff inflation and deflation may be used to obtain blood pressure measurements. A common approach, as shown in [Figure 26-5](#), is for the cuff to be rapidly inflated to a predetermined initial pressure expected to be above SP. A sensor checks to ensure that pressure fluctuations **11** are not present. The cuff is then decrementally deflated. At each interval, the sensor measures the magnitude of oscillations that are present in the cuff pressure. Once the cuff pressure falls below the point at which oscillations can be detected, the cuff is rapidly and completely deflated.

**Figure 26-5** Sequence of oscillometric blood pressure determination. The pressure oscillations increase in magnitude, then decrease. The oscillations are analyzed to determine systolic, mean, and diastolic pressures as shown. (Adapted from Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 4th ed. Baltimore, MD: Williams & Wilkins; 1999.)

Another common strategy involves the opposite approach of incrementally inflating the cuff. Once the cuff pressure has increased above the SP, the sensor no longer perceives oscillations, and the cuff is rapidly and completely deflated.

### Indications

ASA<sup>1</sup> Standard 4.2.2 mandates the following: “Every patient receiving anesthesia shall have arterial blood pressure and HR determined and evaluated at least every five minutes.” The use of an oscillometric noninvasive blood pressure cuff usually provides a straightforward method for satisfying this requirement for those patients whose medical comorbidities do not require continuous monitoring of blood pressure.

### Contraindications

Noninvasive blood pressure cuffs apply force to the encircled limb that is sufficient to occlude blood flow. Contraindications to their use therefore exist in circumstances in which the patient is likely to sustain traumatic injury from this repeated mechanical process. Examples include local bone fracture (such as a humeral fracture), open injuries to the extremity, local presence of an arteriovenous dialysis fistula, or indwelling peripherally inserted central catheter (PICC) line. The site of measurement should also be carefully chosen

in patients who have undergone axillary lymph node dissection, as these patients may have impaired lymphatic drainage from the associated limb and may be susceptible to limb edema from repeated vascular occlusion.

Noninvasive blood pressure cuffs can potentially become a source of iatrogenic injury even in normal use on a healthy limb. The repeated cycling of the blood pressure cuff during very prolonged surgical cases may lead to local skin abrasion or contusion; applying a light dressing underneath the cuff may mitigate these side effects. The radial nerve describes a spiraling path around the humerus and is also potentially susceptible to neurapraxia from mechanical compression.<sup>61,62</sup> During very prolonged surgical cases, it may be prudent to relocate the blood pressure cuff every few hours.

### *Common Problems and Limitations*

The American Heart Association recommends that the bladder width for indirect blood pressure monitoring should approximate 40% of the circumference of the extremity. Bladder length should be sufficient to encircle at least 80% of the extremity. Falsely high estimates result when cuffs are too small, when cuffs are applied too loosely, or when the extremity is below heart level. Falsely low estimates result when cuffs are too large, when the extremity is above heart level, or after quick deflations.<sup>63</sup>

The detection of changes in Korotkoff sounds is subjective and prone to errors based on deficiencies in sound transmission or hearing. Cuff deflation rate also influences accuracy; quick deflations underestimate blood pressure. Noninvasive blood pressure cuffs are also subject to significant wear-and-tear from repeated use in the operating room. The development of a small air leak in the hose or cuff will often prevent the device from following its inflation strategy and render it inoperative.<sup>64</sup>

Palpation, auscultatory, and oscillometric techniques require pulsatile blood flow and may be unreliable during conditions of low flow or if the arterial walls are sufficiently sclerotic or stiffened such that pulsations are not readily transmitted.

Automated oscillometry has been demonstrated to correlate well with direct intra-arterial measurement of MAP and DP.<sup>65–67</sup> Oscillometry does require additional signal processing to smooth out pronounced respiratory variations or motion artifacts, but these events tend to occur at frequencies that are distinct from pulsatile variations in pressure. Cuff movement, erratic pulse transmission, arrhythmias, and inadvertent occlusion of the pressure tubing may influence accuracy. Periods of significant hemodynamic variability may require more frequent measurement of blood pressure to guide optimal intraoperative management.<sup>68</sup> This problem can be approached statistically by assessing the ability of a blood pressure measurement to

predict the next blood pressure measurement, and hence the ability of the anesthesiologist to infer and intervene upon unacceptable trends in the blood pressure. Although Standard 4.2.2 mandates that blood pressure be measured only every 5 minutes, some evidence exists that this predictive ability may begin to decline for measurement intervals of greater than 3 minutes.<sup>69</sup>

Automated noninvasive blood pressure cuffs are usually placed around the upper arm, but it is usually acceptable to place the cuff around the forearm, wrist, or ankle if the upper arm is inaccessible or if the patient's body habitus is otherwise unfavorable.<sup>70–72</sup> As the site of measurement is moved more peripherally, the measured SP tends to increase, and the DP tends to decrease. An exception is the parturient undergoing cesarean section; the correlation between calf and upper arm blood pressures was found to be poor in this patient population.<sup>73</sup>

In pediatric patients, the upper extremity is generally the preferred site for blood pressure monitoring as it more closely correlates with cerebral perfusion. The greatest disparity between blood pressures measured in the upper versus lower extremity is found in patients weighing less than 1,000 g.<sup>74</sup> Premature infants, particularly those with pulmonary hypertension or respiratory distress, are at higher risk for having patent ductus arteriosus. Placing the blood pressure cuff on the right arm (preductal) gives the best approximation of cerebral perfusion in this patient population.<sup>75</sup>

## Monitoring of Central Venous and Right-Heart Pressures

### *Principles of Operation*

Central venous cannulas are important portals for intraoperative vascular access and for the assessment of changes in vascular volume. Central venous cannulas permit the rapid administration of fluids, insertion of pulmonary artery catheters (PACs) or central venous oximetry catheters, insertion of transvenous electrodes, monitoring of central venous pressure (CVP), and a site for observation and treatment of venous air embolism. The main value of monitoring central venous and right-heart pressures lies in their ability to approximate or trend in conjunction with the left ventricular end-diastolic pressure (LVEDP). The LVEDP predicts left-ventricular filling (i.e., left ventricular end-diastolic volume, LVEDV) through the Frank–Starling mechanism.

**Figure 26-6** demonstrates the progression of pressures from CVP through LVEDP. Ideally, all proximal pressures reflect changes in LVEDP. The CVP is the easiest to measure as it does not require that any portion of the catheter to be placed within the heart. The CVP is essentially equivalent to right atrial pressure and serves as a reflection of right

▶ 12

▶ 13

ventricular preload.<sup>76</sup> The output of the right ventricle and the output of the left ventricle must be approximately the same in a structurally normal cardiopulmonary system, notwithstanding a small amount of physiologic shunt. However, it has been well demonstrated that right-sided pressures in the heart often are poor indicators of left ventricular filling, either as absolute numbers or in terms of the direction of change in response to therapy. The correlation of these pressures as estimates of LVEDP (and, by extension, LVEDV) is directly related to their proximity to the left ventricle and the status of ventricular compliance. PACs therefore provide more clinical information than central venous monitoring alone; PACs are able to separate the behavior of the right side of the heart, the lung parenchyma, and the left side of the heart. Pulsatile pressures in the pulmonary artery provide an assessment of right ventricular function. The *pulmonary capillary wedge pressure* (PCWP) provides the closest approximation to LVEDP. The PAC is allowed to wedge, with the balloon inflated, in the pulmonary vasculature. During end-diastole, there is cessation of forward blood flow and a static fluid column is presumed to exist from the left ventricle to the PAC tip with no pressure drop.

**Figure 26-6** The progression of intracardiac pressures from central venous pressure to end-diastolic left ventricular pressure. The anatomic position of a pulmonary artery catheter in the pulmonary artery is shown. The dashed line shows the position of the inflated pulmonary artery catheter balloon in the “wedged” position. CVP, central venous pressure; RA, right atrium; RV, right ventricle; PA, pulmonary artery; Alv, alveolus; PCap, pulmonary capillary; PV, pulmonary vein; LA, left atrium; LV, left ventricle. I, II, and III characterize the relationship of  $P_{\text{alveolar}}$ ,  $P_{\text{arterial}}$ , and  $P_{\text{venous}}$  as described by West et al.<sup>77</sup> The bottom of the figure shows a progressive correlation of vascular pressures. (Adapted from Vender JS. Invasive cardiac monitoring. *Crit Care Clin.* 1988;4:455–477.)

The measurement of right-heart pressures can therefore indirectly assess left ventricular preload, diagnose the existence of pulmonary hypertension, or differentiate cardiac and noncardiac causes of pulmonary edema.

### Proper Use and Interpretation

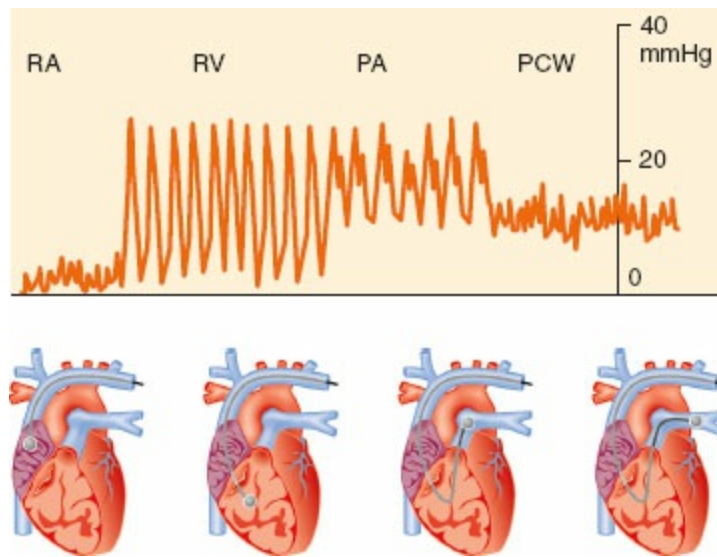

Careful leveling and zeroing of the pressure transducers is essential, as **14** described earlier for invasive arterial pressure monitoring. The normal CVP waveform, as shown in [Figure 26-7](#), consists of three peaks (a, c, and v waves) and two descents (x, y), each resulting from the ebb and flow of blood in the right atrium. The character of the CVP trace depends on many factors, including HR, conduction disturbances, tricuspid valve function, normal or abnormal intrathoracic pressure changes, and changes in right ventricular compliance. In patients with atrial fibrillation, a waves are absent. When resistance to the emptying of the right atrium is present, large a waves are often observed. Examples include tricuspid stenosis, right ventricular hypertrophy as a result of pulmonic stenosis, or acute or chronic lung disease associated with pulmonary hypertension. Large a waves may also be observed when right ventricular compliance is impaired.

Tricuspid regurgitation typically produces giant v waves that begin immediately after the QRS complex. Large v waves are often observed when right ventricular ischemia or failure is present or when ventricular compliance is impaired by constrictive pericarditis or cardiac tamponade. A prominent v wave during CVP monitoring may suggest right ventricular papillary muscle ischemia and tricuspid regurgitation. When right ventricular compliance decreases, the CVP often increases with prominent a and v waves fusing to form an *m* or *w* configuration.

CVP monitoring can be unreliable for estimating left ventricular filling pressures, especially when cardiac or pulmonary parenchymal disease processes alter the normal cardiovascular pressure–volume relationships. However, CVP monitoring is less invasive and less costly than pulmonary artery monitoring and offers an understanding of right-sided hemodynamic events and the status of vascular volume. The validity of PAC monitoring depends on a properly functioning pressure monitoring system, correctly identifying the “true” PCWP and integration of the various factors that affect the relationship of PCWP, and the other cardiac pressures and volumes that are determinants of ventricular function. [Figure 26-8](#) depicts the transduced pressure waves observed as a PAC is floated to the wedged position. Catheter placement is most commonly performed by observing the pressure waves as the catheter is floated from the CVP position through the right heart chambers into the pulmonary artery.

**Figure 26-7** The normal central venous pressure (CVP) trace. ECG, electrocardiogram. (Adapted from Mark JB. Central venous pressure monitoring: Clinical insights beyond the numbers. *J Cardiothorac Vasc Anesth.* 1991;5:163–173.)

**Figure 26-8** Pressure tracing observed during the flotation of a pulmonary artery catheter. RA, right atrium; RV, right ventricle; PA, pulmonary artery; PCW, pulmonary capillary wedge pressure. (Adapted from Dizon CT, Barash PG. The value of monitoring pulmonary artery pressure in clinical practice. *Conn Med.* 1977;41:622–625.)

West et al.<sup>77</sup> described a gravity-dependent difference between ventilation and perfusion in the lung. The variability in pulmonary blood flow is a result of differences in pulmonary artery ( $P_A$ ), alveolar ( $P_{alv}$ ), and venous pressures ( $P_V$ ) and is categorized into three distinct zones, as shown in Figure 26-6. Only Zone III ( $P_A > P_V > P_{alv}$ ) meets the criteria for uninterrupted blood flow and for a continuous communication via a static fluid column with distal intracardiac pressures. Flow-directed PACs usually advance to gravity-dependent areas of highest blood flow. However, increases in alveolar pressure, decreases in perfusion, or changes in the position of the patient can convert areas of zone III into either zone II or I. The following characteristics suggest that the PAC tip is not in zone III: PCWP  $>$  pulmonary artery end-diastolic pressure (PAEDP), nonphasic PCWP tracing, and inability to aspirate blood from the distal port when the catheter is wedged.

## Indications

Even without the monitoring of pressures, central venous access may be indicated to provide a route of administration for vasoactive drugs, parenteral nutrition, higher-concentration electrolyte solutions, prolonged vascular access, or a temporary pacemaker.

CVPs correlate well with right ventricular preload and so provide a quantitative, direct means of assessing the volumetric status of a patient. CVP monitoring may be indicated in cases in which there are expected to be rapid or large shifts in intravascular volume. CVP monitoring may also be useful in assessing volumetric status when other clinical signs of volumetric status, such as urine output, may be inaccurate or unavailable due either to the procedure or to the patient's comorbidities.

**7** PACs have not been shown to improve outcomes.<sup>78</sup> The decision to place a PAC therefore requires careful individualization of patient care. There must be a specific question regarding the patient's management that can only be addressed with the data that the catheter will provide. This question should be of sufficient importance that the plan of management will potentially be altered depending on the results of PAC monitoring. The information that PACs provide may be particularly informative in the management of patients with severe pulmonary hypertension or to help differentiate noncardiogenic and cardiogenic shock.

## Contraindications

Obstruction at the mitral valve from mitral stenosis, atrial myxoma, or clot can interfere with the ability of left atrial pressure to reflect LVEDP. Similarly, mitral regurgitation, a noncompliant left atrium, or left-to-right intracardiac shunting often is associated with large v waves. Decreases in left ventricular compliance, aortic regurgitation, or premature closure of the mitral valve may reverse the left atrial pressure–LVEDP pressure gradient. When these comorbidities occur, PCWP is not a valid reflection of LVEDP.

Central venous access represents an invasive process with inherent risks, some of which are rare but are potentially life-threatening. Adverse effects from CVP or PAC monitoring can be a result of accessing the central venous circulation, the catheterization procedure, or from use or presence of the catheter after placement. Unintentional puncture of nearby arteries, bleeding, neuropathy, and pneumothorax may result from needle insertion into adjacent structures. Air embolism may occur if a cannula is open to the atmosphere and air is entrained during or after catheter placement. Dysrhythmias are common during the catheterization procedure, with a reported incidence of 4.7% to 68.9%. Ventricular tachycardia or fibrillation may be induced during

catheter advancement. Catheter advancement has been associated with right bundle-branch block and may precipitate complete heart block in patients with pre-existing left bundle-branch block. The most dreaded complication associated with PAC monitoring is pulmonary artery rupture. Pulmonary hypertension, coagulopathy, and heparinization are often present in patients who have died of pulmonary artery rupture. Perforations and subsequent hemorrhage can be avoided by restricting “overwedging,” minimizing the number of balloon inflations, and using proper technique during balloon inflations. [Table 26-4](#) summarizes the adverse effects as reported by the ASA Task Force on pulmonary artery catheterization.<sup>79</sup>

### ***Common Problems and Limitations***

The right internal jugular vein is the most common site for cannulation by anesthesiologists because it is accessible from the head of the operating table, has a predictable anatomy, and has a high success rate in both adults and children.<sup>80</sup> The left-sided internal jugular vein is also available but is less desirable because of the potential for damaging the thoracic duct or difficulty in maneuvering catheters through the jugular–subclavian junction. Accidental  carotid artery puncture is a potential problem with either location. Use of an ultrasound-guided technique is now strongly recommended to reduce complications and improve first-attempt success rates.<sup>81</sup>

**Table 26-4** Adverse Effects Associated with Pulmonary Artery Monitoring

Complication	Reported Incidence (%)
Central venous access	
Arterial puncture	0.1–13
Postoperative neuropathy	0.3–1.1
Pneumothorax	0.3–4.5
Air embolism	0.5
Flotation of pulmonary artery catheter	
Minor dysrhythmias	4–68.9
Ventricular tachycardia or fibrillation	0.3–62.7
Right bundle-branch block	0.1–4.3
Complete heart block (prior left bundle-branch block)	0–8.5
Complications associated with catheter residence	
Pulmonary artery rupture	0.03–1.5
Positive cultures from catheter tip	1.4–34.8
Sepsis secondary to catheter residence	0.7–11.4
Thrombophlebitis	6.5
Venous thrombosis	0.5–66.7
Pulmonary infarction	0.1–5.6
Mural thrombus	28–61
Valvular or endocardial vegetations	2.2–100
Deaths attributed to pulmonary artery catheter	0.02–1.5

Reprinted with permission from American Society of Anesthesiologists Task Force on Pulmonary Artery Catheter. Practice guidelines for pulmonary artery catheterization: an updated report by the American Society of Anesthesiologists Task Force on Pulmonary Artery Catheterization. *Anesthesiology*. 2003;99(4):988–1014.

Alternatives to the internal jugular vein include the external jugular, subclavian, antecubital, and femoral veins. Although the Centers for Disease Control and Prevention suggests that the preferred site for central venous cannulation should be the subclavian site to potentially reduce bloodstream infections, this recommendation must be taken in the context of the particular clinical situation.<sup>81</sup> The internal jugular approach may be superior in those patients with coagulopathies (in whom bleeding at the subclavian site may be more difficult to stop) or patients with severe acute lung injury (for whom the risk of pneumothorax may be heightened). When comparing the subclavian approach with the femoral approach, the reported reduction in infection risk favors subclavian. However, there is a paucity of prospective randomized data when comparing subclavian to internal jugular.<sup>82</sup> Infection is a potential complication of the continued use of CVP catheters and PACs, although ongoing research suggests that this complication may be preventable with scrupulous attention to sterile technique.<sup>83</sup>

Femoral, subclavian, and internal jugular veins are all utilized for central venous access in infants and children. Physician experience and comfort is the

primary determinant of insertion site and has the greatest impact on complication rates for each site.<sup>84</sup> At all three sites, routine use of ultrasound for central venous catheter placement may decrease risk of iatrogenic vascular injury.<sup>85</sup> Subclavian venous catheters in pediatric patients may have a lower risk of dislodgment as well as being less restrictive to patients' range of motion.<sup>84</sup> Disadvantages of subclavian lines include lower success rates of placement and increased rates of catheter malposition, inadvertent arterial puncture, and pneumothorax.<sup>86</sup> The femoral vein may be the preferential site of central venous access in critically ill pediatric patients.<sup>87</sup> As with femoral arterial line placement, the use of ultrasound guidance for femoral venous line placement in children may decrease risk of iatrogenic vascular injury.<sup>50</sup> Femoral venous lines in children do not appear to carry an increased risk of infection compared with subclavian and jugular venous catheters,<sup>88</sup> although there is a higher risk of line maintenance-related complications, particularly catheter thrombosis, and accidental dislodgment. Internal jugular catheterizations appear to have the highest placement success rate, though they may cause increased patient discomfort, as site dressings may limit neck mobility.<sup>86</sup>

## Monitoring of Cardiac Output by Pulmonary Arterial Catheter

### *Principles of Operation*

Provided that the heart is structurally normal, without septal defects and without a patent ductus so that no intracardiac recirculation or shunting of blood can occur, the time-averaged flow of blood through the right ventricular outflow tract (RVOT) will accurately approximate the CO. A small amount of venous return to the left side of the heart from the bronchial circulation and thebesian veins is neglected. Time averaging suppresses the effects of beat-to-beat pulsatility.

A properly positioned PAC passes through the RVOT. CO monitoring using a pulmonary arterial catheter therefore depends on assessing the rate of blood flow through the right side of the heart and using this as a measure of CO. Techniques to measure the flow rate are based upon the idea of measuring the dilution by the passing blood flow of some known quantity of an indicator.<sup>89</sup> This indicator could be a dye, O<sub>2</sub> content (Fick method), or CO<sub>2</sub> content (indirect Fick method).<sup>90</sup> However, the most commonly used technique in  clinical practice is based upon thermodilution.<sup>91</sup> Thermodilution cardiac output (TCO) depends on the measurement of temperature near the tip of the PAC using a thermistor.

CO can be assessed intermittently by using a bolus injection of room-temperature or chilled fluid as the indicator. The thermistor on the pulmonary

arterial catheter records the fall in temperature as this bolus is injected via a more proximal port on the PAC and mixes with the surrounding blood flow. The total flow through the RVOT, and hence the CO, can be estimated from the area under this blood temperature curve, combined with knowledge of the specific heat capacity and gravity of blood and the injectate, the volume of the injectate, and the size of the catheter. When performed properly, TCO measurements correlate well with direct Fick or dye dilution estimates of CO.<sup>92</sup>

Continuous CO monitoring offers the potential to identify acute changes in ventricular performance as they occur. Pulsed thermodilution uses a coiled filament that applies a low-power heating signal within the right atrium and ventricle in a cyclical manner based on a proprietary pseudorandom sequence. The thermistor at the tip of the PAC detects these changes in blood temperature and sends the temperature information to a microcomputer that uses stochastic analysis to create a thermodilution curve. CO is then computed in a similar fashion to the bolus technique, using a conservation of heat equation, although effectively using a warmed bolus rather than a chilled bolus.<sup>93</sup> Another technique applies heat to a thermistor located at the tip of a PAC. The blood flow through the right ventricular outflow subsequently cools the tip, and the temperature changes registered are proportional to the rate of blood flow. Although a time lag can exist, continuous CO monitoring compares favorably with bolus CO measurements, even under conditions of varying patient temperature and CO.

### *Proper Use and Interpretation*

TCO estimates can vary with the respiratory cycle. Performing measurements at peak inspiration or end expiration can reduce this variability. Ensuring that the rate of injection and the volume are constant enhances precision. Most TCO computers require that repeat measurements be delayed for 30 to 90 seconds to stabilize the thermal environment of the PAC thermistor. The TCO computer displays the CO directly in L/min.

TCO measurements depend on the assumption that changes in thermal energy are carried forward to the thermistor; thus, the measurements depend on the correct positioning of the catheter. If the catheter is insufficiently advanced such that the port through which a bolus injectate is administered is still within the introducer sheath, then there will be reflux of the injectate within the introducer sheath. This will result in some of the change in thermal energy being “lost” into the sheath. A smaller-than-expected change in temperature will then be seen at the thermistor, appearing as if the injectate had been injected into a larger volume of blood flow. The TCO computer will interpret and present this as an erroneously high CO. Similarly erroneous

readings may be produced if the catheter is advanced too far, such that the heating filament of a continuous TCO catheter lies beyond the pulmonic valve. Hypothermia and the rapid concurrent administration of unwarmed intravenous fluids may affect the accuracy of TCO measurements.

## Indications

Measurement of CO is required to determine physiologic factors such as the rate of oxygen delivery to peripheral tissues. Possible clinical indications include severe sepsis, cardiogenic shock, and dependence on inotropes. An additional technologic refinement of the pulmonary arterial catheter is the *oximetric* PAC, which uses reflectance spectrophotometry to identify the saturation of the mixed venous blood surrounding the tip of the PAC, SvO<sub>2</sub>. Three-wavelength in vivo systems correlate well with simultaneous samples measured by co-oximetry.<sup>94</sup> Knowledge of the SvO<sub>2</sub> allows the rate of extraction of oxygen by peripheral tissues ( $\psi_{O_2}$ ) to be calculated. Neglecting the small amount of oxygen dissolved in blood:

$$\psi_{O_2} = 13.8 \times [\text{Hgb}] \times \text{CO} \times (\text{SaO}_2 - \text{SvO}_2)$$

where [Hgb] is the concentration of hemoglobin, 13.8 is a conversion factor for the oxygen-carrying capacity of hemoglobin, CO is the cardiac output in L/min, and (SaO<sub>2</sub> - SvO<sub>2</sub>) is the difference between the arterial and mixed venous oxygen saturations.

The use of PACs in practice has diminished over the last decade<sup>95</sup>; this may partly be due to the greater use of techniques such as transesophageal echocardiography and arterial waveform analysis that can estimate CO in a less-invasive manner. However, thermodilution via a PAC remains the clinical **8** gold standard for the determination of CO and should be considered when knowledge of the CO is necessary for the patient's management and when other comorbidities would render less invasive techniques inaccurate.

## Contraindications

Measurement of CO requires a PAC that is designed for the purpose. There are no additional contraindications for CO monitoring.

## Common Problems and Limitations

The intermittent TCO technique assumes that there is adequate mixing of the cooled injectate with the surrounding blood flow. It is necessary that the temperature of the injectate be distinct from the temperature of the

blood in order to generate a change in the distal temperature measurement. Improved measurements can be obtained by using a cooler injectate, producing a greater temperature change to detect and hence an improved signal-to-noise ratio.<sup>96</sup>

The presence of intracardiac shunts or significant tricuspid regurgitation can invalidate the assumptions underlying TCO. Intracardiac shunts allow accessory blood flow paths, such that flow through the RVOT may no longer approximate CO accurately. Significant tricuspid regurgitation can compromise thermodilution methods by permitting retrograde blood flow, invalidating the assumption that all changes in thermal energy caused by the indicator are carried forward to the detecting thermistor.

Clinicians are unable to estimate the cardiac index in pediatric patients reliably, even using associated clinical indicators such as SV variation, blood pressure, and HR.<sup>97,98</sup> Nevertheless, continuous CO monitoring is rarely used in the perioperative management of pediatric patients. Femoral arterial thermodilution (FATD) has been validated as an alternative to pulmonary arterial thermodilution techniques in patients ranging from infancy to adolescence.<sup>99,100</sup> FATD correlates closely with Fick-based calculations while only minimally overestimating cardiac index.<sup>100</sup> When compared to pulmonary-arterial sampling methods, FATD monitoring systems are less hazardous to place, as they avoid the potential for pneumothorax and pulmonary arterial injury.<sup>99</sup>

17

## Monitoring of Cardiac Output by Arterial Waveform Analysis

### *Principles of Operation*

The use of a PAC remains the gold standard for the determination of CO, but the use of PACs in the management of patients requiring intensive care has not been demonstrated to be associated with reduced mortality.<sup>101</sup> PACs can be associated with a high rate of iatrogenic complications,<sup>102</sup> and the ASA recommends that only clinicians with regular ongoing experience of the procedure<sup>79</sup> should place pulmonary catheters. Nevertheless, the determination of CO allows more accurate assessment of the hemodynamic status of a critically ill patient than can be obtained by clinical assessment alone. This conundrum has created increasing interest in biomedical devices that can estimate CO in a less invasive manner; arterial waveform analysis is one such technique.<sup>103</sup>

There are three arterial waveform CO devices on the market that are based on peripheral arterial pressure readings from an invasive arterial cannula: FloTrac (Edwards Lifesciences, Irvine, CA), PiCCO (PULSION Medical Systems AG, Munich, Germany), and LiDCOrapid (LiDCO Ltd.,

London, UK).<sup>104</sup> These devices directly measure the fluctuations in arterial pressure and the HR, from which they estimate the beat-to-beat SV. The CO is given by the product of the HR and SV ( $CO = HR \times SV$ ).

A more recent device, ClearSight (Edwards Lifesciences, Irvine, CA) does not use an invasive arterial cannula, but instead uses a noninvasive finger blood-pressure cuff (Nexfin, Ultron, The Netherlands) that is dynamically inflated and deflated to attempt to track the blood pressure in the brachial artery. This means of inferring arterial blood pressure relies on a method originally described by Peñáz,<sup>105</sup> in which the fingertip is compressed by a pressure cuff while simultaneously being transilluminated by infrared light. Arterial pulsations cause the volume of blood within the fingertip to increase, increasing the absorption of infrared light by hemoglobin. The system rapidly changes the inflation pressure of the cuff to attempt to hold the absorption of infrared light constant. Because the infrared absorption is held constant, according to the Peñáz method, the volume of blood within the fingertip must be constant, which means that the pressures applied to the fingertip are exactly equal and opposed to the arterial pulsation. Consequently, the cuff pressures must equal the arterial pressures. This simple model has been subsequently refined to include compensation for pressure reflection in the vascular tree between the fingertip and brachial artery<sup>106</sup> and to reflect the variable vertical fluid column between the fingertip and the heart.<sup>107</sup> This noninvasive reconstruction of an arterial waveform also allows CO to be estimated by waveform analysis.

It is a straightforward matter to measure HR from an arterial waveform tracing; it is the estimation of beat-to-beat SV that presents the technical challenge. The first modern mathematical description of the shape of the arterial waveform was described by Otto Frank,<sup>108</sup> and gave rise to the “Windkessel” (German: *air chamber*) model for arterial behavior. Usually when considering the flow of an incompressible fluid, such as blood, in a section of tube, the assumption is made that the volume of the fluid entering the tube is the same as the volume of the fluid leaving the tube. This assumption allows a *continuity equation* to be created from which models of fluid flow can be derived. The basis of the Windkessel model is the realization that although blood is incompressible, the artery itself is distensible, and so the volumes of blood entering and leaving an arterial segment at any given moment may be different. There is storage of blood and distension of the artery during systole and ejection of blood and relaxation of the artery during diastole. The volumes of blood entering and leaving are only the same when averaged over the cardiac cycle, as shown in [Figure 26-9](#).

This behavior is mathematically similar to that seen in the modeling of a compressible fluid, such as air, when flowing in rigid vessels, hence the name of the “Windkessel” model. The air may store and release energy through

changes in pressure and compression. In arterial waveform analysis, it is the fluid that is incompressible, and it is the nonrigid arterial vessel that may store and release energy by elastic deformation. The behavior of the artery is dependent on its resistance to flow  $R$  and its compliance  $C$ ; from cadaveric studies of the human aorta,<sup>109</sup> these values are known to be predictable.

The total SV must be equal to the forward flow in systole  $Q_s$  plus the forward flow in diastole  $Q_d$ , assuming the aortic valve is competent.

$$SV = Q_s + Q_d$$

**Figure 26-9** Depiction of blood flow into and out of a prototypical “Windkessel artery.” Several points are to be noted: first, during systole, inflow into the artery is less than outflow because some of the blood is stored in the expanding compliant vessel. Second, during diastole, inflow into the artery is zero and outflow is enhanced by the contracting vessel. C, compliance; P, pressure; R, resistance; V, volume. (Adapted from Thiele RH, Durieux ME. Arterial waveform analysis for the anesthesiologist: Past, present, and future concepts. *Anesth Analg.* 2011; 113:766–776.)

At the beginning of diastole, there is no further inflow into the aorta, and so  $Q_d$  is proportional to the difference between the pressure in the aorta and the pressure in the arterial beds. This is described as the end-systolic mean distending pressure  $P_{md}$ , equivalent to the idea of a “pressure head.” Therefore,

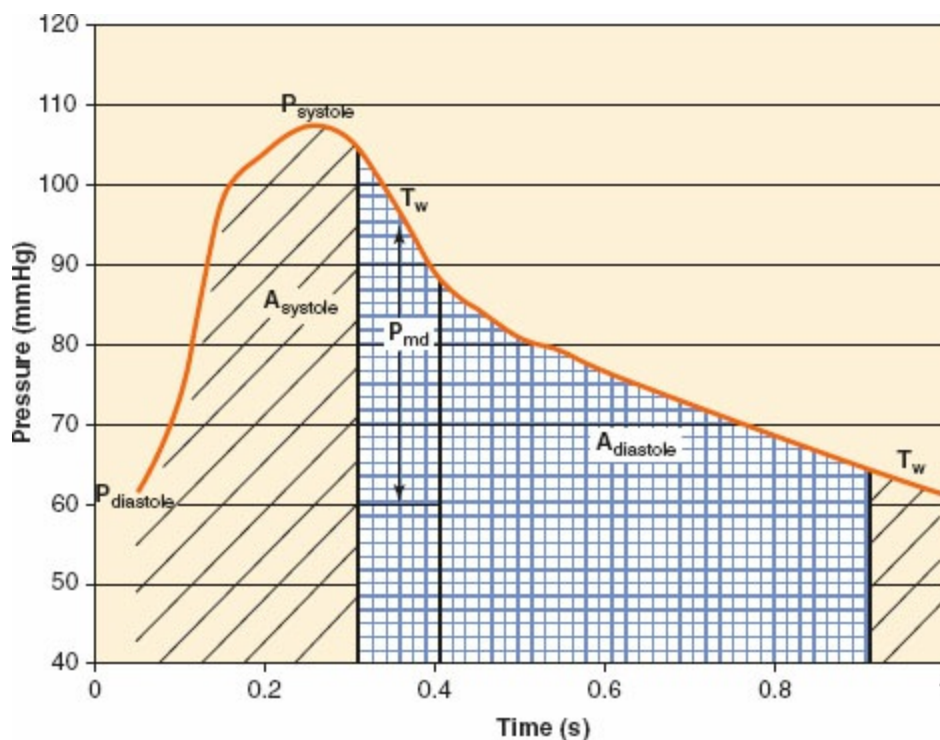

$$Q_d = k \times P_{md}$$

where  $k$  is a constant of proportionality dependent on the properties of resistance and compliance, as described earlier. As the peripheral vascular resistance should not change over a single cardiac cycle, the values of  $Q_s$  and  $Q_d$  should be proportional to  $A_s$  and  $A_d$ , the areas under the pressure curve during systole and diastole, respectively, as shown in [Figure 26-10](#). Therefore,

$$Q_s/A_s = Q_d/A_d \quad \text{or, alternatively,} \quad Q_s = Q_d \frac{A_s}{A_d}$$

Rearranging these model equations:

$$SV = Q_d \left( 1 + \frac{A_s}{A_d} \right) \quad \text{and so} \quad SV = kP_{md} \left( 1 + \frac{A_s}{A_d} \right)$$

**Figure 26-10** A graphical depiction of the components of the arterial waveform used by the Windkessel-based area under the curve method. Note that  $P_{md}$  represents the increment in mean pressure over the whole arterial bed at the end of systole<sup>168</sup> and that  $T_w$  represents the transmission time (from the aorta to the periphery). (Adapted from Thiele RH, Durieux ME. Arterial waveform analysis for the anesthesiologist: Past, present, and future concepts. *Anesth Analg.* 2011;113:766–776.)

This model demonstrates how, in principle, a beat-to-beat estimate of SV can be generated from measurements of the arterial waveform. The algorithms used by actual clinical devices are more complex and proprietary. Although the previous analysis is necessarily simplified, it nevertheless illustrates the fundamental principles and requirements of these devices. For instance, the model depends on an additional value  $k$ , which has to be

determined either by calibrating the prediction of this model to another measurement of SV (such as transesophageal echocardiography [TEE] or thermodilution) or in an uncalibrated manner by estimating its value from biophysical models based on variables such as the patient's age, sex, height, and weight.<sup>110</sup> The PiCCO device makes use of an external calibration reading, whereas the FloTrac and LiDCOrapid devices use an uncalibrated biophysical model approach.

### *Proper Use and Interpretation*

Arterial waveform CO monitors make use of standard equipment for arterial cannulation. A stiff arterial line, flushed from a pressurized fluid source, is attached to the arterial cannula in the usual fashion. However, in place of the usual piezoelectric pressure sensor with a single electrical connection, a specialized sensor is used with two connectors so that pressure information can be supplied simultaneously to the anesthesia monitor and to the CO monitor. The arterial line is zeroed in the usual fashion. The display of arterial pressures by the anesthesia monitor is unaffected by the presence of the CO monitor. It is possible to transduce arterial pressures alone without connecting the CO monitor. Uncalibrated devices, such as the FloTrac and LiDCOrapid, require information about the patient such as age, height, weight, and sex in order to estimate the physiologic properties of the patient's arterial system and estimated body surface area. The device may require a brief interval of time to gather initial arterial pressure data, but will shortly begin to report CO and other indices such as cardiac index, SV, stroke volume variation (SVV), and SV index. These indices represent various combinations of SV, HR, and body surface area. Further user intervention is not generally required. These values, in the manner estimated by the device, are most useful for assessing relative volume status and for assessing the response to fluid resuscitation.<sup>111-114</sup> The ability of the device to respond to changes in CO caused by inotropes or vasopressors<sup>111,115</sup> is uncertain; the limits of its reliability, accuracy, and utility in this setting are the subject of ongoing research and algorithmic refinement.

### *Indications*

The use of an arterial waveform CO monitor is not mandated so the indications for use are at the discretion of the practitioner. The device is likely to be most helpful to the clinician in cases in which there are expected to be large fluid shifts and in which the patient's intravascular volume status may become difficult to determine by clinical assessment and usual monitoring techniques. It may be preferable, and less invasive, to guide fluid

resuscitation with arterial waveform CO measurements rather than placing a central venous catheter or a PAC. This approach is particularly attractive if the patient already requires an arterial line for other indications or if the patient's comorbidities relatively contraindicate the placement of a central line or PAC. The FloTrac device has been demonstrated to show excellent concordance with TEE in measuring CO under conditions of changing fluid preload.<sup>111</sup>

It is possible to extract other indices from analysis of the arterial waveform, and measurements such as systolic pulse variation (SPV) and SVV may also be useful in predicting responsiveness to fluid resuscitation.<sup>116,117</sup>

### **Contraindications**

Devices such as the FloTrac and LiDCOrapid that do not require additional calibration are no more invasive than the arterial line to which they are attached. The same contraindications that apply to arterial lines, such as poor or absent collateralization of arterial supply to the extremity, also apply to these devices.

Devices that estimate CO from the arterial waveform do so based upon a number of physiologic assumptions that were touched upon during the derivation of the simplified model. There are many disease states, some common, which violate these assumptions and can significantly compromise the accuracy of the device; these are discussed later.

### **Common Problems and Limitations**

All arterial waveform CO monitors are dependent on accurate, high-fidelity measurement of arterial pressures. Satisfactory operation depends upon good arterial perfusion to the site of measurement and good peripheral arterial cannulation. The pressure transducer system must use appropriate tubing and be flushed and zeroed correctly so that bias, signal dampening, or flail are not seen in the arterial waveform. These artifacts corrupt the frequency spectrum of the arterial waveform, and impair accurate measurement. The use of an intra-aortic balloon pump may distort the arterial waveform to such an extent that the resulting waveform is uninterpretable, rendering the device inoperative.<sup>118</sup>

The simplified model of arterial waveform analysis made use of information obtained from only a single cardiac cycle. In contrast, all of the current monitors make use of algorithms that depend on information obtained over many cardiac cycles. The FloTrac monitor depends, for example, upon the standard deviation, skewness, and kurtosis of the statistical distribution of arterial pressures obtained over the preceding 20 seconds.<sup>110</sup> This implicitly

assumes that the CO remains relatively beat-to-beat constant over the sampling interval. This assumption can be violated in the presence of irregular heart rhythms, in which the preload of the left ventricle and hence the SV can demonstrate significant beat-to-beat variability. Arterial waveform CO monitors are therefore known to be prone to inaccuracy in the setting of atrial fibrillation.<sup>119</sup>

In the simplified model, the properties of systemic vascular resistance (SVR) and arterial compliance (C) were subsumed into the parameter  $k$ , and it was proposed that  $k$  might be obtained from a population-based biophysical model. However, in the presence of sepsis<sup>115,120</sup> or some other high-output state, such as liver transplantation surgery,<sup>114</sup> the deviation of these values from the expected population norms can cause inaccuracy when compared to the measurement of CO by PAC. With ongoing research and refinement of the devices and their algorithms, this situation appears to be improving.<sup>113</sup> However, a similar problem applies to the iatrogenic reduction of the compliance of arterial vessels through the administration of vasopressors. Arterial waveform CO devices appear to be reliable at assessing changes in CO caused by fluid resuscitation, of some utility at detecting changes caused by inotropes,<sup>111</sup> but poor at assessing changes caused by alteration in vascular tone by agents such as phenylephrine<sup>111</sup> or norepinephrine.<sup>112</sup>

Finally, arterial waveform analysis depends upon the assumption that there is no further inflow into the arterial system at the end of systole, as used in the analysis based on the parameter  $P_{md}$ . This assumption is violated in the setting of aortic insufficiency, in which there is negative regurgitant flow to the left ventricle. Arterial waveform analysis is expected to demonstrate inaccuracy in this presentation.<sup>118</sup> Conversely, aortic stenosis does not appear to impair the accuracy of measurement of CO.

Use of the entirely noninvasive ClearSight/Nexfin system has so far been limited in clinical practice. In one published trial, the CO estimated by the device showed a satisfactory correlation with a different invasive arterial waveform CO monitor (PiCCO).<sup>121</sup> However, when compared directly to the gold standard of CO monitoring via a PAC, the absolute accuracy of the device appeared to be limited.<sup>122</sup>

In summary, arterial waveform analysis has been demonstrated in many studies to provide a reasonable estimate of CO and a reasonable approximation to more invasive techniques. The degree to which a new monitoring technique must agree with the gold standard to be clinically useful is a matter of clinical judgment and not a question that can be definitively addressed by statistics alone. Presently, these devices appear to be most useful as guides to fluid resuscitation and for trend monitoring rather than as guides to the administration of inotropes or vasopressors. There are a number of relatively common clinical scenarios in which the accuracy of these devices

can be anticipated to be impaired based upon violation of the underlying physiologic assumptions on which their algorithms depend. The clinician must exercise caution in interpreting the measurements of CO obtained under those circumstances.

In the pediatric population, estimation of CO via arterial waveform analysis has proven more challenging. A technique called pressure recording analytical method (PRAM) has had only mixed results in its ability to reliably estimate pediatric CO despite the use of more advanced algorithms and higher sampling frequencies.<sup>123-125</sup> Moreover, pediatric studies of this technology have excluded children with hemodynamic instability, arguably the clinical circumstance in which CO monitoring would be most useful to the anesthesiologist.<sup>123,124</sup>

## Monitoring of Body Temperature

### *Principles of Operation*

Heat is produced as a consequence of cellular metabolism. In adults, thermoregulation involves the control of basal metabolic rate, muscular activity, sympathetic arousal, vascular tone, and hormone activation balanced against exogenous factors that determine the need for the body to create heat or to adjust the transfer of heat to the environment. Both general and regional anesthesia inhibit afferent and efferent control of thermoregulation.<sup>126,127</sup>

Heat losses may result from radiation, conduction, convection, and evaporation. Radiation refers to the infrared rays emanating from all objects above absolute temperature. Conduction refers to the transfer of heat from contact with objects. Convection refers to the transfer of heat from air passing by objects. Evaporation represents the heat loss that results when water vaporizes. For every gram of water evaporated, 0.58 kcal of heat is lost. Perioperative hypothermia predisposes patients to increases in metabolic rate (shivering) and cardiac work, decreases in drug metabolism and cutaneous blood flow, and creates impairments of coagulation. Anesthesiologists frequently monitor temperature and attempt to maintain central core temperature at near-normal values in all patients undergoing anesthesia. Clinical studies have demonstrated that patients in whom intraoperative **9** hypothermia develops are at a higher risk for development of postoperative myocardial ischemia and wound infection compared with patients who are normothermic in the perioperative period.<sup>128,129</sup>

### *Proper Use and Interpretation*

Central core temperatures can be estimated using probes that can be placed

into the bladder, distal esophagus, ear canal, trachea, nasopharynx, or rectum.<sup>130</sup> Pulmonary artery blood temperature is also a good estimate of central core temperature. Thermoregulatory responses are based on a physiologically weighted average reflecting changes in the mean body temperature. Mean body temperature is estimated by the following equation:

$$T_{\text{mean body}} = 0.85 T_{\text{core}} + 0.15 T_{\text{skin}}$$

### **Indications**

The ability to monitor body temperature is a standard of anesthesia care.<sup>1</sup> The continual observation of temperature changes in anesthetized patients allows for the detection of accidental heat loss or malignant hyperthermia.

### **Contraindications**

There are no absolute contraindications to temperature monitoring. In patients whose thermoregulatory responses are intact, such as conscious patients or patients receiving light or moderate sedation, continuous temperature monitoring is usually uninformative.

### **Common Problems and Limitations**

Skin temperature monitoring has been advocated to identify peripheral vasoconstriction but is not adequate to determine alterations in mean body temperature that may occur during surgery. Core temperature sites have been established as reliable indicators of changes in mean temperature. During routine noncardiac surgery, temperature differences between these sites are small. When anesthetized patients are being cooled, changes in rectal temperature often lag behind those of other probe locations, and the adequacy of rewarming is best judged by measuring temperature at several locations. Although liquid crystal skin temperature strips are convenient to apply, they do not correlate with core temperature measurements.<sup>131</sup>

## **Monitoring of Processed EEG Signals**

### **Principles of Operation**

EEG monitoring initially entered anesthetic practice as a highly sensitive and moderately specific means of monitoring for cerebral ischemia, and as such found use in carotid surgery. Occlusion of one of the carotid arteries for surgery makes the ipsilateral side of the brain

dependent on perfusion from the contralateral carotid artery via the Circle of Willis, creating a risk of ipsilateral ischemia. In this form, a dedicated technician usually performs intraoperative EEG monitoring.

More recently, EEG monitoring has begun to gain acceptance as a means of estimating depth of anesthesia. Statistical signal-processing techniques have been developed and embodied as biomedical devices that are able to take an ensemble of EEG data and, in real time, display an estimate of “anesthetic depth.” The two most commonly used processed EEG monitors are the bispectral index (BIS) (Covidien, King of Prussia, PA) and SedLine (Masimo Irvine, CA) The operation of these devices is similar. After first cleaning the patient’s forehead, a single-use set of small adhesive electrical sensors are applied. The sensors are positioned to enable the device to detect EEG activity in the frontal lobes of the brain. The sensors are attached to the main device via a single connector. The device checks the quality of the electrical connection to the sensors, and checks that each of the sensors has made a good electrical contact with the patient’s forehead and that the sensors are not in inadvertent electrical connection with each other. In the event that the configuration of the sensors is unacceptable, the device displays a pictorial indication of the problem so that the practitioner can attempt to remedy the problem. If the electrical connection between the sensor and the skin is poor, signal reception will be impaired and the device will warn that the sensor impedance (i.e., its electrical resistance) is too high. The sensors make use of a conductive electrical gel; this can often be remedied by applying firm but careful pressure to the affected sensor to produce a better electrical contact. However, too much pressure may cause the gel to leak out from under the sensor and cause a “gel bridge,” an inadvertent direct electrical connection to a neighboring electrode. In this case, the surplus gel may be wiped away or a new set of sensors may be required. When all the electrical connections are satisfactory, the device will begin to acquire and process EEG data.

Although the algorithms used by processed EEG monitors are proprietary, the general features of the EEG that they use are well described.<sup>132</sup> Processed EEG monitors make use of the following statistical measures:

- Zero Crossing Frequency (ZXF). An estimate of the “average” frequency of the EEG, obtained by calculating the number of times the EEG voltage crosses the zero voltage level per second.<sup>133</sup>
- Burst Suppression Ratio (BSR). During periods of deep anesthesia, the EEG may demonstrate periods of low voltage or even zero (isoelectric) voltage, and bursts of higher voltage activity are no longer seen. Suppressed states are defined as those periods for which the EEG demonstrates a voltage of less than 5 mV for a period of at least 0.5 seconds, and the BSR is defined as that ration of that time fraction to the overall EEG recording. Profoundly burst suppressed (isoelectric)

states are sometimes induced as part of neuroanesthesia,<sup>134</sup> as they may provide some protection against cerebral ischemia by reducing cellular metabolic demand. Burst suppression is also seen in unanesthetized comatose patients, although in these patients it carries a grave prognosis.<sup>135</sup>

- Median Power Frequency (MPF) and Spectral Edge Frequency (SEF): The EEG signal can be converted to a frequency spectrum using the Fast Fourier Transform,<sup>136</sup> making it possible to describe the amount of signal power present at various frequencies. The MPF is the frequency at which the power in the signal can be split into two equal frequency bands, above and below. The SEF is the frequency below which 95% of the total signal power can be found.<sup>132</sup>
- Beta ( $\beta$ )-Power Ratio: The  $\beta$ -power ratio describes the relative amount of  $\beta_2$ -wave activity in the EEG signal (signal power between 30 and 47 Hz) compared to the amount of  $\beta$ -wave activity (signal power between 11 and 20 Hz). Changes in this ratio appear to correlate clinically with the onset of light sedation.
- Bispectrum. The bispectrum is a second-order property of the frequency spectrum of the EEG signal.<sup>137</sup> The bispectrum can be used to calculate bicoherence, a mathematical property that describes the similarity in phase between signals at three different frequencies:  $f_1$ ,  $f_2$ , and  $f_1 + f_2$ . A high level of bicoherence is suggestive that the signals may be generated from a common underlying rhythm. As sedation is increased, local cortical activity becomes suppressed and the EEG activity begins to demonstrate a greater underlying cortical synchronization, which can be detected as increased bicoherence in the EEG signal.

### *Proper Use and Interpretation*

Both the BIS and SedLine devices display a unitless number in the range of 0 to 100, which is derived from the measured EEG data by the device's proprietary algorithms. A value of 0 corresponds to an absence of any discernable electrical activity. A value of 100 corresponds to the EEG activity seen in a fully awake and alert individual. The algorithms used in the devices specify a differing "optimal range" for general anesthesia: for the BIS it is defined as between 40 and 60, for the SedLine it is 25 to 50.

The algorithms used in the devices appear to correlate best with clinical assessment of the depth of anesthesia when anesthetic agents such as volatile gases or propofol are used, as shown in [Figure 26-11](#), although increasing concentrations of these agents do not always reliably lower the reported number further<sup>138-140</sup> if the patient is already deeply anesthetized. This

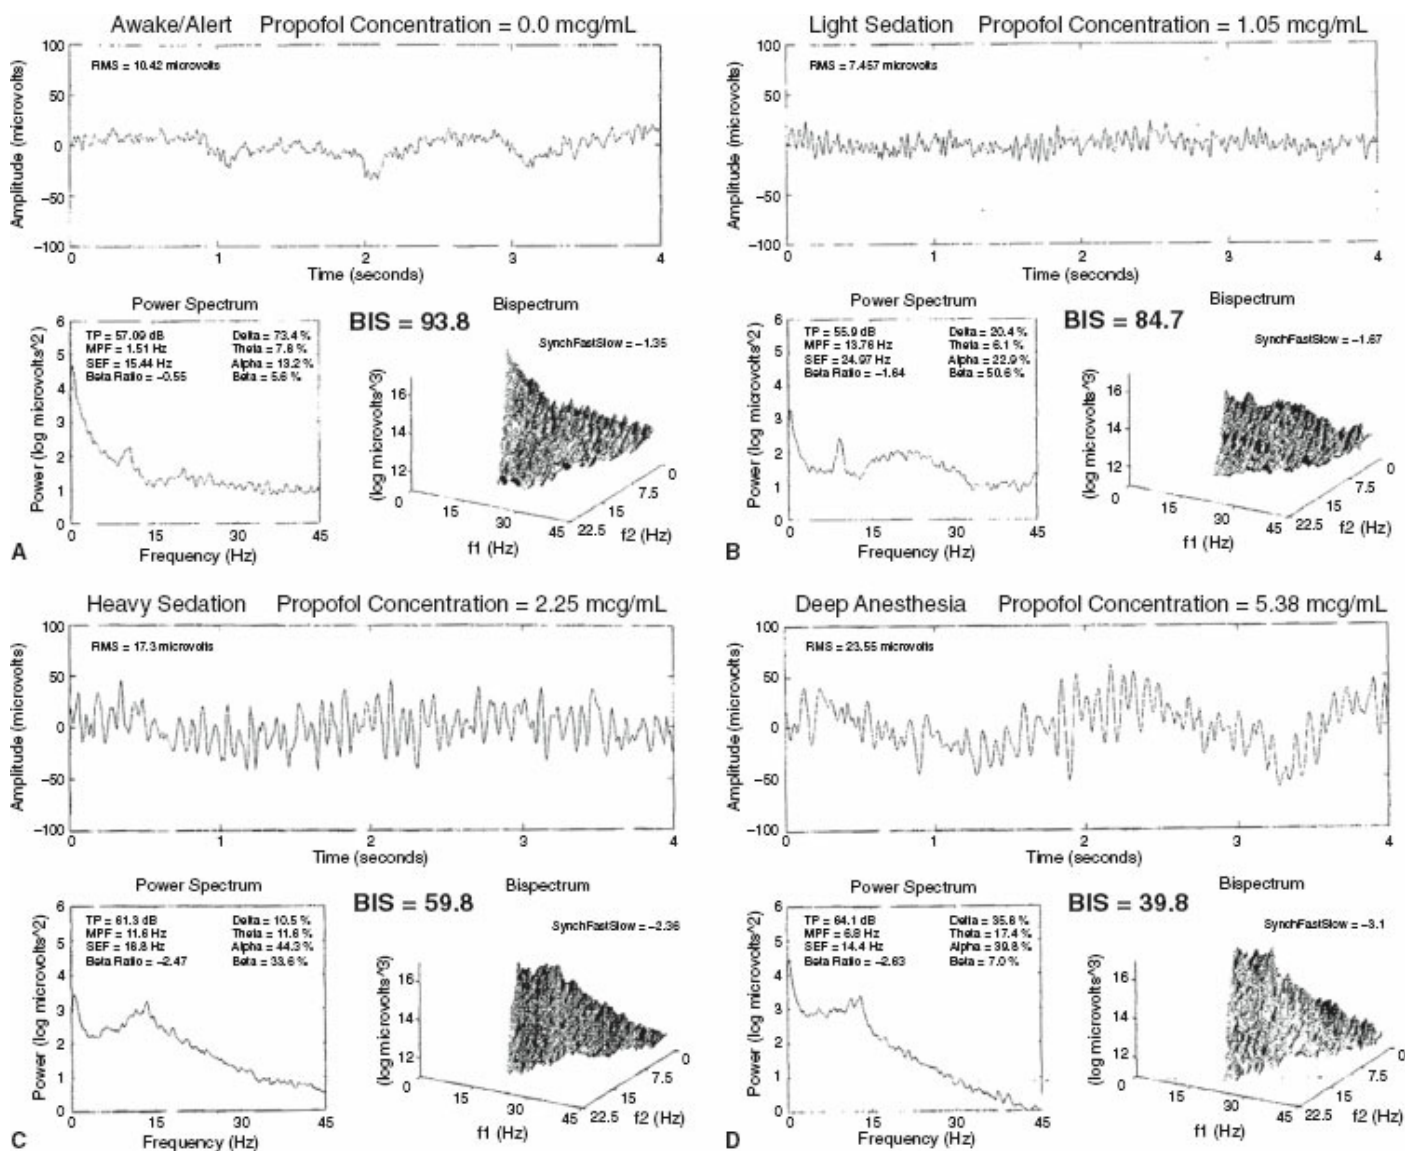

relationship between concentration and effect is not seen for all anesthetic agents.

Dissociative intravenous agents such as ketamine can actively confound processed EEG monitors through paradoxical cortical excitation; the monitor tends to misread the increased cortical activity as a sign of lessened anesthesia.<sup>141</sup> Lower doses of ketamine may be desirable as part of an overall anesthetic plan to reduce opioid administration; appropriate quantities of ketamine can be infused more slowly without apparently affecting the processed EEG reading.<sup>142</sup> Propofol and remifentanyl are often used in combination for total intravenous anesthesia (TIVA), but processed EEG monitors can be insensitive to the administration of even high concentrations of opioids.<sup>143</sup> The monitor may therefore reflect mostly the action of the propofol on the anesthetic state.

### *Indications*

The use of processed EEG monitors is not mandated; thus, the indications for use are at the discretion of the practitioner. Processed EEG monitors have not been demonstrated to be superior to end-tidal agent concentration monitoring in the prevention of awareness under anesthesia. However, the use of end-tidal agent concentration monitoring assumes that volatile anesthetic gases are used and that their end-tidal concentrations provide a reasonable surrogate for their action on consciousness. Processed EEG monitoring may be useful as a guide when a TIVA approach is planned, since it can provide some degree of feedback on the current pharmacodynamics effects of the administered agents when there is no end-tidal agent concentration to measure.

Patients with pre-existing cognitive deficits, sensory impairment,<sup>144</sup> or known risk of postoperative delirium may benefit from the administration of less anesthesia than would be indicated by end-tidal agent monitoring alone.<sup>145</sup> Processed EEG monitoring may be useful in satisfactorily titrating their anesthetic plan to permit faster recovery from anesthesia.<sup>146</sup>

**Figure 26-11** Representative data from a single human volunteer demonstrating changes in EEG with increasing serum concentrations of propofol. In each of the four concentrations, 4 seconds of raw EEG data is plotted in the top half of the figure. In the lower left is the corresponding power spectrum and spectral parameters computed from the same EEG epoch. The lower right quadrant displays the bispectrum for the same raw data. The final BIS score is shown. Figures **A**, **B**, **C**, and **D** represent increasingly deeper levels of anesthesia. (Adapted from Rampil IJ. A primer for EEG signal processing in anesthesia. *Anesthesiology*. 1998;89:980–1002.)

For types of emergent surgery, such as cesarean sections under general anesthesia,<sup>147</sup> trauma laparotomies, or surgery in the critically ill hemodynamically unstable patient, it may not be physiologically possible to administer the usual quantities of anesthesia, placing these patients at a greater risk of intraoperative awareness. Processed EEG monitoring may provide some assistance in titrating anesthesia in these vulnerable patients and some reassurance that explicit recall will be unlikely. A prior history of intraoperative awareness may therefore also be an indication.

Mechanically ventilated patients in the intensive care unit are usually

assessed clinically for their level of sedation, but the use of the standard Sedation-Agitation Scale or the Richmond Agitation-Sedation Scale may be impossible in some patients due to therapeutic neuromuscular paralysis. Processed EEG monitors may provide some guidance to sedation management under these circumstances.<sup>148,149</sup>

## **Contraindications**

Use of a processed EEG device may be contraindicated in a patient with significant craniofacial trauma, such that the physical pressure required to place the sensors cannot be safely applied. Placement may also be relatively contraindicated in patients with existing superficial injury to the forehead in the region where the sensors will be applied.

The use of processed EEG sensors for patients who will be in prone position for surgery is controversial and may be a relative contraindication. In prone position, the patient's head may rest such that excessive continuous pressure is applied to the skin underneath the sensors. Disfiguring injury to the forehead has been reported,<sup>150</sup> perhaps related to a combination of pressure and irritation from the conductive gel on the sensors. This can lead to a dilemma: prolonged spinal surgery performed using somatosensory or motor evoked potential monitoring can relatively contraindicate the use of volatile gases and neuromuscular blockers, and make a propofol–remifentanyl TIVA technique attractive. This anesthetic technique provides an indication for processed EEG monitoring, but the prolonged prone positioning provides a relative contraindication. Prone positioning requires vigilant attention to facial features, such as the eyes and nose, to avoid injury by pressure and impingement. Therefore, if it is determined that processed EEG monitoring is to be applied to a prone patient, it is recommended that equally vigilant attention be paid to the condition of the forehead.

## **Common Problems and Limitations**

It has been suggested that processed EEG monitoring devices may reduce the **10** risk of intraoperative awareness.<sup>151</sup> However, subsequent studies have either failed to demonstrate a reduction<sup>152</sup> in intraoperative awareness or even, conversely, have found an increase in intraoperative awareness<sup>26</sup> when compared to anesthetic practice guided by the end-tidal agent concentrations<sup>20</sup> of anesthetic gases<sup>25</sup>.

Cases of intraoperative awareness were found when using either end-tidal agent concentration monitoring or processed EEG monitoring; neither technique was sufficient to avoid awareness with complete reliability. This difficulty may relate to our lack of understanding of what “anesthetic depth”

even means.<sup>145,153</sup> Intraoperative awareness as a phenomenon is dependent on the interaction of consciousness, memory, and the biologic action of anesthetic agents. These, even taken individually, are complex and incompletely understood processes.<sup>154–156</sup> It should not therefore be surprising that any device or algorithm that seeks to reduce these processes to a single numerical readout may prove to be fallible.

Compared to adults, pediatric patients have more than three times greater incidence of awareness under anesthesia.<sup>157–159</sup> At the same time, there is a conflicting pressure to reduce exposure to anesthetic agents in young children. An increasing body of evidence suggests that anesthetic agents harm early brain development, reinforced by recent studies demonstrating a decline in listening comprehension and performance IQ in young children following surgery with anesthesia.<sup>160</sup> A number of attempts have been made to investigate the utility of perioperative processed EEG monitoring to guide care in these younger patients. Some evidence supports the application of the adult BIS algorithm in children age above 12 months, but infant BIS values do not closely correlate with end-tidal sevoflurane concentrations.<sup>161</sup> As with adults, processed EEG may be a useful adjunct in this patient demographic, but is not a substitute for provider vigilance and contextual clinical judgment.

## Future Trends in Monitoring

Anesthesiologists have been at the forefront of the incorporation of innovative biomedical devices and technologies into their practice. We will continue to adapt our practice to make use of new technologies to enhance patient safety. There are three trends in device design that appear most likely to lead to further improvements in our practice: greater automated marshaling of monitoring and clinical data, the dissemination of our current devices into wider hospital use, and the development of devices with greater algorithmic sophistication to obtain clinical data less invasively.

The Anesthesia Information Management Systems (AIMS) will continue to become more interconnected with patient monitoring devices, as well as with drug delivery systems such as infusion pumps and vaporizers. The AIMS will also begin to interface more deeply with hospital-wide Computerized Provider Order Entry (CPOE) systems, allowing patient clinical data and documentation to be available immediately to the anesthesiologist. The safety of the administration of intravenous medications will be enhanced by the routine use of machine-readable labels, whether by barcoding or radiofrequency identification (RFID), so that the intended administration of a medication will be known to the AIMS prior to the actual administration. The AIMS will make use of this information to alert to the potential for drug interactions and allergies during the case itself immediately prior to

administration. The automatic availability of this data will allow the AIMS to provide decision support to the anesthesiologist, tracking the administration of intravenous medications and providing predictions of plasma and effect site concentrations to improve dose titration. Overall, improvements in the automated marshaling and display of patient data will assist the anesthesiologist with situational awareness. Further, using more intelligent alarm systems to decrease false-positive alerts will more accurately guide the anesthesiologist to aspects of the patient's management that require attention. The sophistication of AIMS user interfaces will continue to improve so that the interaction between the anesthesiologist and the tasks of computer-based monitoring and charting will become smooth, fast, natural, and efficient.

In the recent revision of the ASA Standards for Basic Monitoring,<sup>1</sup> the indications for capnography have been broadened to include the evaluation of ventilation during moderate or deep sedation. Moderate sedation may be performed by clinicians untrained in the practice of anesthesia; the effect of this standard will be the dissemination of capnographic equipment previously used only by anesthesiologists to the wider care environment. Anesthesiologists should be at the forefront of educational efforts to ensure that our medical colleagues use these devices appropriately, enhancing patient safety.

A trend in the development of biomedical devices is toward devices that use complex algorithmic models to infer clinical data in a less invasive or more rapid manner. Examples are arterial waveform CO monitors that produce an estimate of CO from the arterial pressure tracing alone, noninvasive hemoglobin monitors that estimate serum hemoglobin from infrared pulse oximetry, target-controlled infusion pumps that make use of population pharmacokinetic and pharmacodynamics data to estimate the redistribution and effect of a medication, and processed EEG monitors that attempt to reduce an ensemble of EEG data to a quantitated end point of consciousness. These devices are examples of incredible biomedical sophistication, usually the product of decades of scientific research and subsequent engineering refinement. However, the algorithms that these devices use are generally derived from the responses of healthy volunteers. The protocols used for the development of the algorithms are often seemingly simplistic or artificial when compared to the complexity of actual anesthetic practice. The result is that, during their initial introduction to practice, the functionality of the devices in the sickest of patients is not necessarily well characterized or understood. To put it more briefly: it may work, but does it *really* work? It is our sickest patients who have the most to gain from devices that allow us to assess their clinical condition more rapidly and less invasively, but it is our sickest patients who are the most vulnerable should the devices tend to become inaccurate under just those clinical conditions. The

limits of the reliability and clinical applicability of these devices must be a matter of concern for the practicing anesthesiologist. Though devices are becoming “smarter,” that knowledge does not excuse us of the knowledge to know how to employ them wisely.

## **KEY POINTS**

- 1 Understanding the principles of ultrasound and echocardiographic instrumentation is essential in optimizing image quality.
- 2 Two-dimensional and Doppler techniques have complementary roles in the assessment of cardiovascular function.
- 3 Global left ventricular systolic function is influenced by load and contractility alterations; regional wall motion grading is based on systolic endocardial excursion and myocardial thickening.
- 4 Doppler assessments of transmitral flow and myocardial tissue velocities provide accurate diastolic function assessment.
- 5 Severity of aortic stenosis is estimated based on maximal pressure gradient across the aortic valve and the aortic valve area calculated by the continuity equation.
- 6 The ratio of the width of the regurgitant jet to the diameter of the left ventricular outflow tract is useful in assessing the severity of aortic insufficiency. Diastolic flow reversal in the descending thoracic aorta is significant for severe aortic insufficiency.
- 7 Mitral regurgitation can be of structural or functional etiology. The vena contracta of the regurgitant jet is useful to grade severity.
- 8 Aortic atheromas larger than 4 mm are harbingers of thromboembolic events.
- 9 The false lumen of aortic dissection does not have diastolic flow.
- 10 Transthoracic-focused cardiac ultrasound provides rapid bedside assessment of cardiac pathology and potential causes of altered hemodynamics.

Echocardiography is the first imaging technique to enter the mainstream of intraoperative patient monitoring. A remarkably versatile tool, real-time echocardiography provides a comprehensive evaluation of myocardial, valvular, and hemodynamic performances. These capabilities attracted the attention of anesthesiologists and surgeons challenged by the unique difficulties of perioperative cardiovascular management. Over the 30 years following the first report of intraoperative echocardiography to assess ventricular function by Barash and colleagues in 1978, echocardiography has emerged as the technique of choice for a wide variety of intraoperative case challenges.<sup>1</sup>

The benefit of intraoperative echocardiography in both cardiac and noncardiac surgical populations is supported by several case series.<sup>2-8</sup> Applications range from guiding the placement of intracardiac and intravascular catheters and devices, to the assessment of the severity of valve pathology and immediate evaluation of a surgical intervention, to the rapid diagnosis of acute hemodynamic instability and directing appropriate therapies.<sup>9-11</sup> Consequently, expertise in intraoperative echocardiography is highly desired among anesthesiology practitioners. The National Board of Echocardiography has established a certification pathway in perioperative transesophageal echocardiography (TEE), <http://www.echoboards.org/certification/certexpl.html>. The American Society of Anesthesiologists in conjunction with the National Board of Echocardiography has established a second certification pathway in basic perioperative echocardiography, [www.echoboards.org/content/basic-pteexam](http://www.echoboards.org/content/basic-pteexam). These efforts are unique in intraoperative monitoring and attest to the critical role that accurate and thorough echocardiographic interpretation plays in current anesthetic practice.

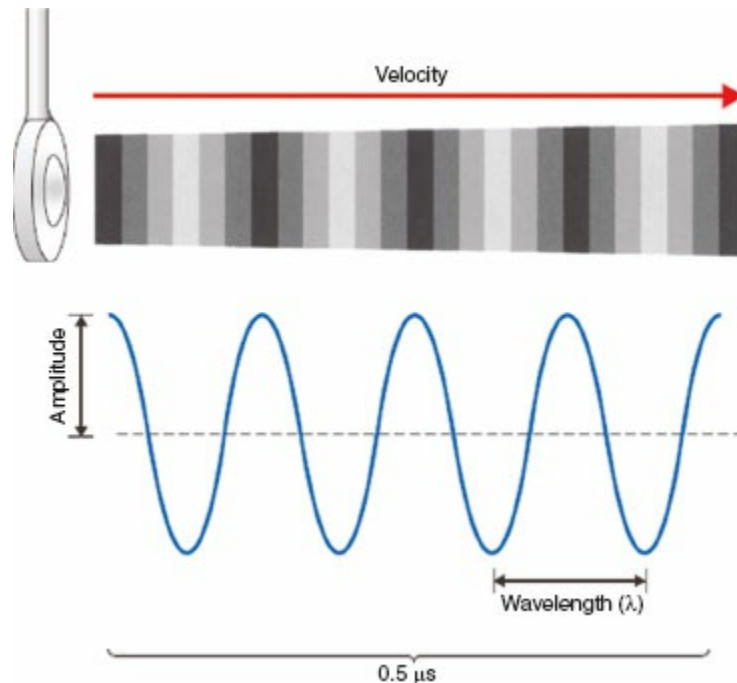

## Principles and Technology of Echocardiography

 Echocardiography generates dynamic images of the heart from the reflections of sound waves. The echocardiography system transmits a brief pulse of high-frequency sound (i.e., ultrasound) that propagates through and is subsequently reflected from the cardiac structures encountered. The ultrasound transducer records the time delay and signal intensity for each returning reflection. Since the speed of sound in tissue is constant, the time delay allows the echo system to precisely calculate the location of cardiac structures and thereby create an image map of the heart.

### Physics of Sound

Sound is the vibration of a physical medium. In clinical echocardiography, a

mechanical vibrator, known as the *transducer*, is placed in contact with the esophagus (TEE), skin (transthoracic echocardiography [TTE]), or the heart (epicardial echocardiography) to create tissue vibrations. The resulting tissue vibrations create a longitudinal wave with alternating areas of *compression* and *rarefaction* (Fig. 27-1).

**Figure 27-1** Sound wave. Vibrations of the ultrasound transducer create cycles of compression and rarefaction in the adjacent tissue. The ultrasound energy is characterized by its amplitude, wavelength, frequency, and propagation velocity. In this example, four sound waves are shown in a period of 0.5 μs. The frequency can be calculated as four cycles divided by 0.5 μs and equals 8 MHz.

The *amplitude* of a sound wave represents its peak pressure and is appreciated as loudness. The level of sound energy in an area of tissue is referred to as *intensity*. The intensity of the sound signal is proportional to the square of the amplitude and is an important factor regarding the potential for tissue damage with ultrasound. Since levels of sound pressure vary over a large range, it is convenient to use the logarithmic decibel (dB) scale:

$$\text{Decibels} = 10 \log_{10} I/I_r = 10 \log_{10} A^2/A_r^2 = 20 \log_{10} A/A_r$$

where A is the measured sound amplitude and A<sub>r</sub> is a standard reference sound level; I is the intensity and I<sub>r</sub> is a standard reference intensity. The Food and Drug Administration limits the intensity output of cardiac ultrasound systems to be below 720 W/cm<sup>2</sup> because of concerns of potential tissue injury.<sup>12</sup>

Sound waves are also characterized by their *frequency* (f), or pitch, expressed in cycles per second, or Hertz (Hz), and by their *wavelength* (λ).

These attributes significantly impact the depth of penetration of a sound wave in tissue and the image resolution of the ultrasound system.

The propagation *velocity* of sound ( $v$ ) is determined solely by the medium through which it passes. In soft tissue, the speed of sound is approximately 1,540 m/s. As the product of wavelength and frequency equals velocity:  $V = \lambda \times f$ , it becomes apparent that the wavelength and frequency are inversely related:  $\lambda = v \times 1/f$  and that  $\lambda = (1,540 \text{ m/s})/f$ . High-frequency, short-wavelength ultrasound is more easily focused and directed to a specific target location. Image resolution also increases with short-wavelength sound waves; for these reasons, ultrasonic frequencies of 2 to 10 MHz are preferred in clinical echocardiography.

### ***Properties of Sound Transmission in Tissue***

The propagation of a sound wave through the body is markedly affected by its interactions with the various tissues encountered. These interactions result in reflection, refraction, scattering, and attenuation of the ultrasound signal and determine the resulting appearance of the two-dimensional image.

Echocardiographic imaging relies on the transmission and subsequent reflection of ultrasound energy back to the transducer. A sound wave propagates smoothly through uniform tissue until it encounters the interface between two tissues varying in acoustic impedance (a property largely related to the *density* [ $\rho$ ] of the tissue and the speed that ultrasound travels). A large interface oriented perpendicular to the sound beam will produce a mirror-like reflection of sound back toward the transducer with only a portion of the signal passing through the interface. Since cardiac structures are detected by their reflected echocardiography signal, echocardiographers adjust the position of the TEE transducer so that the direction of its beam is perpendicular to the cardiac structure of interest.

Refraction causes a change in direction of propagating sound and occurs when an interface lies oblique to the sound beam. Refraction is an important factor in the formation of artifacts as the transducer mistakenly interprets a reflection from the refracted beam as originating from a cardiac structure located within the *intended* scanning field.

*Scattering reflections* occur when an ultrasound beam encounters small or irregularly shaped surfaces, such as red blood cells. These reflectors scatter ultrasound energy in all directions so that far less energy is reflected back to the transducer. This type of reflection is the basis of the Doppler analysis of blood flow (see following).

Even when traveling through uniform tissue, sound undergoes a steady loss (i.e., *attenuation*) in intensity as a consequence of dispersion and absorption. Attenuation results in less energy returning to the transducer and

**1** low-quality images with poor signal-to-noise ratios. To combat attenuation, echocardiographers select better penetrating low-frequency signals (e.g., 2.5 instead of 7.5 MHz) and choose an imaging window that is close to the structure of interest. Adjusting the gain controls to amplify the weak returning signals makes their appearance brighter on the display. Unfortunately, this increases the brightness of artifactual noise, which negatively impacts the image appearance.

## Instrumentation

### Transducers

Ultrasound transducers use piezoelectric crystals to create a brief pulse of ultrasound. Alternating electrical current stimulates polarized particles within the crystal's matrix to rapidly vibrate, generating ultrasound. Conversely, when a sound reflection strikes the crystal, the impact vibrates the polarized particles and generates an electric current. This property allows the piezoelectric crystal to function as both a transmitter and a receiver of ultrasound.

The shorter the length of the sound pulses, the better the axial resolution of the system. High-resolution imaging transducers emit sound pulses of just two to four cycles of short-wavelength, high-frequency sound.

### Beam Shape

The ultrasound transducer emits a three-dimensional ultrasound beam similar to a movie projection (Fig. 27-2). The beam is narrow in the near field and then diverges into the far field zone. Focusing of the beam is used to improve spatial resolution by narrowing the ultrasound beam at the desired depth. The dense, narrow beam is preferred because it provides improved spatial resolution, produces high-intensity reflections, and reduces artifact. Echocardiographers adjust focal depth and focus to optimize the image resolution.

### Resolution

Three parameters are evaluated when assessing the resolution of an ultrasound system: the resolution of objects lying along the axis of the ultrasound beam (*axial resolution*), the resolution of objects horizontal to the beam's orientation (*lateral resolution*), and the resolution of objects lying vertical to the beam's orientation (*elevational resolution*).

Short pulses of high-frequency ultrasound offer the greatest axial resolution but have a decreased tissue penetration. As resolution is highest

along the axial plane, echocardiographic measurements are most precise when taken parallel to the beam's axis. Accordingly, echocardiographers select transmitted frequency based on the particular imaging need.

Beam size determines the lateral and elevational resolution. Broad beams produce a "smeared" image of two nearby objects, whereas narrow beams can identify each object individually. Beam size is reduced by selecting high-signal frequencies and minimizing imaging depth.

## Signal Processing

To convert echoes into images, the returning ultrasound pulses are received, electronically processed, and displayed. The oscillator repeatedly cycles the transducer from a brief transmission to a relatively long receive mode. During the receive phase, the reflected echocardiography signals are captured and converted to electrical signals by the piezoelectric crystal. The echocardiography system employs a series of controls, including system gain, time gain compensation, compression, and postprocessing settings (not unlike those available with digital imaging software) to optimize the signal for display. Adjustments are used, for example, to emphasize edge detection versus tissue texture or to improve the delineation of weaker reflectors. The choice of settings is dictated by the examination and preferences of the echocardiographer.

**Figure 27-2** Three-dimensional beam. The ultrasound probe projects a three-

dimensional beam. The dimensions of this projection have important effects on the imaging resolution and artifact. Typically, a narrow profile is preferred. **A:** Unfocused beam. The beam is narrow in the near field and then diverges in the far field. **B:** Focused beam. Focusing has resulted in a narrower beam in both the lateral and elevational planes so that the imaging resolution of structures in the focal zone is improved. Distal to the focal zone, the beam rapidly diverges and the images of structures in this area will be of lower quality.

## Image Display

Ultrasonic imaging is based on the amplitude and time delay of the reflected signals. Since the velocity in tissue is a relatively constant 1,540 m/s, only the distance of the structure from the transducer alters the time required for the ultrasound wave to travel to and from the reflected structure. So, by timing the interval between transmission and return of the reflections, the echocardiography system can precisely calculate the distance of a structure from the transducer.

Current imaging is based on brightness mode, or *B-mode technology*. With B-mode, the amplitude of the returning echoes from a single pulse determines the display brightness of the representative pixels. *M-mode*, or motion mode, adds temporal information to B-mode by displaying a series of sequentially collected B-mode images. M-mode echocardiography provides a one-dimensional, single-beam view through the heart but updates the B-mode images at a very high rate, providing dynamic real-time imaging. M-mode remains the best technique for examining the timing of cardiac events (Fig. 27-3).

**Figure 27-3** Method-mode (M-mode) echocardiography of a normal aortic valve. The M-mode cursor is placed at the center of the aortic valve and the motion of the aortic

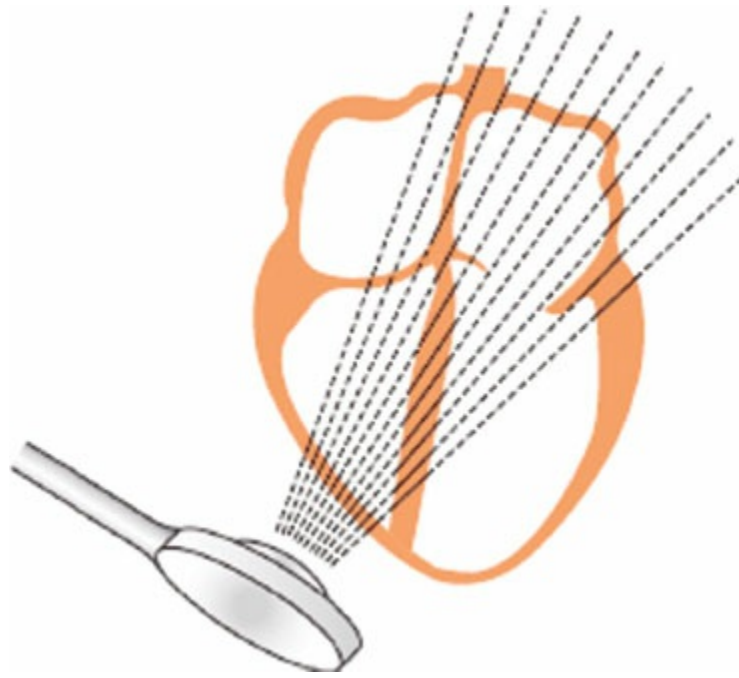

cusps over time is shown. During diastolic coaptation, the aortic valve cusps appear as a thick, bright white line (*long arrow*), whereas in systolic apposition they form a “shoe-box” (*short arrow*).

*Two-dimensional (2D) echocardiography* is a modification of B-mode echocardiography and the mainstay of the echocardiographic examination. Instead of repeatedly firing ultrasound pulses in a single direction, the transducer in 2D echocardiography sequentially directs the ultrasound pulses across a sector of the cardiac anatomy. In this way, 2D imaging displays a tomographic section of the cardiac anatomy and, unlike M-mode, reveals the shape and lateral motion ([Fig. 27-4](#)).

Two-dimensional scanning is achieved using phased array technology, which sequentially activates each crystal in the array and thereby steers the beam without the transducer itself being moved. The two commonly used electronic scanning systems in medical ultrasound are the linear scanners and sector scanners.

The *linear scanner* uses a long linear array. Groups of crystals are activated sequentially from one end of the transducer to the other. The firing of each group of crystals creates an image of the structures directly in front of them. With sequential firing, the anatomic features from one end of the transducer to the other are imaged ([Fig. 27-5](#)). The disadvantage of this approach is that the transducer face must be large to cover a broad anatomic area. The linear array is commonly used to guide vascular access and regional anesthetic procedures.

The phased array *sector scanner* is the most commonly used in echocardiography. Here, the ultrasound scan is sequentially directed in a fan-like arc. The resulting sector image, known as a *frame*, is similar in shape to that covered by a windshield wiper. The 2D scanner then repeats the entire process to update the image and capture motion.

**Figure 27-4** Scan lines. Illustration of the arced sector from a phased array two-dimensional echocardiogram. Each *dotted line* represents an individual brightness mode scan line. Any structure that interacts with a scan line will create reflections (*dark highlight*); however, structures that lie between the scan lines are not interrogated and the echocardiography system averages the neighboring signals to fill in this defect. Accordingly, the closer the scan lines, the better the image quality.

### ***Spatial versus Dynamic Image Quality***

Expert echocardiographers select machine settings to optimize particular image qualities for the examination at hand. As discussed in the following sections, these selections will determine whether sector size, spatial resolution, or dynamic motion is best displayed.

The *pulse repetition frequency* is the rate at which sound pulses are triggered. The greater the pulse repetition frequency, the greater the number of scan lines that are emitted in a given period of time. This enhances motion display. Unfortunately, sector depth must be reduced because pulse repetition frequency is inversely related to the sector depth, as a longer period of time is required for the ultrasound to travel the increased distances.

The *frame rate* is the frequency at which the sector is rescanned. A high frame rate improves the capture of movement. Typically, frame rates greater than 30 per second are desired. The frame rate is critically dependent on the sector depth, which determines the time required for each scan line to be received, and the sector width, which increases the number of scan lines that must be transmitted. Consequently, increases in sector size and depth come at the cost of a decreased frame rate and poor motion imaging.

**Figure 27-5** Linear scanners image a rectangular section of the anatomy compared with the arced sector imaged with phased array scanners.

The number of scan lines per degree of the sector (*scan line density*) greatly affects the image resolution. Doubling the scan lines essentially doubles the lateral resolution. However, the cost is a decrease in the frame rate and motion imaging.

The echocardiographer must thoughtfully select among settings that will often have opposing effects between the size of the imaging field, the imaging resolution, and the frame rate. A common approach is to focus each part of the examination on a given structure of interest and select the imaging plane that best delineates the structure in the near field. Motion display can then be enhanced without costs in lateral resolution by decreasing the sector angle and depth. In situations in which the maximal frame rate is desired, M-mode is chosen.

## Two-dimensional and Three-dimensional Transesophageal Echocardiography Examination

TEE is the favored approach to intraoperative echocardiography. Compared with TTE, TEE offers additional “windows” to view the heart, often with improved image quality from the anatomic proximity of the esophagus and heart. In the operating room (OR), TEE is useful because the probe does not interfere with the operative field and can be left in situ, providing continuous, real-time hemodynamic information used to diagnose and manage critical cardiac events. TEE is also useful in situations in which the transthoracic examination is limited by various factors (obesity, emphysema, surgical dressings, and prosthetic valves) and for examining cardiac structures not well visualized with TTE (left atrial appendage).

This section is designed to introduce TEE image orientation and the diagnostic utility of each view. In addition, examination sequences useful for obtaining a comprehensive or targeted examination are provided. Readers are referred to *A Practical Approach to Transesophageal Echocardiography*<sup>13</sup> for a

more detailed description of the TEE examinations described in this section.

## *Probe Insertion*

 The TEE probe is inserted in the anesthetized patient in a manner similar to insertion of an orogastric tube. For improved image quality, the stomach is emptied of gastric contents and air prior to probe insertion. The jaw is lifted with the left hand and the TEE probe, well lubricated, is inserted with the right hand by applying gentle but constant pressure. If significant resistance is encountered, additional force should be strictly avoided as oropharyngeal or esophageal injury may result. Rather, a decrease in neck extension and/or use of a laryngoscope to visualize the oropharyngeal structures often will allow easy passage of the probe. The TEE probe is advanced beyond the larynx and the cricopharyngeal muscle (around 25–30 cm from teeth) until a loss of resistance is appreciated. At this point, the TEE probe lies in the upper esophagus and the first cardiovascular images are seen. Extrinsic compression of the esophagus (e.g., osteophytes or an aortic aneurysm) may impede probe placement.<sup>9,10</sup>

## *Transesophageal Echocardiography Safety*

TEE is a semi-invasive procedure. When performed by qualified operators, TEE has a low incidence of complications. A retrospective study performed on 846 patients who underwent TEE described the following complications: three patients with pharyngeal abrasions, one patient with a chipped tooth, and few patients with transient vocal cord paresis.<sup>14</sup> Another retrospective study performed on a large case series of 7,200 patients showed that the morbidity associated with TEE placement is 0.2% and the mortality is 0%.<sup>15</sup> The most common complaint (0.1%) was postoperative odynophagia. Various studies have suggested an association between swallowing dysfunction after cardiac surgery and the use of intraoperative TEE.<sup>16,17</sup> This fact is important, as postoperative swallowing dysfunction is associated with pulmonary complications.<sup>16</sup>

## *Contraindication to Transesophageal Echocardiography Probe Placement*

To maintain the safety profile of TEE, each patient should be evaluated before the procedure for signs, symptoms, or history of esophageal pathology. Among the most feared complications of TEE are esophageal or gastric perforation.<sup>18</sup> For skilled practitioners, this complication is extremely rare.

Patients with extensive esophageal and gastric diseases are at highest risk of perforation. Contraindications to TEE probe placement are esophageal stricture, rings or webs, esophageal masses (especially malignant tumors), recent bleeding of esophageal varices, Zenker diverticulum, status postradiation to the neck, and recent gastric bypass surgery.<sup>13,18</sup> In the rare case in which TEE is essential and is the only alternative, placement of the TEE probe can be performed under direct visualization with a combined gastroscopic and echocardiographic examination.<sup>13</sup>

### **Probe Manipulation**

Image acquisition depends on precise manipulation of the TEE probe. By advancing the shaft of the probe, the probe position can be moved from the upper esophagus to the midesophagus and into the stomach. The shaft can also be manually rotated to the left or to the right. By using the large knob on the probe handle, the head of the probe can be anteflexed (turning the knob clockwise) and retroflexed (turning the knob counterclockwise). The smaller knob, located on top of the large knob, is used to tilt the head of the probe to the right or to the left. Using the electronic switch on the probe handle, the operator can rotate the ultrasound beam from 0 (transverse plane) to 180 degrees in 1-degree increments.

### **Orientation**

The previously mentioned controls allow experienced echocardiographers to perform comprehensive cardiac imaging. However, the diversity of imaging planes can confuse less experienced echocardiographers, leaving them unable to recognize the various anatomic structures presented. Thus, an understanding of the basic rules of imaging orientation is essential to echocardiographic interpretation.

The ultrasound beam is always directed perpendicular to the probe face. The 2D TEE image is displayed as a sector scan. The apex of the sector is in close proximity to the TEE probe and the structures seen in this area will be the posterior ones (e.g., left atrium). The arc of the sector will display the more distal and thereby more anterior structures. The angle of rotation of the imaging array determines the right and left orientations. An easy way to understand this orientation is to place your right hand in front of your chest with the palm facing down, the thumb oriented left and the fingers oriented anterior right. The scan lines that generate the TEE image start at your fingers and sweep toward the thumb. Consequently, the right anatomic structures will be displayed on the left side of the monitor (similar to chest x-ray orientation; Fig. 27-6). Increasing the imaging plane angle produces

clockwise rotation of the sector scan. This can be visualized by rotating your hand in a clockwise fashion. For example, at the 90-degree imaging plane, the left side of the screen now displays posterior structures (note position of fingers) and the right side of the screen anterior structures (note the position of the thumb; Fig. 27-7).

**Figure 27-6** Orientation of the hand, as described in the text, for an imaging plane of 0 degrees. The imaging plane is projected like a wedge anteriorly through the heart. The image is created by multiple scan lines traveling back and forth from the patient's left (*green line*) to the patient's right (*red line*). The resulting image is displayed on the monitor as a sector with the green edge (*green line*) on the right side of the monitor and the red edge (*red line*) on the left.

### **Goals of the Two-dimensional Examination**

Each TEE examination is performed with the goal that no important diagnosis is missed. For this reason, a comprehensive evaluation is preferred with each cardiac chamber and valve imaged in at least two orthogonal planes. However, in an emergency situation, such examination may not be possible. In these cases, most echocardiographers will focus the TEE examination to those views most likely to provide a diagnosis, that is, in a hypotensive patient the transgastric short-axis view of the left ventricle is examined for diagnosing hypovolemia, coronary ischemia, or acute heart failure.

To achieve the goals of the intraoperative TEE examination, the Society of Cardiovascular Anesthesiologists together with the American Society of Echocardiography has published guidelines for performing a comprehensive intraoperative TEE examination.<sup>19</sup> These guidelines include 28 standardized

2D echocardiographic views. Each TEE examination should be recorded along with a detailed report of the examination. Miller et al.<sup>20</sup> proposed a shortened version of the comprehensive examination that would meet the goals established by these guidelines for basic intraoperative TEE proficiency and is particularly useful when time constraints preclude a more extensive examination. Additionally, guidelines for a basic perioperative transesophageal examination geared toward intraoperative monitoring and rapid delineation of the cause of hemodynamic instability has been established.<sup>21</sup> In the following section, we detail the acquisition and anatomic features of the 11 views composing the basic examination. The ultrasound appendix in the electronic version of this textbook provides video examples of the additional cross sections included in the comprehensive examination.<sup>19</sup>

### 1. Midesophageal four-chamber view

This view is obtained at a multiplane angle between 0 and 20 degrees and slightly advancing the probe to the level of the mitral valve (MV). In this view, the four cardiac chambers and the TV and MV are visualized (Fig. 27-8). Slight withdrawal or anteflexion of the probe will visualize the LVOT and AV and represents the midesophageal five-chamber view. The midesophageal four-chamber view is one of the most recognizable and valuable diagnostic views. Its main uses are to evaluate the:

- Left atrium, right atrium, RV, and the LV (inferoseptal and anterolateral walls) size and function
- TV and MV structure and function; color-flow Doppler (CFD) will detect valvular pathology
- Diastolic function
- The presence of atrial or ventricular septal defect

**Figure 27-7** Orientation of the hand, as described in the text, for an imaging plane of 90

degrees. The imaging sector is rotated so that the green edge (*green line*) has moved clockwise and is now cephalad and the red edge is now caudad. As previously described, the green edge is displayed on the right side of the monitor and the red edge on the left.

## 2. Midesophageal two-chamber view

This view is obtained from the previous view by rotating the multiplane angle to 90 degrees. In this view, the left atrial appendage is examined for the presence of thrombus. Slight retroflexion is used to avoid a foreshortened view of the LV so as to visualize the LV apex (Fig. 27-9). The main uses of the midesophageal two-chamber view are to evaluate the following:

- a. LV anterior and inferior wall function
- b. LV apex as well as to diagnose apical thrombus

## 3. Midesophageal long-axis view

This view is obtained from the previous view by rotating the multiplane angle to 120 to 135 degrees (Fig. 27-10). The main uses of the midesophageal long-axis view are to evaluate the following:

- a. LV anteroseptal and posterior wall function
- b. LV outflow tract (LVOT) pathology
- c. MV anatomy and function

**Figure 27-8** Midesophageal four-chamber view. RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle.

4. **Midesophageal (ME) ascending aorta (AA) long-axis (LAX) view** (Fig. 27-11)

This view is obtained by withdrawing the probe from the ME LAX view. The main uses of this view are to evaluate the following:

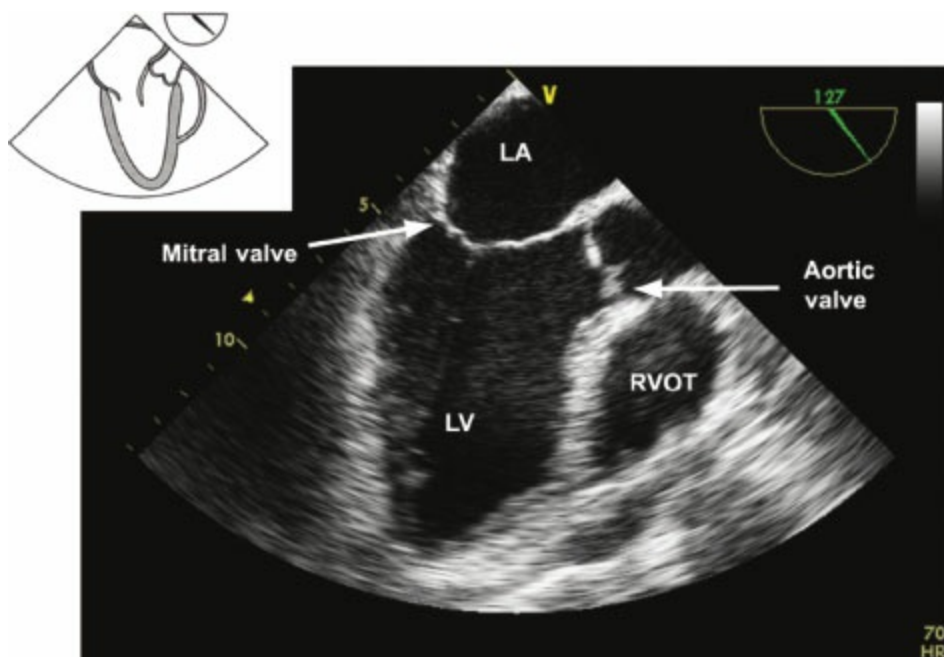

- a. Ascending aorta in the long axis (atheroma, dissection)
- b. Pulmonary artery in the short axis

5. **Midesophageal ascending aorta short-axis view**

The view is obtained by advancing the probe from the upper esophagus until the AA is seen and then rotating the multiplane angle from 0 to 45 degrees to obtain a true short axis (Fig. 27-12). This “great vessel view” images the ascending aorta and superior vena cava in short axis and the pulmonary artery in long axis. The view is used to:

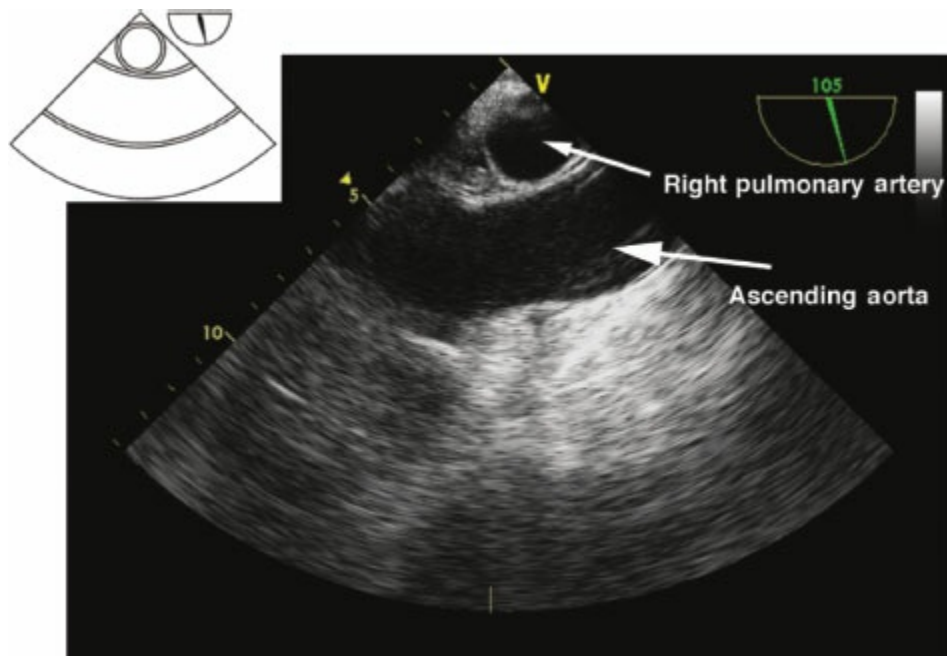

**Figure 27-9** Midesophageal two-chamber view. LA, left atrium; MV, mitral valve; LV, left ventricle.

**Figure 27-10** Midesophageal long-axis view. LA, left atrium; LV, left ventricle; RVOT, right ventricular outflow tract.

**Figure 27-11** Midesophageal ascending aortic long-axis view.

**Figure 27-12** Midesophageal ascending aortic short-axis view. SVC, superior vena cava.

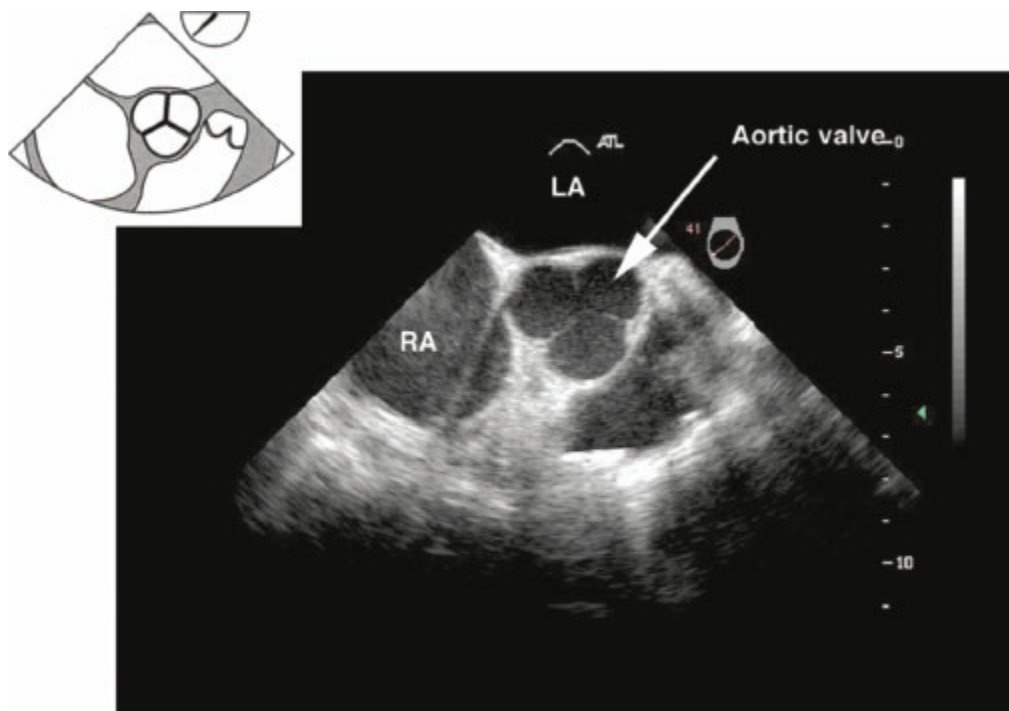

- a. Measure the AA dimensions and evaluate the presence of dissection flaps
- b. Evaluate the PA (position of pulmonary artery catheter [PAC] or rule out thrombus)
- c. Align the Doppler beam parallel to the blood flow in the main PA

## 6. Midesophageal aortic valve short-axis view

This view is obtained from the previous view by advancing the probe until the aortic valve (AV) is visible, and then rotating the multiplane

angle between 30 and 60 degrees. In the closed position, the three cusps of the AV form what is known as the “Mercedes Benz” sign (Fig. 27-13). This view is used to:

**Figure 27-13** Midesophageal aortic valve short-axis view. RA, right atrium; LA, left atrium.

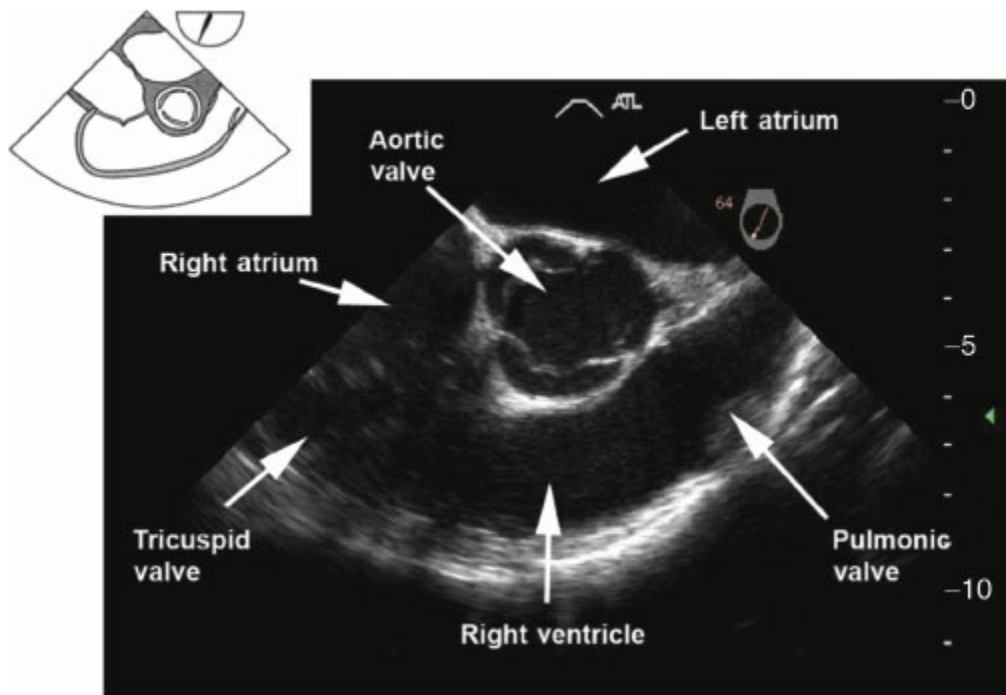

- a. Evaluate the size, number, appearance and motion of AV cusps
- b. Measure the area of the AV orifice (planimetry)
- c. Evaluate the presence of aortic insufficiency (AI) or aortic stenosis (AS) by applying CFD
- d. Assess the interatrial septum for patent foramen ovale (PFO) or atrial septal defect (ASD)

#### 7. **Midesophageal right ventricular inflow–outflow view**

This view is obtained from the previous view by decreasing the multiplane angle to approximately 60 to 90 degrees (Fig. 27-14).

The main uses of the view are to evaluate the:

- a. Pulmonic valve (PV) by measuring the Pulmonic annulus and to detect Pulmonic insufficiency by applying CFD
- b. RV and right ventricular outflow tract (RVOT) structure and function
- c. Tricuspid valve (TV) anatomy and function by aligning the Doppler beam with the RV diastolic blood inflow or a systolic regurgitation
- d. Passage of a PAC across the RV to the PA

**Figure 27-14** Midesophageal right ventricular inflow–outflow view.

**8. Midesophageal bicaval view**

This view is obtained from the previous view by turning the probe shaft to the patient's right and decreasing the multiplane angle to 110 degrees (Fig. 27-15). The view is used to:

- a. Assess the interatrial septum (aided by CFD) to detect a PFO or ASD. Evaluate the passage of agitated saline across the interatrial septum following release of a Valsalva maneuver
- b. Guide placement of catheters, wires, and cannulae
- c. Examine for the presence of thrombus or tumors

**Figure 27-15** Midesophageal bicaval view. IVC, inferior vena cava; LA, left atrium; SVC, superior vena cava; RA, right atrium.

### 9. Transgastric midpapillary short-axis view

The view is obtained by advancing the TEE probe from the midesophageal four-chamber view into the stomach, anteflexing and then withdrawing until contact is made with the gastric wall. The LV is visualized as a doughnut in cross-section; both papillary muscles should be seen (Fig. 27-16). Additional anteflexion obtains the transgastric basal short-axis view, which allows for inspection of the anterior and posterior mitral valve leaflets. Advancement of the probe with anteflexion reveals the deep TG long axis view. The transgastric midpapillary short-axis view is unique in that it visualizes LV walls perfused by each of the three major coronary arteries. The view is considered to be the most useful one in situations of intraoperative hemodynamic instability, as it allows immediate diagnosis of hypovolemic state, contractile failure, or coronary ischemia.

The primary uses of the transgastric midpapillary short-axis view include assessment of the:

- a. LV size (enlargement, hypertrophy) and cavity volume
- b. Global ventricular systolic function and regional wall motion

**Figure 27-16** Transgastric short-axis view. LV, left ventricle.

### 10. Descending aortic short- and long-axis views

The descending aortic short-axis view is obtained from the midesophageal four-chamber view by turning the TEE probe to the left until the descending aorta in cross-section is seen as a circular structure (Fig. 27-17). Rotating the multiplane angle to 90 degrees visualizes the descending aorta in a longitudinal section as a tubular vascular structure (Fig. 27-18). To examine the entire descending aorta, the probe is gradually advanced and withdrawn in the esophagus. These views are used to:

- a. Identify pathology of the descending aorta (atheroma, hematoma, dissection flaps, aneurysm)
- b. Assist with placement of guide wires and cannulae (intra-aortic balloon pump [IABP], aortic cannula)

**Figure 27-17** Descending aortic short-axis view.

### **Three-dimensional Echocardiography**

In order to better conceptualize the morphology and pathology of the heart, three-dimensional (3D) image presentation has been developed. The recent introduction of a real-time 3D TEE probe makes this goal a reality for intraoperative echocardiographers. This technology is capable of acquiring full volumes of the left ventricle, of visualizing heart valves in three dimensions (Fig. 27-19), and assessing the synchrony of LV contraction.<sup>22</sup>

**Figure 27-18** Descending aortic long-axis view.

Uses of 3D TEE are continuing to emerge. The utility of 3D imaging of the MV in MV repair surgery is of particular interest (Fig. 27-20).<sup>23</sup> This technique allows assessment of LV contraction synchrony in patients undergoing resynchronization therapy with biventricular pacing and may offer a means to maximize their cardiac output. Additional intraoperative applications have emerged, involving percutaneous procedures (transcatheter aortic valve insertion, noninvasive mitral repair, repair of paraprosthesis leaks, closure of ASD) and open surgical procedures. Guidelines on the use of 3D echocardiography have also been published.<sup>24</sup>

**Figure 27-19** Three-dimensional transesophageal echocardiographic imaging of the base of the heart with the atria removed, in systole and diastole. AV, aortic valve; MV, mitral valve; PV, pulmonic valve; TV, tricuspid valve.

**Figure 27-20** Three-dimensional imaging of prolapsing middle scallop of the posterior mitral valve leaflet (*asterisk*). A1–3, lateral, middle, and medial scallops of the anterior mitral valve leaflet; P1, lateral scallop of the posterior mitral valve leaflet; P3, medial scallop of the posterior mitral valve leaflet.

## Doppler Echocardiography and Hemodynamics

**2** The use of 2D echocardiography captures high-fidelity motion images of cardiac structures but not blood flow. Blood flow indices—such as blood velocities, stroke volume (SV), and pressure gradients—are the domain of Doppler echocardiography. Unlike 2D imaging, which relies on the time delay and amplitude of reflected ultrasound, Doppler technologies are based on the change in frequency that occurs when ultrasound interacts with moving objects. Reflections from red blood cells are used to determine blood flow velocity and calculate hemodynamic parameters. The combination of 2D images and quantitative Doppler measurements creates a uniquely powerful diagnostic tool. Accordingly, Doppler assessments are an essential element of the echocardiographic examination.<sup>25</sup>

The motion of an object causes a sound wave to be compressed in the direction of the motion and expanded in the direction opposite to the motion. This alteration in frequency is known as the *Doppler effect*. By monitoring the frequency pattern of reflections of red blood cells, Doppler echocardiography can determine the speed, direction, and timing of blood flow. The *Doppler equation* describes the relationship between the alteration in ultrasound frequency and blood flow velocity (Fig. 27-21):

$$\Delta f = v \times \cos \theta \times 2f_t/c$$

where  $\Delta f$  is the difference between transmitted frequency ( $f_t$ ) and received frequency,  $v$  is blood velocity,  $c$  is the speed of sound in blood (1,540 m/s), and  $\theta$  is the angle of incidence between the ultrasound beam and blood flow. Conceptually, the equation is simplified by observing that the change in ultrasound frequency is related to just two variables: blood velocity and  $\cos \theta$ . For this reason, the Doppler signal is shifted *only* by the component of the blood velocity that is in the direction of the beam path (i.e.,  $v \cos \theta$ ). When the beam angle divergence is greater than 30 degrees, the value of  $\cos \theta$  decreases rapidly and the Doppler system will markedly underestimate blood velocity. The requirement of near-parallel orientation ( $\cos \theta = 1$ ) for Doppler examinations contrasts with the near-perpendicular orientation preferred for 2D imaging. Consequently, the preferred imaging planes for Doppler will differ from those used for 2D imaging.

**Figure 27-21** Calculating blood flow velocity. The Doppler equation calculates blood flow velocity based on two variables: The Doppler frequency shift ( $\Delta F$ ) and the cosine ( $\cos$ ) of the angle of incidence between the ultrasound beam and the blood flow. The Doppler frequency shift is measured by the echocardiographic system, but  $\cos \theta$  is unknown, and manual entry by the echocardiographer is required for its estimation.  $v$ , blood flow velocity;  $F_T$ , transmitted signal frequency;  $F_R$ , reflected signal frequency;  $\Delta F$ , difference between  $F_R$ , and  $F_T$ ;  $c$ , speed of sound in tissue;  $\theta$ , angle of incidence between the orientation of the ultrasound beam and that of the blood flow.

### Spectral Doppler

Two Doppler techniques, *pulsed wave* (PW) and *continuous wave* (CW), are commonly used to evaluate blood flow. A thorough understanding of the advantages and disadvantages of each technique is critical in selecting the one most appropriate for the clinical setting at hand.<sup>26,27</sup> In clinical practice, PW and CW Dopplers are frequently used in conjunction with 2D imaging. The 2D image is used to identify the area of interest and guide the echocardiographer

in precisely localizing the sampling volume in a PW study or in directing the beam in a CW study.

## Pulsed-wave Doppler

PW Doppler offers the echocardiographer the ability to sample blood flow velocity from a particular location. The PW transducer uses a single crystal as both the emitter and the receiver of ultrasound waves. Like the pulsed echocardiography system described for 2D imaging, the PW Doppler system transmits a short burst of ultrasound toward the target and then switches to receive mode to interpret the returning echoes. Since the speed of sound ( $c$ ) in tissue is constant, the time delay for a signal to reach its target and return to the transducer depends solely on the distance ( $d$ ) to the target. Consequently, reflected signals from locations more distant from the transducer return after a greater time interval. By *time gating*, the electronic circuitry of the PW transducer interprets returning echoes only after a predetermined time delay following the transmission of an ultrasound pulse. In this way, only those signals associated with a location, referred to as the *sample volume*, are selected for evaluation.

The pulsed-Doppler system uses a repeating pattern of ultrasound transmission and reception. The rate at which the device repeatedly generates sound bursts is known as the *pulse repetition frequency*. Since the speed of sound through tissue is a constant, the pulse repetition frequency is directly related to the depth of the sample volume. The pulse repetition frequency is analogous to the frame rate of a movie camera. Like the multiple frames on a roll of movie film, each ultrasound pulse interacts with the blood flow for a brief period of time, and just as a series of movie frames displays motion, a series of pulsed cycles is consecutively analyzed to determine the blood flow. The Doppler data are frequently presented as a velocity–time plot known as the *spectral display* (Fig. 27-22B).

Since the pulsed-Doppler data are collected intermittently, the maximal frequency and blood flow velocity that can be accurately measured by PW Doppler are limited. The maximal frequency, which equals half the pulse repetition frequency, is known as the *Nyquist limit*. At blood velocities above the Nyquist limit, analysis of the returning signal becomes ambiguous, with the velocities appearing to be in the opposite direction. A similar effect is seen in movie animation, in which a rapidly spinning wheel appears to spin backward because of the slow frame rate. The ambiguous signal from frequencies above the Nyquist limit produces *aliasing* and the velocity signal may appear on the other side of the zero-velocity baseline, hence the term *wraparound*. The Nyquist limitation has led to an alternative approach for the assessment of high-velocity blood flows, continuous-wave Doppler (CW

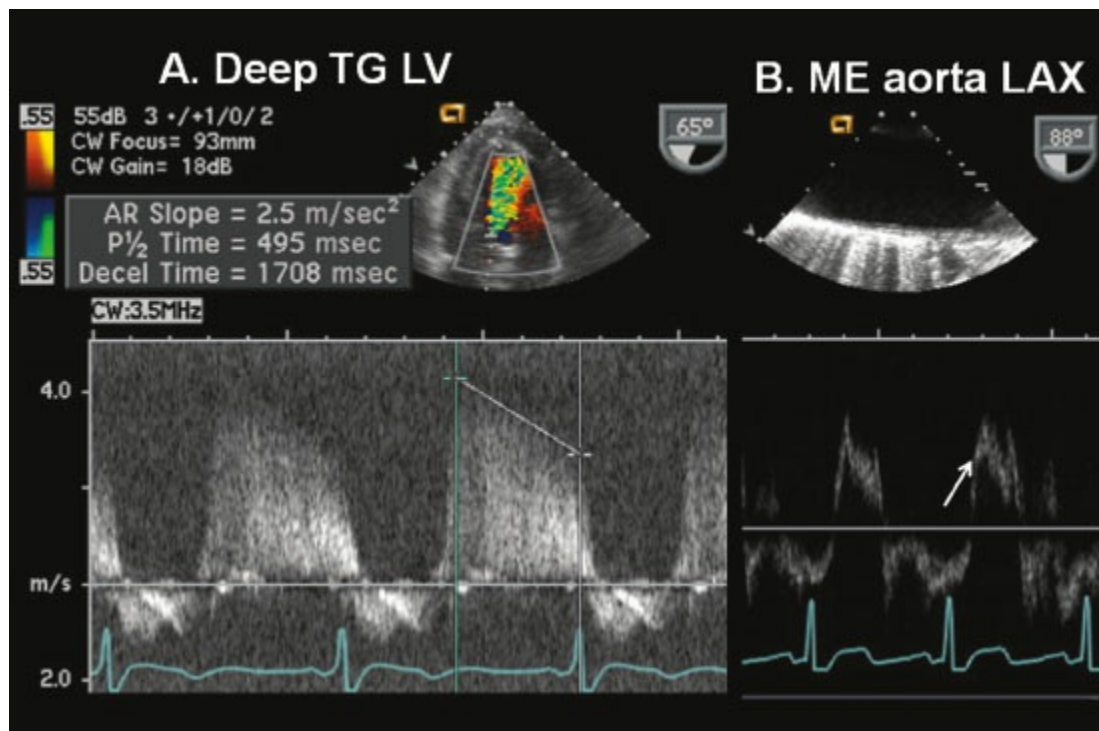

Doppler).

### **Continuous-wave Doppler**

The CW Doppler technique avoids the maximal velocity limitation of PW systems by using two crystals, one continuously transmitting and the other continuously receiving the reflected ultrasound signal. With continuous reception of the Doppler signal, the Nyquist limit is not applicable, and blood flows with very high velocities are recorded accurately. The CW mode receives reflected signals from blood flow throughout its beam path because it is not time-gated like the PW technique (Fig. 27-22A). The inability to select blood flow from a specific location favors the selection of CW Doppler primarily for the detection of the highest velocities along the beam path, which is useful in applications such as determining the high-velocity jet of aortic stenosis.

### **Color-flow Doppler**

CFD provides a dramatic display of both blood flow and cardiac anatomy by combining 2D echocardiography and Doppler (Fig. 27-23). The PW Doppler used for CFD differs from that previously discussed in two important ways. CFD performs *multiple* sample volume recordings along each scan line as the beam is swept through the sector. This approach provides flow data at each location in the sector, which can be overlaid on the structural data obtained by 2D imaging. The Doppler velocity data from each sample volume are color-coded and superimposed on top of the gray-scale 2D image. In the most widely accepted color code, red hues indicate flow toward the transducer and blue hues indicate flow away from the transducer. The ability to provide a real-time integrated display of flow and structural information makes CFD useful for assessing valvular function, aortic dissection, and congenital heart abnormalities. However, an important caveat to its use in the clinical setting must be noted. Since it relies on PW Doppler measurements, CFD is susceptible to alias artifacts. Aliasing in the color flow map is illustrated in Figure 27-24.

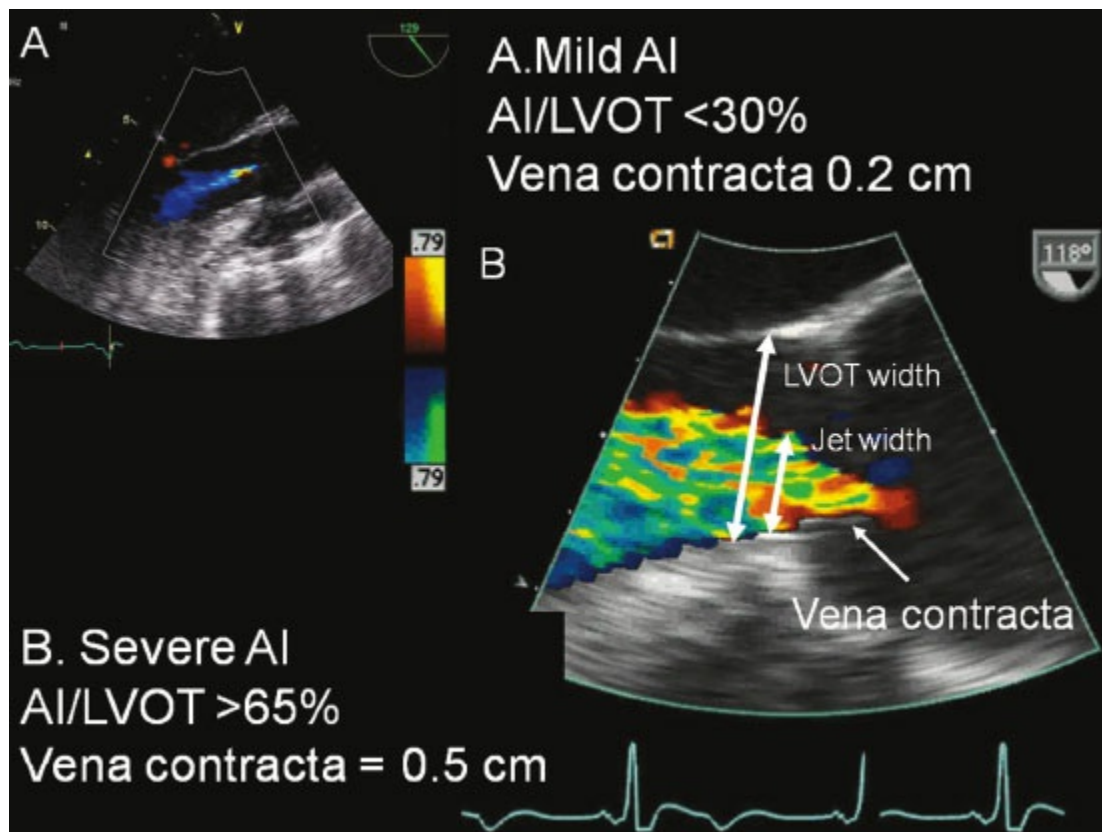

**Figure 27-22** Doppler echocardiography in aortic insufficiency. **A:** The deep transgastric (deep TG) long-axis view is displayed. A color-Doppler sector is placed over the aortic valve and LV outflow tract and the aortic insufficiency (AI) jet is imaged. The continuous-wave (CW) Doppler cursor is positioned at the center of the AI flow and the spectral display of the AI jet is shown against time. The slope of the AI jet is used to calculate the pressure half-time ( $P_{1/2}$  time). A short  $P_{1/2}$  time is associated with severe AI. **B:** The descending aorta is imaged in long axis. The sample volume of pulsed-wave Doppler is placed upstream. There is a systolic wave above the baseline, as the blood moves toward the transesophageal echocardiography transducer, and a diastolic wave (arrow), indicating reversal of aortic flow because of severe AI. Decel, deceleration.

## Hemodynamic Assessments

Doppler echocardiography's ability to quantitatively measure blood velocity yields a wealth of information on the hemodynamic state. Stroke volume, chamber pressures, valvular disease, pulmonary vascular resistance, ventricular function (systolic and diastolic), and anatomic defects are commonly assessed with perioperative Doppler echocardiography.<sup>28</sup>

## Volumetric Flow Assessments

Measurements such as stroke volume and cardiac output express the volume of blood ejected by the heart over time. Volumetric parameters are calculated using the principle that volumetric flow ( $Q$ ) equals blood flow velocity ( $v$ ) times the cross-sectional area (CSA) of the conduit, that is,  $Q = v \times \text{CSA}$ . To determine volumetric flows with echocardiography, a Doppler measurement of the blood flow velocities and a 2D measurement of the CSA are recorded.

**Figure 27-23** Evaluation of aortic insufficiency (AI). Color-flow Doppler of the aortic valve (AV) in the midesophageal long-axis view. AI is graded using (A) the relative ratio of the AI jet thickness to the diameter of left ventricular outflow tract (LVOT); both measurements are performed at the same site, usually within 0.5 to 1 cm proximal to the AV plane; and (B) the width of the AI jet as it crosses the AV cusps (vena contracta).

**Figure 27-24** Doppler evaluation of mitral regurgitation (MR; midesophageal five-chamber view). Aliasing of the color signal and vena contracta (arrow) are visualized.

### Stroke Volume and Cardiac Output

To calculate stroke volume, the instantaneous velocities during systole are traced from the spectral display and the echocardiographic system's software package calculates the time-velocity integral (VTI, in centimeters). In effect, the VTI represents the distance ( $v \times t = d$ ) blood traveled during systole

(i.e., stroke distance). By multiplying the VTI by the CSA (in square centimeters) of the conduit (e.g., aorta, MV, PA) through which the blood traveled, the stroke volume (in cubic centimeters) is obtained:  $SV = VTI \times CSA$  (Fig. 27-25).<sup>29-31</sup> Cardiac output (CO), which expresses volumetric flow in cubic centimeters per minute, is estimated from the product of SV and heart rate:  $CO = VTI \times CSA \times HR$ . Figure 27-26 demonstrates calculation of cardiac output and SV from the LVOT.

## Valve Area

**The Continuity Equation.** The principle of conservation of mass is the basis of the *continuity equation*, which is commonly used to measure the aortic valve area.<sup>32</sup> The continuity equation simply states that the volume of blood passing through one site in the heart (e.g., the LVOT) is equal to the mass or volume of blood passing through another site (e.g., the aortic valve).

Volumetric flow<sub>1</sub> = volumetric flow<sub>2</sub>; therefore:

$$CSA_1 \times VTI_1 = CSA_2 \times VTI_2 \text{ and}$$

$$CSA_1 = CSA_2 \times VTI_2/VTI_1$$

Figure 27-27 demonstrates calculation of AV area using this approach.

## Pressure Assessment

**The Bernoulli Equation.** Pressure gradients are used to estimate intracavitary pressures and to assess conditions such as valvular disease (e.g., aortic stenosis), septal defects, outflow tract obstruction, and major vessel pathology (e.g., coarctation). As blood flows across a narrowed or stenotic orifice, blood flow velocity increases. The increase in velocities relates to the degree of narrowing. In the clinical situation, the *simplified Bernoulli equation* describes the relation between the increases in blood flow velocity and the pressure gradient across the narrowed orifice<sup>11</sup>:

**Figure 27-25** Determination of stroke volume. Volumetric flow can be determined from a combination of area and velocity measurements. In this example, the flow through the ascending aorta is used to determine the stroke volume. Integrating the Doppler-derived flow velocities over time (known as the time–velocity integral) during a single cardiac cycle calculates the stroke distance. The cross-sectional area measurement is obtained by two-dimensional echocardiography. The product of these two measurements, conceptualized as a cylinder, is the stroke volume. CSA, cross-sectional area; AoV, aortic valve.

$$\Delta P = 4V_{\max}^2$$

where  $\Delta P$  in millimeters of mercury is the pressure gradient across the narrowed orifice and  $V_{\max}$  in meters per second is the maximum velocity across that orifice measured by Doppler.

Thus, in clinical echocardiography the pressure gradient is obtained by the straightforward process of measuring the peak velocity of blood flow across the lesion of interest.<sup>33,34</sup> The measured peak velocity is then entered into the simplified Bernoulli equation to estimate the pressure gradient.

The Bernoulli equation is commonly employed to measure the pressure gradient across a stenotic valve. In addition, the rate of decline in the pressure gradient across the valve is related to the severity of the disease.<sup>35,36</sup> This *pressure half-time* is the time required for the peak transvalvular pressure gradient to decrease by 50%. Typically, a larger orifice will have a shorter pressure half-time, as pressures equalize faster.

**Figure 27-26** Stroke volume calculation. Stroke volume is equal to the blood flow crossing the left ventricular outflow tract (LVOT). In the deep transgastric long-axis view, the LVOT orifice (*large oval*) can be calculated from the LVOT diameter (D). The blood flow velocity across the LVOT is measured with pulsed Doppler and the velocity time integral (VTI) by tracing the velocity envelope. RV, right ventricle; LA, left atrium.

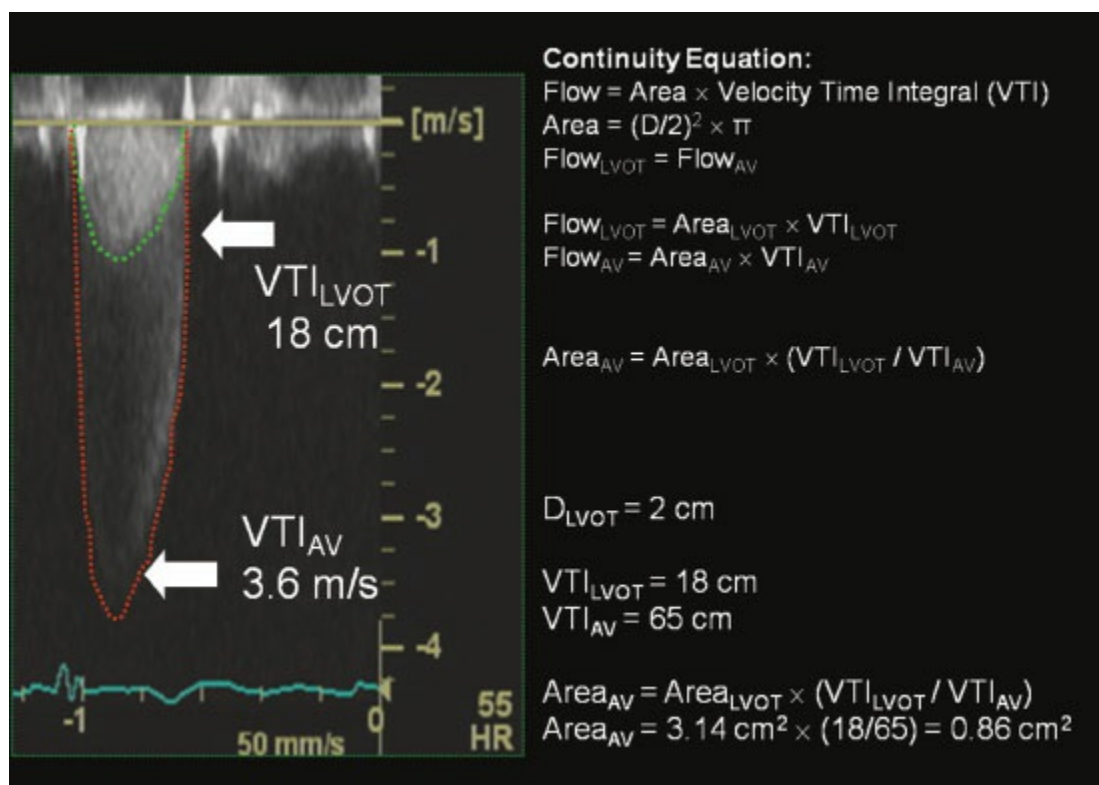

### Measurement of Intracavitary Pressures

Intracavitary and pulmonary arterial pressures are estimated from the pressure gradient across two adjacent chambers. The pressure gradient is defined as the difference in pressure from the “driving” chamber to the “receiving” chamber. Echocardiographically, the pressure gradient is calculated from the Doppler-derived velocities of the regurgitant jet into the receiving chamber.<sup>37-39</sup> Table 27-1 provides calculations of intracardiac and PA pressures.

## Echocardiographic Evaluation of Systolic Function

Evaluation of LV systolic function is a primary component of every **3** echocardiographic examination. Information about global as well as regional LV performance is accomplished by assessing the size, shape, and LV contractile function. Both qualitative assessments (which are inherently subjective) and quantitative techniques (which produce hard numerical estimates) are useful: 2D and M-mode image the LV walls and cavity and Doppler echocardiography measures the velocity of blood flow and moving

tissue.

**Figure 27-27** Evaluation of aortic stenosis. Calculation of aortic valve area using the “double envelope” technique. The cursor of continuous-wave Doppler is placed in the middle of the blood flow traversing the stenosed aortic valve, and two envelopes are identified. The one with the slower velocity is from the left ventricular outflow tract (LVOT) and the one with the fastest is from the aortic valve (AV). The envelopes of the velocities are traced to derive the respective velocity time integrals (VTI). The aortic valve area is calculated using the continuity equation. D, diameter.

**Table 27-1** Calculation of Cardiopulmonary Pressures

Pressure	Equation
RVSP or PASP	$= 4(V_{TR})^2 + RAP$
PAMP	$= 4(V_{early PI})^2 + RAP$
PADP	$= 4(V_{late PI})^2 + RAP$
LAP	$= SBP - 4(V_{MR})^2$
LVEDP	$= DBP - 4(V_{AI end})^2$

RVSP, right ventricular systolic pressure; PASP, pulmonary artery systolic pressure; V, peak velocity; TR, tricuspid regurgitation; RAP, right atrial pressure; PAMP, pulmonary artery mean pressure; PI, pulmonic valve insufficiency; PADP, pulmonary artery diastolic pressure; LAP, left atrial pressure; SBP, systolic blood pressure; MR, mitral regurgitation; LVEDP, left ventricular end-diastolic pressure; DBP, diastolic blood pressure; AI, aortic insufficiency.

### Left Ventricular Walls

The LV cavity and walls at the basal, mid, and apical levels are evaluated in

the midesophageal and transgastric views. From the midesophageal position, the TEE imaging array is rotated electronically in a clockwise fashion to scan the entire circumference of the LV cavity and walls in a longitudinal orientation. Further advancement of the TEE probe to the transgastric position combined with anterior flexion (anteflexion) of the probe sequentially images the LV short axis from its base to apex. The echocardiographic imaging of blood and myocardium is based on their different acoustic properties: Muscle tissue is reflective and imaged in shades of gray, whereas ultrasound easily propagates through blood, resulting in the LV cavity appearing dark. Their interface is the endocardial surface, which typically produces the brightest signal. The evaluation focuses on the shape, size, and motion of LV walls.

## Shape

The LV's longitudinal shape is evaluated in the midesophageal views (Fig. 27-28). It appears bullet-shaped with the mitral annulus and leaflets comprising its broad base, and the walls tapering toward its apex. In the midesophageal view at 0-degree rotation (midesophageal four-chamber, midesophageal five-chamber) the inferolateral wall of the LV appears on the right of the TEE monitor screen and the inferoseptal wall on the left. Clockwise rotation of the multiplane angle to about 90 degrees (midesophageal two-chamber) will image the long axis of the LV, with the anterior and inferior walls presented on the right and left sides of the monitor, respectively. Further rotation to approximately 135 degrees will image the LV anteroseptal and inferolateral walls on the right and left sides of the screen.

The echocardiographer must be careful to image the LV along the true long axis in the midesophageal views. Often, in the midesophageal four-chamber view, the imaging plane may cut obliquely in an anterior direction, which causes an increase in the apparent wall thickness and foreshortens the LV cavity. This is avoided by confirming that the LV long-axis measurement approximates that of the LV length (as measured from the mitral annular plane to the apex, typically in the midesophageal two-chamber view). In many cases, slight retroflexion or rotation of the multiplane angle from 0 to 20 degrees is helpful to achieve the best alignment. The LV walls are divided into three segments each—basal, mid, and apical—as defined by lines drawn perpendicular to the LV long axis at the tips and base of the papillary muscles.

**Figure 27-28** Left ventricular (LV) walls. In the esophagus, the transesophageal echocardiography (TEE) probe is rotated clockwise from 0 to 140 degrees to obtain the midesophageal (ME) views. Advancement of the TEE probe inside the stomach obtains the transgastric (TG) midpapillary short-axis view. In the ME views, the LV is divided in basal, mid, and apical segments. 4C, four-chamber; 2C, two-chamber; LA, left atrium; RA, right atrium; RV, right ventricle.

From the transgastric position, the LV is seen along its short axis; its shape resembles a doughnut. The basal segments are imaged in the short axis with the TEE probe in the distal esophagus or very high up inside the stomach. At this depth, the mitral leaflets (base of heart) are seen “enface.” Gradual advancement of the TEE probe into the stomach images the mid-LV segments (Fig. 27-16). Here, the anatomic landmark is the body of the papillary muscles at 2 o’clock (posteromedial) and 5 o’clock (anterolateral). Further advancement of the TEE probe will image the LV apex, much thicker and with a smaller cavity. In either midesophageal or transgastric imaging planes, the LV walls thicken in systole and thin in diastole. As seen in the midesophageal views, the LV base descends toward the LV apex and ascends at diastole.

## Aneurysms

Aneurysms appear as a dilated part of the LV perimeter with thinned wall(s) and decreased motion. Aneurysms are always pathologic and usually due to ischemia-related necrosis and weakening of the LV wall. Aneurysms are separated into true and false. If all myocardial layers (epi-, mid-, and

endocardium) are present in the wall of the aneurysm, it is called a *true aneurysm*. The “neck” of a true aneurysm is usually wide, and the aneurysmal cavity shallows with a smooth transition from normal to aneurysmal walls. An aneurysm is called *false* or “pseudo” if the LV wall contains only some of the myocardial layers (usually the epicardium and part of the midwall). False aneurysms are caused by necrosis of the LV wall, usually from myocardial infarction. Sometimes, the wall of a false aneurysm consists only of the attached pericardium. False aneurysms have a narrower neck and the transition between healthy and diseased wall segments is abrupt. A false aneurysm is prone to rupture and is treated surgically. Blood flow is sluggish within aneurysms. Red blood cells clump together, which increases echogenicity and creates spontaneous echocardiography contrast, a smoke-like appearance inside the LV cavity. Thrombus, appearing with brightness similar to that of myocardium but clearly separated from the LV wall, can also develop in aneurysms.

## Texture

The *texture* of the LV walls may offer additional information in patients with infiltrative cardiomyopathies, such as amyloid, where the thickened myocardium has a speckled appearance.

## Wall Thickness

LV hypertrophy is termed *concentric* if the cavity is not increased (usually resulting from increased pressure work) and *eccentric* when there is LV dilation (usually resulting from increased volume work). The diagnosis is made by summing the end-diastolic (ED) wall thickness of the anteroseptal and inferolateral LV segments in the basal transgastric short-axis view, just at the tips of the papillary muscles (Fig. 27-29). Normal values are  $18 \pm 2$  mm (men) and  $15.5 \pm 1.5$  mm (women).

## Segments and Regional Function

Abnormal myocardial wall systolic thickening is a sensitive marker of myocardial ischemia that appears earlier than electrocardiographic and hemodynamic changes.<sup>40–42</sup> Regional LV systolic function reflects the regional myocardial blood flow.<sup>43</sup> The association of the regional LV wall motion with the underlying coronary artery distribution is used to diagnose local perfusion defects. The LV is divided into 17 regional segments (Fig. 27-28).<sup>44</sup> Along the longitudinal plane, each wall is divided into basal, mid, and apical levels. The basal and mid-levels are further divided into anterior, inferior, two septal (anteroseptal and inferoseptal), and two lateral (anterolateral and

inferolateral) segments. The apical level is divided into four segments (anterior, inferior, septal, and lateral) and the apical cap is the 17th segment. To limit misdiagnosis, evaluation of each segment is done in at least two different views, ensuring that both endocardium and epicardium are visible. A midesophageal or transgastric view is digitally stored and played over time. The segmental (or regional) function is evaluated by noticing the presence or absence of endocardial excursion (toward the LV cavity) and degree of systolic wall thickening during one or two consecutive cardiac cycles (Fig. 27-29). The electrocardiogram is used to define systole and diastole. The function of each wall segment is scored as shown in Table 27-2.<sup>45</sup> The wall motion score index is the sum of all scores divided by the number of segments evaluated. The evaluation of segmental wall motion to detect ischemia is not error-free. In addition to being a subjective assessment, wall motion may be affected by tethering, regional loading conditions, and stunning.<sup>46</sup> Epicardial pacing of the free wall of the RV (as in the post-bypass period) produces a left bundle block and induces septal wall motion abnormalities. Interobserver reproducibility is better for normally contracting segments than for dysfunctional segments.<sup>47</sup> Because of these issues, wall thickening is a more reliable marker of regional function.

**Figure 27-29** Two-dimensional evaluation of left ventricular (LV) global and regional functions. Regional and global evaluation of the LV using the transgastric short-axis view at the midpapillary level. Measurements are performed at end-diastole (ED) and end-systole (ES). **Top panels:** Measurement of diameters (D), areas (A), and wall thickness. Wall thickness is measured at ED in the anteroseptal and inferolateral wall

segments. **Bottom panel:** Diameter and wall thickness measured using method mode with the cursor crossing the middle of inferior (**top**) and anterior (**bottom**) segments. The percent change of wall thickness of the midanterior wall segment can be used to grade its regional function. In this example, wall motion score (WMS) is 1 (**normal**) because the segment thickens >30%.

**Table 27-2** Grading of Wall Function

Regional Function	Grade	Inward Radial Motion (Systolic Wall Thickening)
Normal	1	>30% (marked)
Hypokinetic	2	>10% to <30% (reduced)
Akinetic	3	<10% (negligible)
Dyskinetic	4	Paradoxical systolic motion (systolic thinning)
Aneurysmal	5	Thin wall, no thickening

## Left Ventricular Cavity

### Diameters

The LV cavity is defined by its long and short axes. The LV major (or long) axis dimension is measured in the midesophageal two-chamber view, from the base of the mitral annulus to the LV apex ([Fig. 27-30](#)); the minor (or short) axis dimension is measured in either the midesophageal or transgastric two-chamber views, perpendicular to the long axis, at the height of the papillary muscle tips. The minor axis is equal to one-half of the long-axis measurement. Proper measurement of the LV minor axis is used to quantify the LV ED volume. Normal LV ED dimensions (EDDs) are 4.2 to 5.9 cm (men) and 3.9 to 5.3 cm (women). An increased LV EDD denotes LV dilation and volume overload, whereas a decreased LV EDD denotes hypovolemia and inadequate preload.

### Global Systolic Function

Systolic function is responsible for delivering a sufficient amount of blood to the vessels at a high enough pressure to perfuse the tissues adequately. A variety of echocardiographic measurements are used to evaluate the components (preload, afterload, and contractility), which collectively define LV global systolic function. The techniques for LV evaluation are described in detail in references.[48,49](#)

### Percent Fractional Shortening (%FS)

FS measures the relative change of the LV short-axis diameter between ED

and end-systole (ES; Fig. 27-29). FS is a one-dimensional, unitless measurement of systolic function. Measurements are done in the transgastric midpapillary short-axis view, just above the papillary muscles. A larger number occurs when the LV has normal or increased systolic function. FS is not a substitute for ejection fraction (EF) and may overestimate systolic function if there is LV dilation or abnormal wall motion at another level.  $\%FS = (LV\ EDD - LV\ ESD)/(LV\ EDD) \times 100$  and is normally 27% to 45%.

**Figure 27-30** Quantitation of left ventricular (LV) systolic function. The midesophageal (ME) LV four-chamber (ME 4C) and two-chamber (ME 2C) views are obtained. The images are examined in end-diastole (ED) and end-systole (ES). The LV endocardium is traced. This automatically defines the LV area (A) and long axis (L). The system software will calculate LV volumes using either the method of discs (MOD) or the area-length method (AL). EF, ejection fraction; EDV, end-diastolic volume; ESV, end-systolic volume; SV, stroke volume.

## Volumes

LV volume measurements are used to calculate preload (ED volume [EDV]) as well as SV and EF. The ED and ES LV volumes can be derived from manually tracing the endocardial border in ED and ES, respectively.

LV volume is commonly measured using the modified Simpson or the area length method. The biplane method of discs (or modified Simpson rule) conceives a series of disks inside the LV cavity, which have equal thickness and are stacked like coins along the LV long-axis dimension (Fig. 27-30). The

diameter of each disk is the short-axis dimension as defined from the LV endocardium tracing. Measurements are performed in the midesophageal four- and two-chamber views. Alternatively, the area length method can be used to calculate LV volume:  $LV\ volume = 5/6 \times ([area] \times [length])$ . This approach is performed in one of the previous views and calculates the LV volume using the endocardial-enclosed area and the LV major axis (Fig. 27-30). In most adults, an ED area less than 12 cm<sup>2</sup> indicates hypovolemia.<sup>50</sup> Reliable and correct visualization of the endocardial border is paramount for accurate measurement of LV volumes with either method. The methods underestimate LV volume when the LV cavity is “foreshortened.”

### **Percent Fractional Area Change**

Fractional area change (FAC) is the percent difference between ED and ES LV areas (Fig. 27-29). The LV area is measured by manually tracing the endocardial border in the transgastric midpapillary short-axis view in ED and in ES. The papillary muscles are not traced. Unlike LVEF measurements, FAC does not take into account the presence of wall motion abnormalities at a different level: for example, the function of the LV apex, which is frequently involved in coronary artery disease. Therefore, caution is advised when interpreting FAC. Normal values are 56% to 65%.<sup>51</sup>

### **Visual Estimation of FAC**

The most frequently used technique to evaluate global LV function as well as preload is visual estimation of FAC, often referred to as the *eyeball* EF. Although highly subjective, it is practiced widely and is accurate in experienced echocardiographers, especially in normally contracting ventricles.<sup>52</sup> With LV dysfunction, visual evaluations of FAC become less reproducible among different observers.<sup>47</sup>

### **Ejection Fraction**

EF is the most frequently used estimate of LV systolic function. The evaluation of EF provides prognostic information about mortality and morbidity.<sup>53</sup> EF and SV are affected by factors such as preload, afterload, and heart rate, and thus are not always indicators of intrinsic systolic function. Typical clinical scenarios in which EF does not represent LV systolic function include the hypercontractile LV in mitral regurgitation (MR; where more than half of ED volume may regurgitate inside the left atrium) or the hypocontractile LV in aortic stenosis (where LV systolic performance is poor despite preserved contractility).

## Stroke Volume

Stroke volume is calculated as the difference between EDV and ESV (end-systolic volume), and percent EF is calculated as  $\%EF = SV/EDV \times 100 = (EDV - ESV)/EDV \times 100$ . Normal values are EDV, 67 to 155 mL (men), 56 to 104 mL (women); ESV, 22 to 58 mL (men) and 19 to 49 mL (women); %EF, greater than 55%.

## Associated Findings

Sluggish flow will clump together red blood cells, producing spontaneous echocardiography contrast, which is imaged as “smoke.” Thrombus is also found if there is blood stasis, such as inside an aneurysm or at the LV apex. These findings are often present when LV function is depressed.

## Tissue Echocardiography—Myocardial Velocity

Tissue Doppler imaging (TDI) measures the velocity of myocardial motion along the longitudinal axis and is a sensitive measurement of regional and global functions and outcome.<sup>54</sup> The myocardial velocity is measured from the basal LV segments with the sample volume placed next to the mitral annulus. The velocities are comprised of a systolic (S') followed by, in the opposite direction, two diastolic waves, one early (E') and one following atrial contraction (A'). A reduced or delayed S' velocity is associated with development of regional ischemia (Fig. 27-31).<sup>55</sup>

## Evaluation of Left Ventricular Diastolic Function

An increased recognition of the impact of LV diastolic function on the overall cardiac function and outcome has driven efforts to both monitor and optimize diastolic performance in the perioperative period. The presence of preoperative asymptomatic ventricular dysfunction in patients undergoing vascular surgery is associated with increased short- and long-term morbidity and mortality.<sup>56</sup> Furthermore, there is a significant association between the presence of perioperative diastolic dysfunction and postoperative heart failure as well as increased hospital length of stay.<sup>57</sup> Several echocardiographic studies have suggested that patients with diastolic dysfunction presenting for cardiac surgery may be prone to intraoperative hemodynamic instability and worse outcomes.<sup>58,59</sup> These reasons support diastolic function assessment as part of the comprehensive perioperative echocardiographic examination.<sup>60</sup> Doppler echocardiography is the preferred technique to assess diastolic performance and grade the severity of the disease process.

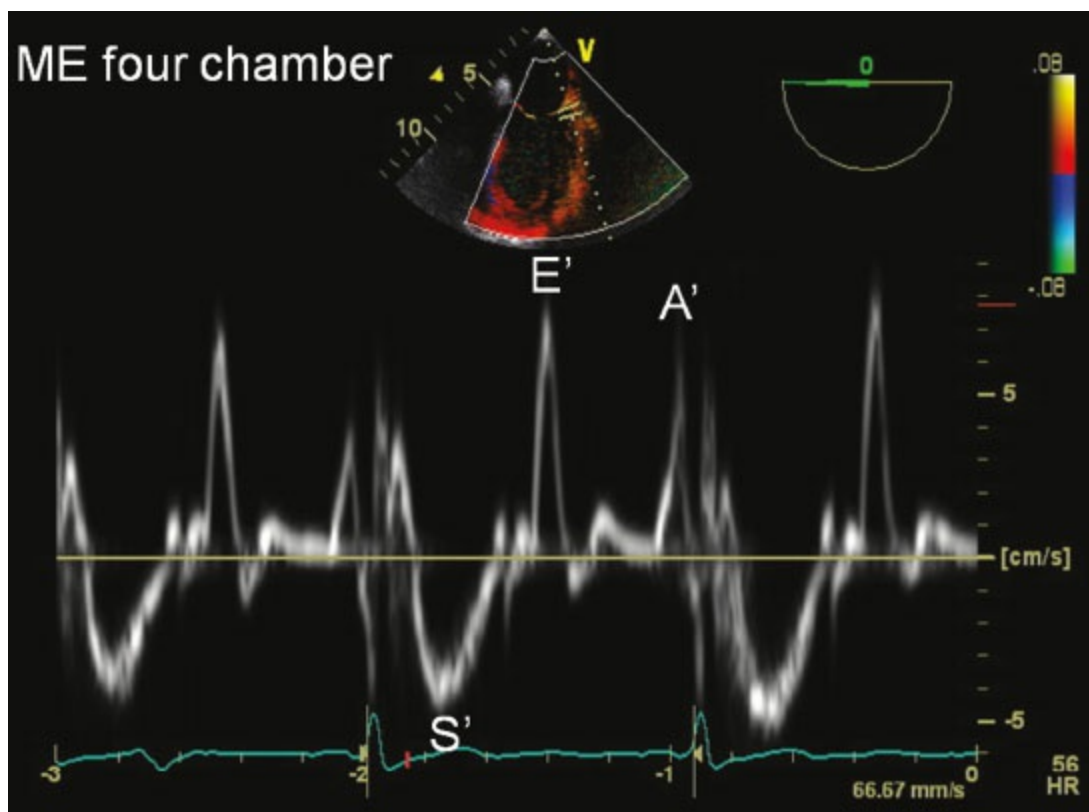

Diastolic dysfunction is defined as the inability of the LV to fill at normal

left atrial (LA) pressures and is characterized by a decrease in relaxation and/or LV compliance. Diastolic dysfunction may be present in the absence of clinical symptoms of heart failure. When these symptoms occur in the presence of diastolic dysfunction, then the diagnosis of diastolic heart failure is made.

### Diastolic Physiology

Traditionally, the cardiac cycle has been divided into two phases: systole, comprising isovolumic contraction and ejection, and diastole, comprising isovolumic relaxation, rapid filling, diastasis, and atrial contraction. Rather than a passive phase of the cardiac cycle when filling of the heart occurs, diastole is currently regarded as being intimately coupled and interdependent with systole. In this respect, Nishimura and Tajik<sup>61</sup> have proposed dividing the cardiac cycle into three phases: contraction, relaxation, and filling. Contraction encompasses the isovolumic contraction and the first half of ejection. The critical insight into the proposal of Nishimura and Tajik is that relaxation begins during the second part of *ejection*, and then continues during the isovolumic relaxation and rapid filling phases, illustrating the interdependency of systole and diastole. The filling phase consists of the early rapid filling phase, diastasis, and atrial contraction.

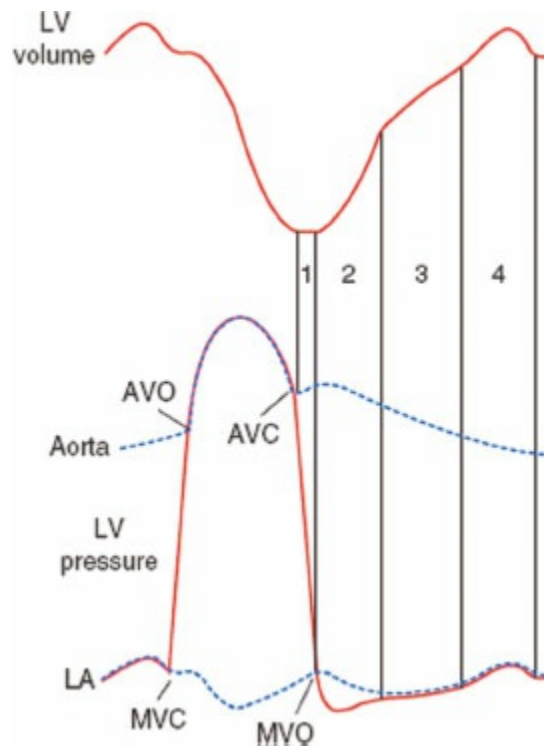

**Figure 27-31** Tissue Doppler imaging. Myocardial velocity of basal anterolateral segment of left ventricle is measured with pulsed-wave tissue Doppler. ME, midesophageal; S', systolic velocity; E', early diastolic velocity; A', late diastolic velocity.

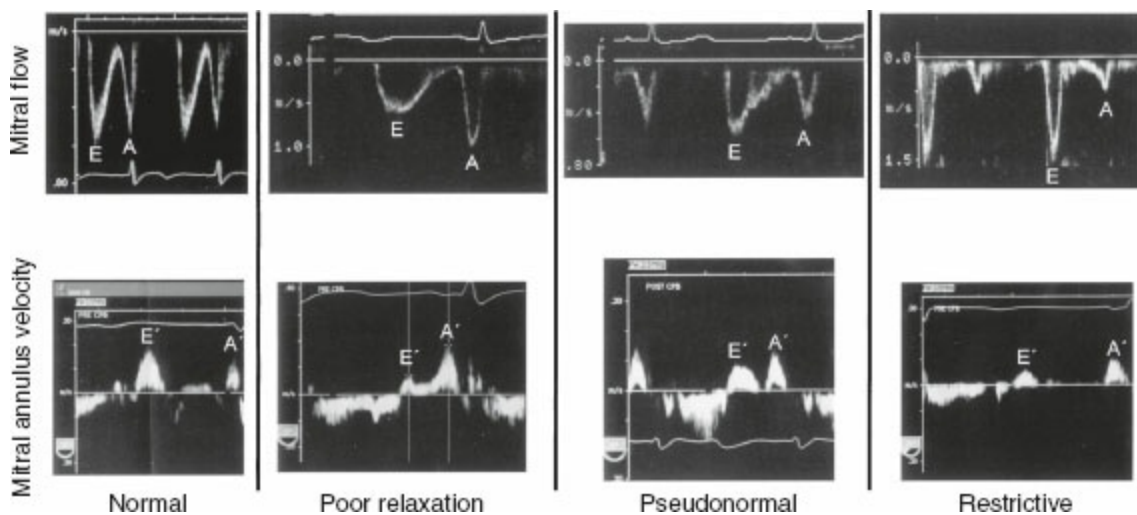

Relaxation, the active phase of diastole, commences with the dissociation of actin–myosin cross-bridges and a lowering of the intracellular calcium. LV pressure begins to fall and eventually becomes lower than ascending aortic pressure, resulting in closure of the AV. As the ventricle continues to relax, the LV pressure falls below LA pressure, reaching its nadir, and promotes opening of the MV. At this point, the pressure gradient between the LA and LV is maximal and early rapid filling phase of the LV occurs. This phase coincides with and depends on the continuation of relaxation. The early filling phase is responsible for 80% to 90% of LV filling. As the ventricle fills, the LV pressure gradually rises and equates the pressure in the LA; thus, minimal flow or diastasis occurs. With commencement of the atrial contraction phase, the pressure gradient between the LA and LV rises once again and blood flows from the LA to the LV. At the end of the LA systole, the pressure in the LV rises above the LA pressure and promotes closure of the MV (Fig. 27-32).

Ventricular filling is affected by load factors (preload and afterload) as well as mechanical factors, such as ventricular relaxation and compliance, ventricular contraction, atrial contraction and MV dynamics, viscoelastic forces of the myocardium, and pericardial restraint.

The early manifestation of diastolic dysfunction is characterized by an impaired relaxation, implying that the rate and duration of decrease in LV pressure after systolic contraction is prolonged. This results in an inability of the LV to fill adequately during the rapid filling phase. A compensatory increase in filling occurs with atrial contraction. This stage of disease is known as *grade I diastolic dysfunction*. In more advanced stages of disease, grades II and III of diastolic dysfunction, a decrease in LV compliance ensues. Compliance is defined as a change of volume with respect to a change in pressure. Thus, a decrease in LV compliance will lead to a disproportionate increase in LV pressures and, ultimately, LA pressures.

**Figure 27-32** Diastolic phase of the cardiac cycle. During isovolumic relaxation (1) left ventricular (LV) pressure falls rapidly following aortic valve closure (AVC). When LV pressure decreases below left atrial (LA) pressure, the mitral valve opens (MVO), initiating early, rapid LV filling (2). Equilibration of LV and LA pressures results in diminished transmitral flow during diastasis (3) until atrial contraction (4). Diastole terminates with mitral valve closure (MVC). (Reproduced from Plotnick GD. Changes in diastolic function—difficult to measure, harder to interpret. *Am Heart J.* 1989;118:637, with permission.)

**Figure 27-33** The impact of progressive left ventricular (LV) diastolic dysfunction on transmitral mitral flow (E, A) and mitral annular velocities (E', A'). In the first stage, diastolic dysfunction both E and E' are decreased. However, with progressing grades of disease, while the E velocity increases (due to LA pressure increases) the E' velocity remains reduced. This supports the utility of E' as a measure of LV relaxation as well as its relative load independence. (Reprinted with permission from Shernan SK. A practical approach to the echocardiographic evaluation of ventricular diastolic function. In:

## **Echocardiographic Assessment of Left Ventricular Diastolic Function**

**4** Echocardiography has become the diagnostic modality of choice for patients with diastolic dysfunction. Echocardiographic assessments have been validated by cardiac catheterization and correlate with clinical presentation.<sup>62</sup> The American Society of Echocardiography has issued recommendations for evaluating and grading left ventricular diastolic function using a combination of 2D echocardiography, pulsed-wave Doppler, M-mode color Doppler, and tissue Doppler.<sup>60,63</sup> This section is limited to the discussion of the two most commonly used methods: pulsed-wave Doppler of transmitral flow and TDI.

### **Imaging Views and Techniques**

The echocardiographic acquisition of the diastolic parameters is best done when integrated in a standard examination. The typical view used for both transmitral flow (TMF) Doppler as well as for the TDI is the midesophageal four-chamber view. The interrogation volume sample should be placed at the tips of the MV for TMF assessment. For TDI of myocardial velocity profiles, the sample volume is typically placed at the junction of the mitral annulus and the lateral wall.

### **Interpretation of Pulsed-wave Doppler Velocity Curves**

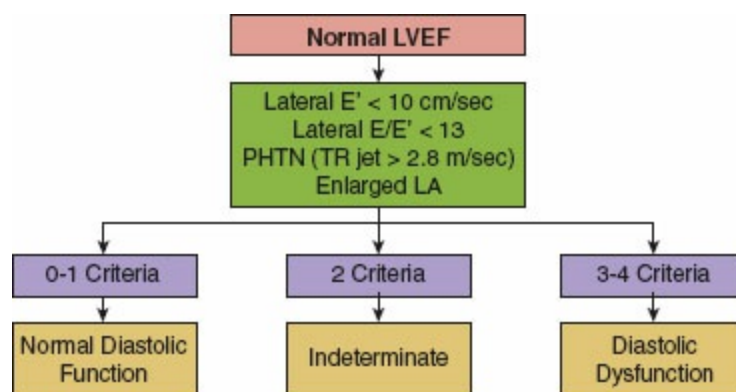

Doppler assessment of the TMF velocities reflects the instantaneous pressure gradient (see previous discussion of the Bernoulli principle). Therefore, the displayed velocity waveforms parallel the changes in pressure gradient occurring in the left heart. The TMF profile consists of two waves, the “E” and “A” waves. The peak E wave represents the peak early filling velocity. The rate of decrease of velocity following the peak E velocity is known as the *deceleration time* (DT). The DT depends on how fast the pressure rises in LV during the rapid filling phase and represents a direct measure of ventricular compliance. Thus, if the ventricular compliance decreases, the DT shortens. The peak A wave represents the peak blood velocity during atrial contraction. In a normal individual, the E wave is slightly larger than the A wave and the DT is  $200 \pm 40$  ms (Fig. 27-33).

The mitral annular TDI technique assesses diastolic function by evaluating the myocardial velocities at the level of the mitral annulus. The myocardial motion produces high-amplitude low-velocity signals. A normal profile has a

biphasic diastolic component: the early diastolic wave E', which represents the myocardial elongation caused by early filling, and the late diastolic wave A', which represents the myocardial distension generated by blood flow during atrial contraction (Fig. 27-31). In a healthy patient, the TDI pattern mirrors the TMF pattern, except with lower velocities. E' reflects LV relaxation and values less than 10 cm/s are considered a sign of diastolic dysfunction.<sup>64</sup> Thus, in patients with pseudonormal or restrictive disease, in whom normal or elevated E wave TMF velocities occur despite advanced pathology, the TDI E' wave remains reduced, making it a useful approach to diagnosis.

As diastolic dysfunction develops, the patterns of the flow velocity curves change in concordance with the pressure gradient changes in the pulmonary vein—LA—LV system. In grade I diastolic dysfunction, as the LV is incompletely relaxed when early ventricular filling occurs, the pressure gradient, and thus E wave velocity, is less than normal. The delayed relaxation prolongs LV filling late into diastole, and therefore the DT is prolonged. A compensatory increase in TMF during atrial contraction, due to the higher residual atrial preload, generates a high A wave velocity. Thus, the TMF curve of an individual with abnormal relaxation is represented by a low E, high A, and prolonged DT (Fig. 27-33).

Progression of diastolic disease leads to grade II diastolic dysfunction, which is marked by decreases in LV compliance. LA pressure rises as a compensatory mechanism to normalize the pressure gradient across the MV. In this scenario, the TMF velocities resemble the normal curve; thus, this stage is known as *pseudonormal* (Fig. 27-33).

**Figure 27-34** Algorithm for diagnosis of left ventricular diastolic dysfunction. LVEF, left ventricular ejection fraction; PHTN, pulmonary hypertension; TR, tricuspid regurgitation; LA, left atrium. Adapted from the 2016 Recommendations for evaluation of left ventricular diastolic dysfunction by echocardiography.<sup>63</sup>

Grade III diastolic dysfunction, known as the *restrictive phase*, is characterized by a significantly decreased LV compliance. The high LA—LV pressure gradient produces a fast acceleration of blood flow in the LV. A high

E velocity on the TMF curve is representative for grade III diastolic dysfunction. LV pressure increases rapidly during filling because of the increased LV stiffness resulting in a short DT. The forward filling velocity at atrial contraction is low (small A wave) because of the decreased compliance (Fig. 27-33). One of the important caveats to assessing diastolic function using pulsed-wave Doppler is that the flow patterns depend on pressure gradients and therefore are affected by both preload and afterload. In settings in which the load conditions vary at a fast pace, such as the operating room, changes in TMF velocities may be difficult to interpret. TDI, which directly measures myocardial velocities, provides a more load-independent method of diastolic function assessment.<sup>65</sup> The updated guidelines utilize 4 criteria to diagnose diastolic dysfunction (Fig. 27-34).<sup>63</sup>

### **Pericardial Disease: Constrictive Pericarditis and Pericardial Tamponade**

Diastolic filling is also impacted by pericardial restraint. Pericardial pathologies, such as constrictive pericarditis or pericardial tamponade, impede diastolic flow.<sup>66</sup> On TMF Doppler profiles, these diseases resemble the diastolic restrictive filling pattern. Two-dimensional echocardiography can be helpful in differentiating among these pathologies. In constrictive pericarditis, the pericardium appears thick, fibrotic, calcified, and thus echogenic; the inferior vena cava is dilated and the ventricular septum has an abnormal motion.

Pericardial effusions can be global, surrounding the entire heart, or loculated, as seen mostly after cardiac surgery (Fig. 27-35). Since the intrapericardial volume is constant, cardiac chambers are compressed when at their lowest pressure (atria in systole, ventricles in diastole). Pericardial tamponade is characterized by the presence of a large pericardial effusion seen as an echo-free (black) space, a “swinging motion” of the heart, early diastolic RV collapse, and late diastolic right atrium (RA) collapse.

In summary, diastolic filling is an active process and a major component of effective cardiac performance. The presence of diastolic dysfunction, whether resulting from loss in fluid volume, LV disease, or pericardial restraint, is associated with potential deleterious surgical outcomes. Doppler echocardiography, in particular TDI, provides the anesthesiologist the means to rapidly diagnose and guide therapy of such patients in the perioperative period.

## **Evaluation of Valvular Heart Disease**

Two-dimensional echocardiography and Doppler are complementary methods

in valve assessment. The 2D echocardiography provides evaluation of valve anatomy and function; Doppler assesses the physiologic consequences and severity of the lesion.

**Figure 27-35** Echocardiographic findings in pericardial effusion. **A:** Global pericardial effusion (*asterisks*) surrounding both right ventricle (RV) and left ventricle (LV). Transgastric short-axis (TG SAX) view. **B:** M-mode echocardiography demonstrates separation of the epicardium from the pericardium (*asterisks*) from pericardial effusion. **C:** Regional pericardial effusion (*asterisk*) compressing the left atrium (LA), seen in the midesophageal long-axis (ME LAX) view. **D:** M-mode echocardiography reveals systolic compression (*asterisk*) of LA. **E:** After evacuation of the fluid collection, the LA size increases.

**Table 27-3** Grading of Aortic Stenosis

	Aortic Sclerosis	Mild	Moderate	Severe
Peak AV velocity (m/s)	≤2.5	2.6–2.9	3.0–4.0	>4
LVOT/AV velocity ratio		>0.5	0.25–0.5	<0.25
Mean transvalvular gradient (mmHg)		<20	20–40	>40
AVA (cm <sup>2</sup> )		>1.5	1.5–1.0	<1

AV, aortic valve; LVOT, left ventricular outflow tract; AVA, AV area.

## Aortic Stenosis

### Two-dimensional and M-mode Echocardiography

The normal AV has three cusps, which open without restriction in systole, yielding an AV area 3 to 4 cm<sup>2</sup>. The AV is imaged enface in the midesophageal aortic valve short-axis view (Fig. 27-13) and its profile in the midesophageal aortic valve long-axis view. With the TEE probe inside the stomach, the AV is imaged in the deep transgastric long-axis and transgastric long-axis views (see Ultrasound Appendix for examples of these views). Owing to the increased afterload, associated findings may include concentric hypertrophy of the LV, decreased EF, as well as MR and left atrial dilatation.

## Doppler Echocardiography

*Jet Velocity, Transvalvular Pressure Gradient.* The transvalvular pressure gradient can be calculated from the CWD-measured velocity (V) using the modified Bernoulli equation:  $\Delta\text{pressure}$ .<sup>67</sup> The mean gradient, calculated from the VTI tracing, is commonly reported as it correlates well with the angiographically determined pressure gradient.<sup>68</sup> However, for any given valve area, the flow velocity and pressure gradient vary with changes in stroke volume and cardiac output. An LV with normal function will generate a large pressure gradient across a critically stenosed AV and a dysfunctional LV will not.<sup>69</sup>

### Valve Area

**5** Using the continuity equation, the flow across the LVOT equals the flow across the stenosed AV or  $\text{VTI}_{\text{LVOT}} \times \text{Area}_{\text{LVOT}} = \text{VTI}_{\text{AV}} \times \text{Area}_{\text{AV}}$ . By rearranging the equation,  $\text{Area}_{\text{AV}} = (\text{VTI}_{\text{LVOT}} \times \text{Area}_{\text{LVOT}}) / (\text{VTI}_{\text{AV}})$ . The  $\text{Area}_{\text{LVOT}}$  is calculated using the LVOT diameter at the site of the Doppler measurement (Fig. 27-27). An error in the LVOT diameter measurement is geometrically increased as  $\text{Area}_{\text{LVOT}} = \pi \times (D/2)^2$ . The  $\text{VTI}_{\text{LVOT}} / \text{VTI}_{\text{AV}}$  ratio is often calculated to avoid this error as flow changes will be reflected proportionally across both the AV and LVOT (Doppler dimensionless index). An index value less than 0.25% indicates an AV area less than 0.75 cm<sup>2</sup>. The echocardiographic cut-off values for grading aortic stenosis are shown in Table 27-3.<sup>70</sup>

## Mitral Stenosis

### Two-dimensional Echocardiography

The MV is imaged in the midesophageal views and in the basal transgastric short-axis views. The leaflets can appear thickened and calcified (thus, strongly echogenic), and there may be fusion of the chordae and papillary muscles. The major and most striking finding in mitral stenosis (MS) is the

inability of the two mitral leaflets to separate from each other in diastole. Instead, their tips remain opposed while the body of the leaflets bows toward the LV cavity because of the incoming blood (Fig. 27-36). The area of the MV orifice can be traced by planimetry in the transgastric basal short-axis view.<sup>71</sup> Associated findings in MS are a dilated left atrium and left atrial appendage (because of increased pressure) and the presence of thrombus or spontaneous echocardiographic contrast due to low flow in the LA. The LV cavity appears small, with a thickened and immobile interventricular septum. The right ventricle may be dilated and/or hypertrophied, with thickened walls, because of increased pressure work (Fig. 27-36 and Table 27-4).

## Doppler Echocardiography

*Transvalvular Pressure Gradient.* The increased diastolic pressure gradient is measured with continuous Doppler in the midesophageal four-chamber or long-axis view.<sup>67</sup> The early diastolic velocity of the transmitral flow (E wave) is increased (usually >1.5 m/s). This is not specific to MS, as E velocity will also be elevated in the presence of increased blood flow, as in severe MR.<sup>72</sup> In severe MS, the mean pressure gradient is greater than 10 mmHg (Fig. 27-37).

### *Pressure Half-time (PHT)*

The deceleration of E velocity is decreased, because in MS the equalization of transmitral valve pressures takes a longer time. PHT is the time required for the peak pressure to decrease to half its value. The decaying velocity is traced on the CWD signal obtained from across the MV in diastole and the analysis package calculates the PHT (Fig. 27-37B). MV area (MVA) is calculated as  $220/\text{PHT}$ . A prolonged PHT greater than 220 ms is related to severe MS (calculated MVA <1 cm<sup>2</sup>) as smaller MV orifices will prolong the pressure decay across the valve.<sup>73</sup> When LV compliance is decreased or there is coexisting aortic regurgitation, the increased LV pressure results in a faster pressure equilibration across the stenosed MV. In such cases, PHT will be shortened, and the calculated MVA may be erroneously overestimated.<sup>74</sup>

**Table 27-4** Grading of Mitral Stenosis

	Mild	Moderate	Severe
Mean pressure gradient (mmHg)	<6	5–10	>10
Pressure half time (ms)	≤100	100–220	>220
Mitral valve area (cm <sup>2</sup> )	>1.5	1.0–1.5	<1.0
Systolic pulmonary artery pressure (mmHg)	<30	30–50	>50

**Figure 27-36** Two-dimensional echocardiographic findings in mitral stenosis. **A:** In the midesophageal four-chamber (ME 4C) view, echocardiographic signs of mitral stenosis include a dilated left atrium (LA) with a rightward displacement of the interatrial septum (indicating elevated LA pressure), and a small left ventricle (LV). **B:** In the midesophageal bicaval view, red blood cell clumping creates spontaneous echocardiography contrast. Note the rightward displacement of the interatrial septum toward the right atrium (RA). **C:** A zoom image of the mitral valve and neighboring structures in ME 4C view. The anterior mitral leaflet exhibits diastolic doming whereas the posterior mitral leaflet is immobile. **D:** In the transgastric midpapillary short-axis (TG mid-SAX) view, the LV cavity is relatively small as compared with the right ventricle (RV), and the interventricular septum appears thickened.

## Associated Findings

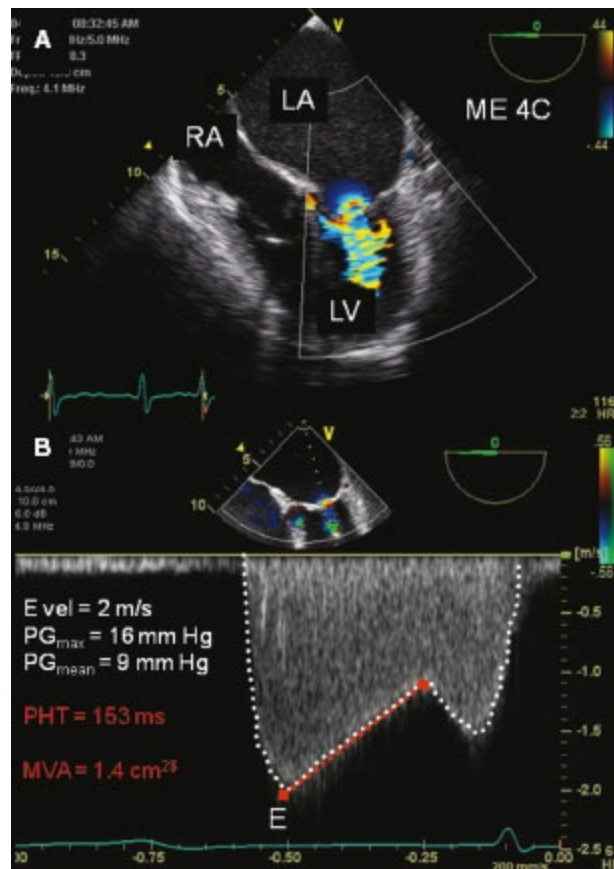

CFD will display a “rising sun” pattern of diastolic velocities inside the LA, indicating the high velocity (and increased pressure gradient) across the stenosed MV that exceeds the limits of the color scale (Fig. 27-37A). Associated findings include pulmonary insufficiency due to pulmonary hypertension and tricuspid regurgitation (TR).

## Aortic Regurgitation

### Two-dimensional and M-mode Echocardiography

The AV is imaged in the same views used for the assessment of aortic stenosis. Associated findings may include dilated aortic root (Marfan syndrome),

endocarditis lesions, dilated ascending aorta, calcified AV, aortic dissection (may be associated with acute aortic AI), fluttering of the anterior mitral leaflet and restricted diastolic opening of the MV from the AI jet, or a dilated LV in chronic AI (Table 27-5).

**Figure 27-37** Doppler echocardiography findings in mitral stenosis. **A:** Diastolic blood acceleration upstream of the mitral valve is seen with color-flow Doppler (“rising sun”). **B:** Spectral display of the diastolic velocity decay is imaged with a pulsed-wave Doppler sample volume placed at the tips of the mitral valve. Tracing of the velocity envelope (*white dots*) calculates the maximum and mean pressure gradient (PG). The pressure half-time (PHT) is calculated from the deceleration of the peak velocity (*Evel*) (*red dots*). The mitral valve area (MVA) is derived from the empiric formula:  $MVA = 220/PHT$ .

**Table 27-5** Grading of Aortic Insufficiency (AI)

	Mild	Moderate	Severe
AI jet height/LVOT diameter (%)	<25	25–64	>65
Vena contracta (mm)	<0.3	0.3–0.6	>6
PHT (ms)	>500	200–500	<200
Aortic diastolic flow reversal	—	—	Holodiastolic

LVOT, left ventricular outflow tract; PHT, pressure half-time.

## Doppler Echocardiography

*Color Flow.* In either the midesophageal or the transgastric views of the AV, a CFD sector over the AV and the LVOT will demonstrate the presence or absence of the AI regurgitant jet. CFD reveals the characteristics of the AI jet as it enters the LVOT in diastole. The following techniques are used to grade the severity of AI.

### *Ratio of Jet Height to LVOT Diameter*

**6** The maximal height of the AI jet (within <1 cm from the AV plane) is compared with the LVOT diameter at the same point. The recommended view is the midesophageal aortic valve long-axis view. A central jet usually is caused by aortic root dilation, whereas an eccentric jet implies an AV cusp lesion. The propagation of the jet into the LV does not correlate well with the angiographic degree of AI and should not be used to grade AI (Fig. 27-23).<sup>75</sup>

### *Vena Contracta*

Vena contracta is the narrowest “neck” of the AI jet as it traverses the AV plane, usually best appreciated in the midesophageal aortic valve long-axis view. The largest diameter of the vena contracta in diastole is selected (Fig. 27-23). The size of vena contracta is relatively load-independent and provides a reliable way to quantitate AI intraoperatively in the presence of fluctuating hemodynamics.<sup>75</sup>

### *Pressure Half-time*

PHT of the AI jet is recorded in the transgastric long-axis or deep transgastric long-axis view (see Ultrasound Appendix for examples of these views). PHT expresses the pressure equilibration of the diastolic blood pressure (“driving” pressure) and the diastolic LV pressure (“resistance” pressure). A short PHT (<200 ms) is associated with severe AI. Factors associated with decreased LV compliance (e.g., LV failure with restrictive filling pattern) will cause the transaortic pressure gradient to dissipate faster and will overestimate the severity of AI (Fig. 27-22A).

### *Aortic Diastolic Flow Reversal*

Retrograde diastolic flow in the descending and abdominal aorta is sensitive and specific for severe AI. This is imaged with PWD in the midesophageal long-axis view of the distal descending aorta (Fig. 27-22B).<sup>76</sup>

### *Other Findings*

Severe AI rapidly elevates LV diastolic pressure and shortens the early transmitral flow velocity, resulting in a *restrictive LV filling pattern*. The *regurgitant volume* is calculated using the continuity equation and equals the

difference between LVOT flow and the diastolic transmitral flow. Values greater than 60 mL are consistent with severe AI.

## Mitral Regurgitation

### Two-dimensional Echocardiography

The normal MV anatomy consists of two leaflets (anterior and posterior), their coaptation surface, the fibrous mitral annulus, the subvalvular apparatus with the two papillary muscles (anterolateral and posteromedial), and their chordae tendineae, which attach to the underside of the mitral leaflets. The competency of the MV depends on adequate coaptation between the D-shaped anterior leaflet and the crescent-shaped posterior leaflet. Common causes of MR are myxomatous valve degeneration, endocarditis, and ischemic, rheumatic, and congenital heart disease (CHD).

**Table 27-6** Carpentier Classification of Mitral Regurgitation (MR)

Carpentier Type	Motion Leaflet	Jet Direction
1	Normal	Central
2	Excessive (prolapse, flail)	Away from lesion
3a	Restricted, structure is abnormal	Variable
3b	Restricted, structure is normal	

The TEE views for imaging of the MV include the midesophageal four-chamber (Fig. 27-8), midesophageal commissural, midesophageal two-chamber (Fig. 27-9), midesophageal aortic valve long-axis view, and the basal transgastric short-axis and two-chamber views (see also Ultrasound Appendix).<sup>77</sup> Echocardiographic findings may include any of the following: abnormal texture of leaflets (myxomatous degeneration), flail and/or prolapsing leaflet, ruptured chordae, papillary muscle dysfunction or rupture (secondary to ischemia), mitral annulus calcification, or endocarditis lesions. The leaflet motion is commonly reported using Carpentier classification as described in Table 27-6.

### Doppler Echocardiography

CFD is commonly used as a screening tool for the detection of MR. It provides an easy, qualitative technique, but additional tests are advised to grade the severity of MR (Fig. 27-38). Despite its appearance, the color area associated with MR is not equivalent to regurgitant volume. CFD simply shows the area

within the LA where blood has abnormal velocity and is dependent on the systolic pressure gradient between the LV (adequate LV systolic function) and the LA (chamber compliance). In acute MR, for example, the MR jet velocities are low because MR occurs in a noncompliant chamber. Eccentric jets that are in contact with the LA walls are underestimated (Coanda effect),<sup>78</sup> whereas machine settings such as frame rate and color Doppler scale influence the appearance of the MR jet.

### Vena Contracta

**7** Vena contracta is the narrowest part of the MR jet, and reflects the effective or physiologic area of the MR jet (Fig. 27-24). MR is severe if vena contracta is 7 mm or greater.

### Pulmonary Vein Inflow Pattern

The increased volume inside the LA will augment the transmitral diastolic pressure gradient and will produce a restrictive filling pattern in severe MR (E to A wave ratio >2). For the same reasons, the systolic filling of the LA via the pulmonary veins (S wave) will be decreased in moderate and severe MR (Table 27-7).

**Figure 27-38** Mitral regurgitation. The anatomy of the mitral valve (MV) is depicted with two-dimensional (A and C) echocardiographic imaging, and the presence of mitral regurgitation (MR) is imaged with color Doppler (B and D). The MV is incompetent because of posterior leaflet prolapse inside the left atrium (LA) during systole (arrows

left in **A** and **C**). Left ventricular (LV) systolic contraction generates an anterior-directed MR jet away from the MV lesion area. ME 4C, midesophageal four-chamber view; ME 2C, midesophageal two-chamber view.

### Tricuspid and Pulmonic Valve Regurgitation

Similar approaches are used for the grading of severity of TR and PV regurgitation (Tables 27-8 and Table 27-9).

## Diseases of the Aorta

The evaluation of the aorta is an important part of perioperative TEE. In routine cases, such as coronary artery bypass surgery, evaluation of the aorta may reveal previously unknown, significant atheromatous disease of the aorta and alter the surgical plan (off-pump bypass, alternative sites for cannulation). In emergencies, the diagnosis of aortic pathology (dissection, aneurysm, transection) may prove life-saving.

**Table 27-7** Grading of Mitral Regurgitation

	Mild	Moderate	Severe
<b>Qualitative Findings</b>			
Jet area/LA area	<20%	—	>40%
Density of CW signal	—	—	Dense, complete envelope
Pulmonary blood flow	—	S blunted (S/D < 1)	S reversed (S < 0)
<b>Quantitative Measurements</b>			
Vena contracta (mm)	<3	3–7	≥7

LA, left atrium; CW, continuous wave; S, S wave; S/D, systolic wave of pulmonary vein flow to diastolic wave of pulmonary vein flow ratio; EROA, effective regurgitant orifice area.

**Table 27-8** Grading of Tricuspid Regurgitation

Echocardiographic Parameter	Mild	Severe
TV morphology	Normal	Prolapse, malcoaptation, endocarditis lesion, mass
IVC/RA/RV size	Normal	Dilated/increased
TR jet area (cm <sup>2</sup> )	<5	>10
Vena contracta width (mm) (Nyquist limit 50–60 cm/s)	—	>7
TR jet features	Soft, parabolic	Dense, triangular, early peak
Hepatic vein flow pattern	S > D	Systolic wave below baseline

TV, tricuspid valve; IVC, inferior vena cava; RA, right atrium; RV, right ventricle; PISA, proximal isovelocity surface area; TR, tricuspid regurgitation; S, systolic wave of hepatic vein flow; D, diastolic wave of hepatic vein flow.

**Table 27-9** Grading of Pulmonary Regurgitation

Parameter	Mild	Severe
PV morphology	Normal	Abnormal
RV size	Normal	Dilated
PR jet size	Length <1 cm, narrow origin	Large, wide origin
PR jet features	Soft, slow deceleration	Dense, rapid deceleration

PV, pulmonary vein; RV, right ventricle; PR, pulmonary regurgitation.

### **Two-dimensional and Motion-mode Echocardiography**

The entire thoracic aorta can be imaged with TEE, apart from the distal ascending and proximal arch segments, where the interposition of the left main bronchus between the esophagus and the left atrium prohibits the propagation of ultrasound. This blind spot can be imaged using epiaortic scanning.<sup>79</sup> The normal aorta has a smooth endothelial surface, and blood flow is laminar. Atherosclerotic plaques are irregularly shaped, sometimes mobile protrusions inside the aortic lumen. The search for atheromas should be done by imaging the entire circumference of the aortic lumen (short-axis views). Once a particular lesion is found, scanning in long-axis view should be performed (Fig. 27-39). Plaques thicker than 4 mm are more likely to cause an embolic event.<sup>80,81</sup>

**Figure 27-39** Aortic atheromas imaged in descending thoracic aorta short-axis (**A** and **C**) and long-axis (**B** and **D**) views.

**Figure 27-40** Aortic disease. Ascending aorta aneurysm distal to the sinotubular junction (midesophageal ascending aorta long-axis (**A**) and short-axis (**B**) views). The diameter of the aorta is 5 cm. **C**: Ascending aorta dissection (Stanford type A) originating from the sinotubular junction. The true lumen (TL) expands in systole and

the flap is convex toward the false lumen (FL). **D:** Descending aorta dissection (DeBakey type III).

**Figure 27-41** Aortic dissection. The descending aorta is seen in short axis. The aortic true lumen (TL) contains the aortic endothelium and has a smooth endoluminal surface. The intimal flap usually bows toward the false lumen (FL). Color-flow Doppler demonstrates blood flow inside the true lumen (which expands in systole) and the absence of flow inside the false lumen.

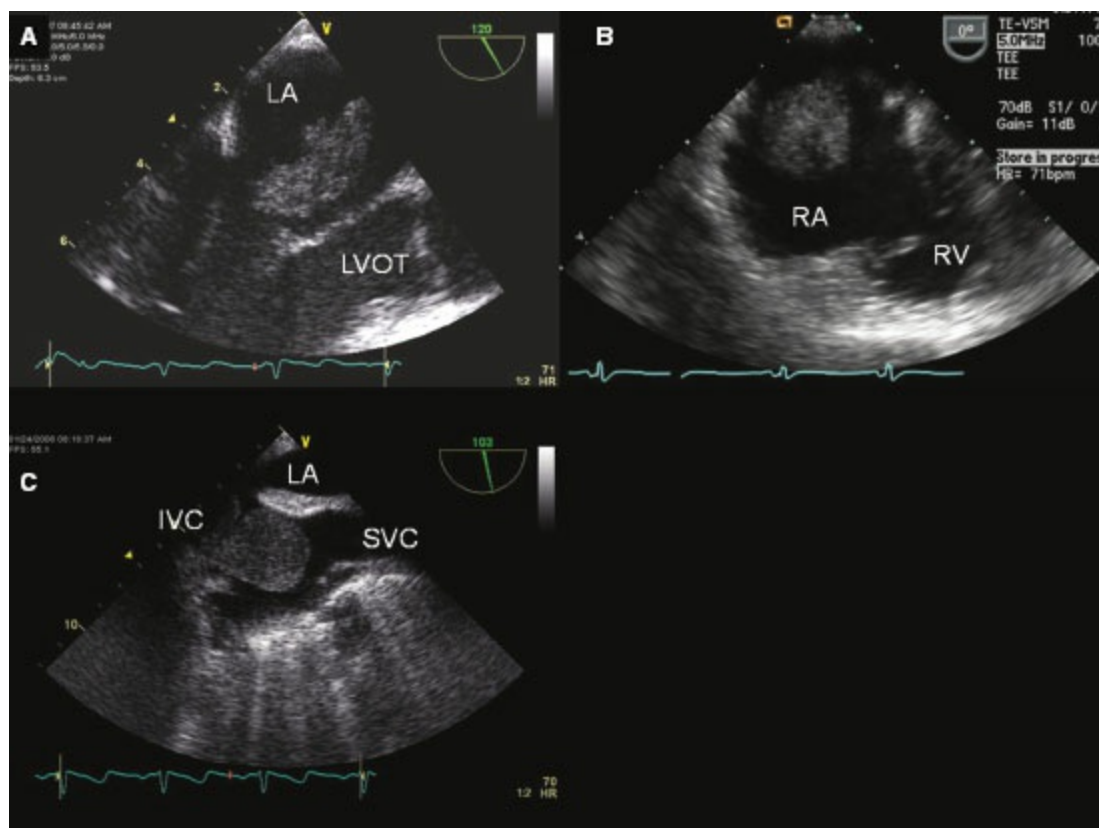

Aortic aneurysm is a dilatation of the aorta, usually greater than 4 **9** cm. Once the aneurysm is greater than 5.5 cm, the probability of rupture increases (Fig. 27-40A,B). Dissection is a separation between the intimal and medial layers of the aortic wall, creating a false lumen for blood flow (Figs. 27-40C,D and 27-41).<sup>82</sup> Both the true and false lumens fill with blood during systole, but only the true lumen has blood flow during diastole. Intramural hematoma is considered a precursor of dissection and should be treated similarly.<sup>83</sup> Compared with an atheroma, an intramural hematoma has a smooth surface.

## Cardiac Masses

Cardiac tumors either can originate from the heart or are metastases from other sites. They can embolize, cause arrhythmias, or cause heart failure. The most common primary tumor is myxoma, which is located most frequently at the interatrial septum (Fig. 27-42). The potential of

myxomas to obstruct the inflow or outflow region of a ventricle is demonstrated with Doppler echocardiography. The next most frequent tumor is fibroma of the ventricular wall. Fibromas are usually calcified and can decrease the ventricular volume. Renal cell tumors often extend into the inferior vena cava and right atrium (Fig. 27-42C). Pacemaker wires, thrombus, and normal anatomic structures that mimic the appearance of pathology (Eustachian valve, crista terminalis, Chiari network, or “Coumadin” ridge) should be differentiated from tumors.

**Figure 27-42** Cardiac masses. **A:** Left atrial (LA) myxoma seen in the midesophageal long-axis view. **B:** Right atrial myxoma seen inside the right atrium (RA) in the midesophageal four-chamber view. **C:** Renal cell tumor occupying the inferior vena cava (IVC) and extending inside the RA. LVOT, left ventricular outflow tract; RV, right ventricle; SVC, superior vena cava.

## Congenital Heart Disease

The spectrum of CHD seen in adults varies widely. Echocardiography is the primary imaging modality for diagnostic assessment of CHD. Advances in surgery have increased the survival rate of children with repaired CHD and, as a consequence, adults with repaired CHD are increasingly common in the OR. Common lesions evaluated with TEE include ASD, ventricular septal defect, patent ductus arteriosus, coarctation of the aorta, bicuspid AV, and repaired tetralogy of Fallot (Fig. 27-43).<sup>84</sup>

## Echocardiography-assisted Procedures

In addition to its role in diagnostics, echocardiography is also employed to assist various procedures such as the placement of a central venous catheter, intra-aortic balloon pump (IABP) catheter, coronary sinus (CS) cannula, and guide wires for other venous or arterial cannulae.

### *Ultrasound-guided Central Vein Cannulation*

The placement of central venous catheters is associated with complications including injury to vascular structures (carotid artery), pleura, nerve bundles, lymphatic system, and even the spinal canal. Historically, anatomic landmarks guided needle orientation during central venous access. However, multiple studies have demonstrated that the anatomic relationship between the internal jugular vein and the carotid artery varies and that even experienced physicians encounter complications.<sup>85</sup> Visual guidance by ultrasound provides real-time feedback, reducing the complication rate and the procedure time.<sup>86</sup> For patient safety reasons, the National Institute for Clinical Excellence and the Society of Cardiovascular Anesthesiologists have recommended that internal jugular central lines be placed under guidance of 2D ultrasound imaging.<sup>87,88</sup>

A linear array handheld transducer with high frequencies (7.5 to 12 MHz) is preferred for ultrasound-guided central line placement. The technique relies on placing the transducer over the traditional anatomic landmarks and identifying the internal jugular vein (IJV) and carotid artery (CA) in short axis and their anatomic relationship (Fig. 27-44). The 2D criteria of differentiating the CA from the IJV are distensibility (the IJV increases in size with the Valsalva maneuver and the Trendelenburg position) and compressibility (the IJV will decrease in size with pressure applied over it by the transducer). Applying CFD with the transducer oriented slightly caudad displays the CA with red pulsating flow and the IJV with a continuous blue flow (Fig. 27-44). If the transducer is oriented cephalad, the colors are reversed. The needle insertion and venous puncture is performed under ultrasound guidance. The longitudinal view (Fig. 27-45A) is then used to view the wire's placement in the vessel. TEE can confirm the guide wire's position in the superior vena cava (Fig. 27-45B).

For PAC placement, TEE is useful in guiding the catheter through the right heart and confirming proper position in the PA. In the midesophageal right ventricular inflow–outflow view, the PAC can be followed from the RA, passing the TV into the RV, and then passing the PV into the PA. The midesophageal ascending aortic short-axis view may be used to position the PAC so that its tip lies in the right PA (if that is the desired position; some

clinicians prefer positioning the PAC in the main PA).

**Figure 27-43** Atrial septal defect (ASD). In the midesophageal four-chamber view, a color-Doppler sector is positioned over the interatrial septum. An ASD with a left-to-right communication is shown in *blue*, as the blood moves away from the transducer (**top panel**). Pulsed-wave Doppler interrogation of the ASD measures a peak velocity gradient of 1 m/s.

**Figure 27-44** Internal jugular vein (IJV) and carotid artery (CA) and their anatomic relationship. **Top panel:** Two-dimensional examination, using a linear scanner, showing the IJV lateral to the CA. **Bottom panel:** Color-flow Doppler is applied showing continuous blue flow in the IJV and pulsating red flow in the CA (transducer oriented caudad).

Although ultrasound can be a valuable tool in decreasing the number of complications associated with central vein cannulation and PAC placement, it does not eliminate the risks.

## Epicardial and Epi-aortic Echocardiography

### *Epicardial Echocardiography*

During surgeries performed via sternotomy or thoracotomy, epicardial echocardiography can be performed and is particularly valuable in those cases in which the TEE probe cannot be placed or is contraindicated. The epicardial views are similar to the ones obtained via TTE. The American Society of Echocardiography in collaboration with the Society of Cardiovascular

Anesthesiologists has issued guidelines for the performance of epicardial echocardiography.<sup>89</sup> The epicardial probe uses high-frequency transducers (5 to 12 MHz) that may require a standoff device and/or saline in the mediastinum for best imaging. Epicardial imaging offers superior image quality as well as a better window to the anterior cardiac structures (aorta and AV, PA and PV).

**Figure 27-45 Top:** Ultrasound confirmation of guide wire position. A sector scanner transducer is used to visualize the internal jugular vein (IJV) in long axis. The guide wire is seen as a thin echo-dense linear structure positioned in the lumen of the vein. **Bottom:** Transesophageal echocardiographic confirmation of guide wire position. The midesophageal bicaval view is used. The guide wire is seen in the superior vena cava (SVC), with the tip in the right atrium (RA). LA, left atrium.

### *Epiaortic Examination*

Because of the interposition of the left bronchus, the distal aortic arch (AA) and the proximal AA cannot be visualized with TEE. The ascending and proximal AAs are of particular interest during cardiac surgeries, as they represent sites for aortic cannulation. Epiaortic scanning for atheroma is performed using a small footprint, linear array transducer. Guidelines for intraoperative epiaortic examination were published in 2007.<sup>79</sup>

## Echocardiography Outside the Operating Room

An understanding of echocardiography is also relevant to anesthesiologists in that many patients with a history of heart disease will have undergone an echocardiographic examination prior to surgery. The echocardiography report from a preoperative examination is useful for assessing surgical risk and developing the anesthetic plan. Echocardiography has also established itself as particularly valuable in the assessment of postoperative hemodynamic instability. It offers rapid diagnosis by differentiating among the potential complications faced in postoperative care, such as hypovolemia, pericardial tamponade aortic dissection, myocardial infarction, endocarditis, and pulmonary embolism.

### Focused Transthoracic Cardiac Ultrasound

**10** A focused transthoracic cardiac ultrasound (FoCUS) is a collection of echocardiographic images often obtained in urgent or semiurgent settings where a complete echocardiogram may not be feasible. FoCUS is aimed toward a rapid, qualitative assessment of cardiac pathology and potential causes of altered hemodynamics.<sup>90,91</sup> For example, in a patient with a heart murmur heard during preoperative visit for urgent or same day surgery, FoCUS can identify aortic stenosis and trigger appropriate management (Fig. 27-46). Similarly, in a postoperative patient with unexplained hemodynamic instability, FoCUS can rapidly identify conditions such as pericardial effusion (Fig. 27-47) or severe LV dysfunction.

Advancements in portable ultrasound technology have led to the wide availability of these devices throughout the hospital. As such, focused exams are increasingly performed at the bedside as an adjunct to the clinical exam by anesthesiology and critical care physicians lacking advanced training in echocardiography.<sup>92-94</sup> The FoCUS exam is often obtained in urgent settings under time constraints, where image quality may be suboptimal. Because of the inherent procedural and diagnostic challenges to FoCUS, physicians must obtain appropriate didactic education as well as training in hands-on skills and image interpretation in order to avoid diagnostic pitfalls.

Training in FoCUS is increasingly being recognized as a fundamental for teaching curriculums in medical school and post-graduate training programs.<sup>95,96</sup> Such training applied to anesthesiology residency has been shown to enhance detection of new pathology and impact clinical decision making.<sup>97,98</sup> Importantly, FoCUS training should involve the institution's reference echocardiography laboratories, which can also provide oversight, quality control, and ensure maintenance of skills. The importance of structured training and maintenance of competencies has been recognized by

professional societies as essential components to fully utilize the advantages and minimize drawbacks of this type of cardiac ultrasound examination.<sup>90,99–101</sup>

**Figure 27-46** Parasternal long-axis view of a patient with aortic stenosis detected on preoperative echo. The aortic valve (*arrow*) is thickened and heavily calcified with restricted mobility. LA, left atrium; LV, left ventricle; RV, right ventricle.

**Figure 27-47** Subcostal four-chamber view of a patient with cardiac tamponade. Large circumferential pericardial effusion (EFF) is seen. Arrows point to diastolic collapse of the right ventricular (RV) free wall. LA, left atrium; RA right atrium; LV, left ventricle.

### Focused Exam Views

A focused cardiac examination uses transthoracic echocardiographic images obtained from the parasternal, apical, and subcostal windows. At each window, the corresponding orthogonal views of the heart are obtained. For the purpose of FoCUS, the parasternal and subcostal windows are preferred, as they are the easiest to access in a supine patient with limited mobility. In

addition, most of the cardiac abnormalities sought out can be easily recognized from these windows.

Parasternal views are obtained in the third intercostal space at the left sternal border with the patient in left lateral position. The parasternal long-axis view (PLAX) is obtained by holding the ultrasound probe notch or  marker aligned toward the right shoulder (Fig. 27-48A). In this view, the LA, MV, LV, and a small portion of the RV are seen. The orthogonal parasternal short axis (PSAX) view is obtained by clockwise rotation of  the probe (Fig. 27-48B).

Apical views are obtained at the point of maximal impulse (apex) with the patient in the left lateral position. The apical four-chamber view (A-4Ch) is obtained by aligning the probe notch to the left of the patient (Fig. 27-48C). In this view, the LA, LV, RA, and RV are seen together with mitral and tricuspid valves. 

Subcostal views are obtained from below the xiphoid process with the patient in supine position. The subcostal four-chamber view is obtained  by aligning the probe notch to the patient's left side (Fig. 27-48D). In this view, all four cardiac chambers can be seen. A counterclockwise rotation renders the subcostal short-axis view and visualization of RA and IVC.

**Table 27-10** Common Clinical Conditions and Associated Focus Targets

Clinical Condition	Suspected Abnormality	FoCUS Targets	FoCUS Views	Findings
Heart Failure	Severe LV dysfunction, cardiomyopathy	LV	PLAX, PSAX, A-4Ch, Subcostal	Dilated poorly contracting LV
Hypotension	Hypovolemia	IVC	Subcostal	Small, collapsed
Acute Respiratory Compromise	Pulmonary hypertension, pulmonary emboli	RV	PSAX, A4Ch, subcostal	Markedly enlarged
Murmur	Aortic stenosis	Aortic valve	PLAX	Thickened with restricted mobility
Hypertension	Left ventricular hypertrophy	LV	PLAX, PSAX	Thickened walls
Post CT Surgery	Pericardial effusion	Pericardium	Subcostal, PLAX, A-4Ch	Echo-free space

LV, left ventricle; PLAX, parasternal long-axis view; PSAX, parasternal short-axis view; A-4Ch, apical four-chamber view; IVC, inferior vena cava; RV, right ventricle.

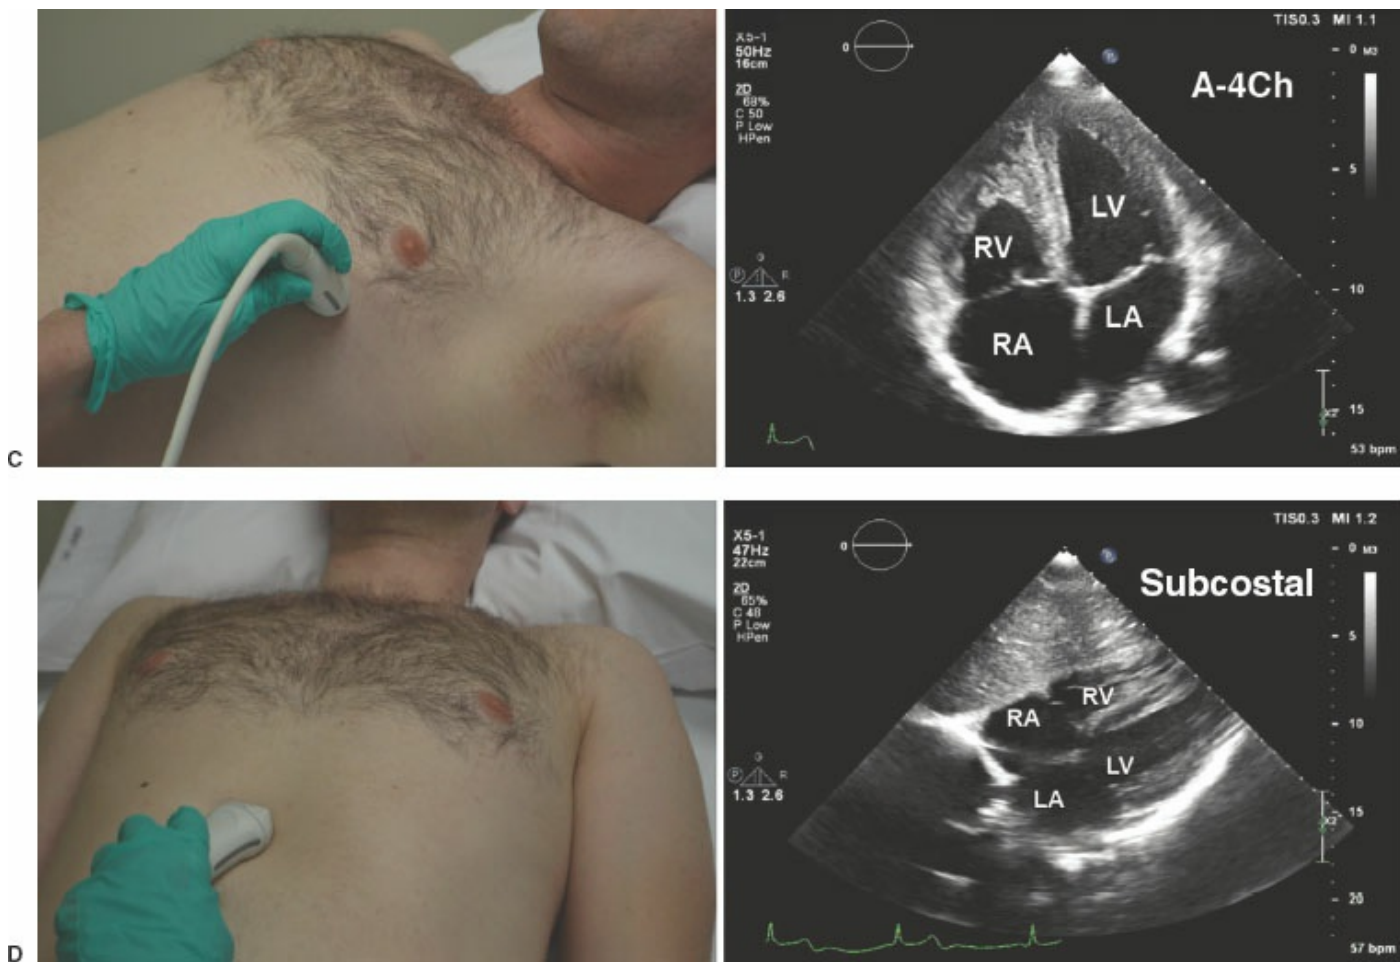

### **Focused Assessed Transthoracic Echo**

Multiple focused ultrasound protocols have been proposed for detection of cardiac abnormalities at bedside.<sup>102,103</sup> One of the commonly used protocols among anesthesiologists, especially as a “rescue echo” during unexplained hemodynamic instability, is the Focused Assessed Transthoracic echo, or FATE exam.<sup>103</sup> This protocol involves rapidly obtaining a series of key transthoracic images to identify conditions such as pericardial effusion, hypovolemia, and severe chamber enlargement and dysfunction. In addition, this protocol involves lung ultrasound imaging which is useful to identify pleural effusions,

lung edema, and pneumothorax. [Table 27-10](#) shows the utility of the FoCUS exam in common clinical scenarios.

**Figure 27-48** Standard transthoracic echo (TTE) images obtained during a FoCUS exam; each panel shows the ultrasound probe positioning and corresponding echo images: **Panel A:** Parasternal long-axis view (PLAX) obtained at parasternal window probe is positioned with the marker pointing toward the right shoulder; LA, left atrium; LV, left ventricle; Ao, Aorta. **Panel B:** Parasternal short axis (PSAX) view at the level of papillary muscles; LV, left ventricle; RV, right ventricle. (*continued*)

**Figure 27-48 (Continued) Panel C:** Apical four-chamber view (A-4Ch) obtained at apical window probe is positioned with the marker pointing toward the left flank; LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle. **Panel D:** Subcostal four-chamber view (Subcostal) obtained with the probe positioned below the xiphoid process and marker pointing toward the left flank. LA, left atrium; RA, Right atrium; LV, left ventricle; RV, right ventricle.

### KEY POINTS

- 1 Management of the airway is paramount to safe perioperative care. A series of evaluation procedures favorably affects outcomes.
- 2 The anatomically complex airway undergoes growth and development, including significant changes in its size, shape, and relation to the cervical spine, from infancy into childhood.
- 3 The advent of the laryngeal mask airway, as well as other supraglottic airways, has revolutionized both routine and emergency airway management.
- 4 Airway management always begins with a thorough airway-relevant

- history and physical examination.
- 5 Preoxygenation (also commonly termed *denitrogenation*) should be practiced in all cases when time allows.
  - 6 The goal of direct laryngoscopy is to produce a direct line of sight from the operator's eye to the larynx.
  - 7 Videolaryngoscopy mimics the actions of direct laryngoscopy, but places an imaging device toward the distal end of the laryngoscope blade. This moves the provider's point of view past the tongue, avoiding the need for a direct line of sight to the glottis.
  - 8 The technique of rapid-sequence induction is performed to gain control of the airway in the shortest period of time after the ablation of protective airway reflexes with the induction of anesthesia.
  - 9 The period of extubation may be far more treacherous than that of induction of anesthesia and tracheal intubation.
  - 10 In most instances, awake intubation can be accomplished successfully if approached with care and patience.
  - 11 Awake airway management remains a mainstay of the American Society of Anesthesiologists' difficult airway algorithm.
  - 12 An ever-increasing number of airway management devices are commercially available.
  - 13 When intubation and mask and SGA ventilation fail, airway access via the extrathoracic trachea may be warranted.

## Perspectives on Airway Management

In the nearly three decades since the publication of the first edition of this text, the field of airway management has undergone a vigorous revolution. Although many of the tools available in 1988 remain in use, the array of devices, algorithms, and pharmaceuticals in the modern airway armamentarium can be daunting. Fortunately, careful planning and expertise in a limited, albeit complementary, set of tools typically suffices. The final decade of the last century saw a resolute swing toward the application of supraglottic ventilation. More recently, the introduction of videolaryngoscopy (VL) has offered us yet another quantum leap that promises to address many of the failings of direct laryngoscopy, a technique that has been in use for more than 200 years.

Along with offering the provider better tools, technology has also aided in the creation of large databases of airway-related records from which a wealth of information can be collected retrospectively. With databases as large as 2.9 million anesthetics,<sup>1</sup> we can begin to better understand the incidence of, and contributing factors to, even rare airway events.

Techniques and practices in airway management have long been an

important concern of anesthesia societies, as illustrated by the publication and revision of various difficult airway guidelines.<sup>2,3</sup> Analysis of the American Society of Anesthesiologists' (ASA) Closed Claims Database in the periods before and after the 1993 publication of the ASA difficult airway guidelines reveals both encouraging and disturbing trends. A significant decrease in claims related to death/brain death at the induction of anesthesia is not matched with similar progress during emergence and in the postoperative period.<sup>4</sup> Although the closed claims data is useful, it has significant limitations, including its retrospective nature and the lack of a denominator.

**1 Management of the airway is paramount to safe perioperative care.** Difficult and failed airway management account for 2.3% to 16.6% of anesthetic deaths <sup>5,6</sup> and the following steps become necessary to favorably affect outcome: (1) thorough airway history and physical examination; (2) consideration of the ease of rapid tracheal intubation by direct or indirect laryngoscopy; (3) preinduction formation of a management plan, which includes the use of supraglottic ventilation (e.g., facemask supraglottic airway [SGA]); (4) aspiration risk assessment; and (5) estimation of the relative risk of failed airway maneuvers.<sup>7</sup> This chapter will reflect the need to consider these five factors when approaching any patient who requires or may require airway control. This text will focus on routine and rescue airway management techniques that are the fundamentals upon which all airway management is based. Specialty-specific techniques (e.g., elective suspension laryngoscopy) will not be addressed.

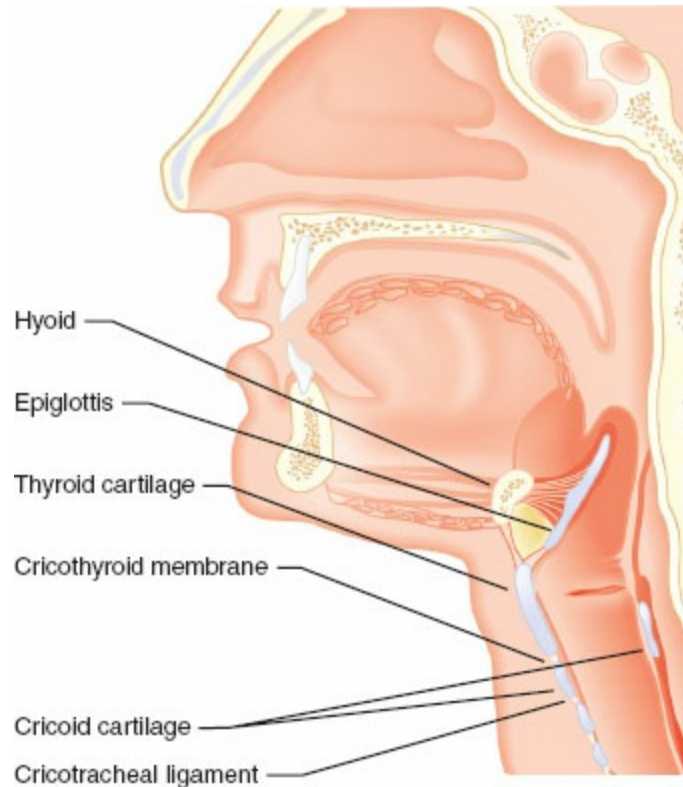

## Review of Airway Anatomy

The term *airway* refers to the upper airway—consisting of the nasal and oral cavities, pharynx, larynx, trachea, and principal bronchi. The airway in humans is primarily a conducting pathway. Because the oroesophageal and nasotracheal passages cross each other, anatomic and functional complexities have evolved for protection of the sublaryngeal airway against aspiration of food passing through the pharynx. As are other bodily systems, the airway is not immune from the influence of genetic, nutritional, and hormonal factors.

**2 The anatomically complex airway undergoes significant changes in its size, shape, and relationship to the cervical spine from infancy into childhood.**<sup>8</sup> Table 28-1 illustrates the anatomic differences in the larynx of infants and adults.

## Table 28-1 Anatomic Differences between Infant and Adult Larynxes

Infant larynx proportionately smaller  
Vertical location: C3–C5 in infant; C4–C6 in adult  
Pliable laryngeal cartilage in the infant/child  
Vocal folds: Anterior angle with respect to perpendicular axis of larynx in infant/child  
Aryepiglottic folds closer to midline in infant/child  
Epiglottis: Relatively longer, narrower, and stiffer in infant  
Mucosa more vulnerable to trauma in infant

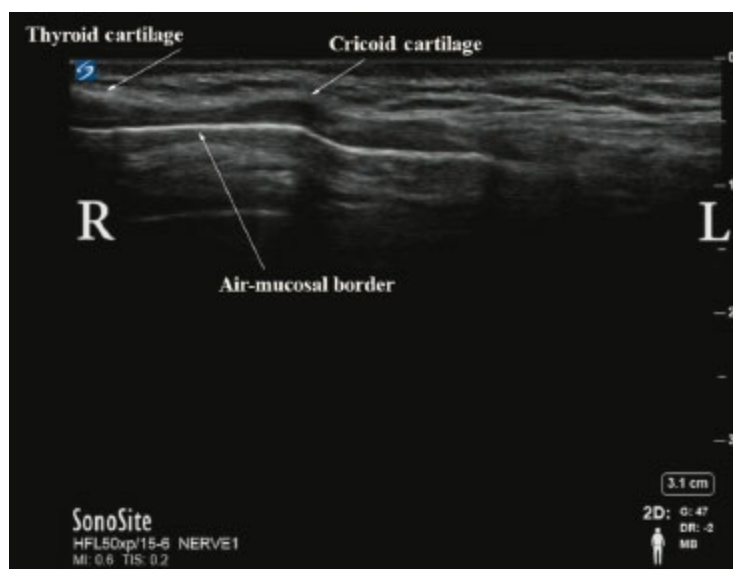

**Figure 28-1** The major landmarks of the airway mechanism. Note that the cricoid cartilage is <1 cm in height in its anterior aspect, but may be 2 cm in height posteriorly.

The laryngeal skeleton consists of nine cartilages (three paired and three unpaired); together, these house the vocal folds, which extend in an anterior–posterior plane from the thyroid cartilage to the arytenoid cartilages. The shield-shaped thyroid cartilage acts as the anterior “protective housing” of the vocal mechanism (Fig. 28-1). Movements of the laryngeal structures are controlled by two groups of muscles: the extrinsic muscles, which move the larynx as a whole; and the intrinsic muscles, which move the various cartilages in relation to one another. The larynx is innervated by the superior and recurrent laryngeal nerves, which are branches of the vagus nerve. Because the recurrent laryngeal nerves supply all of the intrinsic muscles of the larynx (with the exception of cricothyroid muscle), trauma to these nerves can result in vocal cord dysfunction. With unilateral recurrent laryngeal nerve injury, hoarseness is the primary symptom, though the protective role of the larynx in preventing aspiration may be compromised. Bilateral injury can

result in complete airway obstruction due to fixed cord adduction and may be a surgical emergency.

An important externally identifiable structure is the cricothyroid membrane (CTM), which joins the superior aspect of the cricoid cartilage and the inferior edge of the thyroid cartilage. In an adult, the membrane is typically 8 to 12 mm in width and 10.4 to 13.7 mm in height and is composed of a yellow elastic tissue that lies directly beneath the skin and a fascial layer. It can be identified 1 to 1.5 fingerbreadths below the laryngeal prominence (thyroid notch).<sup>9</sup> The membrane has a central portion known as the *conus elasticus* and two lateral thinner portions. Directly beneath the membrane is the laryngeal mucosa. Because of anatomic variability in the course of veins and arteries and the membrane's proximity to the vocal folds (which may be 0.9 cm above the ligaments' upper border), it is suggested that any incisions or needle punctures to the CTM be made in its inferior third and be directed posteriorly (a posterior probing needle will strike the back side of the ring-shaped cricoid cartilage). Identification of an appropriate incision or puncture site may be difficult. Campbell et al.<sup>10</sup> found that, though 80% of anesthesiologists were able to correctly identify the skin over the CTM in males, this number fell to 30% in females. The ASA difficult airway guidelines suggest that every patient be evaluated for difficult surgical airway.<sup>2</sup> This should lead to routine examination of laryngeal structures, including the marking of surface anatomy, and the use of ultrasound identification, especially in at-risk patients (Fig. 28-2).<sup>11</sup>

**Figure 28-2** Ultrasound image of the cricothyroid membrane (CTM, midline sagittal).

At the base of the larynx, suspended by the underside of the CTM, is the signet ring-shaped cricoid cartilage. This cartilage is approximately 1 cm in height anteriorly, but almost 2 cm in height in its posterior aspect as it extends in a cephalad direction (Fig. 28-1). The tracheal cartilages are

interconnected by fibroelastic tissue, which allows for expansion of the trachea in both length and diameter with inspiration/expiration and flexion/extension of the thoracocervical spine. Inferiorly, the trachea is suspended from the cricoid cartilage by the cricotracheal ligament.

The trachea measures approximately 15 cm in adults and is circumferentially supported by 17 to 18 C-shaped cartilages, with a membranous posterior aspect overlying the esophagus. In adults, the first tracheal ring is anterior to the sixth cervical vertebra.

The trachea ends at the carina (opposite the fifth thoracic vertebra), where it bifurcates into the principal bronchi. The right principal bronchus is larger in diameter than the left and deviates from the sagittal plane of the trachea at a less acute angle. For these reasons, aspirated materials, as well as a deeply inserted endotracheal tube (ETT), tend to gain entry into the right principal bronchus, although left-sided positioning cannot be excluded. Cartilaginous ring support continues through the first seven generations of the bronchi.

### *History of Airway Management*

Prior to 1874, mechanisms of airway obstruction were poorly understood. Opening the mouth with a wooden screw and drawing the tongue forward with a forceps or a steel-gloved finger was the height of nonsurgical airway management.<sup>12</sup> Not until 1880 was it recognized that most airway obstruction resulted from the tongue falling against the posterior pharyngeal wall. Though it is possible that similar devices were used toward the end of the first millennium, the first use of a SGA is credited to Joseph Thomas Clover (1825–1882), who used a nasopharyngeal tube for the delivery of chloroform anesthesia.<sup>13</sup> Over the next 50 years, several modifications of the basic oropharyngeal airway were described. In the 1930s, Ralph Waters introduced the now-familiar flattened tube oral airway. Arthur Guedel modified Waters' concept by fitting his airway within a stiff rubber envelope in an attempt to reduce mucosal trauma.

Tracheal intubation was first described in 1788 as a means of resuscitation of the “apparently dead,”<sup>14</sup> but was not used for the delivery of anesthesia until almost 100 years later. The forerunner of the modern oral ETT was designed by Joseph O'Dwyer in the 1880s. O'Dwyer cared for pediatric patients suffering airway obstruction secondary to diphtherial pseudomembrane formations. He was aware of the work of Emile Trousseau, a French physician who reported having performed over 200 tracheostomies in patients with diphtheria. O'Dwyer, hoping to provide his patients nonsurgical relief from airway obstruction, designed brass tracheal tubes that were placed in the larynx using blind digital intubation technique. Some 20 years later, German otolaryngologist Dr. Franz Kuhn (1866–1929) developed

a flexometallic tube that resisted kinking and could be shaped to the patient's upper airway anatomy. Like O'Dwyer's tubes, it was inserted using blind digital technique. The patients were intubated awake and the hypopharynx was sealed with oiled gauze packing.

Sir Ivan Magill and Stanley Rowbotham are credited with the initial development of modern tracheal intubation. Performing anesthesia for reconstructive facial surgery during World War I, they developed a two-tube nasal system. One narrow tube (gum elastic design) was passed through the nares and guided into the larynx using a surgical laryngoscope. The other tube was blindly passed into the pharynx to provide for the escape of gases. During use of this "Magill" tube, the exhaust lumen would occasionally pass blindly into the larynx, leading Sir Ivan to describe "blind nasal intubation."<sup>15</sup>

Cuffed SGAs were initially described in the early part of the 20th century. Three factors led to the development of these devices: (1) the introduction of cyclopropane (which was explosive and required an airtight circuit for appropriate gas containment), (2) appreciation that blind and laryngoscope-guided tracheal intubation remained a difficult task, and (3) a need for protection of the lower airway from blood and surgical debris in the upper airway.<sup>13</sup> The Primrose cuffed oropharyngeal tube, the Shipway airway (a Guedel oropharyngeal airway fitted with a cuff and a circuit connector designed by Sir Ivan Magill), and the Lessinger airway were predecessors of the modern supraglottic devices. In 1937, Leech introduced a "pharyngeal bulb gasway" with a noninflatable cuff that fit snugly into the hypopharynx.

The use of SGAs remained dominant until the introduction of curare in 1942, and the mass training of anesthesiologists in tracheal intubation in anticipation of casualties during World War II. The description by Mendelson<sup>16</sup> of gastric-content aspiration in parturients managed with a mask airway (66 of 44,016 patients, with 2 deaths) furthered the shift toward tracheal intubation in most surgical procedures. Within a few years, proficiency in direct laryngoscopy and tracheal intubation became a mark of professionalism. The advent of succinylcholine in 1951 furthered the dominance of tracheal intubation by providing rapid and profound muscle relaxation.

By 1981, two types of airway management prevailed—tracheal intubation and facemask ventilation with or without a Guedel airway. Although time-tested, both had failings. Tracheal intubation was associated with dental and soft tissue injury as well as cardiovascular stimulation, and mask ventilation often required a prolonged hands-on-the-airway technique. These difficulties led to the reconsideration of SGAs.

The advent of the laryngeal mask airway (LMA) and other SGAs revolutionized both routine and emergency airway management. In 1981, Dr. Archie Brain conceived the idea of fitting a mask-like structure over

the larynx. The motivation behind his early concepts and the evolution of his designs was the belief that airway control could be achieved less traumatically than with tracheal intubation and more reliably than with facemask ventilation. The first prototypes of the LMA were built from the Goldman dental mask, fitted with a tracheal tube. The LMA Classic (Teleflex, Research Triangle Park, NC) was introduced into practice in the United Kingdom in 1989 and approved by the U.S. Food and Drug Administration in 1991. The variety of advanced models that followed (e.g., with intubation and gastric drainage capabilities) will be discussed later in this chapter. With the expiration of the early patents and the introduction of other design concepts (e.g., non-inflatable masks), several additional devices applying the supraglottic concept were introduced.

Parallel to the development of SGAs, the concept of indirect laryngoscopy was increasingly being considered. Although fiberoptic devices were applied to the problem of difficult tracheal intubation in the late 1960s, this technology was expensive and required a unique skill set. It was not until the late 1980s, when the technology became readily available, that skill in flexible fiberoptic airway management was considered critical to safe practice.<sup>17</sup> Bullard introduced the use of a fiberoptic bundle to the rigid laryngoscope. The Bullard laryngoscope (ACMI/Circon, Southborough, MA) incorporated optical and light-transmitting fiberoptic bundles into an anatomically shaped blade. A detachable stylet held the tracheal tube near the optic objective, which could be placed proximal to the larynx with minimal movement of the head and neck. Though less commonly used today, the Bullard laryngoscope can be considered the vanguard of the modern videolaryngoscopes and optical and video stylets.<sup>18</sup> Fiberoptic elements were also incorporated into standard laryngoscope blades, such as the Storz Video-Macintosh blade (Karl Storz, Tuttlingen, Germany), which was developed by Dr. George Berci, an endoscopic surgery pioneer.

In the first years of the 21st century, the era of VL was born with the advent of inexpensive and miniaturized light-sensitive computer chip devices (e.g., complementary metal-oxide-semiconductors or CMOS). The Glidescope (Verathon, Bothell, WA) was the first of a generation of devices to use CMOS technology to visualize the larynx indirectly. The Glidescope's acutely angled blade placed the clinician's point of vision around the base of the tongue, obviating the need to establish a direct line of sight from the operator's eye to the larynx. Difficulty in placement of the ETT quickly led to the introduction of both specialized stylets and channeled-type laryngoscopes. Each of these advents will be discussed within this chapter.

## **Limitations of Patient History and Physical Examination**

**4 Airway management always begins with a thorough airway-relevant history and physical examination**, including a search for documentation of previous airway-related anesthetic events. When a patient requires more than routine care (anticipated or unanticipated), the patient should be made aware of diagnostic evaluations and therapeutic interventions that were employed. It is becoming common practice for a dedicated “difficult airway note” to be incorporated into electronic medical records and for a “difficult airway letter” to be given to, and reviewed with, patients and their families, describing critical and nonanticipated airway events. The patient may also be referred to difficult airway registries, such as the MedicAlert (<http://www.medicalert.org/everybody/difficult-airwayintubation-registry>). In the absence of such documentation, the clinician should seek the anesthetic records of past surgical visits, which in some cases may involve contacting other institutions. When this information is not available, adopting a low threshold for using a more conservative approach to airway management (e.g., awake intubation) will mitigate risk. This, though, assumes that the clinician is skilled in these techniques. It is not unusual for a patient to be referred to a different facility or practitioner due to airway management concerns. Signs and symptoms related to potentially difficult airway management, including aspiration risk, should be sought (Tables 28-2 and 28-3). Many congenital and acquired syndromes are associated with difficult airway management (Table 28-4).

Several physical evaluation measures have become popular (Table 28-5), although their reproducibility and predictability have been disputed. The difficulty in developing the perfect airway evaluation tool lies in two interrelated areas: simplicity and interdependency. Simple bedside evaluation tools are useful, but adequate evaluation may require endoscopic, radiologic, or other currently uncommon examinations.<sup>19-21</sup> Interdependency refers to the predictive value of one airway examination measure based on the findings of another. Details of the various examinations and their interdependency are discussed later in “Direct Laryngoscopy,” under the topic of Functional Airway Assessment.

Historically, airway assessment has been synonymous with evaluation for the ease of direct laryngoscopy (DL), the end point being the anticipated degree of visualization of the larynx. The changing landscape of laryngoscopy (i.e., the rapid proliferation of indirect techniques, including VL) may make many evaluation indices irrelevant. Efforts to define attributes that identify patients who may be difficult to intubate by DL have been only modestly successful. In their meta-analysis of the physical predictors of difficult DL, Shiga et al.<sup>22</sup> concluded that, when interpreted as individual tests, currently used techniques of evaluation have only modest discriminative power (Table 28-6).

**Table 28-2** Physical Exam Features with Airway Management Implications

Physical Exam Feature	Significance
Mouth opening	Difficult blade insertion/tongue displacement if limited
Jaw protrusion	Difficult tongue displacement if limited
Dentition	Obstructed view (if large central incisors), increased risk of dental trauma (if poor or restored dentition), difficult mask ventilation (if edentulous)
Retrognathia	Difficult tongue displacement
Thyromental distance	Reflects neck mobility and degree of retrognathia
Mallampati grade	Describes the relationship between mouth opening, tongue size, and pharyngeal space
Presence of beard	Difficult mask seal
Airway pathology	Potential for difficult mask ventilation (obstructive masses/tissue, atypical facial contours) and laryngoscopy (friable tissue, atypical or absent landmarks, and limited mouth opening, jaw protrusion, tongue displacement, and neck mobility)

**Table 28-3** Conditions with Airway Management Implications

<p><b>Increased risk of difficult laryngoscopy, mask ventilation, or SGA ventilation</b></p> <ul style="list-style-type: none"> <li>History of failed or traumatic airway management                             <ul style="list-style-type: none"> <li>Dental damage or prolonged airway soreness after a previous anesthetic</li> </ul> </li> <li>History of head/neck surgery or radiation therapy</li> <li>Various congenital and acquired syndromes (Table 28-4)</li> <li>Supraglottic pathology                             <ul style="list-style-type: none"> <li>Obstructive sleep apnea (BMI &gt;35 kg/m<sup>2</sup>, loud snoring, daytime somnolence, gasping or pauses in breathing during sleep)</li> <li>Lingual tonsillar hyperplasia</li> </ul> </li> <li>Acute airway pathology                             <ul style="list-style-type: none"> <li>Airway cyst or tumor</li> <li>Airway bleeding</li> <li>Stridor</li> </ul> </li> </ul> <p>Cervical spine disease or limited range of motion Temporomandibular joint disease</p>	<p><b>Increased aspiration risk</b></p> <p>Recent meal</p> <p>Acute trauma</p> <p>Acute gastrointestinal pathology</p> <p>Acute narcotic therapy</p> <p>Significant gastroesophageal reflux</p> <p>Current intensive care unit admission</p> <p>Pregnancy (gestational age ≥12 weeks)</p> <p>Postpartum (before second postpartum day)</p> <p>Frequent pneumonia</p> <p>History of voice change, vocal cord polyp, or coughing after eating/drinking</p> <p>Systemic-disease associated with gastroparesis: diabetes mellitus, collagen vascular disease, advanced Parkinson disease, central nervous system tumors</p>

**Table 28-4** Syndromes Associated with Difficult Airway Management

Pathologic Condition	Features Affecting Airway Management
<b>Congenital</b>	
Pierre Robin sequence	Micrognathia, relative macroglossia, glossoptosis, cleft palate
Treacher Collins syndrome	Malar and mandibular hypoplasia, microstomia, choanal atresia
Down syndrome	Macroglossia, microcephaly, cervical spine abnormalities
Klippel-Feil syndrome	Congenital fusion of cervical vertebrae, decreased cervical range of motion
Cretinism	Macroglossia, compression or deviation of larynx/trachea by goiter
Cri du chat syndrome	Micrognathia, laryngomalacia, stridor
Alport syndrome	Maxillary hypoplasia, prognathism, cleft soft palate, tracheobronchial cartilaginous anomalies
Beckwith syndrome	Macroglossia
Cherubism	Mandibular and maxillary fibrous tissue overgrowth
Meckel syndrome	Microcephaly, micrognathia, cleft epiglottis
Neurofibromatosis type I (von Recklinghausen disease)	Tumors may occur in the larynx and right ventricle outflow tract. Increased incidence of pheochromocytoma
Hurler/Hunter syndrome	Stiff joints, upper airway obstruction due to infiltration of lymphoid tissue, abnormal tracheobronchial cartilages
Pompe disease	Muscle deposits, macroglossia
<b>Acquired Infections</b>	
Epiglottitis	Epiglottal edema
Croup	Laryngeal edema
Papillomatosis	Obstructive papillomas
Intraoral/retropharyngeal abscess	Airway distortion/stenosis, trismus
Ludwig angina	Airway distortion/stenosis, trismus
<b>Arthritis</b>	
Rheumatoid arthritis	Restricted cervical spine mobility, temporomandibular joint ankylosis, atlantoaxial instability
Ankylosing spondylitis	Ankylosis/immobility of cervical spine and temporomandibular joints
<b>Tumors</b>	
Cystic hygroma, lipoma, adenoma, goiter	Airway distortion or stenosis
Carcinoma of tongue/larynx/thyroid	Airway distortion or stenosis, fixation of larynx or adjacent tissues
<b>Trauma</b>	
Head/facial/cervical spine	Airway edema or hemorrhage, unstable facial or mandibular fractures, intralaryngeal damage
<b>Miscellaneous Conditions</b>	
History of head/neck radiation	Friable tissue, edema from impaired lymphatic drainage
Morbid obesity	Short, thick neck, large tongue and obstructive sleep apnea are likely
Acromegaly	Macroglossia, prognathism
Acute burns	Airway edema, bronchospasm, decreased apnea tolerance

**Table 28-5** Techniques of Common Airway Indexes Measurement

Examination	
Thyromental distance	Measured from tip of mentum to thyroid notch in neck-extended position
Mouth opening	Interincisor distance (or interalveolar distance when edentulous) with the mouth maximally opened
Mallampati score	(See Fig. 28-8)
Head and neck mobility	Range of motion from full flexion to full extension
Ability to prognath	Capacity to bring lower incisors in front of upper incisors

Despite the disappointing usefulness of these individual indexes, other authors have recognized that combinations of tests can provide improved predictability. El-Ganzouri et al.<sup>23</sup> designed a statistical model for stratifying

risk of difficult DL in a large population. This multivariate index assigned relative weights to each physical examination or historical finding based on the odds of a high-grade laryngeal view being achieved with DL. The authors noted that with increasing multivariate index scores, positive predictive value increased, but sensitivity decreased (i.e., higher multivariate index scores occur when there are more positive physical findings, but not all difficult laryngoscopy patients will manifest multiple findings). Compared with the Mallampati classification alone, the multivariate composite index had improved positive predictive and specificity values at equal sensitivity. Of course, some pathology will only present with the induction of anesthesia and/or attempts at laryngoscopy.<sup>24,25</sup> Other groups have used similar regimens to increase the predictability of multivariate indexes by incorporating imaging technologies. In a small population of patients, Naguib et al.<sup>26</sup> were able to achieve high predictive accuracy (90% or higher) when physical examination and imaging scores (x-ray and three-dimensional computed tomography) were weighted. A simplified scoring system, studied on a multi-institution population of 3,763 patients, recognized both the difficulty of constructing a complex analysis in the preoperative holding area and the failure of any model to be completely predictive.<sup>27</sup> Accepting a discriminating power of 70%, this model found five attributes that could be used to predict difficult laryngoscopy (Table 28-7).

**Table 28-6** Summary of Pooled Sensitivity and Specificity of Commonly Used Methods of Airway Evaluation<sup>22</sup>

Examination	Sensitivity (%)	Specificity (%)
Mouth opening	46	89
Mallampati classification	49	86
Thyromental distance	20	94
Sternomental distance	62	82

**Table 28-7** Simplified Risk Score for Difficult Intubation<sup>27</sup>

Number of Risk Factors <sup>a</sup>	Incidence of Difficult Intubation
0	0
1	2%
2	4%
3	8%
4 or 5	17%

<sup>a</sup>Presence of upper front teeth, history of a difficult intubation, Mallampati >1, Mallampati of 4, mouth opening <4 cm.

Until recently, there was limited data on external airway findings that may

indicate failure of *indirect* laryngoscopy. Studies comparing DL with a Macintosh laryngoscope and VL with the Glidescope indicate that, though no single examination finding may predict the success or failure with each device, the failure to visualize the larynx with the Glidescope was characterized by higher multivariate risk scores of the same clinical finding.<sup>28</sup> Others have found that the following preoperative findings contribute to failure of VL: scarring, radiation, masses or thickness of the neck, thyromental distance of less than 6 cm, limited cervical motion, and operator experience.<sup>29</sup> In 2016, based on a secondary analysis of 1,100 VL intubations, Aziz et al.<sup>30</sup> identified four distinct predictors of difficult acute-angle VL. Of note, the “supine sniffing” position was associated with more difficult VL than the “supine neutral” position (Odds Ratio: 1.646), suggesting that this common position may be best avoided when initial plans include VL.

In general, tracheal intubation should be considered nonroutine under the following conditions: (1) the presence of equally important priorities to the management of the airway (such as a “full stomach” or emergency surgery); (2) abnormal airway anatomy; or (3) direct injury to the upper airway, larynx, spine, and/or trachea. Although the finding of abnormal anatomy is not synonymous with difficult airway management, it should kindle heightened suspicion.

Few studies have objectively determined findings that identify patients who will be difficult to mask ventilate as defined in [Table 28-8\(A\)](#). In a study of 1,502 patients, Langeron et al.<sup>20</sup> found 5% of patients to be difficult to mask ventilate, with only one patient in the series being impossible to mask ventilate. [Table 28-8\(B\)](#) describes the five independent clinical predictors found by Langeron, with the presence of two or more indicating a high likelihood of difficult mask ventilation. Kheterpal et al.,<sup>31</sup> using different criteria, found 0.15% of patients to be impossible to mask ventilate. The same study showed that high Mallampati score, male sex, the presence of a beard, and a history of sleep apnea or neck radiation were independent predictors of impossible mask ventilation.

Ultrasound (US) technology is widely used, portable, and provides rapid, real-time, dynamic images. Bedside US can confirm endotracheal intubation with both a sensitivity and specificity of 0.98<sup>32</sup> and can be used to identify the CTM, rule out esophageal intubation and verify ventilation in the absence of CO<sub>2</sub> detection (assuring bilateral lung excursion).<sup>33</sup> Subglottic hemangiomas, papillomas, and laryngeal cysts and stenosis have also been identified by US. Another use for US imaging is the estimation of ETT (including double lumen) size. Although it may be possible to examine the upper airway for changes such as hypertrophic lingual tonsils, the clinical relevancy (e.g., impact on laryngoscopy and ventilation) of ultrasonography has not been studied<sup>33</sup> and the applications of US in preoperative airway evaluation are still limited.

When using ultrasound for airway evaluation, the linear high-frequency transducer is the most useful probe.

**Table 28-8** Assessment and Predictability of Difficult Mask Ventilation<sup>20</sup>

<b>(A) Criteria for Difficult Mask Ventilation</b>	
Inability for one anesthesiologist to maintain oxygen saturation >92%	
Significant gas leak around facemask	
Need for $\geq 4$ L/min gas flow (or use of fresh gas flow button more than twice)	
No chest movement	
Two-handed mask ventilation needed	
Change of operator required	
<b>(B) Independent Risk Factors for Difficult Mask Ventilation</b>	
Risk Factors	Odds Ratio
Presence of a beard	3.18
Body mass index $>26$ kg/m <sup>2</sup>	2.75
Lack of teeth	2.28
Age $>55$ yr	2.26
History of snoring	1.84

Predicting difficult DL remains, in large part, an enigma. As previously illustrated, the commonly used indexes may not only be less predictive than originally thought, but may also be misleading. The advent of VL may make these deficits irrelevant and new criteria would need to be explored.

## Clinical Management of the Airway

### Preoxygenation

**Preoxygenation should be practiced in all cases when time allows.**<sup>34</sup>

**5** This procedure entails the replacement of the nitrogen volume of the lung (as much as 95% of the functional residual capacity) with oxygen in order to provide an apneic oxygen reservoir. Under ideal conditions, a healthy patient breathing room air ( $F_{IO_2} = 0.21$ ) will experience oxyhemoglobin desaturation to a level of less than 90% after approximately 1 to 2 minutes of apnea. In the same patient, several minutes of preoxygenation with 100% O<sub>2</sub> via a tight-fitting facemask may support at least 8 minutes of apnea before desaturation occurs. Patients with pulmonary disease, obesity, or conditions affecting metabolism frequently evidence desaturation sooner, owing to decreased functional residual capacity, increased O<sub>2</sub> extraction, and/or right-to-left transpulmonary shunting. In one study, healthy nonobese patients breathing 100% O<sub>2</sub> preoperatively sustained an oxygen saturation of greater than 90% for  $6 \pm 0.5$  minutes, as opposed to  $2.7 \pm 0.25$  minutes for obese patients under the same conditions.<sup>35</sup>

Time-sparing methods of preoxygenation have also been described. Using a series of four vital capacity breaths of 100% O<sub>2</sub> over a 30-second period, a high arterial PaO<sub>2</sub> (339 mmHg) can be achieved, but the time to desaturation remains shorter than with traditional techniques.<sup>34</sup> A modified vital capacity technique, wherein the patient is asked to take eight deep breaths in a 60-second period, shows promise in terms of prolonging the time to desaturation.<sup>34</sup> The authors of the current chapter prefer the technique of applying a tight-fitting mask for 5 minutes or more of tidal volume breathing 100% oxygen at flows of 10 to 12 L/min. The mask is placed immediately after the patient has been made comfortable on the operating room (OR) table and remains in place during OR check-in and the application of monitors.

In the obese patient, bilevel positive airway pressure and reverse-Trendelenburg position have been advocated to reach maximal preinduction arterial oxygenation and to delay oxyhemoglobin desaturation.<sup>34,36</sup> Pharyngeal insufflation of oxygen can also delay the onset of oxyhemoglobin desaturation during apnea. In this technique, oxygen is insufflated at a rate of 3 to 15 L/min via a nasal cannula or nasal-only facemask upon induction of anesthesia.<sup>34,37,38</sup> This technique relies on the phenomenon of apneic oxygenation, a process by which gases are entrained into the alveolar space during apnea.

Transnasal Humidified Rapid-Insufflation Ventilatory Exchange (THRIVE) has recently been introduced not only as a method of preoxygenation but also for use during periods of unplanned or intentional apnea (e.g., failed tracheal intubation or suspension laryngoscopy, respectively).<sup>39</sup> Oxygen flows of 30 to 70 L/min of oxygen are delivered via specialized nasal cannulae (OptiFlow™, Fisher and Paykel Healthcare Limited, Panmure, Auckland, New Zealand) throughout the preinduction and intubation phases or during other apneic periods. Apneic durations of 55 minutes have been reported with this technique. Hypercapnia occurs to a limited degree as compared to traditional apnea, which is attributed to turbulent flow at the glottic opening.

Certain circumstances can limit the effectiveness of preoxygenation, as exemplified by the patient who experiences claustrophobia with the anesthesia facemask (which can almost always be overcome by having the patient hold the mask or by removing the mask and allowing the patient to breathe directly from the anesthesia machine circuit) or the use of self-inflating breathing bags (which do not deliver an FIO<sub>2</sub> of 100% during spontaneous breathing) or nasal-only masks. Likewise, leaks around the facemask can allow entrainment of air, thereby reducing the FIO<sub>2</sub>. Leaks as small as 4 mm (cross-sectional) can cause significant reductions in the inspired oxygen content.<sup>40</sup>

## *Support of the Airway with the Induction of Anesthesia*

With the induction of anesthesia and the onset of apnea, ventilation and oxygenation must be supported. Traditional methods include the anesthesia facemask, SGA, and ETT. High-flow nasal oxygen, as noted earlier, has also been used.

### **The Anesthesia Facemask**

With the induction of anesthesia, the patient's level of consciousness changes from the awake state, with a competent and protected airway, to the unconscious state, with an unprotected and potentially obstructed airway. This drug-induced central ventilatory depression, along with relaxation of the upper airway musculature, can lead rapidly to hypercapnia and hypoxia. The anesthesia facemask is the device most commonly used to deliver anesthetic gases and ventilate an apneic patient. Facemask ventilation is highly effective, minimally invasive, and requires the least sophisticated equipment, making it critical to initial management of the airway and a mainstay in the delivery of anesthesia.

**Figure 28-3** Holding the anesthesia mask on the face. The thumb and the first finger grip the mask in such a fashion that the anesthesia circuit (or self-inflating resuscitation bag) connection abuts the web between these digits. This allows the palm of the hand to apply pressure to the left side of the mask, while the tips of these two digits apply pressure over the right. The third finger helps to secure under the mentum, and the fourth finger is under the angle of the mandible or along the lower mandibular ridge. Mask straps (on pillow) may be used to complement the hand grip by securing the right side of the mask.

A facemask is gently held on the patient's face with the thumb and first finger of the operator's left hand, leaving the right hand free for other tasks (Fig. 28-3). Most modern masks can be distorted by the operator's fingers to

form a seal around facial contours. Air leaks around the mask's edges can be prevented by gentle downward pressure with the awake patient or, if the patient is asleep, by pulling the mandible upward into the mask. A two-handed jaw-thrust technique has been shown to be superior to the classic one-handed grip for this maneuver.<sup>41</sup> Elastic "mask straps" may also be used and can be particularly helpful for the clinician with short fingers or for "hands-off" preoxygenation while other tasks are being performed. Gas leaks should be avoided, as the most common reason for suboptimal preoxygenation is a loose-fitting mask, which allows the entrainment of room air.<sup>34</sup>

Appropriate positioning of the patient is paramount for delivery of positive pressure ventilation via facemask. With the patient supine, "ramped," or in reverse Trendelenburg position, the head and neck are placed in the *sniffing* position, described later (see discussion of *tracheal intubation*). This position improves mask ventilation by anteriorizing the base of the tongue and the epiglottis.<sup>42</sup>

After induction of anesthesia, a tight fit of the facemask is achieved by upward displacement of the mandible into the mask, which is held in position by the thumb and first finger. This maneuver, commonly known as a *jaw thrust*, raises the soft tissues of the anterior airway off the pharyngeal wall and allows for improved ventilation. In patients who are obese, edentulous, or bearded, two hands or a mask strap may be required to ensure an adequate mask seal. When two hands are required for holding the facemask, a second operator may be required to squeeze the reservoir bag. If necessary, the second operator can improve the mask's fit by providing additional jaw-thrust and chin lift. If no help is available, the ventilator can be used to deliver the breaths.

One useful, albeit poorly characterized, maneuver that aids in facemask ventilation is the *expiratory chin drop*. When positive-pressure inspiration is successful, but is not followed by passive gas escape during expiration, allowing phasic head flexion and reducing chin/jaw lifting will often improve gas egress.

Well-secured dentures may improve the mask seal for an edentulous patient.<sup>43</sup> The advantage of this must be weighed against the risk of denture displacement or damage. Dentures may be removed when laryngoscopy is initiated.

A patient with normal lung compliance should require no more than 20 to 25 cm H<sub>2</sub>O pressure for lung inflation, as measured on the anesthesia circle manometer. If more pressure is required, the adequacy of the mask technique should be re-evaluated. This includes adjusting the mask fit, seeking aid with the mask hold, administering muscle relaxants, or considering adjuncts such as oral and nasal airways. Both oral and nasal airways can bypass upper airway obstruction by creating an artificial passage to the hypopharynx. Nasal

airways are less likely to stimulate coughing, gagging, or vomiting in the lightly anesthetized patient but may cause epistaxis. For this reason, nasal airways are typically avoided in patients at high risk for bleeding (e.g., iatrogenic or pathologic coagulopathy, pregnancy, hereditary hemorrhagic telangiectasia, uncontrolled hypertension).

The nasal airway should be long enough to reach from the nare to the thyroid notch when placed alongside the patient's face. It is inserted along the floor of the nose, in an anterior–posterior direction, and should always be prepared with water-soluble lubricant to reduce trauma to the highly vascular nasal mucosa. A vasoconstrictor agent (e.g., oxymetazoline or phenylephrine) may be applied before insertion of the nasal airway to decrease this risk. Resistance to insertion should prompt repositioning of the airway bevel, reassessment of the direction of insertion, or change to a smaller airway or the contralateral nare.

The typical rounded oral airway is placed with its longitudinal concavity rotated in a rostral direction. Once the distal end of the airway has been inserted to the level of the oropharynx, the device is rotated 180 degrees and insertion is continued to its ultimate position. This maneuver avoids displacement of the tongue into the hypopharynx and can be aided by caudal displacement of the tongue with a tongue depressor. A small oral aperture, intrapharyngeal mass or foreign body, intact gag reflex or otherwise light anesthesia may prevent oral airway placement. As will be discussed later, some intubating oral airways are large and have a rectangular cross-section. These devices tend to be too large for intraoral rotation and are inserted with the concavity facing caudally while the tongue is stabilized by a tongue depressor or held by the operator. Similar to nasal airway sizing, oral airways should reach from the teeth (or alveolar ridge) to the mandibular angle.

Obstruction to mask ventilation may be caused by laryngospasm, a local reflex closure of the vocal folds. Laryngospasm may be triggered by a foreign body (e.g., oral or nasal airway), saliva, blood, or vomitus touching the glottis. It may also result from pain or visceral stimulation. Hypoxia as well as noncardiogenic (negative pressure) pulmonary edema can result from continued spontaneous ventilation against closed vocal cords (or other obstruction). Management of laryngospasm consists of removing the offending stimulus (if identified), administering oxygen with continuous positive airway pressure (CPAP), deepening the plane of the anesthesia, and, if other maneuvers are unsuccessful, administering a rapid-acting muscle relaxant.<sup>44</sup>

The practice of withholding muscle relaxants prior to the establishment of facemask ventilation, which has been a fixture of anesthetic teaching, has recently come into question.<sup>45</sup> Objective evidence supports administration of depolarizing or nondepolarizing muscle relaxants simultaneously with

anesthetic induction agents<sup>45</sup> to facilitate mask ventilation, SGA ventilation, and tracheal intubation. This is discussed in detail in the clinical cases later (case 4).

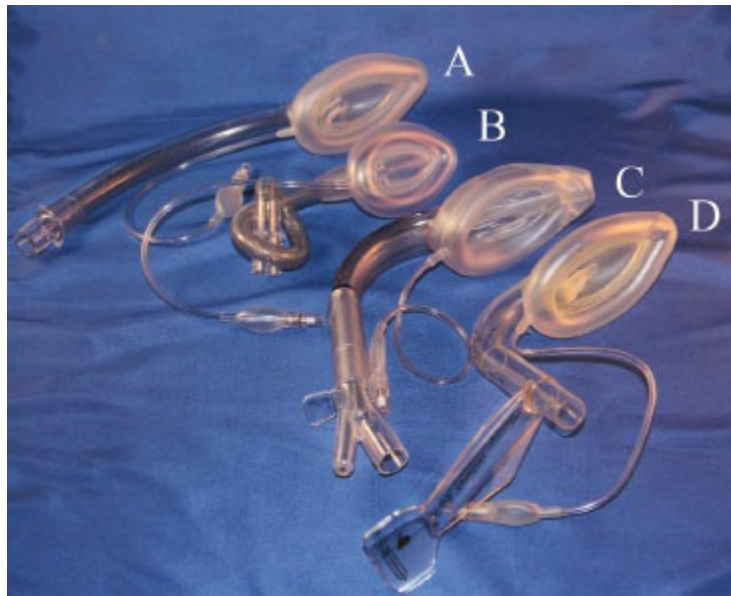

If there are no contraindications (e.g., increased aspiration risk), mask ventilation can be the primary ventilatory technique for anesthetic maintenance. Otherwise, it is commonly used to administer anesthetic gases and oxygen and to facilitate ventilation until the anesthetic state is adequate for use of another means of airway support, such as an SGA or ETT. This decision should be made after careful consideration of the patient's coexisting diseases and surgical requirements.

## Supraglottic Airways

Devices that isolate the airway above the vocal cords are referred to as SGAs. Although initially approved as a substitute for facemask ventilation and when tracheal intubation was not achievable, SGAs soon became widely used in surgical cases traditionally managed with tracheal intubation.<sup>46,47</sup> SGAs are associated with lower incidence of sore throat, coughing, and laryngospasm on emergence, as well with decreased reversible bronchospasm than seen with tracheal intubation.<sup>48,49</sup> With the expiration of the US patents on the original LMA in 2002, there was a proliferation of similar devices. Although older data suggest that 35% or more of general anesthetics in the United States are performed with SGAs, more recent data from the United Kingdom imply a 56% incidence.<sup>46,50,51</sup>

As the first device of its kind, a wealth of information exists on the LMA Classic and its subsequent iterations (Fig. 28-4). Much of this knowledge may be applied to newer SGAs as well. That this chapter devotes considerable text to the LMA family of devices is not meant to infer preference, but rather the availability of information.

The advent of the LMA as well as other SGAs has led some to question the relative safety of tracheal intubation.<sup>52</sup> This, along with the ASA Closed Claims Database information, lends support to the search for safe alternatives to tracheal intubation whenever possible.<sup>53</sup> Similarly, pharyngeal mucosa appears to be more resilient to trauma from SGAs than tracheal mucosa to damage from ETTs. In one animal study, mucosal injury from the LMA ProSeal (Teleflex, Research Triangle Park, NC) did not occur until more than 9 hours of continuous use.<sup>54</sup> The hemodynamic effects associated with airway management are also reduced with SGAs. Increases in heart rate, blood pressure, and intraocular pressure are all less during airway management with an SGA than with an ETT.<sup>55,56</sup>

**Figure 28-4** The family of laryngeal mask airways (from top): (A) Unique, (B) Flexible, (C) Supreme, (D) Fastrach.

**The LMA Classic.** The original SGA, the LMA Classic, is composed of a perilaryngeal mask and an airway barrel. The device is designed to sit in the hypopharynx with an anterior surface aperture overlying the laryngeal inlet. The mask has an inflatable cuff that fills the hypopharyngeal space, creating a seal that allows positive-pressure ventilation with up to 20 cm H<sub>2</sub>O pressure. The adequacy of the seal depends on correct placement, appropriate size, and patient anatomy, and is less dependent on the cuff-filling pressure or volume. Attached to the posterior surface of the mask is a barrel (airway tube) which extends proximally from the mask's central aperture and can be connected to a self-inflating resuscitation bag or anesthesia circuit. While the LMA Classic is constructed of reusable silicone, several models constructed with silicone or polyvinyl chloride (PVC) are currently available from various manufacturers.

LMAs come in varying sizes, from neonatal to large adult, and selection is critical to both successful use and complication avoidance. The manufacturer recommends that the clinician choose the largest size that will fit comfortably within the oral cavity. LMA insertion technique mimics the processes of swallowing. Just as food intended for the esophageal opening is pressed cephalad and posteriorly against the palate, so is the tip of the LMA, as it shares the same destination. As with swallowing, head extension and neck flexion enlarge the space behind the tongue to allow passage into the hypopharynx. These functions allow the food bolus, or the LMA, to reach its mark while avoiding contact with the anterior pharyngeal structures or stimulation of protective airway reflexes.

The insertion of the LMA as described by its inventor, Dr. Archie Brain, has been modified by a number of writers. Discussion of these various alternatives is beyond the scope of this text. The principles of LMA insertion can be applied to many other SGAs, though the individual manufacturer's

recommendations should be consulted. The currently recommended insertion technique, illustrated in [Figure 28-5](#), has a 94% success rate.<sup>57</sup> In this technique, the mask is completely deflated and the palatal surface lubricated with a non-local anesthetic containing lubricant. The operator's nondominant hand is placed under the occiput to flex the neck on the thorax and extend the head at the atlanto-occipital joint (creating a space behind the larynx; this action also tends to open the mouth).<sup>58</sup> The index finger of the dominant hand is placed in the cleft between the mask and barrel. The hard palate is visualized and the superior (nonaperture) surface of the mask is placed against it. Force is applied by the index finger in an upward direction toward the top of the patient's head. This causes the mask to flatten and follow the contour of the palate into the pharynx and hypopharynx. The index finger continues along this arc, continually applying an outward pressure until resistance from the upper esophageal sphincter is met. The most common error made by clinicians is the application of pressure with a posterior vector, causing the LMA's tip to impact the posterior pharyngeal wall, often  resulting in tip folding, device misplacement, and tissue trauma.

Prior to attachment of the anesthesia circuit, the LMA is inflated with the minimum amount of pressure that allows ventilation to 20 cm H<sub>2</sub>O without an air leak. The manufacturer recommends keeping the intracuff pressure under 60 cm H<sub>2</sub>O and evidence exists for keeping it under 44 mmHg.<sup>59</sup> When  an adequate seal cannot be obtained with 60 cm H<sub>2</sub>O cuff pressure, the LMA's positioning, sizing, or type should be re-evaluated. Light anesthesia and laryngospasm also may contribute to poor seal. With inflation, one should be able to observe a rising of the cricoid and thyroid cartilages and a lifting of the barrel out of the mouth by approximately 1 cm as the mask expands. If a midline position is not possible due to the patient's position or the surgical procedure, a flexible LMA (discussed later) should be considered. A bite block is recommended to prevent biting and occlusion of the LMA barrel. Cuff pressure should be measured after insertion and periodically monitored if nitrous oxide is being used.

**Figure 28-5** Insertion of the laryngeal mask airway (LMA). The LMA is inserted with the index finger of the dominant hand pressing with a force vector against the hard palate (**A** and **B**). The outward force vector is continued from the hard palate to the pharynx and hypopharynx (**C**) until the index finger meets resistance against the upper esophageal sphincter and is removed (**D**).

Although the distal tip of the LMA mask sits in the esophageal inlet, it does not reliably seal it. The LMA was not designed to protect against the aspiration of gastric contents nor does it reliably do so. Despite this, when used in patients at low risk for regurgitation, the rate of aspiration during LMA use is similar to that in all non-LMA general anesthetics (approximately 2 in 10,000 cases).<sup>60,61</sup> The incidence of gastroesophageal reflux may be increased when compared with use of the facemask,<sup>60</sup> but when populations of patients considered to have a full stomach are studied (in controlled trials, prospective series, or anecdotally), there is still a low incidence of aspiration noted with elective or emergency LMA use. Reports have included safe use in patients who are morbidly obese or have experienced frequent gastroesophageal reflux, those undergoing elective cesarean section or airway rescue during labor, and those presenting to emergency departments or paramedic crews.<sup>62,63</sup> During cardiopulmonary resuscitation, the incidence of gastroesophageal regurgitation is four times greater with a bag-valve mask than with the LMA.<sup>64</sup>

If at any time gastric contents are noted in an SGA barrel, maneuvers similar to those applied when using an ETT should be instituted. The SGA should be left in place, the barrel suctioned, the patient placed in Trendelenburg position, and 100% oxygen administered.

Although first introduced for use with spontaneous ventilation, the LMA has proved useful and safe for cases in which positive-pressure ventilation is either desired or preferred.<sup>56,65</sup> There is no difference in gastric inflation with positive-pressure ventilation (<17 cm H<sub>2</sub>O) when comparing an LMA to an ETT.<sup>66</sup> With the LMA Classic, tidal volumes are limited to 8 mL/kg and airway pressure to 20 cm H<sub>2</sub>O. These devices have been used successfully with supine, prone, lateral, oblique, Trendelenburg, and lithotomy positions. Although the manufacturer recommends use for a maximum of 2 to 3 hours, reports of use for more than 24 hours exist.<sup>67</sup> In a porcine model, Goldmann et al.<sup>54</sup> saw no evidence of mucosal changes with up to 9 hours of LMA ProSeal use, though damage was consistently evident after 12 hours.

**The LMA Flexible.** The introduction of flexible barrel SGAs (e.g., the LMA Flexible, Teleflex, Research Triangle Park, NC; [Fig. 28-4](#)) has permitted extension of SGA use to a variety of cases in which the airway is within the surgical field or shared with the surgical team (e.g., ophthalmologic or otolaryngologic procedures). These devices differ in design from traditional SGAs by virtue of a thin-walled, small-diameter, wire-reinforced (kink-resistant) barrel, which can be positioned out of the midline without affecting the hypopharyngeal position of the mask. This device was designed to be paired with a tonsillar mouth gag commonly used in oral and pharyngeal surgery.<sup>68</sup> Additionally, the LMA Flexible has proved useful when heavy drapes are placed over the airway (e.g., ophthalmic procedures), when there is movement of the head during surgery (e.g., tympanostomy tubes), or when the LMA barrel cannot be secured in the midline (e.g., mid or lateral facial surgery). The use of this mask in surgery above the level of the hypopharynx, including tonsillectomy, affords a number of clinically important advantages over tracheal intubation ([Table 28-9](#)). When correctly placed, LMAs protect the airway from blood, secretions, and surgical debris from above the level of the mask better than tracheal tubes, which do not protect the trachea from liquids instilled into the pharynx.<sup>69,70</sup>

**Table 28-9** Advantages of the Laryngeal Mask Airway in Supraglottic Surgery

Improved protection of the airway from blood and surgical debris  
Reduced cardiovascular responses  
Reduced coughing on emergence  
Reduced intraoperative bronchospasm  
Reduced laryngospasm after airway device removal  
Improved oxygen saturation after airway device removal  
Ability to administer oxygen until complete restoration of airway reflexes

**The SGA and Bronchospasm.** SGAs produce significantly less reversible bronchospasm than ETTs. For this reason, they appear to be well suited to the patient with a history of bronchospasm (e.g., chronic obstructive pulmonary disease) who is not at risk for reflux or aspiration.<sup>49</sup> Because the halogenated inhaled anesthetics are potent bronchodilators, bronchospasm is more likely to occur at the times of induction and emergence. SGAs present a unique opportunity for the clinician to conveniently and effectively control the airway without introducing a foreign body into the trachea and stimulating the sensitive bronchial tree. If uncontrollable bronchospasm does occur (e.g., from vagal stimuli), intubation can be performed through many SGAs or after SGA removal. When tracheal intubation is mandatory for the surgical procedure and bronchospasm concerns exist, the Bailey maneuver can be employed. In this maneuver, the deflated LMA is placed behind the *in situ* ETT. The ETT is removed, the LMA is inflated, and the patient is emerged on the LMA.<sup>71</sup> If an SGA was utilized as a conduit for tracheal intubation, the option exists to deflate the SGA cuff and leave the device *in situ*. When the ETT is no longer needed, it can be removed, leaving the SGA as the primary airway. This latter technique can be of great benefit in cases where an ETT is needed intraoperatively, but coughing or hypertension during emergence would be deleterious.

**SGA Removal.** The timing of SGA removal is critical.<sup>72</sup> An SGA should be removed either when the patient is deeply anesthetized or after protective airway reflexes have returned and the patient is able to open the mouth on command. Removal during excitation stages of emergence can be accompanied by coughing and/or laryngospasm. Many clinicians remove the LMA fully inflated so that it acts as a “scoop” for secretions above the mask, bringing them out of the airway.<sup>73</sup>

**Contraindications to SGA Use.** SGAs do not reliably prevent the aspiration of regurgitated gastric contents. Thus, SGAs are contraindicated in clinical scenarios with an increased risk of regurgitation (e.g., full stomach, hiatus hernia with significant gastroesophageal reflux, intestinal obstruction, delayed gastric emptying, unclear history), though their use as an airway salvage technique in these populations is acceptable. Other contraindications

include high airway resistance, glottic or subglottic obstruction, and limited mouth opening (<1.5 cm).<sup>74</sup>

**Complications of SGA Use.** Apart from aspiration, reported complications include laryngospasm, coughing, gagging, and other events characteristic of airway manipulation. The incidence of SGA-induced postoperative sore throat varies from 4% to 50% and is highly dependent on the study methods. No single device shows a consistently lower rate of dysphagia. All appear to be better than tracheal intubation in this regard, with expected rates of 30% to 70%.<sup>75</sup> Rare reports exist of nerve injury associated with SGA use, including damage to the hypoglossal, lingual, and recurrent laryngeal nerves. These injuries typically manifest within 48 hours postoperatively and resolve spontaneously in 1 hour to 18 months. Predisposing factors include the use of small masks, lidocaine lubrication, and nitrous oxide, cuff overinflation, difficult or alternate insertion techniques, nonsupine positioning, and cervical bone or joint disease.<sup>76</sup> Pressure neuropraxia from the tube or cuff is the most common cause.

**The King Laryngeal Tube** (King LT, Ambu, Ballerup, Denmark) consists of a single-lumen tube with distal and proximal low-pressure cuffs that are inflated via a common pilot valve (Fig. 28-6). When positioned correctly, the distal cuff sits within and obstructs the upper esophageal sphincter and the proximal cuff seals the oral and nasal pharynx. In this position, apertures between the cuffs approximate the larynx and serve as orifices for spontaneous or positive-pressure ventilation. The King LT requires a mouth opening of at least 2.3 cm and is inserted either blindly or with the aid of a laryngoscope. The Laryngeal Tube Suction (King LTS-D, Ambu, Ballerup, Denmark) is a single-use device which adds a lumen terminating distal to the esophageal cuff, facilitating gastric drainage. One case report describes the successful use of the LTS-D as an emergency airway for a pregnant woman who underwent cesarean section but could not be intubated. The device improved oxygenation and facilitated drainage of gastric contents during the patient's emergence from a failed rapid-sequence intubation.<sup>77</sup>

**Figure 28-6** (A) The King LT, (B) I-Gel, (C) air-Q, and (D) Aura-l.

The Laryngeal Tube is available in six sizes (0 to 5) suitable for children to large adults. In children under 10 years old, the Laryngeal Tube is less effective than the LMA during spontaneous or assisted ventilation and for fiberoptic evaluation of the airway.<sup>78</sup> The Laryngeal Tube is not recommended for children weighing less than 10 kg, as it is associated with technical difficulties and inadequate ventilation.<sup>79</sup>

A cadaveric study demonstrated that mucosal pressures in the lateral pharynx, base of tongue, and posterior pharynx were similar between the Laryngeal Tube and LMA ProSeal. The pressure with the Laryngeal Tube was higher on the posterior hypopharynx, though, and the investigators expressed concern that this increased pressure might impede pharyngeal perfusion.<sup>80</sup> A case of acute tongue and uvula ulceration after using the Laryngeal Tube for hysteroscopy has been reported.<sup>81</sup>

**Cookgas air-Q.** Developed by Dr. Daniel Cook, the air-Q perilaryngeal airway (Cookgas LLC, St. Louis, MO; Fig. 28-6) can function both as an elective SGA and a conduit for blind or flexible scope-aided intubation (described later in this chapter). A cuff, grossly the shape of the LMA Classic cuff, seals the perilaryngeal space and has airway seal pressures of 25 to 30 cm H<sub>2</sub>O, similar to that of the LMA ProSeal.<sup>82</sup> The device comes in sizes 0.5 to 4.5 and is inserted using a technique similar to that recommended for the LMA (see previous discussion). The inventor recommends filling the cuff with less than 10 mL of air, as a poor seal is often secondary to cuff *overinflation*. If, after insertion, the airway is obstructed, an up-down motion of the barrel

often realigns the epiglottis. A recent innovation, the self-pressurizing air-Q sp, does not require cuff insufflation but rather varies intracuff pressure based on airway pressure.

**Second-Generation Supraglottic Airways.** The LMA ProSeal was the first SGA with a gastric port and thus the first “second-generation” SGA (Table 28-10). The original intent of the ProSeal’s gastric drain was to aid the clinician in the diagnosis of SGA malposition. If the device’s distal tip were not appropriately within the esophageal opening, then gas escape would be detected via the esophageal port with positive-pressure ventilation. Additional tests have subsequently been developed to verify device positioning.<sup>83–86</sup> The gastric port also allows passive (regurgitation) and active (gastric tube insertion) emptying of the stomach.<sup>84,86–88</sup> The design of the ProSeal cuff improves airway seal during positive-pressure ventilation as compared with other LMA devices ( $\geq 40$  cm H<sub>2</sub>O). These advanced capabilities allow its use in the care of obese patients, patients undergoing intra-abdominal procedures, and in airway resuscitation.<sup>89–91</sup> A single-use version of the ProSeal, the LMA Supreme (Teleflex, Research Triangle Park, NC), incorporates a fixed curvature, replicating the insertion ease of the LMA Fastrach<sup>92</sup> (Fig. 28-4). The Supreme also supports inspiratory pressures of greater than 35 cm H<sub>2</sub>O, and has been used for intra-abdominal procedures.<sup>93</sup>

**Table 28-10** Features of the LMA ProSeal

Feature	Clinical Impact
Gastric drain	Confirmation of device positioning <ul style="list-style-type: none"> <li>• Suprasternal notch test<sup>a85</sup></li> <li>• No gas leak via gastric port<sup>b84</sup></li> </ul> Gastric tube placement <ul style="list-style-type: none"> <li>• Active and passive gastric emptying</li> </ul> Protection from gastric-content aspiration
Posterior cuff	Increased seal pressure
Bite block	Prevention of obstruction from biting Confers rotational stability Confirmation of device positioning—50% or more of the bite block should be within the oral cavity <sup>85</sup>
Placement	First insertion less successful than LMA Classic
Size choice	Size down from LMA Classic

<sup>a</sup>When a small amount of lubricant is used to occlude the gastric drain, gentle pressure on the suprasternal notch is reflected in movement of the lubricant meniscus.

<sup>b</sup>If the lubricant meniscus does not move with positive-pressure ventilation, there is no connection between the esophageal and laryngeal ports and ventilation is unlikely to cause gastric insufflation.

**The i-gel.** This uniquely designed SGA has a solid elastomer gel body mounted on a plastic barrel without an inflatable cuff (Intersurgical Inc., East Syracuse, NY, Fig. 28-6). A drain tube runs from the distal tip, which sits over

the esophageal inlet, to an outlet lateral to the airway circuit connector. A gastric tube may be placed via this drain (the largest size accommodating a 14-French tube), which also serves as a passage for passively regurgitated gastric contents. Airway leak pressures have been reported as ranging from 24 to 30 cm of water in adults. The incidence of sore throat appears to be less than with the LMA<sup>94</sup> and some reports note a lower rate of visible blood on the device at time of removal. Success rates (first-time insertion, adequate seal pressure, etc.) are comparable to the LMA Classic and ProSeal.<sup>95</sup> Contrary to a widely held belief, the solid mask of the i-gel does not change shape as it is warmed by the pharyngeal mucosa (personal communication, Muhammed Nasir, MD).

## Tracheal Intubation

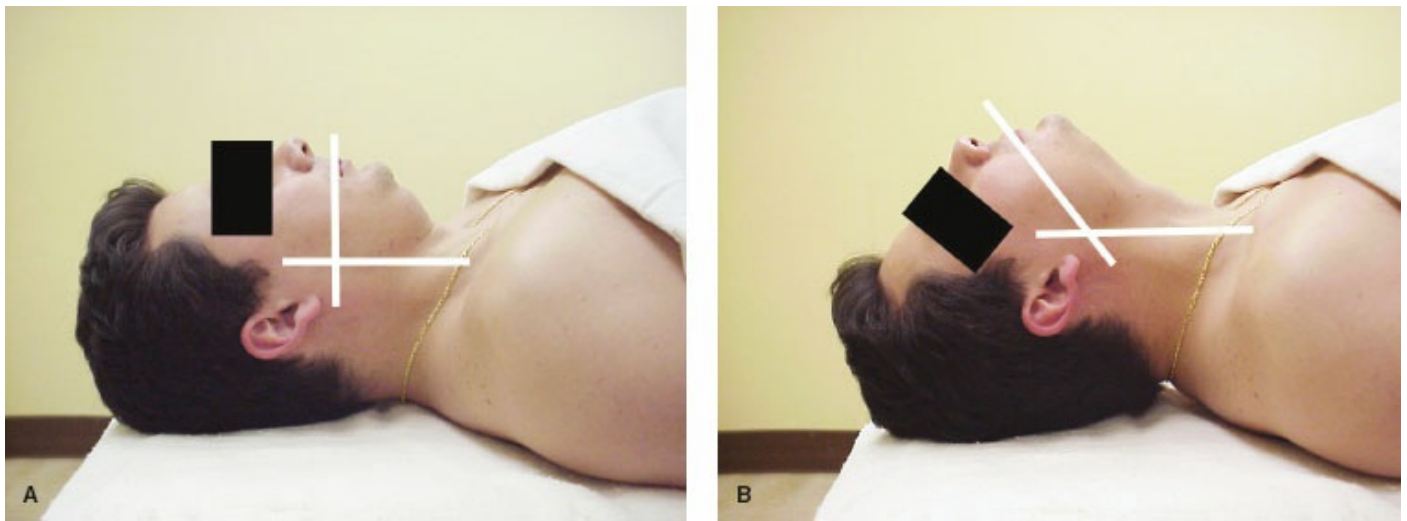

**Direct Laryngoscopy.** The goal of direct laryngoscopy is to produce **a direct line of sight from the operator's eye to the larynx.** This requires the creation of a new nonanatomic visual axis, achieved via maximal alignment of the axes of the oral and pharyngeal cavities, and displacement of the tongue. Unanticipated failure of DL is primarily a problem of tongue displacement, as inability to align the axes typically can be predicted by physical examination. As pointed out in the ASA Difficult Airway Practice Guidelines, no one measure may be adequate to determine difficulty of DL and multiple measures must be integrated in order to make sensible airway management decisions.<sup>2</sup> Shiga et al.<sup>22</sup> published a meta-analysis of studies regarding airway physical examination scores and cautioned on the poor sensitivity and modest specificity of all routine tests.

In 1944, Bannister and MacBeth proposed a three-axis model to explain the anatomic relationships involved in airway axis alignment.<sup>96</sup> Based on this model, alignment of the laryngeal, pharyngeal, and oral axes would result in adequate glottic view. This model explains the rationale of the intubation sniffing position (SP) in which the neck is flexed by 35 degrees and the head extended by 15 degrees. This positioning is achieved by placing a support (around 7 cm in the adult) under the patient's occiput. The three-axis explanation has been challenged by Adnet et al.<sup>97</sup> who noted that, although extension at the atlanto-occipital joint maximally facilitated an oral cavity/pharyngeal alignment, no significant improvement was achieved with flexion of the cervical spine on the thorax.

Chou and Wu<sup>98</sup> proposed a two-axes/tongue-displacement model. This model does not depend on the alignment of all axes to create an in-line view of the larynx but rather maximizes the spaces between the alveolar ridge and laryngeal aperture through oropharyngeal alignment and tongue displacement. This concept may explain difficulties with DL as well as why

common methods of airway assessment lack predictive power. This concept has been described as Functional Airway Assessment (FAA).<sup>99</sup>

**Figure 28-7 A:** With the patient supine, the oral and pharyngeal axes do not overlap. **B:** Extension at the atlanto-occipital joint maximally overlaps the oral and pharyngeal axes.

FAA is a method of examining the functional nature of each of the anatomic correlates of the commonly used airway assessment indices. FAA places an emphasis on the interdependence of these anatomic characteristics rather than on their individual size or functional integrity. As explained by Chou and Wu,<sup>98</sup> when the head and neck are in the neutral position, the oral and pharyngeal axes are perpendicular to each other. With maximal extension of a normal atlanto-occipital joint, 35 degrees or more of motion is attained (Fig. 28-7). This brings the angle between the oral and pharyngeal axes to 125 degrees. Although an improvement, it is certainly not the 180 degrees required for creating a line of sight to the glottis. Additional space must be created, which is accomplished by displacement of the tongue with the laryngoscope. Although atlanto-occipital extension cannot by itself allow direct laryngeal vision, it does provide anterior displacement of the mass of the tongue and bring the alveolar ridge into an improved position relative to the tongue and larynx. The extension of the atlanto-occipital joint also provides an advantage in mouth opening; Calder et al.<sup>58</sup> showed that maximal mouth opening is 26% greater in full atlanto-occipital extension as compared with the neutral head position. Mandibular mobility also facilitates displacement of the tongue away from the required visual axis—rotation and translation of the temporomandibular joint result in relaxation of the tongue insertion as well as creation of the aperture width needed for instrumentation.

Using the FAA approach to airway evaluation also helps to explain the value of the popular, yet highly criticized, Mallampati and thyromental distance indices.<sup>100</sup> These two measures have historically been considered

important because they approximate the relative mass of the tongue (Mallampati) and the anterior–posterior borders of space into which it will be displaced by the laryngoscope (Fig. 28-8). As noted elsewhere, these indices have shown to have poor and/or variable predictive power. Two groups have studied the interrelated nature of these measures in a way that reveals why they perform poorly when considered individually. Ayoub et al.<sup>101</sup> found a high Mallampati score to be predictive of difficult DL when the thyromental distance was less than 4 cm. When the thyromental distance was more than 4 cm, relative tongue size, as determined by the Mallampati classification, was not predictive. Iohom et al.<sup>9</sup> found similar results using a thyromental distance cutoff of 6 cm. The finding that the predictive power of the Mallampati improves when the mandible is short is consistent with the concept of FAA: when the mandibular space is restricted, tongue size is important. When the space is large, a tongue of any nonpathologic size should be accommodated easily. An exception to this may be a hypopharyngeal tongue, as described by Chou and Wu,<sup>102</sup> although, according to those authors, measurement of the mandibular hyoid distance should help in diagnosing this.

As noted earlier, a common cause of difficulty in DL is a pathologic increase in tongue size. Ovassapian et al.<sup>104</sup> identified lingual tonsil hyperplasia as the most common cause of *unanticipated* difficult DL. In a review of all cases of unanticipated difficult DL in their institution from 1999 to 2000, 33 patients were identified. All patients were found, on fiberoptic examinations, to have lingual tonsil hyperplasia (Fig. 28-9).

Devices that aid in obtaining a sniffing position are commercially available. These include the Sniff Position Pillow (Popitz Pillow, Alimed, Dedham, MA) and Pi's Pillow (American Eagle Medical, Holbrook, NY), which can be configured for the awake (neutral position) then asleep (functional position) patient. Some have suggested positioning the patient with the external auditory meatus level with the patient's sternal notch (EAM-SN position). This is especially helpful in obese patients<sup>105</sup> to move the mass of the chest away from the airway and allow space for manipulation of the laryngoscope handle. This may require placing a wedge-shaped lift (e.g., the Troop Elevation Pillow, Mercury Medical, Clearwater, FL) under the scapula, shoulders, and nape of neck. This raises the head and neck above the thorax, producing the EAM-SN position and allowing gravity to pull the pannus away from the airway.

After the head and neck have been positioned, the mouth is opened by one of two techniques. The first method encourages extension of the atlanto-occipital joint by the use of the right hand under the occiput. This maneuver is reserved for patients with stable cervical spines and leads to passive opening of the mouth, which can be accentuated by using the fourth finger of

the left hand (holding the laryngoscope) to apply pressure over the chin in a caudad direction. In the second technique, which tends to be more effective but requires contact of the (gloved) hand with the teeth and/or gums, the right thumb applies caudad pressure to the mandibular canine/bicuspid on the patient's same side while the first or second finger, crossed below the thumb, applies cephalad pressure to the ipsilateral maxillary canine/bicuspid. The ultimate goal of both techniques is rotation and translation of the temporomandibular joint to maximize the interincisor gap.

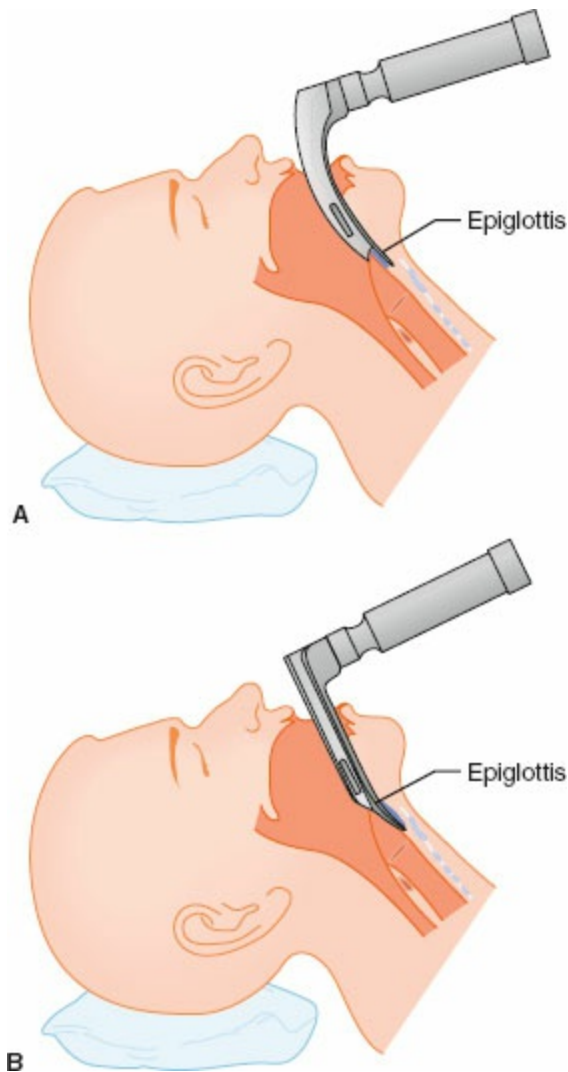

**Figure 28-8** Mallampati/Samsoon–Young classification of the oropharyngeal view.<sup>103</sup> **A:** Class I: Uvula, faucial pillars, soft palate visible. **B:** Class II: Faucial pillars, soft palate visible. **C:** Class III: Soft and hard palate visible. **D:** Class IV: Only hard palate visible (added by Samsoon and Young).

**Figure 28-9** Lingual tonsil hyperplasia. The vallecule is filled with hyperplastic lymphoid tissue in a patient who had an unanticipated difficult direct laryngoscopy.

**Direct Laryngoscope Blades.** Two blades, each with a unique manner of application, are in common use. Many other blades are described in the literature but will not be discussed here. There are some excellent reviews detailing these.<sup>106</sup>

The Macintosh (curved) blade is used to displace the epiglottis out of the line of sight by placement of the distal tip in the vallecule and tensing of the glossoepiglottic ligament. The Miller (straight) blade reveals the glottis by compressing the epiglottis against the base of the tongue (Fig. 28-10). Both blades include a flange along the left side of their length which is used to sweep the tongue to the left. Blades with a right-sided flange are available for the left-handed practitioner, but are not found in common practice.

**Figure 28-10 A:** When a curved laryngoscope blade is used, the tip of the blade is placed in the vallecula, the space between the base of the tongue and the pharyngeal surface of the epiglottis. **B:** The tip of a straight blade is advanced beneath the epiglottis.

Blade size needs to be chosen appropriately and, on occasion, exchanged after a failed attempt at laryngoscopy. As a generalization, the Macintosh blade is regarded as advantageous whenever there is little room to pass an ETT (e.g., small mouth), whereas the Miller blade is considered better in the patient who has a small mandibular space, large incisors, or a large epiglottis.<sup>44</sup> Ultimately, the optimal blade tends to be the one with which the provider has the most experience.

For laryngoscopy, the laryngoscope handle is held in the left hand and the mouth opened, as described earlier. The blade is inserted into the right side of the mouth, with care taken to avoid unnecessary contact with the lips or teeth. As the blade is advanced toward the epiglottis, the tongue is swept leftward and compressed into the mandibular space. Once reaching the base of the tongue (with the Macintosh blade in the vallecula or the Miller blade compressing the epiglottis against the base of the tongue), the operator's arm and shoulder lift in an anterior–caudad direction.

With either blade, the laryngoscopist must avoid rotating the laryngoscope in a cephalad direction, bringing the blade into contact with the upper incisors. Inserting either blade style too deeply can result in the tip of the blade resting under the larynx itself such that forward pressure lifts the airway from view.

Special considerations apply to the technique of laryngoscopy and intubation in the infant and child. Because of the relatively larger size of the occiput in children, elevation of the head is not required to achieve a sniffing position.<sup>44</sup> In fact, on occasion, the practitioner may need to elevate the thorax instead. Hyperextension at the atlanto-occipital joint, as done in adults, may cause airway obstruction from the relative pliability of the trachea and should be avoided. The comparatively short neck of a child gives the impression of an anterior position of the larynx and external laryngeal manipulation is often required to move the laryngeal inlet into view. A straight blade often is chosen, as it is helpful in displacing the stiff, omega-shaped epiglottis. Because the cricoid cartilage is the most rigid portion of the airway until 6 to 8 years of age, the intubator must be sensitive to resistance to advancement of an ETT that has easily passed the vocal folds. Due to the short length of the trachea, there is a higher risk of endobronchial intubation or accidental extubation with head movement. Continuous close attention should always be paid to the depth of the tube in pediatric patients.

A laryngeal view scoring system that has won general acceptance was developed by Cormack and Lehane,<sup>107</sup> who described four grades of laryngeal view. Grade 1 includes visualization of the entire glottic aperture, grade 2 includes visualization of only the posterior aspects of the glottic aperture, grade 3 is visualization of the tip of the epiglottis, and grade 4 is visualization of no more than the soft palate (Fig. 28-11). A Cormack–Lehane grade 3 or 4 is expected in 1.5% to 8.5% of adult laryngoscopies.<sup>108</sup> A modification of the Cormack and Lehane score was proposed by Yentis and Lee,<sup>48</sup> who noted that when a partial vocal cord view (2A) is achieved, tracheal intubation was significantly easier than when only the arytenoids and epiglottis were visualized (2B). A finer classification of a Cormack and Lehane grade 3 view has also been described. When the epiglottis can be manipulated with repositioning or an intubating bougie, it is referred to as a “3a” view and a nonmovable epiglottis constitutes a “3b” view.<sup>109</sup> The Cormack and Lehane grades are used to describe the view at laryngoscopy and have never been validated as a correlate of successful tracheal intubation.

Another view scoring system is based on the clinician’s estimate of the percent of glottic opening (POGO) seen during laryngoscopy, for example, 0% to 100% of the span from anterior commissure to the interarytenoid notch. The POGO score has improved interexaminer reliability when compared to the Cormack and Lehane system and has been adopted by many

researchers in the comparative evaluation of video laryngoscopy.<sup>110</sup>

If a satisfactory laryngeal view is not achieved, the backward–upward–rightward pressure (BURP) maneuver may be applied. In this maneuver, the larynx is displaced backward (B) against the cervical vertebrae, upward (U, superiorly) and to the patient’s right (R), using pressure (P) over the thyroid cartilage. The BURP maneuver has been shown to improve the laryngeal view, decreasing the rate of difficult intubation in a study of 1,993 patients from 4.7% to 1.8%.<sup>111</sup> Similarly, Benumof and Cooper describe “optimal external laryngeal manipulation,” which consists of pressing posteriorly and cephalad over the thyroid, hyoid, and cricoid cartilages.<sup>112</sup>

Once the larynx is visualized, the tracheal tube is inserted from the right-hand side, care being taken not to obstruct the view of the vocal cords. Whenever possible, the action of the ETT passing through the vocal cords should be witnessed by the laryngoscopist. This decreases the possibility of accidental esophageal placement or trauma to paraglottic structures. The tracheal tube cuff should be advanced at least 2 cm past the glottic opening to approximate a midtracheal placement. This should correlate to depths of 21 and 23 cm at the teeth for the typical adult female and male, respectively. Though allowances should be made for individual circumstances, a size 7 to 7.5 ID tracheal tube is typically used in the adult female and size 7.5 to 8 ID in the adult male. Larger tracheal tubes may be desirable if pulmonary toilet or diagnostic or therapeutic bronchoscopy is to be part of the clinical course. Pediatric tracheal tube sizes are presented in detail in [Table 28-11](#) (see also [Chapter 42](#)).

**Figure 28-11** The Cormack–Lehane laryngeal view scoring system: grade 1 (A), grade 2 (B), grade 3 (C), and grade 4 (D).

**Table 28-11** Size and Length of Pediatric Tracheal Tubes Relative to Airway Anatomy

Age	Internal Diameter (mm)	Distance from Lips to Midtrachea* (cm)
Premature	2.5	8
Full term	3	10
1–6 months	3.5	11
6–12 months	4	12
2 years	4.5	13
4 years	5	14
6 years	5.5	15
8 years	6.5	16

\*Add 2 to 3 cm for nasal tubes.

An alternative approach to DL has been described by Henderson.<sup>113</sup> In this “paraglossal” approach, a straight-bladed laryngoscope is introduced into the right side of the mouth and advanced between the tongue and palatine tonsil. The blade passes below the epiglottis, which is then elevated. This approach subjects the tongue to less compressive forces and may improve the view of

the larynx in the presence of lingual tonsil hyperplasia.

The gold standard for verification of tracheal intubation is sustained detection of exhaled carbon dioxide. Additional verification techniques include visualization of tube placement through the vocal folds, auscultation over the chest and abdomen, visualization of chest excursion, observation of humidity in the ETT, full return of tidal volume during expiration, use of a self-inflating bulb (TubeChek-B, Ambu, Ballerup, Denmark), flexible scope identification of tracheal anatomy, and ultrasound or chest x-ray.<sup>33</sup>

Although DL remains the most common method for tracheal intubation, it is far from successful in all cases and not always benign when successful. DL may be difficult (Cormack and Lehane grade 3 or 4 view) or impossible in 4.4 and 0.3% to 0.43% of attempts, respectively.<sup>114–116</sup> Analysis of the ASA Closed Claims Database reveals that claims for laryngeal injury during DL arise more often in “easy” as opposed to difficult laryngoscopies.<sup>53</sup> Among the 4,460 cases in the database, 87 instances of laryngeal trauma were recorded. Of these, 80% occurred during routine (nondifficult) tracheal intubation in which no injury was suspected. This has led some to question whether routine tracheal intubation is as safe as assumed.<sup>52</sup>

Image-guided laryngoscopy promises to dominate modern airway management. The first decade of the 21st century saw a proliferation of optical and video-transmitting devices primarily as the result of the availability of inexpensive CMOS technology. The unifying characteristics of these laryngoscopes is that a direct line of sight is no longer needed from the provider’s eye to the glottis. A large variety of these devices exist, some of which are detailed later.

**Optical Stylets.** Optical stylets incorporate both optical and light source elements into a single stylet-like shaft. Some examples of these are the Shikani Seeing Stylet (Clarus Medical, LLC, Minneapolis, MN) and the Bonfils Intubation Fiberscope (BIF, Karl Storz, Tuttlingen, Germany; Fig. 28-12). Both require less cervical spine motion than direct laryngoscopy.<sup>117,118</sup>

The BIF is a long rigid tubular device with conventional optical and light-transmitting fiberoptic elements.<sup>119</sup> The distal end has a 40-degree angulation and the objective lens allows a 100-degree field of view. A proximal-end eyepiece can be used with the naked eye or fitted with a standard endoscopy camera. A cable (or battery-powered attachment) brings illumination from an external light source and suction may be applied through a working channel. Laryngoscopy technique replicates the paraglossal approach discussed previously in this chapter and sizes with external diameters of 2, 3.5, and 5 mm are available.

The Shikani Seeing Optical Stylet (SOS) has a similar configuration to the BIF, with the exception that the distal half of the stylet is malleable (Fig. 28-

13). The light source may be cabled or self-contained with a proprietary handle or a green line laryngoscope handle (Rusch Medical, Duluth, GA). Unlike the BIF, the SOS uses a midline approach. Although the SOS can be used as an independent intubating device, it can also be employed as an adjunct to direct laryngoscopy when a high Cormack and Lehane score is achieved. While the SOS is primarily an oral intubation device, it has been used also for nasal intubation. The pediatric and adult SOSs can accommodate tracheal tubes as small as 2.5 and 5.5-mm ID, respectively.

The Levitan First Pass Success Scope (FPS, Clarus Medical, LLC, Minneapolis, MN) is a shorter (30-cm) version of the SOS designed to be used as an adjunct to DL when a poor laryngeal view is encountered (Fig. 28-13). The shorter length allows easier positioning by the laryngoscopist,<sup>120</sup> but standard tracheal tubes (6-mm ID or larger can be used) should be trimmed in length so that the objective lens is within the bevel.<sup>121,122</sup> The hypothetical benefits of using the device in this manner are the reduction of unanticipated difficult intubations and the maintenance of alternative technique skills by incorporating this or similar devices into daily practice.<sup>122</sup>

**Figure 28-12** The Bonfils (Karl Storz, Tuttlingen, Germany). Inset: Objective end within tracheal tube.

**Figure 28-13 A:** The Shikani Seeing Optical Stylet (Clarus Medical, LLC, Minneapolis, MN).

MN). **B:** The Levitan FPS.

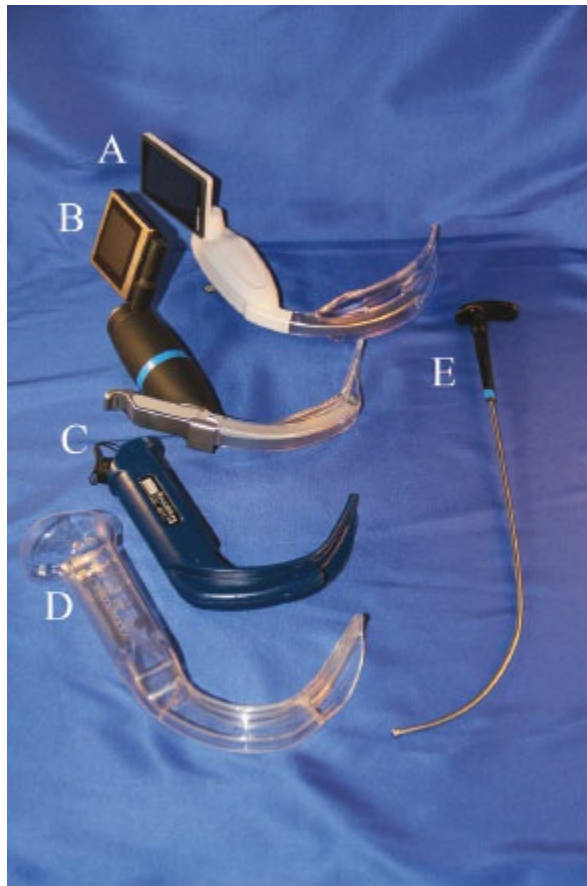

The Clarus Video System (Clarus Medical, LLC, Minneapolis, MN; [Fig. 28-14](#)) marries the malleable stylet concept of the SOS with CMOS technology. A 4-inch adjustable-angle LED screen is mounted on the handle and has a proprietary video-out port. The device also supports intubation via transillumination technique by incorporating a distal, anteriorly positioned red diode that may be visible through the skin when the tip of the device is in the larynx.

## Videolaryngoscopy

VL mimics the operator actions of direct laryngoscopy but places **7** an imaging device toward the distal end of the laryngoscope blade. This moves the provider's point of view past the tongue, avoiding the need for a direct line of sight to the glottis. The ASA Difficult Airway Taskforce recommends that a videolaryngoscope be available as a first attempt or rescue device for all patients being intubated.<sup>2</sup> VL improves the ability to visualize the larynx, and intubation success approaches 97% to 98%. An added benefit is decreased cervical motion when compared with DL, which appears to be more pronounced with the channeled devices.

**Figure 28-14** The Clarus Video System (Clarus Medical, LLC, Minneapolis, MN).

**Figure 28-15** (A) McGrath Mac and (B) Mcgrath Series 5 (Medtronic, Dublin, Ireland), (C) Glidescope Multiuse blade and (D) Glidescope Cobalt single-use blade (Verathon, Bothell, WA), and (E) Gliderite rigid stylet (Verathon, Bothell, WA).

**13** The first widely available videolaryngoscope was the Glidescope (Verathon, Bothell, WA; Fig. 28-15). The Glidescope blade has both a light-emitting diode and a CMOS chip and is cabled to an LCD monitor.<sup>123</sup> The distal portion of the blade has a 60-degree angulation, making it an “acute-angle” videolaryngoscope. The Glidescope design has several advantages: (1) It may be handled with a skill set similar to that used with conventional DL. (2) As the video apparatus is positioned close to the distal end of the blade, the operator “sees” from a position beyond the base of the tongue and tongue displacement is not as critical as it is with DL. Similarly, with the optics positioned distal to the lingual tonsils, tonsillar hyperplasia should not affect the visual axis as it does with conventional DL. (3) The video apparatus eliminates fragile fiberoptic elements. (4) The airway image is displayed on a portable screen, allowing for observation by more than one individual (e.g., aid, mentor, and student). (5) The 60-degree distal angulation reduces cervical spine motion by 50% at the C2–5 segments compared with Macintosh DL.<sup>124</sup>

When used by inexperienced operators, the Glidescope provides a better glottic view than DL (Cormack–Lehane grade 1 view in 85.7% vs. 48.9% of patients) and can obtain a Cormack–Lehane grade 1 or 2 view in 77% of patients in whom no glottic exposure was achieved by DL.<sup>123</sup> A large

prospective, nonrandomized study of 1,755 patients showed a 98% intubation success rate with the Glidescope, including 96% success in patients predicted to be difficult by DL, and 94% success in airway rescue after failed DL.<sup>29</sup> Although achieving an adequate laryngeal view with the Glidescope appears relatively easy, ETT manipulation into the larynx appears to be more difficult. In one study, placement of the ETT required an additional 16 seconds (on average) when compared to DL.<sup>123,125</sup> This is likely due to difficulty in maneuvering the ETT around the acute angle of the blade. For this reason, the use of a stylet is advised.<sup>126,127</sup> A dedicated, nonmalleable stylet, the Gliderite Rigid Stylet (Verathon, Bothell, WA), has a 90-degree distal bend and may be used with various videolaryngoscopes. A study by Jones et al.<sup>128</sup> suggests that the angle of the ETT has greater impact on time to intubation than the Cormack and Lehane grade of the image. Because the stylet is rigid and its distal tip faces anteriorly, it may get caught on the anterior tracheal rings. A 1 to 2 cm withdrawal of the stylet as the glottis is entered may facilitate advancement into the larynx as well as counterclockwise rotation of the tracheal tube as it is advanced off the stylet. Insertion of the stylet into the larynx should be minimal, if any.

Theoretically, the airway axes do not need to be aligned to achieve adequate glottic visualization with VL. Manipulation of the Glidescope to the position needed for adequate image can cause cervical segment extension, though.<sup>129</sup> Care must be taken in that regard, especially if the cervical spine is unstable. The Glidescope has been successfully used to achieve tracheal intubation in patients with limited cervical spine movement because of ankylosing spondylitis and cervical spine trauma, but it may be difficult to use in patients with limited mouth opening.<sup>130,131</sup>

The classic Glidescope insertion technique follows the midline approach. After the uvula is visualized, the blade is advanced in the midline into the vallecula or is passed posterior to the epiglottis.<sup>123</sup> For patients with a limited mouth aperture, the blade can be inserted like a Guedel airway, with the Glidescope blade concavity facing rostrad and rotated 180 degrees counterclockwise once the distal tip is in the oropharynx. This maneuver displaces the tongue to the left and minimizes neck movements.

Practitioners must visualize, to completion, insertion of both the blade and the ETT into the oropharynx. Traumatic complications associated with the use of the Glidescope videolaryngoscope have been related to blind manipulation of the ETT as it enters the airway but is not yet visualized on the video screen. Traumatic events, which appear to be more likely with the use of a rigid stylet, have been reported relating primarily to the soft palate, palatoglossal arch, right palatopharyngeal arch, and right anterior tonsillar pillar (Fig. 28-16).<sup>132,133</sup> Steps to avoid soft tissue trauma include (1) assuring that the stylet is within the bevel of the ETT; (2) maintaining the ETT in a

midline position and as close to the blade as possible; (3) focusing the operator's attention on the patient's oral cavity (as is done during DL) as the blade and then ETT are advanced into the mouth, occasionally glancing at the VL monitor—full attention is turned to the video image only when the distal ETT can be seen on the image monitor; (4) avoiding levering of the blade inward, as this increases the “blind spot” inferiorly; (5) using the least force necessary to advance the ETT; and (6) practicing “reverse loading” of the ETT (as described later).<sup>134</sup> The potential for trauma to the oropharyngeal soft tissues, due to the above-described “blind spot,” is similar for all videolaryngoscopes listed later, unless true direct laryngoscopic technique is used.

Control studies have shown no significant advantage of the Glidescope in preventing hemodynamic responses to orotracheal intubation as compared with the Macintosh direct laryngoscope, although others have shown cardiovascular responses similar to intubation with a flexible intubation scope.<sup>135</sup> The Glidescope has also been used to facilitate nasotracheal intubation with a reduced time to intubation when compared with DL and a high first-time success rate. Reverse loading technique and use of a gum elastic bougie have also been described. Reverse loading entails bending the distal tip of the stylet in the opposite direction of the natural ETT curvature. This promotes a more posteriorly directed delivery of the ETT and decreases the chance of impingement on the anterior commissure or tracheal rings.<sup>136</sup>

**Figure 28-16** Passage of a tracheal tube through the right palatoglossal arch due to a blind spot created with videolaryngoscopy.

A newer version of the Glidescope, the Glidescope Titanium (Verathon, Bothell, WA), is available. Functioning like the original, the new design is made of titanium and has two standard curved blades (MAC T3 and T4) as well as two low-profile acute-angle blades (LoPro T3 and T4). Plastic, single-use versions are also available (LoPro/Mac P3 and P4). The mouth openings

needed for commonly used indirect laryngoscopes are listed in [Table 28-12](#).

**Figure 28-17** The Storz C-MAC (Reprinted with permission from Karl Storz, Tuttlingen, Germany).

The C-MAC system (Karl Storz, Tuttlingen, Germany; [Fig. 28-17](#)) consists of an electronic laryngoscope handle with exchangeable metal blades. One of these, the D-Blade, is an acute-angle blade similar in angulation to the

Glidescope, designed for when difficult DL is anticipated. A large multicenter prospective randomized trial of 1,100 patients showed no difference in intubation success rate (with two attempts) between the Glidescope and C-MAC D-Blade in patients with anticipated difficult laryngoscopy.<sup>137</sup>

The C-MAC platform also works with blades that are identical to standard Macintosh and Miller blades but with integrated illumination and CMOS optics. This allows the device to be used as either a videolaryngoscope or a standard direct laryngoscope. Although the image projected from the C-MAC closely resembles that seen with the naked eye, ETT placement is facilitated because the video image obviates the need to maintain an unobstructed line of sight to the glottis. Use of the C-MAC is identical to standard DL, making the video facility uniquely valuable during supervised instruction. A comparison study of direct and video-assisted views of the larynx revealed significant improvement of the glottic view with C-MAC video assistance.<sup>138</sup>

The McGrath Series 5 videolaryngoscope (Medtronic, Dublin, Ireland, Fig. 28-15) incorporates a blade, handle, power source, and LCD screen into a self-contained device. Unique design features include an acute-angle blade of adjustable length and disposable blade covers. As with the Glidescope, the acute-angle blade improves laryngeal view but has the drawback of more awkward tracheal tube placement, and use of a rigid or semimalleable ETT stylet is advised. In one uncontrolled series, tracheal intubation with the McGrath was successful in 98% of 150 elective surgery patients.<sup>139</sup>

The McGrath Mac (Medtronic, Dublin, Ireland) is the newer-generation McGrath videolaryngoscope with a reduced blade curvature and a slimmer blade design (11.9 mm). Compared to the acute-angle blade of the Series 5, the reduced curvature allows easier use as a direct laryngoscope and an improved screen allows shared viewing. The “blind spot” noted with the Glidescope and McGrath Series 5 is reduced if a DL approach is used. Though there may be less concern for soft tissue trauma, the cautions mentioned earlier still apply. Another McGrath product, the McGrath X blade, has an acute angle tip for anticipated difficult airways, a slimmer design, and a portrait display to decrease blind-spot.

A new generation of videolaryngoscopes, termed “channeled scopes,” employ a J-shaped channel that follows the course of the optical elements from the viewing element (optical or video imaging) to the distal objective lens or CMOS chip. Whereas DL accommodates for the right-angle nature of the airway by displacing the anterior structures and VL accommodates by placing the operator’s point of view beyond the tongue, the “channeled” devices replicate the near 90-degree relationship of the oral and pharyngeal axes, limiting the need for tissue displacement and cervical manipulation. A lubricated ETT is preloaded into the channel and therefore guided in the same trajectory as the objective. When adequate visualization of the glottis is

achieved, the ETT is advanced in the channel until observed approaching the larynx. In theory, as the tracheal tube is never in a blind-spot, this technique should reduce the incidence of soft tissue trauma seen with the classic videolaryngoscope approach. The blades of channeled devices typically have an anatomic shape; therefore, a neutral head and neck position tends to result in improved glottic alignment. Minor manipulations of the videolaryngoscope (anterior, posterior, caudad, rostrad, and rotational) may be needed to align the ETT and facilitate passage through the glottis.

The Airtraq optical laryngoscope (Prodol Meditec S.A., Vizcaya, Spain; [Fig. 28-18](#)) is a single-use, anatomically shaped, channeled laryngoscope with periscopic optics. The device has a built-in antifog system and a low-temperature light that facilitates the laryngeal view. The Airtraq has been used successfully as a rescue device in patients after failed intubation with DL.<sup>140</sup> Anterior forces (e.g., those applied to the tongue) are reduced compared to that found with DL, but some cervical spine movement still occurs.<sup>129</sup> Reports of its use in awake patients, patients with cervical spine disease, and after failed DL have been published as well.<sup>141</sup> One study showed the need for fewer maneuvers to improve glottic exposure and fewer alterations in blood pressure and heart rate when compared with DL.<sup>142</sup> Reduced cervical spine movement in patients with midline axial stabilization also has been demonstrated. The Airtraq AVANT (Prodol Meditec S.A., Vizcaya, Spain), functions similarly, but with reusable prismatic optics sheathed in a disposable blade. A study of 100 patients showed better glottic visualization with the AVANT than with DL utilizing a Macintosh blade.<sup>143</sup>

**Figure 28-18** (A) The Pentax Airway Scope (Hoya-Pentax, Tokyo, Japan). (B) The Airtraq laryngoscope (Prodol Meditec S.A., Vizcaya, Spain).

The Airway Scope (Pentax AWS, AWS-S100; Hoya-Pentax, Tokyo, Japan) is a reusable, channeled device with a CMOS camera cord fitted into a single-use blade ([Fig. 28-18](#)). The handle incorporates a 2.4-inch LCD monitor, the

angle of which can be adjusted for easier viewing. The channel on the disposable blades accepts ETTs with internal diameters between 6.5 and 8.0 mm and incorporates a working channel that can be used for placement of a small suction catheter, injection of lidocaine, or insufflation of oxygen. Unlike the Airtraq, the manufacturer of the AWS recommends using the blade to lift the epiglottis (similar to using a Miller blade) prior to ETT insertion. The difference in technique appears to be related to the ETT being closer to the device tip during tube extrusion with the AWS than with the Airtraq.<sup>144</sup> In one small, nonblinded, noncrossover study, the AWS produced less of a hemodynamic response and had a higher intubation success rate than the Glidescope (100% vs. 96%) in patients predicted to be difficult by DL.<sup>145</sup> As with other channeled devices, the AWS has a higher success rate than the Glidescope in normal volunteers with restricted neck mobility.<sup>29</sup>

The KingVision Video Laryngoscope (Ambu, Ballerup, Denmark) includes a reusable, battery-operated OLED display and disposable channeled and nonchanneled blades. The device can therefore be used as a classic VL or as a channeled scope. The on-handle display gives a higher-quality image than most other VLs and includes a composite video-out port.

## NPO Status and Rapid-Sequence Induction

▶ 15

Aspiration of gastric contents trails only failed intubation in frequency amongst reported adverse events.<sup>1</sup> Induction of anesthesia profoundly depresses intrinsic reflexes that protect the airway from the entrance of foreign bodies, including regurgitated material. In addition, manipulation of the upper esophageal inlet reduces the closing pressure of the lower esophageal sphincter. Many patients will present in situations in which aspiration is a significant risk (Table 28-13A) and rapid-sequence induction (RSI), as described, is practiced. If, in addition, difficult airway management is anticipated, awake intubation is often chosen (see Airway Approach Algorithm below). When aspiration is of concern, pharmacologic therapy can help mitigate risk, with the goal of reducing both the volume and acidity of gastric contents. Obesity has long been considered a risk factor for gastric-content aspiration and preoperative treatment with gastric emptying and acid-reducing agents has been recommended,<sup>146</sup> though this remains controversial. Although initial studies touted the increased volume and decreased pH of gastric secretions in the obese fasting patient, others have refuted this claim.<sup>147,148</sup>

▶ 16

▶ 17

### *Control of Gastric Contents*

Preventing pulmonary aspiration of gastric contents is a primary concern during airway management. Control of gastric contents involves (1)

minimizing intake, (2) increasing gastric emptying, and (3) reducing gastric volume and acidity (Table 28-13B). Altered physiologic states (e.g., pregnancy and diabetes mellitus) and gastrointestinal pathology (e.g., bowel obstruction and peritonitis) adversely affect the rate of gastric emptying, thereby increasing aspiration risk. The extent of delayed gastric emptying with diabetes mellitus correlates well with the presence of autonomic neuropathy but not with age, duration of disease, HbA<sub>1c</sub>, or peripheral neuropathy. The difference in the gastric emptying times between healthy patients and those with type I diabetes ranges from 30 minutes to 2 hours.<sup>150</sup> Human breast milk is cleared more rapidly than other milk products<sup>151</sup> and the ASA recommends a fasting period of 4 hours for breast milk and 6 hours for nonhuman milk, infant formula, and a light solid meal. Clear liquids can be administered to children up to 2 hours, and adults up to 3 hours, prior to anesthesia without increased risk for regurgitation and aspiration (Table 28-13C).<sup>149</sup>

**Table 28-13** Pulmonary Aspiration: Patients at Risk for Aspiration, Methods to Reduce Aspiration Risk, and ASA Recommended Fasting Guidelines

<b>(A) Patients at Risk of Aspiration</b>	
<ul style="list-style-type: none"> <li>• Full stomach (recent ingestion)</li> <li>• Diabetes mellitus (with peripheral neuropathy)</li> <li>• Clinically significant gastroesophageal reflux/hiatal hernia</li> <li>• Pregnancy</li> <li>• Acute pain/acute opioid therapy, renal colic</li> <li>• Bowel obstruction/intra-abdominal process</li> <li>• Trauma/unknown timing of last meal</li> </ul>	
<b>(B) Methods to Reduce Aspiration Risk</b>	
<ul style="list-style-type: none"> <li>• Minimize intake: adequate preoperative fasting, clear liquids only if necessary</li> <li>• Increase gastric emptying: prokinetics (e.g., metoclopramide)</li> <li>• Reduce gastric volume and acidity: preinduction nasogastric tube, nonparticulate antacid (e.g., sodium citrate), H<sub>2</sub>-receptor antagonists, proton pump inhibitors</li> <li>• Airway protection: rapid placement of cuffed ETT after induction, cricoid pressure (controversial)</li> </ul>	
<b>(C) Summary of Preoperative Fasting Recommendations<sup>149</sup></b>	
Ingested material:	Minimum fasting period:
• Clear liquids	2 hours
• Breast milk	4 hours
• Infant formula	6 hours
• Nonhuman milk	6 hours
• Light meal	6 hours
• Meal containing fatty foods or meat	≥8 hours

Reduction of gastric acidity can be achieved with the aid of H<sub>2</sub>-receptor antagonists and proton pump inhibitors (PPIs), which also reduce gastric

volume. Famotidine given a few hours before surgery effectively reduces gastric volume and increases gastric pH better than ranitidine.<sup>152</sup> The PPIs rabeprazole, lansoprazole, and omeprazole are most effective when given in two successive doses: one the evening before and one the morning of anesthesia.<sup>153,154</sup> When given in a single dose, rabeprazole and lansoprazole should be administered on the morning of anesthesia, as they are not sufficiently effective when given the night before. This is in contrast to single-dose therapy with omeprazole, which is most effective when administered the night before.<sup>153–155</sup> Sodium citrate oral solution increases gastric pH and is best administered within 1 hour preoperatively in a dose of 15 to 30 mL. When combined with metoclopramide (10 mg IV), sodium citrate (15 mL PO) reduces gastric volume by 33% and increases gastric pH by 38% versus unmedicated controls.<sup>156</sup> A nasogastric (NG) tube can also be used to reduce gastric volume prior to induction of anesthesia in patients at high risk of regurgitation. An NG *in situ* provides a passage for passive drainage of gastric contents and does not diminish the effectiveness of cricoid pressure.<sup>157</sup> NGs are best left in place and open to freely drain during induction of anesthesia. The presence of an NG tube does not guarantee an empty stomach, though, and may impair the function of the lower and upper esophageal sphincters.

**Rapid-Sequence Induction.** RSI is indicated when there is increased risk of gastric content aspiration. The goal of RSI is to gain control of the airway in the shortest amount of time after the ablation of protective airway reflexes with the induction of anesthesia. In the RSI technique, an intravenous anesthetic induction agent is administered and immediately followed by a rapidly acting neuromuscular blocking drug. Historically, mask ventilation is omitted for fear of gastric insufflation. Laryngoscopy and intubation are performed as soon as muscle relaxation is confirmed. Classically, cricoid pressure is applied (Sellick maneuver), which entails the posterior displacement of the cricoid cartilage against the vertebral bodies, and is held from the beginning of induction until confirmation of ETT placement. In this manner, it was presumed that the lumen of the esophagus was ablated while the circumferential structure of the cricoid cartilage maintained the tracheal lumen.

Early cadaveric studies showed that correctly applied cricoid pressure was effective in preventing gastric fluids from leaking into the pharynx. Recently, MRI studies have suggested that the esophagus is laterally displaced in a majority of normal patients<sup>158</sup>; thus, the adequacy of esophageal ablation has been questioned. In addition, cricoid pressure may worsen the laryngoscopic view<sup>159</sup> and is contraindicated during active vomiting (risk of esophageal rupture), and with cervical spine or laryngeal fracture. There is also little evidence that omission of mask ventilation provides any clinical benefit, especially in patients with poor pulmonary reserve. In fact, if oxyhemoglobin

desaturation occurs, gentle positive-pressure ventilation (<25 cm H<sub>2</sub>O) is recommended as is, in the instance of poor laryngeal view, the release of cricoid pressure.<sup>160</sup> For these reasons, and the lack of randomized controlled trials evaluating outcomes in regard to cricoid pressure,<sup>161</sup> some practitioners have altogether abandoned classic RSIs in favor of gentle mask ventilation, without cricoid pressure, while waiting for fast-acting paralytics to work.<sup>162</sup> If mask ventilation is omitted, high-flow oxygen via nasal cannula can be used to increase apnea tolerance via apneic oxygenation, as discussed earlier.

Another, more insidious, mode of aspiration is “microaspiration,” which occurs when ETT cuff occlusion of the tracheal lumen is imperfect. Leakage of liquids past the cuff may be related to an underinflated cuff or channeling secondary to cuff folding and can be worsened by negative intrathoracic pressure in the spontaneously breathing patient.<sup>163</sup> For these reasons, ETTs with subglottic suction ports are recommended for patients who will likely stay intubated past the immediate postoperative period.<sup>70</sup>

**The Intubating Supraglottic Airways.** Blind, flexible scope-aided, stylet-guided, and laryngoscopy-directed tracheal intubation via SGAs has been widely reported, but many limitations have been described. In an effort to overcome these limitations, Brain et al. introduced a version of the LMA, the LMA (Teleflex, Research Triangle Park, NC), designed specifically as a conduit to intubation (Fig. 28-4). Other manufacturers have introduced similar devices including the Aura-I (Ambu, Ballerup, Denmark) and the air-Q (Fig. 28-6). Most non-Fastrach devices require guided tracheal intubation (e.g., with a flexible intubation scope) during the intubation process. Expert groups, such as the Difficult Airway Society of the United Kingdom, recommend this visually guided approach.<sup>3</sup>

The mask of the LMA Fastrach differs from Dr. Brain’s original LMA design with the incorporation of a vertically oriented, semirigid bar fixed at the proximal end of the bowl aperture. This “epiglottic elevating bar” sits beneath the epiglottis in the average-sized adult and guides the ETT toward the larynx. A handle at the proximal end of the barrel is used for insertion, repositioning, and removal of the device. Originally made of stainless steel and silicone, a plastic single-use version is available. The LMA Fastrach barrel can accommodate up to an 8-mm ID-cuffed ETT, which can be inserted blindly or over a fiberscope or other flexible stylet device. The Fastrach is designed to be used with a wire-reinforced tracheal tube, although the use of both standard and Parker Flex-Tip (Parker Medical, Englewood, CO) PVC tracheal tubes has been described.<sup>164</sup> The LMA Fastrach is available in sizes with cuffs equivalent to the size 3, 4, and 5 LMA Classics. Experience suggests that most adults between 40 and 70 kg are best managed with a size 4 Fastrach and heavier persons require a size 5.

A large study has shown the utility of the LMA Fastrach. Ferson et al.<sup>92</sup>

successfully intubated 234 patients with this device, including patients for whom they anticipated difficult intubation. Successful blind intubation via the LMA Fastrach occurred in 97% of these patients; the remaining intubations were facilitated with adjunct use of a fiberoptic intubation scope. A modification of the LMA Fastrach design, the LMA CTrach (introduced in 2004 but no longer commercially available), incorporated into the device bowl a CMOS camera connected to a handle-mounted monitor.

Prior to insertion, the mask of the LMA Fastrach cuff is tested, deflated, and lubricated as described for the LMA Classic. With the patient's head in neutral position, the device is inserted into the mouth so that the mask lies flat against the palate. Gentle pressure on the handle and barrel reproduces the palatal pressure described earlier for LMA Classic insertion. A smooth backward rotation of the handle toward the top of the head seats the tip of the mask in the hypopharynx, posterior to the cricoid cartilage. Once seated, the mask of the Fastrach is inflated and ventilation is attempted. The position of the device can be optimized by lateral and anterior–posterior manipulation of the handle, known as the *Chandy maneuver* (after Dr. Chandy Verghese, Redding, UK).<sup>165</sup> A seemingly common cause of airway obstruction with the LMA Fastrach is down-folding of the epiglottis. This can be relieved with a smooth rotational movement of the inflated LMA Fastrach out of the airway (6 cm along the axis of the insertion) and immediate replacement (the “up–down maneuver”).

Blind tracheal intubation is undertaken only if the airway is clear and the patient is muscle relaxed and/or sufficiently anesthetized. After adequate ventilation and anesthesia are achieved, the ETT is advanced through the barrel. As the ETT exits the bowl aperture of the LMA Fastrach, the elevating bar is pushed anteriorly, carrying the epiglottis out of the way. If positioned correctly, the ETT can freely enter the glottis.

When blind intubation fails (esophageal insertion or inability to advance the ETT) and flexible intubation scopes or stylets are not available, several maneuvers may be performed.<sup>165</sup> As early obstruction is typically caused by a down-folded epiglottis, an up–down maneuver, as described earlier, can be employed and intubation attempts repeated. If unsuccessful, a second part of the Chandy maneuver may be attempted in which the handle is used to gently lift (without rotation) the device anteriorly, sealing the bowl against the larynx. Early resistance may also signify vallecular entrapment secondary to an LMA Fastrach size. The operator may remove the LMA Fastrach and place a smaller one. Later obstruction may signify entrapment or too small a device and, again, a change may be indicated.

When intubation fails despite these maneuvers and/or a change in the device size, the clinician should recall that ventilation typically will be adequate despite failure to intubate. At this juncture, the clinician can (1)

continue with short surgical procedures using the Fastrach as a simple SGA (procedures longer than 15 minutes may be ill advised because of the pressure exerted by the LMA Fastrach on pharyngeal tissues), (2) change to a different SGA, (3) diagnose the intubation impediment with the aid of another device (e.g., flexible intubation scope), (4) remove the SGA and employ an alternate technique of tracheal intubation, or (5) perform a surgical airway while continuing ventilation via the SGA. This last procedure may be an underappreciated facility of all the SGAs, as these devices may serve as bridges while invasive airway procedures are performed.

Once successful intubation is confirmed by capnography and physical exam, an intubating SGA may be removed. Though this is typically a requirement of the rigid devices (e.g., LMA Fastrach), some intubating SGAs (e.g., the Aura-I or air-Q) may be left *in situ*. For removal, the ETT circuit adapter is removed and the intubating SGA is withdrawn over the ETT. During this removal, the ETT is stabilized either coaxially by a stabilizing rod (supplied by the manufacturer) or by Magill forceps holding the proximal tip of the ETT (as described by Rosenblatt et al.).<sup>166</sup> In the midremoval position, a finger is placed in the mouth to stabilize the ETT while the SGA is fully retreated.

The precurved Aura-I intubating SGA lacks the rigid components as well as the epiglottic lifting bar concept of the LMA Fastrach. Because it does not apply as much pressure to pharyngeal mucosa, it can be left *in situ* after intubation or used for long periods as a simple SGA. When using an Aura-I for tracheal intubation, a flexible intubation scope should be used.

The air-Q SGA also forgoes the rigid components and epiglottic lifting bar. Unlike the devices discussed earlier, it lacks the 90-degree precurvature of the barrel. The air-Q barrel will accept a tracheal tube from 4.5 to 8.0 mm internal diameter (ID) and the keyhole-shaped airway outlet is designed to steer the ETT toward the larynx. For blind intubation, the ETT cuff is deflated, lubricated, and inserted into the device barrel. If the larynx is entered, advancement past 12 to 15 cm should occur with little resistance. If resistance is met, the air-Q can be repositioned and ETT advancement attempted again. Once tracheal intubation is confirmed, the device can be removed with the help of a specialized stylet provided by the manufacturer. In a study comparing like devices, the LMA Fastrach had a higher blind intubation success rate than the air-Q (99% vs. 77%, respectively, with two attempts), though greater than 95% of patients could be intubated with either device if flexible optical guidance was utilized.<sup>167</sup> Unlike the other intubating SGAs, a range of pediatric-sized air-Qs are available and intubation success rates of 95% have been achieved in infants.<sup>168</sup>

## Extubation of the Trachea

Although a wealth of literature is focused on the field of tracheal intubation, few reviews have intensely contemplated the area of extubation after completion of surgery or prolonged ventilatory support.<sup>169</sup> **Indeed, the period of extubation may be far more treacherous than that of intubation.**<sup>1</sup>

### *Routine Extubation*

Extubation of the trachea must not be considered a benign procedure, as it is fraught with its own set of potential complications (Table 28-14). As planning, preparation, and a back-up plan are needed for safe intubation, they are also needed for the procedure of extubation. Appropriately trained personnel and equipment should be immediately available at the time of extubation. This may range from a postanesthetic care unit nurse or respiratory therapist with a set of laryngoscopes to a surgeon prepared to perform an emergency tracheostomy. An excellent reference exists in the Difficult Airway Society Extubation Guidelines, which outline a strategic stepwise approach to decision making before, during, and after both routine and “at risk” extubations.<sup>170</sup>

**Table 28-14** Complications of Tracheal Extubation

Respiratory drive failure (e.g., residual anesthetic, decreased response to high CO <sub>2</sub> /low O <sub>2</sub> )
Hypoxia (e.g., atelectasis)
Upper airway obstruction (e.g., edema, residual anesthetic or paralytic, reduced upper airway tone)
Vocal fold–related obstruction (e.g., laryngospasm, vocal cord edema or paralysis)
Tracheal obstruction (e.g., subglottic edema or tracheomalacia from prolonged intubation)
Bronchospasm (airway irritation from endotracheal tube)
Aspiration (from decreased gag and swallow reflexes)
Hypertension
Increased intracranial pressure
Increased ocular pressure
Increased pulmonary artery pressure
Increased bronchial stump pressure (e.g., after pulmonary resection)
Increased abdominal wall pressure (risk of wound dehiscence)

Most adult patients are extubated after the return of spontaneous respiration, the resolution of neuromuscular block, and the demonstration of the ability to follow simple commands (Table 28-15). After the patient is asked to open their mouth, a suction catheter is used to remove supraglottic secretions or blood. The airway pressure is allowed to rise to 5 to 15 cm of H<sub>2</sub>O to facilitate a “passive cough” and the ETT is removed after the cuff (if present) is deflated.<sup>44</sup> If coughing or straining is contraindicated or hazardous (e.g., increased intracranial pressure), extubation may be performed while the

patient is in a surgical plane of anesthesia and breathing spontaneously (“deep” extubation). The three requirements for deep extubation are (a) easy mask ventilation following induction, (b) non-airway surgery, and (c) empty stomach. If deep extubation is desired and the patient is at risk of gastric content aspiration (e.g., full stomach) or upper airway obstruction (e.g., obstructive sleep apnea), the clinician needs to assess the relative risk of each potential morbidity (e.g., coughing vs. aspiration vs. obstruction).

**Table 28-15** Criteria for Routine “Awake” Postsurgical Extubation

<p>Subjective clinical criteria:</p> <ul style="list-style-type: none"> <li>• Breathing spontaneously</li> <li>• Following commands</li> <li>• Five-second sustained head lift</li> <li>• Intact gag reflex</li> <li>• Airway clear of debris</li> <li>• Adequate pain control</li> <li>• Minimal end-expiratory concentration of inhaled anesthetics</li> </ul> <p>Objective criteria:</p> <ul style="list-style-type: none"> <li>• Vital capacity <math>\geq 10</math> mL/kg</li> <li>• Peak voluntary negative inspiratory pressure <math>&gt; -20</math> cmH<sub>2</sub>O</li> <li>• Tidal volume <math>&gt; 6</math> mL/kg</li> <li>• Sustained tetanic contraction (5 seconds)</li> <li>• T1/T4 ratio <math>&gt; 0.7-0.8</math></li> <li>• Alveolar–arterial Pao<sub>2</sub> gradient <math>&lt; 350</math> mmHg (on Fio<sub>2</sub> of 1)<sup>a</sup></li> <li>• Dead space to tidal volume ratio <math>\leq 0.6^a</math></li> </ul>
---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

<sup>a</sup>Used during weaning from mechanical ventilation in the intensive care setting.

Laryngospasm upon ETT removal accounts for 23% of all critical postoperative respiratory events in adults.<sup>44</sup> The mechanism of laryngospasm is the contraction of the lateral cricoarytenoids, the thyroarytenoid, and the cricothyroid muscles in response to stimulation of the vagus nerve. Potential stimuli include secretions, vomitus, blood, or foreign body in the airway, pelvic or abdominal visceral stimulation, and pain. Management of laryngospasm consists of the immediate removal of the offending stimulus (if identifiable), administration of oxygen with CPAP and, if other maneuvers are unsuccessful, the use of a small dose of short-acting induction agent or muscle relaxant.<sup>44</sup>

Patients who are not fully recovered from neuromuscular relaxation are also at risk of airway obstruction and aspiration at the time of extubation.<sup>171</sup> This is, in part, due to the fact that pharyngeal function is hindered when the train-of-four (TOF) ratio remains less than 0.9.<sup>172</sup> Fortier et al.<sup>173</sup> found that 65% of patients who received nondepolarizing neuromuscular blocker and had been reversed with neostigmine still had residual neuromuscular blockade (TOF  $< 0.9$ ) at the time of extubation and 60% had residual neuromuscular blockade on arrival to the postanesthesia care unit (PACU). This data suggests that neostigmine alone cannot be relied on for adequate reversal and

vigilance is needed during intraoperative titration of neuromuscular blockers. Though cholinesterase antagonists have historically been used to reverse nondepolarizing neuromuscular blockers, a new class of agents has been introduced. Cyclodextrins are hollow-structure molecules capable of trapping other molecules within their core. The lipophilic core of the agent sugammadex (Merck & Co., Whitehouse Station, NJ) so tightly encapsulates rocuronium or vecuronium molecules that it can remove blocking agents that are already bound to the neuromuscular junction. The trapped neuromuscular blocker is unavailable to bind elsewhere and excreted in the urine. This is discussed more thoroughly in [Chapter 21](#).

Mechanical airway obstruction may also result in extubation failure and the risk is higher in patients with obstructive sleep apnea. Obstruction may result from trauma related to intubation (e.g., multiple failed attempts), surgical manipulation (e.g., lingual edema caused by mouth gags), and impaired lymphatic (e.g., after radiation therapy) and venous (e.g., with extreme neck flexion) drainage. Palatopharyngeal edema associated with anterior cervical spine procedures or hematomas (e.g., following endarterectomy) may also result in postextubation airway failure.

Unilateral vocal cord paralysis may result from trauma to the recurrent laryngeal nerve. If the contralateral nerve has been damaged previously, airway obstruction can occur due to unopposed vocal cord adduction. This may occur following neck or intrathoracic surgery or even after internal jugular line placement or endotracheal intubation. Transient vocal cord and swallowing dysfunction has been demonstrated in absence of injury, placing even healthy patients at risk of aspiration after general anesthesia. Many patients will undergo preoperative nasopharyngoscopy to assess the state of laryngeal function prior to one of these high-risk procedures.

Pharmacologic agents used during maintenance and emergence of anesthesia may also affect the success of extubation. Though low concentrations of potent inhalation anesthetics (e.g., 0.2 Minimal Alveolar Concentration [MAC]) do not alter the respiratory response to CO<sub>2</sub>, they may blunt hypoxic drive. Opiates and, to a lesser extent, benzodiazepines affect both hypercarbic and hypoxic respiratory drives. Some nondepolarizing muscle relaxants also reduce the hypoxic ventilatory drive secondary to their effect on cholinergic receptors in the carotid body.<sup>169,171</sup>

A randomized control trial revealed that multiple-dose dexamethasone effectively reduced incidence of postextubation stridor in adult patients at high risk for postextubation laryngeal edema. In contrast, single-dose injection of dexamethasone given 1 hour before extubation did not reduce the number of patients requiring reintubation.<sup>174</sup>

### *Identification of Patients at Risk for Complications after Extubation*

All patients should be evaluated for potentially difficult extubation just as they are evaluated for potentially difficult intubation. A number of well-known clinical situations may place patients at increased risk for difficulty with oxygenation or ventilation at the time of extubation (Table 28-16).

A popular test used to predict postextubation airway competency is the detection of a leak on deflation of the ETT cuff. A meta-analysis showed that the absence of a cuff leak is associated with a higher risk of reintubation, but the presence of a detectable leak has low predictive value.<sup>175</sup>

**Table 28-16** Clinical Situations Presenting Increased Risk for Complications at Time of Extubation

Edema (local, generalized or angioneurotic)	Airway narrowing
Thyroid surgery	Recurrent laryngeal nerve injury
Laryngoscopy (diagnostic)	Edema, laryngospasm (especially after biopsy)
Uvulopalatoplasty	Palatal and oropharyngeal edema
Obstructive sleep apnea	Upper airway obstruction
Carotid endarterectomy	Wound hematoma, glottic edema, nerve palsies
Maxillofacial trauma	Laryngeal fracture, mandibular/maxillary wires
Cervical vertebrae decompression/fixation	Supraglottic and hypopharyngeal edema
Anaphylaxis	Laryngotracheal narrowing
Upper cervical fracture	Prevertebral/retropharyngeal hematoma
Hypopharyngeal infections	Laryngotracheal narrowing
Hypoventilation syndromes	(e.g., residual anesthetic, central sleep apnea, myasthenia gravis, morbid obesity, severe chronic obstructive pulmonary disease)
Hypoxemic syndromes	(e.g., ventilation–perfusion mismatch, increased oxygen consumption, impaired alveolar oxygen diffusion, severe anemia)
Inadequate airway-protective reflexes	Increased aspiration risk

When mask ventilation and intubation are without difficulty and there is no substantial reason to believe that an interim insult to the airway has occurred, extubation may be accomplished in a routine fashion. Even under these circumstances, one must always be prepared for emergent reintubation.

### *Approach to the Difficult Extubation*

When there is a suspicion that a patient may have difficulty with oxygenation or ventilation after tracheal extubation, the clinician may choose from a number of management strategies. These range from continued ventilation, to the preparation of standby reintubation equipment, to the active establishment of a bridge or guide for reintubation or oxygenation.

A number of obturators, which may be left in the airway for extended periods, are available for use in trial extubation. These devices are generally referred to as airway exchange catheters (AECs). The success of first-pass reintubation is significantly higher, and the incidence of hypoxia is lower, in patients with a retained AEC.<sup>176</sup>

19

There are many commercially available AECs. Two examples of these are the Cook Airway Exchange Catheters (Cook Critical Care, Bloomington, IN) and the CardioMed Endotracheal Ventilation Catheter (CardioMed, Gromley, Ontario, Canada). Both of these are available in multiple sizes and have a central lumen and rounded, atraumatic ends. The proximal ends are fitted with a Luer-lock adapter that with an oxygen source can be used to provide insufflated or jet-ventilated oxygen. These adapters are helpful if the patient fails extubation or reintubation attempts and can be quickly decoupled for ETT removal or exchange.

Despite their advantages, AECs have been associated with significant morbidity, and complication rates of up to 60% have been reported.<sup>177</sup> Complications have included loss of airway control, mucosal trauma, esophageal intubation, pneumothorax (even in the absence of gas insufflation), and death.<sup>178</sup> Specific cautions are often exercised to reduce complications with AECs, though little empiric literature is available.

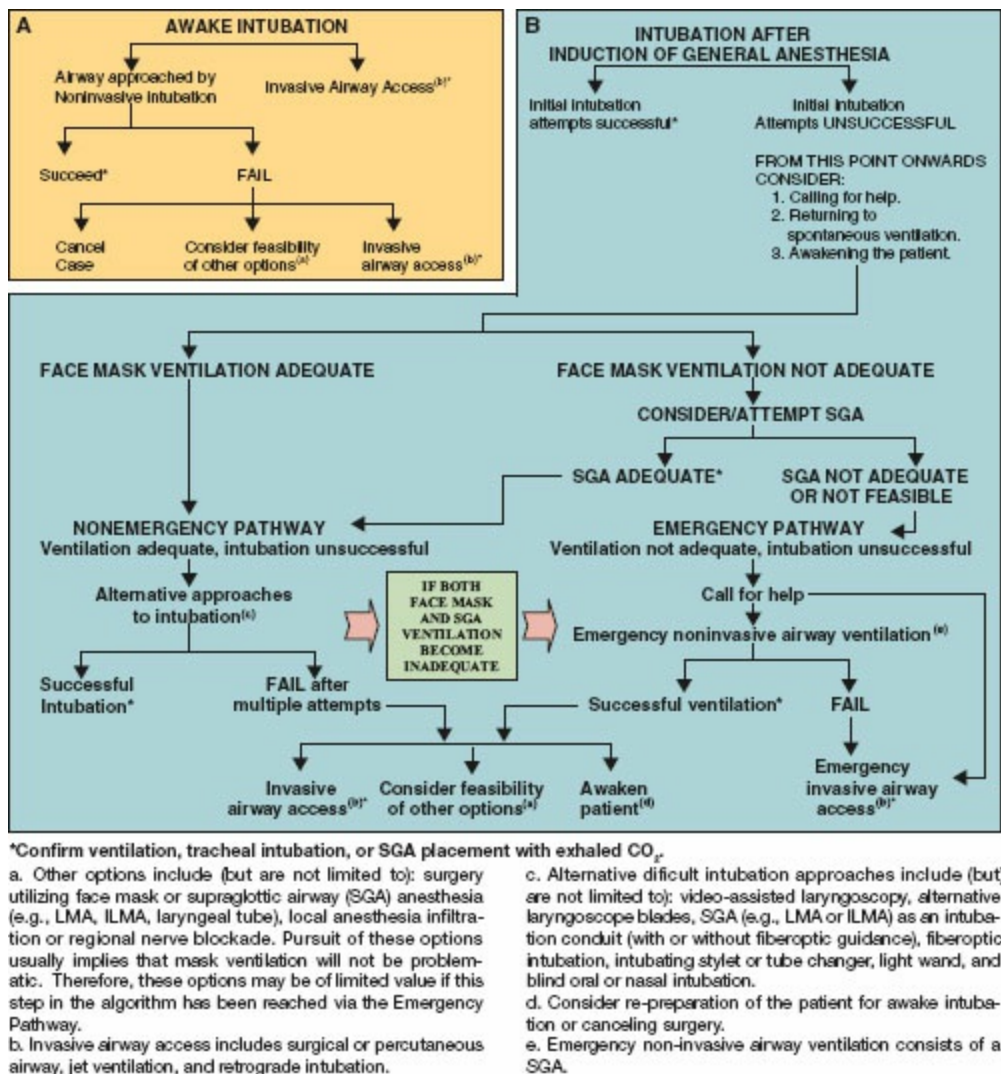

Prior to placement of an AEC, the patient should meet extubation criteria and, in most cases, be fully preoxygenated. An AEC with an external diameter closest to the internal diameter of the ETT that would be used for reintubation should be chosen to prevent “hang-up” (see later under Use of the Flexible Intubation Scope).

When the patient is ready for extubation, the ventilator is disconnected and the distal end of the lubricated AEC is placed to the depth of the tracheal tube bevel. Most AECs have depth markings that may be matched with the markings on the ETT (Fig. 28-19). If care was taken with the initial tracheal tube positioning, this will result in a midtracheal positioning of the AEC and reduce the chance of endobronchial placement. As the ETT is removed, careful attention is paid to maintaining the AEC’s position. If tracheal reintubation is required and the ETT will not pass through the glottis, lifting the tongue with a laryngoscope may facilitate reintubation. A 2 or 3 cm withdrawal of the ETT, counterclockwise tracheal tube rotation (90 degrees), and reinsertion will often overcome “hang-up.”

If jet insufflation of oxygen via the AEC is required, the patient should be

flaccid or muscle relaxed and an oral airway or other device should be used to maintain an open upper airway. In addition, inspiratory pressure and duration must be carefully titrated to observe chest expansion and recoil. These precautions are designed to limit chest-wall resistance and facilitate gas egress.

During removal of the ETT, a flexible intubation scope may be used to view tracheal structures. If extubation is tolerated, the bronchoscope can be slowly withdrawn into the subglottic region and the vocal folds and other structures visualized and evaluated.

**Figure 28-20** The American Society of Anesthesiologists Difficult Airway Algorithm. **A:** Awake intubation. **B:** Intubation attempts after induction of anesthesia.

## The Difficult Airway Algorithm

Difficult and failed airway management accounts for 2.3% of anesthetic deaths in the United States.<sup>5</sup> The ASA defines the difficult airway as the situation in which the “conventionally trained anesthesiologist experiences difficulty with intubation, mask ventilation or both.” In 1993, to address such

a scenario, the ASA Task Force on the Difficult Airway first published an algorithm that has become a staple of modern airway management. This algorithm was reissued in 2003 and again in 2013.<sup>2</sup> The most significant change in the ASA difficult airway algorithm (ASA-DAA) has been the repositioning of the SGA from the emergency to the non-emergency management pathway and the inclusion of VL as an option for both initial airway management and after failed tracheal intubation (Fig. 28-20).

Though the ASA-DAA is a staple in the United States and much of the world, several groups worldwide have written their own airway algorithms emphasizing techniques and approaches native to their practice; the reader is encouraged to explore these as well.<sup>3,108,179,180</sup>

The text of the ASA-DAA succinctly states the challenge of recommending practices for management of the difficult airway: “The difficult airway represents a complex interaction between patient factors, the clinical setting, and the skills of the practitioner.”<sup>2</sup> Although the algorithm largely speaks for itself, its salient features are discussed here.

Entry into the algorithm begins with physical evaluation of the airway. Although there is some debate as to the value of particular evaluation methods, the clinician must use all available data and his or her own clinical experience to reach a general impression as to the likelihood of difficulty in terms of laryngoscopy (e.g., DL or VL), intubation, and supraglottic ventilation. The risk of aspiration and the likely degree of apnea tolerance must also be weighed.

This evaluation should direct the clinician to enter the ASA-DAA at one of its two root points: awake intubation (Fig. 28-20A) or intubation attempts after the induction of general anesthesia (Fig. 28-20B). The decision to enter the algorithm via either approach is made after a thorough preoperative evaluation. Box A is chosen when difficulty is anticipated with either ventilation or intubation that will place the patient at jeopardy. Box B is for the setting in which difficulty may be anticipated but no uncorrectable situations are expected.

**Figure 28-19** Markings of an airway exchange catheter (AEC) are aligned with the

markings on the *in situ* tracheal tube. Aligning these marks as the AEC is inserted prevents bronchial trauma.

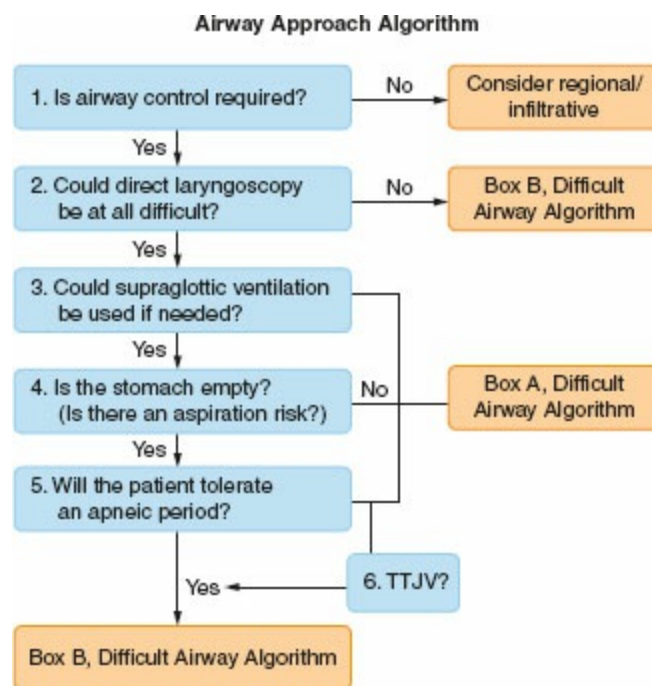

## The Airway Approach Algorithm

These decisions have been further defined in a preoperative decision tree by Rosenblatt<sup>7</sup> known as the *Airway Approach Algorithm* (AAA). [Figure 28-21](#) outlines the AAA, a simple one-pathway algorithm for entering into the ASA-DAA based on five fundamental questions. Movement through the AAA is dependent on the clinician's skill and experience. Details of the AAA can be found elsewhere and are summarized here.<sup>7,181</sup>

1. **Is airway control necessary?** Can regional, neuraxial, or infiltrative anesthesia be applied? Periodic analysis of the closed claims database illustrates that a plan for airway control is always needed independent of the choice of anesthetic technique. This concept was highlighted in the 2013 iteration of the ASA-DAA.<sup>2</sup> However routine the practices of sedation or general anesthesia becomes, whether or not to make a patient apneic should always be considered and alternatives contemplated.
2. **Could tracheal intubation be (at all) difficult?** If there is no indication that rapid tracheal intubation (e.g., by DL, VL, or other means familiar to the operator) will be difficult, the clinician may proceed as clinically appropriate. If there is an indication, based on history or physical examination, that there may be difficulty with rapid tracheal intubation, the AAA is followed to the next question. By choosing to continue down the algorithm, the clinician is not assuming that tracheal intubation will be difficult; rather, he or she is anticipating the viability of rescue maneuvers should difficulty occur.
3. **Can supraglottic ventilation be used if needed?** If the clinician identifies a reason that SGA ventilation (by facemask or SGA) could be difficult, he or she is projecting the possibility that a juncture of “cannot intubate (Question 2)—cannot ventilate (Question 3)” could be reached. Because this is a preoperative algorithm, Box A (awake intubation) of the ASA-DAA may be the preferred root entry point.
4. **Is there an aspiration risk?** The patient at risk for aspiration is not a candidate for elective SGA use. Because the AAA is a preoperative algorithm, and therefore allows the luxury of discretionary paths, the juncture of “cannot intubate/should not ventilate” can be avoided by entering the ASA-DAA at Box A.
5. a. **Will the patient tolerate an apneic period?** Should intubation fail and facemask and SGA ventilation prove inadequate, will the patient rapidly desaturate? Factors such as age, pregnancy, pulmonary

status, abnormal oxygen consumption (e.g., fever), and choice of induction agents will influence this. If time to oxyhemoglobin desaturation is limited, Box A may be prophylactically chosen.

b. **Can hypoxia be rapidly corrected through other means?** This question requires the operator to consider percutaneous emergency airway access (PEAA),<sup>182</sup> including the availability of equipment and the knowledge and experience of the operator and support personnel. For example, if an error in judgment is made and the operator is in a “cannot intubate/cannot ventilate” scenario, will these conditions allow for the use of PEAA to temporize the situation? All conditions may be right, but if the patient is morbidly obese or has had scarring or radiation changes over the larynx/trachea, this option may not be available. These factors have been discussed in detail elsewhere.<sup>7,181</sup>

**Figure 28-21** The Airway Approach Algorithm: a decision tree approach to entry into the American Society of Anesthesiologists Difficult Airway Algorithm. TTJV: transtracheal jet ventilation.

The exception to the AAA is a patient who is unable to cooperate owing to mental disability, language barriers, intoxication, anxiety, depressed level of consciousness, or young age. This patient may still be approached by Box A (Fig. 28-20A), but awake intubation may need to be forgone in favor of techniques that maintain spontaneous ventilation (e.g., inhalational induction or titrated intravenous agents such as dexmedetomidine).

Preparation of the patient for awake intubation is discussed later. In most instances, awake intubation can be accomplished successfully if

approached with care and patience. When awake intubation fails, the clinician has a number of options: (1) canceling the surgical case and arranging specialized equipment or personnel for a return to the operating room; (2) changing to a regional anesthetic technique; or (3) if clinically indicated, calling for a surgical airway (e.g., cricothyrotomy). The decision to proceed with regional anesthesia due to real or anticipated airway management difficulties must be considered in terms of risks and benefits (Table 28-17). The ASA Closed Claims Database project has identified failure of regional anesthesia as a source of serious complication when no airway strategy was prophylactically considered.<sup>2,4</sup>

The ASA-DAA becomes truly useful in the unanticipated difficult airway scenario (Box B in Fig. 28-20). When induction agents (with or without muscle relaxants) have been administered and the airway cannot be controlled, vital management decisions must be made rapidly.

Typically, the clinician has attempted DL or VL and tracheal intubation after successful or failed anesthesia mask ventilation. Even if the patient's oxygen saturation remains adequate, the number of laryngoscopy attempts should be limited.<sup>183,184</sup> The exact number of attempts allowed is unclear and will depend on the clinical scenario, but the authors recommend limiting the number of DL or VL attempts to two (or potentially three if the initial attempts were performed under suboptimal conditions or by an inexperienced provider). This emphasizes the importance of optimizing the first attempt, as significant soft tissue trauma can result from laryngoscopy, especially after multiple attempts, which may diminish the efficacy of a rescue facemask or SGA.

**Table 28-17** Regional Anesthesia (RA) for Patients with Likely Difficult Airways

May Consider RA	Should Not Consider RA
Superficial surgery	Cavity-invading surgery
Minimal sedation needed	Moderate or heavy sedation needed
Local infiltration adequate	Large-volume local anesthetic required or high risk of intravascular injection/absorption
Easy access to the airway	Poor access to the airway
Surgery can be halted at any time	Surgery cannot be stopped once started

If two to three attempts at laryngoscopy fail, mask ventilation should be instituted and, if adequate, the ASA-DAA nonemergency pathway is entered. The clinician may then turn to the most convenient and/or appropriate technique for establishing tracheal intubation, if needed. This might include,

but is not limited to, the use of a flexible intubation scope; an SGA or intubating SGA; or a bougie, lighted stylet, or retrograde wire. A surgical airway will sometimes be the most appropriate approach. (The most widely applied of these procedures, as well as new techniques, will be discussed within the clinical scenarios presented later.)

When mask ventilation fails, the algorithm suggests supraglottic ventilation via an SGA. If successful, the nonemergency pathway of the ASA-DAA has again been entered and alternative techniques of tracheal intubation may be used, if needed. Should SGA ventilation fail to sustain the patient adequately, the emergency pathway is entered and the ASA-DAA suggests use of percutaneous emergency airway access (e.g., via the CTM) or a surgical airway. At any juncture, the decision to awaken the patient should be considered based on the adequacy of ventilation, the risk of aspiration, and the risk of proceeding with intubation attempts or the surgical procedure.

**Table 28-18** The Vortex Approach: Maneuvers and Alterations between Noninvasive Airway Attempts

Manipulation: head, neck, larynx  
Change in device or device size  
Change in operator  
Airway adjuncts: oral/nasal airways, bougie, suction  
Pharmacologic adjuncts: muscle relaxants, reversal agents

A nonalgorithmic approach to the failed and critical airway has also been suggested. The Vortex Approach is a simple cognitive aid to be used during the critical cannot intubate/cannot oxygenate (CICO) scenario (Fig. 28-22).<sup>179</sup> The Vortex Approach is not a substitute for the emergency pathway of the ASA-DAA or any other published recommendation, but rather is a simple visual clue to the steps that may be taken during an airway emergency.

The Vortex Approach assumes that there are three categories of noninvasive techniques available during an airway “code”: mask ventilation, SGA ventilation, and tracheal intubation. Up to three attempts with devices from each of these categories may be attempted prior to pursuing invasive (surgical) airway access. The limitation placed on the number of attempts is because repeated attempts are unlikely to be successful and are likely to incur trauma and waste time, as discussed earlier. Attempts with the three noninvasive techniques can be made in any order that is clinically relevant, but, if a second or third attempt is needed with devices from any given category, a change must be instituted between attempts (e.g., different device, method of insertion, patient positioning, and so on) (Table 28-18).

# T H E V O R T E X

**Figure 28-22** The Vortex Approach. The Vortex is a cognitive aid for use during failed airway exercises. (Reproduced with permission from Chrimes N, Fritz P. *The Vortex Approach: Management of the Unanticipated Difficult Airway*. Smashwords Edition, 2013. Available at: <http://www.vortexapproach.org>.)

After exhaustion of the allowed nine noninvasive attempts, a surgical airway is immediately sought. The choice of invasive airway management technique is dependent on operator experience and equipment availability. As a consequence of this approach, an invasive airway will ideally be initiated prior to oxyhemoglobin desaturation. This is contrary to traditional teaching, in which an invasive airway is not attempted until oxyhemoglobin desaturation has begun. Because more than three attempts at noninvasive techniques are unlikely to be successful,<sup>180</sup> an early approach to an invasive airway should allow for a more controlled technique and lower risk of hypoxic damage.

## *Awake Airway Management*

Awake airway management remains a mainstay of the American Society of **11** Anesthesiologists' difficult airway algorithm. Awake techniques provide maintenance of spontaneous ventilation in the event that the airway cannot be secured rapidly. Other benefits include increased size and patency of the pharynx, relative forward placement of the base of the tongue, posterior placement of the larynx, and the ability of the patient to cooperate with procedures.<sup>185</sup> Additionally, the awake state confers some maintenance of upper and lower esophageal sphincter tone, thus reducing the risk of regurgitation. In the event of regurgitation, the patient can expel aspirated

foreign bodies by cough to the extent that these reflexes have not been obtunded by local anesthesia.<sup>186</sup> Finally, patients at risk for neurologic sequelae (e.g., patients with unstable cervical spine pathology) may undergo active sensory—motor testing after tracheal intubation and positioning. In an emergent situation, there may be cautions (e.g., cardiovascular stimulation in the presence of cardiac ischemia or ischemic risk, bronchospasm, increased intraocular or intracranial pressure) but no absolute contraindications to awake intubation. Contraindications to elective awake intubation include patient refusal or inability to cooperate (e.g., child, profound mental disability, dementia, intoxication) and allergy to local anesthetics.

Once the clinician has decided to proceed with awake airway management, the patient must be prepared both physically and psychologically. Most adult patients will appreciate an explanation of the need for an awake airway examination and will be more cooperative once they realize the importance of and rationale for, any potentially uncomfortable procedures.

Along with an appropriate explanation, medication can be used to reduce anxiety. If sedatives are to be administered, the clinician must keep in mind that producing obstruction or apnea in the difficult airway patient can be devastating and an overly sedated patient may not be able to cooperate with procedures or protect the airway from regurgitated gastric contents. Patients with sleep apnea may be particularly prone to obstruction, even with minimal sedation.

Although almost any sedative agent can be used, some rules should apply to all: dose judiciously, avoid polypharmacy (try to use no more than two agents), and have reversal agents at hand. Small doses of benzodiazepines (e.g., diazepam, midazolam, lorazepam) are commonly used to alleviate anxiety without producing significant respiratory depression (when used as a monotherapy). These drugs may be given in intravenous or oral forms and may be reversed with specific antagonists (e.g., flumazenil). Opioid receptor agonists (e.g., fentanyl, alfentanil, remifentanil) can also be used in small, titrated doses for their sedative and antitussive effects. Extreme caution must be exercised with these medications as (1) their respiratory-depressant effects contradict the goal of maintenance of spontaneous ventilation and (2) when administered with other sedative (e.g., benzodiazepines), their respiratory depressant effect is accentuated. A specific antagonist (e.g., naloxone) should always be immediately available if opiates are administered. If adequately topicalized, little (or no) systemic analgesic should be needed.

Ketamine, droperidol, and dexmedetomidine have also been popular among clinicians. Dexmedetomidine is a highly selective centrally acting  $\alpha_2$ -adrenergic agonist. When combined with topical anesthesia, sedation with dexmedetomidine provides for a smooth intubation without significant

respiratory depression. Dexmedetomidine has been used as a mono-agent for awake intubation in patients with local anesthetic allergy. The success of this technique is likely due to the combined anxiolytic, sedative, and analgesic properties of the drug.<sup>187</sup> A typical loading dose of dexmedetomidine is 1 µg/kg intravenously over 10 minutes followed by a maintenance infusion of 0.2 to 0.7 µg/kg/h.<sup>44</sup> Dexmedetomidine, especially with boluses, may cause bradycardia and both hypo- and hypertension. Bradycardia is reliably treated with atropine or glycopyrrolate, which is often given as a pretreatment for bradycardia prophylaxis as well as its antisialagogue effect. Hypotension can be corrected with phenylephrine or ephedrine and hypertension is treated by decreasing the rate of or stopping, the dexmedetomidine infusion. Deep sedation with any agent should not be confused with awake intubation, during which the patient remains responsive to verbal commands.

Administration of an antisialagogue is important to the success of awake intubation techniques, as even small amounts of liquid can obscure the objective lens of indirect optical instruments (e.g., flexible or rigid intubating scopes and videolaryngoscopes). Antisialagogues have the secondary benefit of increasing the effectiveness of topical anesthetics by limiting secretions that may act as a barrier to mucosal contact. Additionally, copious salivary secretions will act as an intra-airway foreign body and may cause cough or laryngospasm. The commonly used antisialagogues are atropine (0.5–1 mg intramuscularly or intravenously) and glycopyrrolate (0.2–0.4 mg intramuscularly or intravenously). As the drying effects of these medications may take some time (approximately 15 minutes), they are often administered in the preoperative waiting area.

Vasoconstriction of the nasal passages is required if there is to be instrumentation of this part of the airway. Oxymetazoline is a potent  and long-lasting vasoconstrictor commonly used to this effect. As with the antisialagogues, the effects of this medication are not immediate and it is often administered in the preoperative waiting area.

If the patient is at increased risk for gastric regurgitation and aspiration, prophylactic measures should be undertaken as discussed above. Patients should also receive continuous supplemental oxygen until ETT placement is confirmed.

Local anesthetics are a cornerstone of awake airway management (see [Chapter 22](#)). The airway, from the base of the tongue to the bronchi, is exquisitely sensitive as an evolutionary necessity. Topical anesthesia and injected nerve block techniques have been developed to blunt the protective reflexes and provide airway analgesia.

Local anesthetics are both effective and potentially dangerous drugs. Because these agents are used within the tracheal–bronchial tree, there is potential for significant intravascular absorption with some techniques. The

clinician should have a thorough understanding of the mechanism of action, metabolism, toxicities, and acceptable cumulative doses of any drug they choose to employ in the airway. The toxic level of lidocaine, for example, is considered to be 4 µg/mL. In a human study, 400 or 800 mg of lidocaine gel was applied topically to the upper airway. Serial blood lidocaine levels were measured, peaking 60 to 70 minutes later at 0.57 and 1.39 µg/mL, respectively.<sup>188</sup> In another human study, using nebulized lidocaine of the same dose, serum levels of 2.8 and 6.5 µg/mL were measured within 10 minutes of dose completion, respectively.<sup>189</sup> This underscores the need for vigilance and forethought with local anesthetic dosing, especially when applied to the subglottic airways, as with nebulization.

Despite the myriad of local anesthetics available, only those most commonly used in airway preparation will be discussed here. In reality, the choice of local anesthetic employed has little to do with success of the technique of awake intubation; ignoring the other aspects of preparation leads to failure just as readily.<sup>181</sup>

Lidocaine, an amide local anesthetic, is available in a wide variety of preparations and doses. Topically applied, peak analgesia occurs within 15 minutes. This relatively rapid onset and breadth of preparations (e.g., liquid, gel, ointment) make it a common choice for airway topicalization.

Benzocaine, an ester local anesthetic, is popular among some clinicians because of its very rapid onset (<1 minute) and short duration (approximately 10 minutes). It is available in 10%, 15%, and 20% solutions and has been combined with tetracaine in some preparations to prolong the duration of action. A 0.5-second aerosol administration of benzocaine can deliver as much as 30 mg of benzocaine. With the toxic dose being 100 mg,  caution must be taken not to spray too liberally. Benzocaine may also produce methemoglobinemia (especially in children) which is treated with methylene blue (1–2 mg intravenously over several minutes).<sup>190</sup>

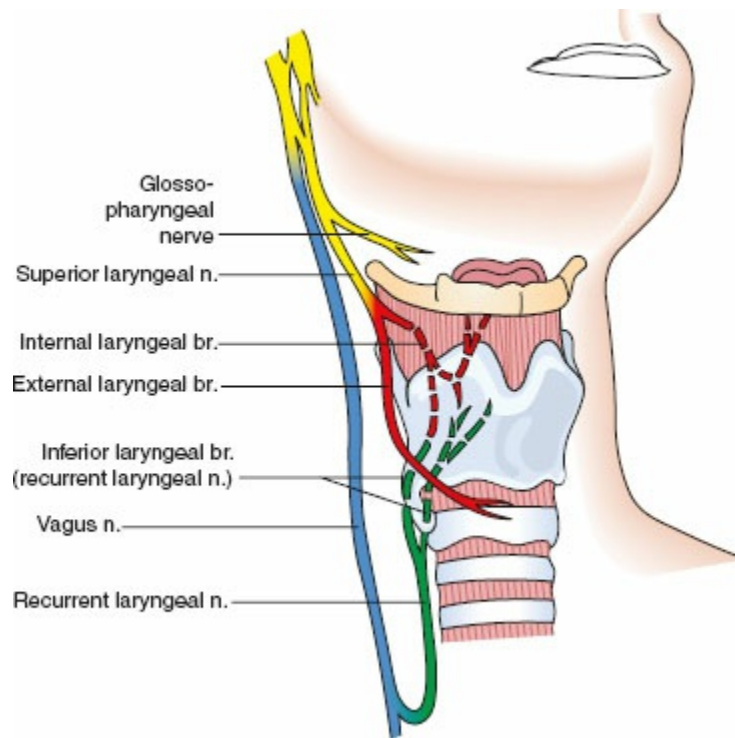

Tetracaine, another ester local anesthetic, has a longer duration of action than lidocaine or benzocaine and is available in solutions of 0.5%, 1%, and 2%. Absorption of this drug from the respiratory and gastrointestinal tracts is rapid. Toxicity after nebulized application has been reported with doses as low as 40 mg, although the acceptable safe dose in adults is 100 mg by other routes of application.<sup>191</sup>

Among otolaryngologists, cocaine is a popular topical agent. Not only is it a highly effective local anesthetic, but it is also the only local anesthetic that is a potent vasoconstrictor. Cocaine is commonly available in a 4% solution and the total dose applied to the mucosa should not exceed 200 mg in the adult. Cocaine should not be used in patients with known cocaine hypersensitivity, hypertension, ischemic heart disease, preeclampsia, or those taking monoamine oxidase inhibitors. Because cocaine is metabolized by

pseudocholinesterase, it is also contraindicated in patients who are deficient in this enzyme.

For awake airway management, local anesthetic therapy is directed to three anatomic areas: the nasal cavity/nasopharynx, the pharynx/base of the tongue, and the hypopharynx/larynx/trachea (Fig. 28-23).

In the authors' experience, the nasal passages should always be included in the preparation for awake intubation for two reasons. First, if during the course of the awake intubation the plan is changed from the oral to the nasal route, preparation is complete. Second, much of the preparation of the nose with local anesthesia will also affect the pharyngeal airway. The nasal cavity is innervated by the greater and lesser palatine nerves (innervating the nasal turbinates and most of the nasal septum) and the anterior ethmoidal nerve (innervating the nares and anterior third of the nasal septum), which are distal branches of the trigeminal nerve (CN V). The palatine nerves arise from the sphenopalatine ganglion located posterior to the middle turbinate. Two techniques for palatine nerve block have been described. In the noninvasive nasal approach, cotton-tipped applicators soaked in local anesthetic are passed along the lower border of the middle turbinate until the posterior wall of the nasopharynx is reached and left there for 5 to 10 minutes. In the invasive oral approach, a needle is introduced into the greater palatine foramen, which can be palpated in the posterior-lateral aspect of the hard palate 1 cm medial to the second and third maxillary molars. A spinal needle inserted in a superior/posterior direction to a depth of 2 to 3 cm and anesthetic solution (1 to 2 mL) is injected, taking care to avoid intravascular (sphenopalatine artery) injection. The anterior ethmoidal nerve can be blocked by cotton-tipped applicators soaked in local anesthetic and placed along the dorsal surface of the nose until the anterior cribriform plate is reached. The applicators are left in place for 5 to 10 minutes.

**Figure 28-23** Airway innervation.

The oropharynx is innervated by branches of the vagus, facial, and glossopharyngeal nerves. A wide variety of techniques may be used to anesthetize this part of the airway. The simplest techniques involve aerosolized local anesthetic solution, or a voluntary local anesthetic “swish and swallow.”

The glossopharyngeal nerve (CN IX) travels anteriorly along the lateral surface of the pharynx and supplies sensory innervation to the posterior third of the tongue, walls of the pharynx (pharyngeal branch), tonsils (tonsillar branch), vallecula, and anterior surface of the epiglottis (lingual branch). As it also supplies the afferent limb for the pharyngeal (gag) reflex, anesthesia of the glossopharyngeal nerve is key to comfortable awake airway management. Even after local anesthetic topicalization, some patients may still require a glossopharyngeal nerve block for complete ablation of the gag reflex.

The branches of the glossopharyngeal nerve are most easily accessed as they transverse the palatoglossal folds. These folds are seen as soft tissue ridges that extend from the posterior aspect of the soft palate to the base of the tongue bilaterally (Fig. 28-24). A noninvasive technique employs anesthetic-soaked cotton-tipped applicators held gently against the inferior most aspect of the contralateral folds for 5 to 10 minutes. When this noninvasive technique proves inadequate, local anesthetic can be injected in a similar manner. Standing on the contralateral side, the operator displaces the extended tongue and a 25-gauge spinal needle is inserted into the fold near the floor of the mouth and an aspiration test is performed. If air is aspirated, the needle has passed through-and-through the membrane and is withdrawn slightly prior to injection. If blood is aspirated, the needle tip is redirected

more medially. The lingual branch is most readily blocked in this manner, but retrograde tracking of the injectate has also been demonstrated.<sup>186</sup> Even though it provides a reliable block, this more invasive technique is reported to be painful and may result in a bothersome and persistent hematoma.<sup>192</sup> A posterior approach to the glossopharyngeal nerve has also been described in the otolaryngologic literature. As the site of needle insertion is behind the palatopharyngeal arch where it is difficult to see, and in close proximity to the carotid artery, this advanced technique will not be described here and the reader is referred to a more authoritative text.<sup>44</sup>

**Figure 28-24** The palatoglossal arch (*arrow*) is a soft tissue fold that is a continuation of the posterior edge of the soft palate to the base of the tongue. A local anesthetic-soaked swab placed in the gutter along the base of the tongue is left in contact with the fold for 5 to 10 minutes to produce an ipsilateral glossopharyngeal nerve block.

The superior laryngeal nerve is a branch of the vagus nerve (CN X). The internal branch of the superior laryngeal nerve provides sensory innervation to the base of the tongue, posterior surface of the epiglottis, aryepiglottic folds, and arytenoids. This branch originates lateral to the cornu of the hyoid bone, pierces the thyrohyoid membrane and travels under the mucosa in the pyriform recess. The external branch of the superior laryngeal nerve supplies motor innervation to the cricothyroid muscle and has no sensory component.

Several blocks of the internal branch have been described. In many instances, topical application of anesthetics in the pharyngeal/hypopharyngeal cavities will provide adequate analgesia. For a targeted noninvasive technique, the patient is asked to open their mouth widely and the tongue is grasped with a gauze pad. Right-angled forceps (e.g., Jackson–Krause forceps) with anesthetic-soaked cotton swabs are slid over the lateral tongue and into the pyriform sinuses bilaterally. The swabs are held in place for 5 minutes. An invasive block may be performed with the patient supine with the head

extended and the clinician standing on the side of the nerve to be blocked. The clinician identifies the greater cornu of the hyoid bone beneath the angle of the mandible. Using one hand, medially directed pressure is applied to the contralateral hyoid cornu, displacing the hyoid toward the clinician. Caution must be taken to locate the carotid artery and displace it if necessary. The needle can then be inserted directly over the ipsilateral greater cornu and “walked” off the bone in an inferomedial direction until it can be passed through the thyrohyoid ligament to a depth of 1 to 2 cm. Before injecting local anesthetic, an aspiration test should be performed to ensure that one has not entered the pyriform sinus or a vascular structure. Local anesthetic (1.5 to 2 mL) is injected in the space between the thyrohyoid membrane and pharyngeal mucosa.

Sensory innervation of the vocal folds and the trachea is provided by the recurrent laryngeal nerve, another branch of the vagus nerve. Transtracheal injection of local anesthetic is a simple technique that can produce adequate analgesia of these structures. A syringe with a fine needle and filled with a local anesthetic solution (e.g., 2–4 mL of 2% or 4% lidocaine) is inserted through the CTM perpendicular to the plane of the cervical spine. In this orientation, a needle advanced too far will likely impact the posterior aspect of the cricoid cartilage instead of puncturing the esophagus. In addition, this angle will help to avoid trauma to the near-lying vocal folds. Constant retraction on the syringe plunger will result in air aspiration when the trachea is entered. Upon entry into the trachea, the anesthetic agent is injected. Coughing is likely to occur; thus, the needle should be stabilized to prevent mucosal abrasions. Coughing can be advantageous for spread of local anesthesia; by having the patient exhale fully prior to injection, a breath will need to be taken prior to coughing, spreading the medication proximally before being spread distally by the cough.

Another effective technique of tracheal and vocal cord topicalization is to inject local anesthetic through the working channel of the flexible intubation scope. A disadvantage of this technique is that the local anesthetic can obscure the objective lens. This can be overcome by use of an epidural catheter inserted through the working channel, as described by Ovassapian.<sup>193</sup> Not only does this prevent the obscuring of the view but it also allows “aiming” of the anesthetic stream. For this procedure, multiorifice catheters should be trimmed in length so that only a single distal orifice exists.

### ***Clinically Difficult Airway Scenarios***

The clinician approaching the patient with a difficult airway has a vast armamentarium of instruments and techniques available.<sup>194</sup> Although this array can be confusing, textbook authors cannot dictate specific approaches in

every situation; moreover, the variability of patient presentation makes specific recommendations difficult. Thus, in order to discuss management, the following section presents a number of brief clinical scenarios and the authors' own approach. Major alternative airway management techniques are discussed in this manner. All of the clinical cases described herein have been managed by the authors or a colleague. Other techniques that might be applied in each situation are also discussed. In these cases, as in actual practice, the first technique applied may not have been the best one. The principle of flexibility (and the willingness to change course quickly) will be emphasized repeatedly—the clinician must be prepared to alter their approach as the situation demands.

### **Case 1: Preoperative Endoscopy**

A 52-year-old man presents for DL, esophagoscopy, and biopsy of a base of the tongue tumor. The patient had sought otolaryngologic consultation after 6 months of progressive difficulty in swallowing and the sensation of fullness in his throat. Aside from sleep apnea requiring CPAP, he had no other medical issues and denied voice change or gastroesophageal reflux disease. Physical examination revealed a left neck mass and a 3-cm base of the tongue mass. In the preoperative holding area, oxymetazoline was applied to both nares, followed by 50 mg of 2% lidocaine viscous solution. A 3.2-mm diameter flexible intubation scope was then inserted via the more patent nare. The scope's objective was positioned in the nasopharynx and, on flexion, the epiglottis and glottis could be visualized. The patient was then taken to the operating room where general anesthesia was induced and the trachea intubated using a videolaryngoscope.

Modeled on the airway exam employed by otolaryngologists in office consultations, Preoperative Endoscopic Airway Evaluation (PEAE) can help guide airway management decisions.<sup>21</sup> In the case described, pathology of the hypopharyngeal airway complicated preoperative decision making—an airway mass might compromise tracheal intubation or facemask or SGA ventilation. As discussed earlier in the Airway Approach Algorithm, with only routine information available, an awake intubation might have been the best approach but, as was observed in this case, was unnecessary. By using PEAE to confirm the airway as nonthreatening, the decision could be made to proceed with routine induction of anesthesia. PEAE was studied in 148 patients presenting for intra-airway surgery. In 24% of patients, PEAE resulted in a modification of the initial clinically decided airway plan. Though clinical assessment dictated awake intubation in 44 patients, only 16 were judged to need awake intubation after PEAE. More importantly, 8 of 94 patients who were to have asleep airway management were switched to an

awake technique after a concerning preoperative endoscopic exam.<sup>21</sup> PEAE typically requires less than 5 minutes to complete. During the exam, the clinician asks three key questions: (1) is there an obstruction to rapid intubation of the trachea, (2) is there a lesion that could interfere with the placement or function of an SGA, and (3) is there a lesion that routine laryngoscopy (direct or indirect) might dislodge or otherwise traumatize? An affirmative answer to any of these questions encourages awake intubation. As noted earlier, PEAE most often serves to reassure the clinician that lesions, otherwise invisible on physical examination, will not be a hindrance to routine airway management. Likewise, PEAE can often reveal unexpectedly compromising lesions for which the clinician might have been otherwise unprepared.

## **Case 2: Flexible Intubation Scope-aided Intubation**

A 50-year-old man with symptomatic cervical vertebral disc herniation presents for disc resection and spinal fixation. His past medical history includes tobacco use, alcohol consumption, and gastroesophageal reflux. In the preoperative holding area, 0.4 mg of intravenous glycopyrrolate and bilateral nasal oxymetazoline are administered. Five percent lidocaine ointment (50 mg) is applied to the nares via long cotton-tipped applicators. Fifteen minutes later, in the operating room, when the patient reports a dry mouth, he receives 2 mg of intravenous midazolam and topical anesthesia is administered to the remainder of the airway as described earlier. An intubating oral airway is placed which does not elicit a gag reflex. A flexible intubation scope, preloaded with a 7.0-ID ETT, is advanced into the hypopharynx. The vocal ligaments are visualized and 4 mL of 4% lidocaine solution is injected toward the laryngeal and sublaryngeal structures through the accessory lumen of the fiberscope (Ovassapian catheter technique).<sup>193</sup> The distal end of the fiberscope is then advanced into the larynx and trachea until the carina is identified. The ETT is advanced and the fiberscope removed, leaving behind the ETT, which is observed to remain above the carina. The anesthesia circuit is attached to the tracheal tube and a steady output of carbon dioxide is detected by capnography. A brief sensory and motor neurologic examination is performed by the attending surgeon and general anesthesia is induced.

## **The Flexible Intubation Scope in Airway Management**

In 1967, the technique of fiberoptic-aided intubation was first performed using a choledochoscope in a patient with Still disease (idiopathic, adult-onset arthritis).<sup>195</sup> By the late 1980s, it was recognized by experts

that the use of the flexible fiberoptic bronchoscope represented such a significant advancement in the management of the patient with a difficult airway that no anesthesiologist could afford not to be facile with the technique.<sup>17</sup> With advancements in imaging technology, the fragile optical strands of fiberoptic scopes are now giving way to video imaging via distally mounted cameras on the same flexible shafts. These flexible (fiberoptic and video) intubation scopes are the most versatile tool available for situations when it is difficult or dangerous to create a line of sight to the glottis.<sup>194</sup>

There is no firm indication for flexible scope-aided intubation. There are, however, many clinical situations in which the flexible intubation scope can be of unparalleled aid in securing the airway.<sup>193</sup> These include anticipated difficult intubation by history or physical examination findings, unanticipated difficult intubation (in which other techniques have failed), lower and upper airway obstruction, unstable or fixed cervical spine disease, mass effect in the upper or lower airways, dental risk or damage, and awake intubation.<sup>193</sup> Unlike the other devices used to intubate the trachea, the flexible intubation scope also allows visualization of structures below the level of the vocal folds. This is useful in verifying single- and double-lumen ETT placement, identifying subglottic pathology and facilitating pulmonary toilet (Fig. 28-25).

Unfortunately, clinicians rarely employ alternative techniques until a difficult situation arises. As with any critical competency, mastery of these techniques involves gaining and maintaining skills through use in *routine* airway management.<sup>122</sup> As an example, Heidegger et al. introduced a simple algorithm for incorporating flexible fiberoptic-aided tracheal intubation into daily practice as a routine alternative to DL. Their incidence of difficult intubation was 6 in 1,324 cases, or 0.049%, markedly lower than reported previously.<sup>122</sup>

Contraindications to flexible scope-aided intubation are relative (Table 28-19). Although flexible scope-aided intubation is a versatile and vital technique, there are several pitfalls, the most common of which are listed in Table 28-20. Because the optical elements are small (the objective lens is typically 2 mm in diameter or smaller), minute amounts of airway secretions, blood, or traumatic debris can hinder visualization. Care must be taken to remove these obstacles from the airway beforehand. Administration of an antisialagogue (as discussed earlier) will produce a drying effect, but caution should be taken in patients who may not be able to tolerate an increase in heart rate. Vasoconstriction of the nose using topical oxymetazoline, phenylephrine, or cocaine reduces the chances of nasal bleeding if this route is chosen. If an awake flexible scope intubation is planned, the patient must be able to cooperate—a “quiet” airway, with little motion of the head, neck, tongue, and larynx, is vital to success. Finally, because flexible scope-aided intubation can require significant time (especially if the clinician is not facile

with the device), hypoxia or impending airway loss is a contraindication and a more rapid method of securing an airway (e.g., SGA or surgical airway) should be considered.

It should also be mentioned that any methods used for tracheal intubation in the asleep patient can also be employed for awake intubation. The authors have used the following devices and techniques for awake intubation: Glidescope, KingVision, McGrath, and C-MAC VLs; Unique and Fastrach LMAs; retrograde wire and blind and bougie-aided nasal intubation techniques.

**Figure 28-25** The flexible intubation scope may be useful for diagnosis and therapy below the level of the vocal ligaments, including examination of bronchial segments and pulmonary toilet. **A:** Laryngeal web found in an asymptomatic patient who had had one previous tracheal intubation. **B:** Tracheal mass in a patient with thyroid cancer.

### **Elements of the Flexible Intubation Scope**

The classic fiberoptic bronchoscope is an innately fragile device with both optical and nonoptical elements. The fundamental element consists of a 60-cm-long glass-fiber bundle (10,000–30,000 fibers per bundle) running the length of the insertion cord. Each fiber is 8 to 12 microns in diameter and is coated with a secondary glass layer termed *cladding*. Broken fibers, which can easily occur with bending of the insertion cord, entrapping of the cord in other equipment, or dropping the fiberoptic bronchoscope, are readily apparent as missing pixels in the image. These are typically just a nuisance until the number of broken fibers interferes with the visual field. The new generation of video-based flexible scopes employ a light-sensitive CMOS chip in the distal insertion cord. This technology offers high-definition images at reduced production costs. A single-use version of this technology is available (aScope 3, Ambu, Ballerup, Denmark; [Fig. 28-26](#)).

Along with imaging elements, the insertion cord contains an *accessory*

*lumen* or “working channel”: a lumen, up to 2 mm in diameter, which travels from the distal tip to the handle. This can be used for applying suction, administering oxygen or medications (e.g., local anesthetics) or placing a wire for wire-guided airway exchange techniques (e.g., the Arndt Airway Exchange Catheter Kit, Cook Critical Care, Bloomington, IN). In general, flexible intubation scopes that are less than 2 mm in external diameter (e.g., pediatric) do not have a working channel.

**Table 28-19** Contraindications to Flexible Scope Intubation

Hypoxia  
 Significant airway secretions not relieved with antisialagogues and suction  
 Airway bleeding not relieved with suctioning  
 Local anesthetic allergy (for awake attempts)  
 Inability to cooperate (for awake attempts)

The distal end of the insertion cord is hinged for movement. Two wires, traveling from the control lever in the handle down the length of the insertion cord, control the movement of the distal tip in the sagittal plane. Coronal plane movement is accomplished by a combined use of the control lever and rotation of the *entire* flexible intubation scope (from handle to distal end). It is key to keep the insertion cord completely straight as this maximizes rotational control by ensuring that rotation of the hand piece translates to identical rotation of the distal tip.

The final element of the flexible scope is the light source. In the fiberoptic devices, illumination of the objective is provided by one or two noncoherent bundles of glass fibers that transmit light from the handle to the distal tip. The light is provided either by a cord that emerges from the handle and is inserted into an endoscopic light source or may be provided by a portable battery-operated light source on the handle. CMOS-based flexible scopes are fitted with an LED light source in the distal tip, obviating the need for glass bundles in the insertion cord.

**Table 28-20** Common Reasons for Failure of Flexible Scope Intubation

Lack of provider experience  
 Failure to adequately dry the airway: antisialagogue under-dose, rushed technique  
 Failure to adequately anesthetize the airway (awake patient)  
 Nasal cavity bleeding: inadequate vasoconstriction/lubrication, rushed technique  
 Obstructing base of tongue: insufficient tongue displacement (may require jaw thrust/tongue extrusion)  
 Hang-up: ETT/scope diameter ratio too large  
 Flexible scope fogging: suction or oxygen not attached to working channel, cold bronchoscope

**Figure 28-26** The Ambu aScope 3 single-use flexible intubation scope. (Ambu, Ballerup, Denmark). **A:** Directional control. **B:** Suction/oxygen activator valve. **C:** Suction/oxygen attachment port. **D:** Working channel access. **E:** Articulating objective end.

Flexible bronchoscope-aided intubation is a technology-intense technique. Apart from the delicate optics, there are cameras, recorders, light sources, and a variety of disposable adjuncts that are typically required. Dedicated wheeled carts, designed to carry equipment in a functional arrangement, are often utilized.

### *Use of the Flexible Intubation Scope*

The flexible intubation scope is held with the thumb over the control lever and the index finger poised over the working channel valve. The contralateral hand is used to steady and hold the insertion cord at the level of the patient. An experienced endoscopist will recognize that the fine control required for steadying the bronchoscope while making minute directional adjustments and advancing it through the airway is where the art of endoscopy lies.

The flexible scope insertion cord is lubricated with a medical-grade lubricant and threaded through the lumen of an ETT with the objective end emerging from the main ETT orifice. A clinically appropriate ETT should be chosen, as the greater the difference between the internal diameter of the ETT and the external diameter of the insertion cord, the greater the risk of “hang-up” on airway structures.

“Hang-up” occurs when a cleft exists between the ETT and intubating

guide (e.g., AEC, flexible scope insertion cord, gum-elastic bougie, retrograde wire, lighted stylet) because of the difference in their sizes (Fig. 28-27). This is most thoroughly described with flexible scope-aided intubation, for which it occurs in 20% to 30% of attempts.<sup>193</sup> Hang-up most commonly involves the right vocal cord, but may involve entrapment of the epiglottis, corniculate/arytenoid cartilages, or aryepiglottic folds. If hang-up occurs, rotation of the ETT 90 degrees counterclockwise places the bevel cleft posteriorly and improves passage. During nasotracheal intubation, the epiglottis may be entrapped and a bevel-up position (rotation of the ETT 90 degrees clockwise) may facilitate passage.<sup>196</sup>

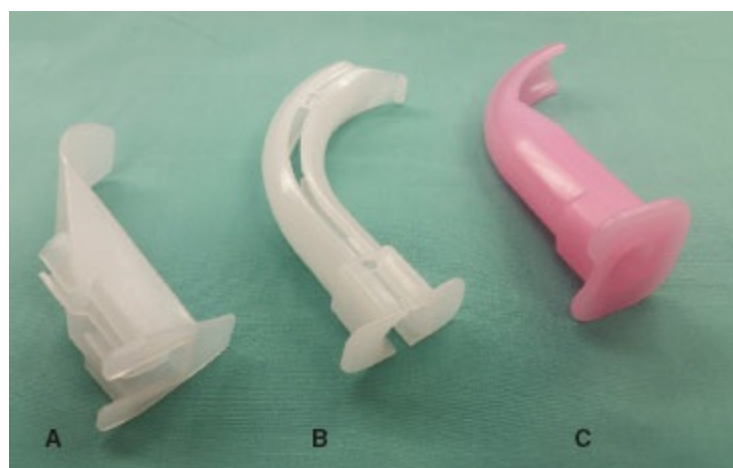

Tracheal tube design may also affect hang-up. It has been suggested that the Parker Flex-Tip tracheal tube may pass the airway structures more easily than a standard ETT bevel.<sup>196</sup> The use of soft-tipped ETTs, asking the patient to inspire deeply during the ETT advancement, and the “double setup,” which uses a small ETT within a clinically adequate ETT (e.g., a 5.0 ID inside a 7.5 ID) to overcome the size differentials, have been described as well.<sup>197</sup>

The route of intubation, either oral or nasal, is based on surgical needs, patient anatomy and clinical condition, operator experience, and other techniques available should primary attempts fail. The nasal route is considered anatomically easier by many clinicians, although cautions apply: the turbinates may obstruct ETT passage, bleed, be avulsed, or be painful when traumatized.<sup>198</sup> Nasal vasoconstrictors should be applied to reduce bleeding and promote nasal patency. An ETT of the smallest size clinically acceptable should be chosen. The nasal tube is softened in warm saline or water<sup>199</sup> and well lubricated prior to insertion.

While mandibular advancement and/or tongue extraction typically suffice, a variety of oral airways designed to facilitate flexible scope orotracheal intubation are commercially available. These devices function to provide a clear visual path from the oral aperture to the hypopharynx, keep the bronchoscope and tracheal tube midline, prevent the patient from biting the insertion cord, and provide a clear airway for spontaneous or mask ventilation. The common characteristic of all intubating oral airways is a channel along the length of the airway that accommodates passage of an ETT.

**Figure 28-27** Size discrepancy between an airway exchange catheter or flexible intubation scope and a tracheal tube can create clefts that can trap tissues and hinder intubation. **A:** A 6.5-ID tracheal tube inserted over a 3.2-mm Storz Endovision F.I.V.E. scope (Karl Storz, Tuttlingen, Germany) with a notable cleft. **B:** The same tracheal tube inserted over a 5.5-mm Storz Endovision F.I.V.E. scope with near-complete obliteration of the cleft.

**Figure 28-28** Intubating oral airways: **(A)** Ovassapian, **(B)** Berman and **(C)** Williams intubating oral airways.

The Ovassapian intubating oral airway (Fig. 28-28) provides two sets of semicircular, incomplete flexible flanges that stabilize the ETT (up to size 9 ID) in the midline and allow easy disengagement from the ETT after successful intubation. The flat lingual surface of the airway affords lateral and

rotational stability. Both the Williams and the Berman airways were designed for blind orotracheal intubation. Both are molded plastic with circular internal lumens that guide the ETT toward the larynx. These airways have a smaller profile than the Ovassapian airway, but tend to have less rotational stability. Because its internal lumen is a complete circle, the ETT circuit adapter must be removed prior to withdrawing a Williams airway. This may pose difficulty if the ETT has a fused circuit adapter. The Berman airway addresses this problem with a split along the length of one side. If the interincisor gap is adequate, malleable plastic seams on the contralateral side allow the airway to be removed laterally from around the ETT.

After successful navigation past the tongue (whether facilitated by tongue extraction, mandibular advancement, or an intubating oral airway), the endoscopist visualizes the vocal folds. If glottic closure, gag, or coughing occurs, the operator can choose to apply local anesthetic through the working channel, administer more intravenous sedation, withdraw the scope and reinforce airway analgesia, or advance the scope into the larynx without further preparation. The action taken must be dictated by the individual clinical situation. In the elective scenario, there is likely to be time for additional airway preparation, whereas in the face of impending respiratory arrest, patient discomfort may need to be tolerated.

Once the larynx is entered, the flexible scope is advanced until the carina is visualized. The ETT is then advanced off the insertion cord and into the trachea. Simply having the flexible scope enter the trachea does not guarantee that the intubation will be successful; hang-up and accidental scope withdrawal (via coughing or inattention) may still occur. Therefore, a patient with a critical airway should not be induced with a general anesthetic until intratracheal tube placement is confirmed. The distance between the ETT and carina can be readily determined by advancing the scope to the carina and measuring how far it can be withdrawn before the objective reenters the ETT bevel.

The primary literature contains a number of variations and adjuncts to flexible scope-aided intubation. [Table 28-21](#), which is not meant to be exhaustive, lists several of these techniques.

**Table 28-21** Flexible Scope-aided Intubation Techniques

Technique	Advantage
Endoscopy mask	Controlled (or assisted) ventilation maintained during or between attempts at flexible scope-aided intubation
Laryngeal mask	Excellent view of the larynx and ability to ventilate during or between attempts
Flexible scope-aided retrograde intubation	Guiding of the flexible intubating scope with a wire known to be in the trachea
Retrograde fiberoptic intubation	Changing a tracheostomy to an oral or nasal tracheal tube when antegrade intubation is difficult or impossible
Flexible scope intubation with the aid of a rigid laryngoscope	Helpful with an obstructing mass or large epiglottis

### Case 3: Failed Rapid-sequence Induction and the SGA

A 39-year-old man who is healthy aside from obstructive sleep apnea (apnea-hypopnea index of 15) and has no surgical history presents for elective uvulopharyngopalatoplasty. His maximal interincisor gap is 5 cm, thyromental distance is 7 cm, and his oropharyngeal view is a Samsoon–Young class 2.<sup>103</sup> There is no limitation in neck flexion or extension. The patient has significant gastroesophageal reflux; thus, an RSI is planned. As cricoid pressure is held (Sellick maneuver), a hypnotic and succinylcholine are administered. DL with a Macintosh 3 blade is made difficult by significant base of tongue hyperplasia and all that can be visualized is a large epiglottis (Cormack–Lehane grade 3 view). The BURP maneuver does not improve glottic visualization. Macintosh 4 and Miller 3 blades are utilized without improvement of the glottic view. Oxygen saturation has fallen from 100% to 92% and facemask ventilation is initiated with maintenance of cricoid pressure. Complete obstruction to ventilation is encountered. Placement of an oral airway, chin and jaw lift, two-person ventilation, and reduction in the degree of cricoid pressure do not result in adequate mask ventilation. The oxygen saturation falls to 85% and a size 5 LMA Classic (which had been prepared prior to induction) is inserted with maintenance of cricoid pressure. A clear airway is immediately noted. A second dose of hypnotic is administered and the patient is intubated by the blind passage of an Aintree Intubation Catheter (Cook Critical Care, Bloomington, IN), guided into position with a flexible intubation scope. The LMA and flexible scope are removed and the Aintree catheter is used to guide a tracheal tube into position.

## The SGA in the Failed Airway

Kheterpal et al. found that 0.4% of patients presented difficulty in both mask ventilation and DL<sup>114</sup> and there have been many reports of cases in which the airway was rescued with an SGA.<sup>200,201</sup> A wealth of literature describes the use of the various SGAs, in both awake and unconscious patients, in anticipated and unanticipated difficult airway situations, cervical spine injury, and pediatric dysmorphic syndromes.<sup>89,90,176</sup>

The characteristics of the SGAs that underlie their superiority as a tool in the management of the difficult airway are numerous: Their placement follows an intrinsic pathway (swallowing) which, unlike laryngoscopy, requires minimal tissue distortion; they can be utilized as part of a blind technique not hindered by blood, secretions, debris, and edema from previous attempts at laryngoscopy<sup>202</sup>; and, as the anatomic issues that result in difficult laryngoscopy do not necessarily result in difficult SGA placement, they are an excellent choice for airway rescue when laryngoscopy has failed. Because the success of SGA placement does not fully depend on anatomy that can be assessed on routine physical examination, many typical airway assessment measures do not apply.<sup>203</sup>

The major disadvantage of SGA use during cardiopulmonary resuscitation is the lack of mechanical protection from aspiration.<sup>204–206</sup> Cricoid pressure is effective with an LMA in situ, but may prevent proper seating in a minority of instances<sup>207</sup>—this may require the brief removal of cricoid pressure until the LMA has been properly seated. Despite these drawbacks, the rate of regurgitation during cardiopulmonary resuscitation with an LMA (3.5%) has been shown to be less than with bag-valve-mask ventilation (12.4%).<sup>64</sup> Even in cases of regurgitation, pulmonary aspiration is a rare event<sup>60</sup> and a secondary concern to life-threatening hypoxemia. Had one been available, an intubating SGA would have been an excellent choice in this case scenario.

### Case 4: Deviation from the Difficult Airway Algorithm

Thirteen hours after admission to the intensive care unit, a 76-year-old woman with head, neck, and facial trauma from a motor vehicle accident is noted to have progressive decline in her level of consciousness and respiratory effort. On examination, there appears to be an adequate interincisor gap and thyromental distance, but the oropharyngeal view and cervical range of motion cannot be evaluated. Because of the inability to evaluate her airway fully with respect to ease of intubation, an awake technique is chosen. Oropharyngeal blood from continued epistaxis suggests that adequate drying and analgesia of the airway may be difficult and that the use of a flexible intubation device may not be prudent. Techniques requiring

significant patient preparation are not considered due to the rapid progression of the patient's respiratory failure. Blind nasal intubation is contraindicated based on the obvious facial trauma and the risk of cribriform plate disruption. Neither an esophageal tube nor equipment for retrograde intubation is readily available. Although the patient's altered mental status is believed to reflect an intracranial process, the risk of airway loss is considered to be the primary clinical hazard. Awake DL is attempted with manual in-line axial stabilization of the neck. After clearing fresh blood from the pharynx, a Cormack–Lehane grade 3 laryngeal view is obtained. Due to significant patient resistance (head and neck movement and biting of the laryngoscope), tracheal intubation is not achieved. The decision is made to proceed with RSI and intubation, with emergency tracheostomy as the back-up plan. After surgical preparation of the neck, application of manual in-line stabilization, and preoxygenation, intravenous etomidate and succinylcholine are administered, DL is undertaken, the larynx is easily visualized, and the trachea is intubated.

### *Muscle Relaxants and Direct Laryngoscopy*

In the case described, the use of muscle relaxants significantly improved laryngeal visualization. In one study, the use of muscle relaxants for DL increased intubation success rate and was associated with fewer intubation attempts, incidents of airway trauma, esophageal intubations, aspiration events, and even deaths.<sup>208</sup> A retrospective study in the pediatric population also found an increased rate of airway complications in patients intubated without the aid of a paralytic.<sup>209</sup> There are few well-controlled trials investigating the effects of muscle relaxants on intubating conditions, though, as the superior conditions achieved with these medications have discouraged inclusion of control groups. Muscle relaxation improves laryngoscopic view by facilitating temporomandibular joint relaxation, relaxation of the supraglottic larynx, and anterior movement of the epiglottis.<sup>210</sup> Muscle relaxants also tend to fix the vocal folds in a neutral open position. Neuromuscular blockade tends to facilitate facemask ventilation and is often utilized in cases in which facemask ventilation is unexpectedly difficult. The classic teaching of withholding muscle relaxants until facemask ventilation has been demonstrated is rapidly being abandoned.

### *Leaving the Algorithm*

The scenario described in case 4 is unusual in that the clinical situation necessitated deviation from the ASA-DAA. The conditions described were more akin to the “crash” airway described by Walls.<sup>211</sup> In this case, the administration of a muscle relaxant, which might be considered contraindicated in the assumed difficult-to-intubate patient, allowed for full

visualization of the larynx. Knowing that failure to intubate would likely result in loss of the airway, the clinical team was wisely prepared for cricothyrotomy. Although the ASA-DAA is a valuable tool in the management of the difficult airway, the clinician must be prepared for cases that do not fit the mold. As stated earlier, adaptability in rapidly changing clinical scenarios is critical to the success of airway management.

## Other Devices

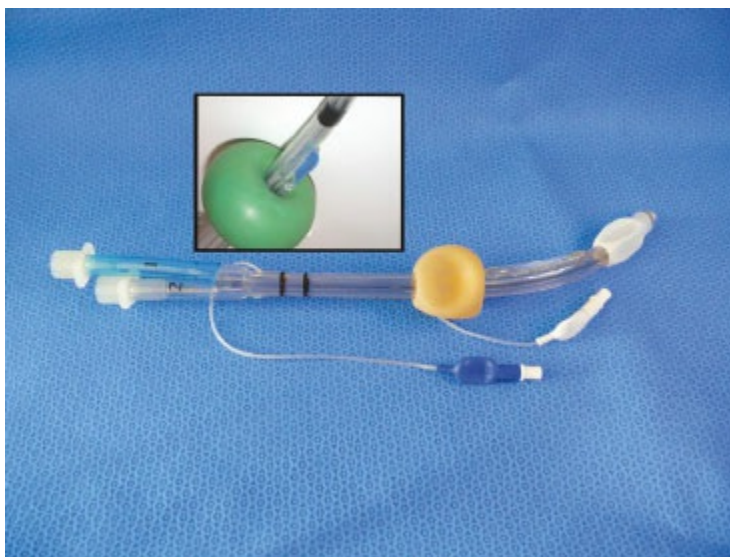

**An ever-increasing number of airway management devices are commercially available.** Although encyclopedic coverage of these tools **12** is beyond the scope of this chapter, a review of the more established equipment follows.

**Esophageal Tubes with Laryngeal Openings.** Esophageal tubes with laryngeal openings are SGAs with designs based on the propensity for blindly inserted oral tubes to enter the esophagus. They can be of single-lumen (King LT, Ambu, Ballerup, Denmark) and double-lumen (Combitube, Covidien, Mansfield, MA, and EasyTube, Teleflex, Research Triangle Park, NC) design with distal esophageal and proximal pharyngeal cuffs on either side of the laryngeal apertures, which act as ventilation ports (Fig. 28-29). When properly inflated, the cuffs prevent esophageal and oral leakage of gasses, making the larynx the route of least resistance for inspired gasses. These devices are quicker and easier for inexperienced providers to place than are ETTs.<sup>212</sup> This, combined with data showing the deleterious effects of repeat laryngoscopy,<sup>183,184</sup> has led to frequent use of these devices by prehospital emergency providers who may have limited or infrequent experience with laryngoscopy.

## Airway Bougie

Airway bougies are semimalleable stylets that may be blindly manipulated through the glottis when a poor laryngeal view is obtained (Cormack-Lehane grade 3 or 4). An ETT is then “threaded” over the bougie and **24** into the trachea. These bougies are generally low cost and highly portable. The Eschmann introducer (Eschmann Health Care, Kent, England) is a 60-cm long, 15 French bougie with a 40 degree coudé tip 3.5 cm from its distal end. This introducer (also known as the *gum elastic bougie*) can be manipulated under the epiglottis, its angled segment directed anteriorly toward the larynx. Once it has entered the larynx and trachea, the operator often feels “clicks” as the bougie’s tip passes over the cartilaginous structures of the anterior trachea. A similar device, the Frova Intubating Introducer (Cook Critical Care, Bloomington, IN) is a disposable device with a narrow internal lumen. The

lumen allows for the insufflation of oxygen, detection of carbon dioxide, and use of a self-inflating bulb to detect inadvertent esophageal placement. An optional “stiffening” stylet can be placed through the lumen to increase device rigidity.

**Figure 28-29** The Esophageal Tracheal Combitube. Inset: The fiberoptic port of the EasyTube.

**Transtracheal Procedures.** When intubation and mask and SGA ventilation fail, airway access via the extrathoracic trachea may be warranted (Table 28-22). Though the noninvasive tools of the modern 13 airway armamentarium can manage most situations, the clinician must be familiar with these alternative techniques of intubation, oxygenation, and ventilation for both elective and emergency airway access. This text will focus on percutaneous techniques, as surgical tracheostomy and cricothyrotomy are beyond the scope of this chapter.

### *Retrograde Wire-Aided Tracheal Intubation*

In 1993, the technique of retrograde wire intubation (RWI) was included in the ASA’s Difficult Airway Algorithm, but removed in the 2013 update. The technique involves the antegrade passage of an ETT into the airway using a wire that has been passed into the larynx via a percutaneous puncture through the cricothyroid or cricotracheal membrane. This wire is blindly passed in the cephalad direction into the hypopharynx, pharynx, and out of the mouth or nose and then used as an intubating conduit. The basic equipment used for retrograde intubation is listed in Table 28-23.

**Table 28-22** Criteria for Performing Emergent Invasive Airway Management

When all five criteria are met, an emergent invasive airway is indicated

- Cannot intubate
- Cannot ventilate
- Cannot awaken patient
- Supraglottic airway has failed
- Clinically significant hypoxemia

**Table 28-23** Equipment for Retrograde Wire Intubation

Angiocatheter (18 gauge or larger)  
Luer-lock syringe (3 mL or larger)  
Guide wire:

- Type: J-type end preferable
- Length: at least 2.5 times the length of a standard ETT (typically 110–120 cm)
- Diameter: capable of passing via chosen angiocatheter

Other: scalpel blade, nerve hook, Magill forceps, silk suture

RWI has been described in a number of clinical situations as a primary intubation technique (both elective and urgently) and for use after failed attempts at DL, fiberoptic-aided intubation, and LMA-guided intubation.<sup>44</sup> The most common indication for RWI is the inability to visualize the vocal folds owing to blood, secretions, unstable cervical spine or anatomic variations (e.g., upper airway malignancy, mandibular fracture, massive airway trauma). Contraindications include lack of access to the CTM or cricotracheal ligament (such as with severe neck deformity, obesity, or overlying mass), laryngotracheal disease (stenosis, malignancy, infection), coagulopathy, and overlying skin infection.

Common complications reported with RWI include bleeding, subcutaneous emphysema, pneumomediastinum, pneumothorax, breath-holding, a caudally traveling wire, and trigeminal nerve trauma.

### *Cricothyrotomy*

Cricothyrotomy, cricothyroidotomy, coniotomy, and minitracheostomy are synonyms for establishing an air passage through the CTM. The CTM is a fibroelastic membrane that overlays the tracheal mucosa and is attached to the inferior border of the thyroid cartilage and superior edge of the cricoid cartilage. Although cricothyrotomy is the procedure of choice in an emergency situation, it may also be of use in elective situations when there is limited access to the trachea (e.g., severe cervical kyphoscoliosis). Cricothyrotomy is contraindicated in children younger than 6 years of age and in patients with laryngeal fractures. Otolaryngologists and other surgical services prefer transtracheal airway access caudad to the cricoid cartilage

whenever feasible due to the high incidence of long-term complications after surgical cricothyrotomy.

**Percutaneous Emergency Airway Access (PEAA)**, as a form of cricothyrotomy, is the most familiar to anesthesiologists. The ASA-DAA  lists PEAA as an option in the “cannot mask ventilate/cannot intubate” (CNV/CNI) situation. PEAA is a simple and relatively safe means to sustain the patient’s life in this critical situation.<sup>44</sup> Three techniques are commonly used for PEAA: narrow-bore catheter over a needle, large-bore cannula over a wire or trochar, and surgical cutdown<sup>182</sup> with or without a tube guide.<sup>213</sup> Success rates of these techniques vary greatly and are highly dependent on operator experience and the clinical scenario. As an example, the success rate of cannula cricothyrotomy performed by an anesthesia provider is roughly 50%,<sup>1</sup> while the success rate of an emergency surgical airway performed by a surgeon or trained prehospital provider is 90% to 100%.<sup>1,214</sup> This is not to suggest that PEAA be avoided by the anesthesia provider, but rather to advise that, if available, a surgeon experienced in cricothyrotomy may be the better choice for the initial attempt at surgical airway management.

A body of literature exists detailing the jerry-rigging of conveyance systems for PEAA and the use of intravenous catheters for transtracheal puncture. These systems have proven to be faulty, inadequate, and dangerous.<sup>215</sup> Catheters designed for intravenous infusion are known to kink in the airway.<sup>216</sup> Experts in the field recommend that all anesthetizing locations have access to both manufactured high-pressure oxygen conveyance devices and percutaneous transtracheal jet ventilation (PTJV, also known as Percutaneous Transtracheal Volume Ventilation–specific translaryngeal catheters). Dedicated devices, such as the Cook TTJV Catheter (Cook Critical Care, Bloomington, IN), are made of kink-resistant materials and designed specifically for this task. The Ravussin translaryngeal catheter (VBM Medizintechnik, Sulz am Neckar Germany) is precurved to reduce kinking.

Before contemplating PEAA, the location of the CTM will need to be identified. Campbell et al.<sup>10</sup> have cast doubt on the ability of anesthesiologists to locate the CTM in elective, let alone emergency, situations. Obesity, cervical kyphosis, female gender, therapeutic radiation, and surgical or traumatic scarring may hinder CTM identification. A careful reading of the ASA-DAA should lead the airway manager to identify the CTM in every patient, and applying this examination in all instances should improve familiarity with the surface landmarks.<sup>182</sup> Bedside ultrasound in the sagittal plane can reveal the CTM as a lucent shadow between opaque cartilaginous structures and may be useful in emergency situations if immediately available.

When performing PEAA, the patient is positioned supine with the head midline or extended on the neck and thorax (if not contraindicated by the

clinical situation). After aseptic preparation, local anesthetic may be injected over the CTM (if the patient is awake and time permits). The clinician stands to the side of the patient with one's dominant hand cephalad and can use the nondominant hand to stabilize the larynx. A large-bore translaryngeal catheter (14 gauge or larger) attached to a 5- to 10-mL empty or fluid-filled (saline or local anesthetic) syringe is used. The catheter-needle is advanced at right angles to the plane of the cervical spine through the caudad third of the CTM. From the moment of skin puncture, there should be constant aspiration on the syringe plunger. Free aspiration of air confirms entrance into the trachea (air-contrast technique) but does not indicate the direction that the catheter travels in the larynx; this is important, as cephalad advancement will not provide adequate oxygenation. Unless there is significant pulmonary fluid (e.g., blood or aspirated liquid), the aspiration of tracheal air should be incontrovertible. The needle-catheter assembly should be advanced slightly prior to threading of the catheter into the airway.

Once the catheter has been successfully placed, a high-pressure oxygen source should be attached. A 50-psi oxygen source with a metered and adjustable hand-controlled valve and a Luer-lock connector (Fig. 28-30) is down-regulated to 15 to 30 psi (central hospital supply or regulated cylinder) and delivered through the catheter. Insufflations should last 1 to 1.5 seconds at a rate of 12 insufflations per minute. Insufflation and expiration ratios, as well as driving pressure, are adjusted to provide visible chest excursion and recoil. If a 14-gauge catheter has been placed, this system will deliver a tidal volume of 400 to 700 mL. Low-pressure systems cannot provide enough flow to expand the chest adequately for oxygenation and ventilation (e.g., Ambu bag, 6 psi; anesthesia machine common gas outlet, 20 psi). Critically, systems delivering pressurized oxygen require a path for gas egress.<sup>217</sup> Standard high-pressure regulating valves, as described earlier, are unidirectional and generally contraindicated when the upper airway is completely obstructed. Fortunately, this tends to be an uncommon situation. In any case, the clinician employing any type of translaryngeal oxygenation must strive to maintain upper airway patency with devices such as oral airways, nasal airways, or SGAs.

**Figure 28-30** System for regulation of a high-pressure oxygen source for transtracheal jet ventilation.

PEAA can also be accomplished using low-flow oxygen delivery meters, which are common in the hospital environment. These systems are capable of delivering a constant flow of 15 L/min and have been shown to be effective for resuscitation. Generally, these devices utilize “flow interruption.” Flow is directed to the patient during the inspiratory phase, then diverted during expiration. As discussed earlier, jerry-rigged devices often fail to function as desired. For example, using a standard three-way stopcock as a flow diverter is potentially hazardous, as forward flow (inspiration) is never fully stopped.<sup>218</sup> The Enk flow modulator (Cook Critical Care, Bloomington, IN) is a simple hand-operated flow diverter that not only stops forward gas flow during the expiratory phase but also acts as a pathway for passive expiratory flow (Fig. 28-31). The Enk flow modulator has been used successfully in models of near and complete upper airway obstruction.<sup>215</sup>

A new concept in PEAA is “expiratory ventilatory assistance.”<sup>219</sup> Using the Bernoulli principle, the Ventrain (Ventnova Medical B.V., Eindhoven, The Netherlands; Fig. 28-31) is capable of *active* gas removal from a rescue catheter during the expiratory phase of PEAA. The clear benefit is the avoidance of air trapping in the lungs, especially when the upper airway is completely obstructed. The device can achieve physiologic minute ventilation via a 2-mm ID transtracheal catheter<sup>219</sup> and has been effective in oxygenation and carbon dioxide removal in two large animal models.<sup>220,221</sup> In the first of these studies, the upper airways were critically or completely obstructed and the animals ventilated for 15 minutes via the Ventrain or a commercially available jet ventilation system. While both devices facilitated reoxygenation, the Ventrain was associated with superior minute ventilation (4.7 vs. 0.1 L/min), a lesser degree of acidosis (pH of 7.34 vs. 7.01) and decreased peak airway pressure on rescue (16 vs. 40 cm H<sub>2</sub>O).<sup>220</sup> In the latter study, in a

complete upper airway obstruction model, the peak airway pressure was significantly less with the Ventrain using an I:E of 1:1 (30 mbar) than with the commercial jet ventilator at a ratio of 1:4 (50 mbar),<sup>221</sup> highlighting the benefit of expiratory ventilatory assistance. The Ventrain has also proven effective in both elective and emergent human airway management.<sup>222,223</sup>

**Figure 28-31** (A) Ventrain. (B) Cook Transtracheal Catheter. (C) Enk flow modulator. (D) Ravussin needle.

Specialized percutaneous cricothyrotomy systems have been developed to improve the ease of transtracheal ventilation. These devices generally provide large-bore access adequate for oxygenation and ventilation with low-pressure systems. The Melker emergency cricothyrotomy catheter set (Cook Critical Care, Bloomington, IN) is placed using Seldinger technique and comes in a variety of cannula sizes (3.5-, 4-, and 6-mm ID, both cuffed and uncuffed). Preparation and positioning of the patient are the same as with needle cricothyrotomy. A 1- to 1.5-cm vertical incision, through the skin only, is made over the lower third of the CTM. Aiming 45 degrees caudally, a percutaneous puncture of the CTM is made with the provided 18-gauge needle–catheter assembly and syringe. After air is aspirated, the catheter is advanced into the trachea as described earlier. The provided guidewire is inserted through the catheter and into the trachea. The catheter is removed and the large-bore tracheal cannula, fitted internally with a curved dilator, is threaded onto the wire. The dilator is advanced through the CTM using firm pressure. Significant resistance on advancement typically indicates that the skin incision needs to be extended. Once the cannula–dilator assembly has been fully inserted, the dilator and wire are removed. The cannula’s 15-mm circuit adapter is attached to a self-inflating resuscitation bag or anesthesia circuit and ventilation is initiated.

Other percutaneous needle systems include the Portex Cricothyroidotomy Kit (Smiths Medical, Minneapolis, MN) and the Quicktrach transtracheal

catheter (VBM Medizintechnik, Sulz am Neckar, Germany). Nonneedle puncture techniques are beyond the scope of this text.

Severe complications of PEAA are typically related to barotrauma. Analysis of the ASA Close Claims Database reveals that 89% of patients reported who received TTJV developed pneumothorax, pneumomediastinum, or subcutaneous emphysema,<sup>4</sup> and bilateral tension pneumothorax has been reported.<sup>224</sup> Causes of air insufflation into the paratracheal spaces include a misplaced cannula, multiple tracheal punctures, and cannula migration due to patient coughing.

## Conclusions

Apart from monitoring, management of the “routine” airway is the most common task of the anesthesia provider. Even during the administration of regional anesthesia, the airway must be monitored and possibly supported. The consequences of a lost airway are so devastating that the clinician can never afford a lackadaisical approach.

Although the ASA’s taskforce on the difficult airway has given the medical community an immensely valuable tool in the approach to the patient with the difficult airway, the ASA’s algorithm must be viewed as a starting point only. Judgment, experience, the clinical situation, and available resources all affect the appropriateness of the chosen pathway through, or divergence from, the algorithm.

Whereas one may argue that the last decade of the 20th century was the decade of the SGA, the first decades of the 21st century have brought the application of digital imaging to airway management. Although an increasingly vast array of devices exists, the clinician does not need to be expert in all the equipment and techniques, and no single device can be considered superior to another when viewed in isolation. Rather, a broad range of approaches should be mastered so that the failure of one does not preclude safe airway management and emergency rescue. The clinician’s judgment and resources, both equipment and personnel, determine the effectiveness of any technique. When managing the difficult airway, flexibility, not rigidity, prevails.

## Summary

## KEY POINTS

- 1 The etiologies of peripheral neuropathies are often not clear. Although there are potential anatomic and neurophysiologic reasons, perioperative inflammation, resulting in microvasculitis, may be an important etiologic factor.
- 2 Stretching nerves 5% or more beyond their resting lengths may kink feeding arterioles and result in ischemia.
- 3 Padding provided by any number of different materials (e.g., gel or foam pads, blankets) should be used to widely disperse point pressure on body parts and soft tissues.
- 4 Sedated or anesthetized patients should be placed in positions that are comfortable while they are awake.
- 5 Permanent loss of vision can occur after nonocular surgical procedures, especially those performed in a prone position.

Positioning a patient for a surgical procedure is frequently a compromise between what the anesthetized patient can tolerate, both structurally and physiologically, and what the surgical team requires for access to its anatomic target. Establishment of the intended surgical posture may need to be modified to match the patient's tolerance. This chapter presents the significance of various positions in which a patient may be placed during an operation, briefly describes the techniques of establishing the positions, and discusses the potential complications of each posture. It also will present data that suggest perioperative inflammatory responses may play an important role in the development of peripheral, and potentially central, neuropathies.

It is very important for clinicians to understand the physiologic and potential pathologic consequences of patient positioning. A number of studies of large surgical populations have provided information on the frequency and natural history of rare perioperative events such as neuropathies and vision loss. However, these studies frequently have provided insufficient data to allow speculation as to potential mechanisms of injury. Based on the findings of these studies, investigators are seeking to confirm mechanisms of injury and the efficacy of novel interventions to decrease the frequency of these perioperative events. Until these investigations are complete, the etiologic mechanisms for many potential positioning-related complications remain unknown.

The lack of solid scientific information on basic mechanisms of positioning-related complications often leads to medicolegal entanglements. Notations on anesthesia and operating room records may be absent or uninformative. Careful descriptive notations about positions used during anesthesia and surgery, as well as brief comments about special protective measures such as eye care and pressure-point padding, are useful to include on the anesthesia record. In potentially complicated or contentious circumstances, a separate brief description of care documented in the patient's record is advisable. Only in this manner can subsequent inquiries be properly answered on behalf of either the patient or the anesthesiologist. When credible expanded knowledge that further delineates mechanisms of positioning-related complications is available, these issues and the care of patients will be improved.

## **General Principles**

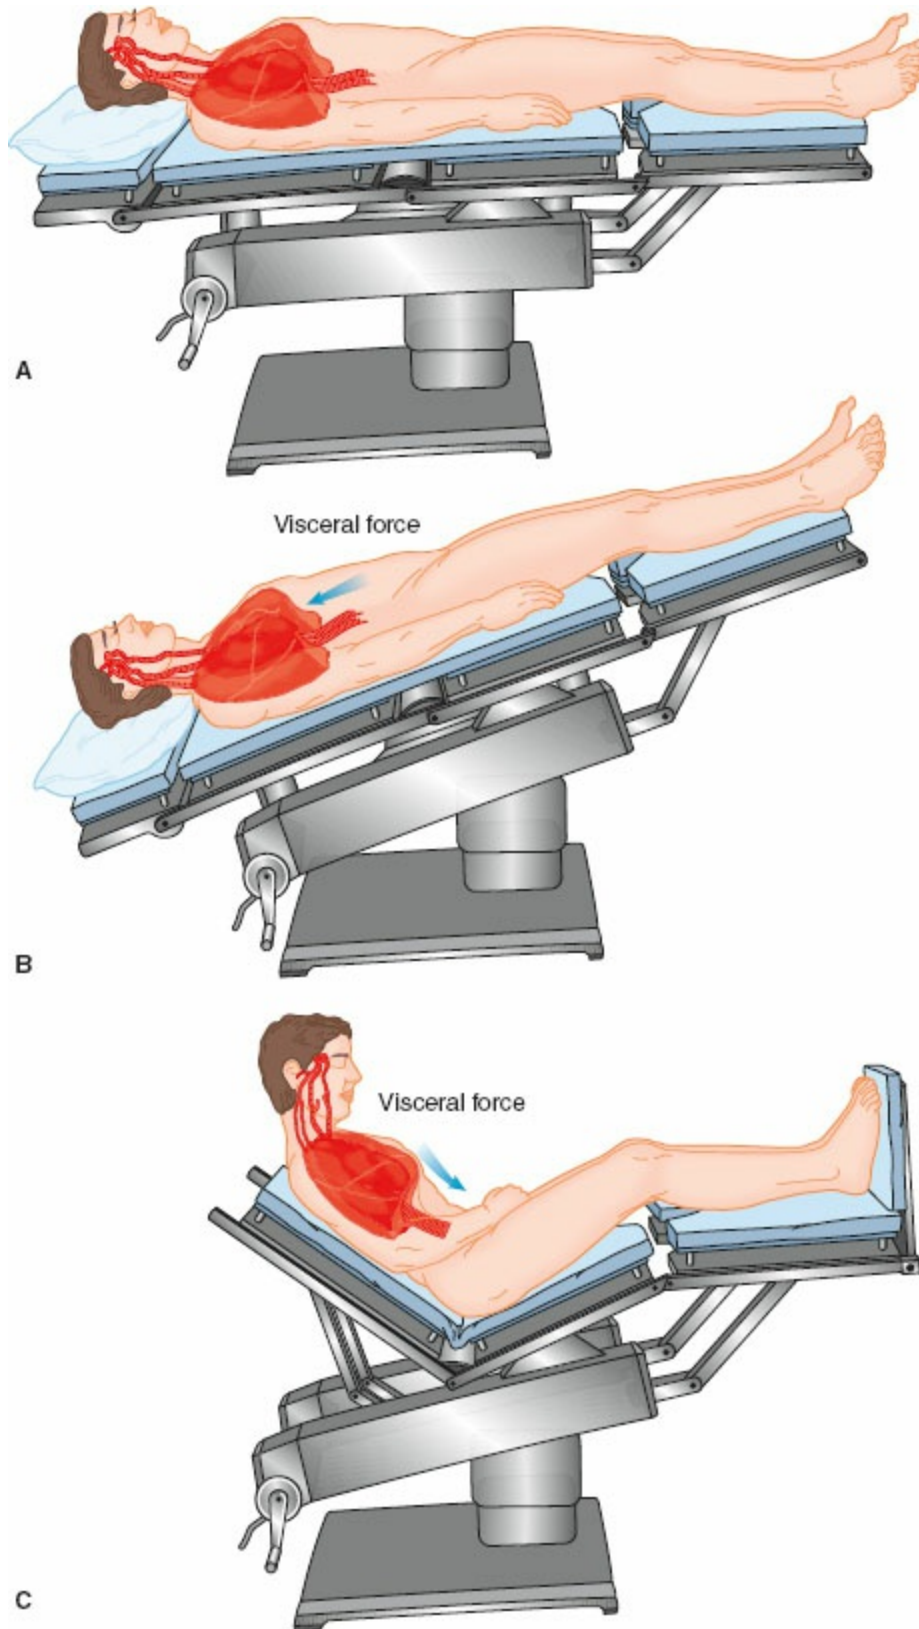

Without doubt, direct compression of neural and soft tissue may result in ischemia and tissue damage. Many efforts have been directed at provider education over the years to reduce direct tissue trauma from compression. Most anesthesia providers are taught from the start of their training that various maneuvers, pads, and positioning devices are useful to reduce point

pressure on neural and soft tissues. Despite these efforts, neuropathies and soft tissue damage still occur. Is it a failure of education, the incorrect application of this information, or other issues that contribute to the continued presence of perioperative positioning injuries? Or perhaps, are there etiologic mechanisms at work that we do not yet understand?

Recent studies and editorials suggest that we do not yet fully understand the etiologic mechanisms of positioning issues.<sup>1-4</sup> These studies reported inflammatory neuropathies in patients who developed severe postsurgical peripheral neuropathies. Surprisingly, the majority of these patients had widespread microvasculitic neuropathies, and many were responsive to immunologic modulation with high doses of corticosteroids. The inflammatory response may be dramatically altered in the perioperative period, and microvasculitic neuropathy appears to be a previously unrecognized cause of peripheral neuropathy. For example, anesthetic drugs and transfusion of blood products are known to promote systemic inflammation.<sup>5,6</sup> Large epidemiologic studies will eventually help determine the role that this new etiology plays in the origin of perioperative neuropathies of all sorts. In the meantime, these reports serve as evidence that a number of perioperative neuropathies may, in fact, have no relationship to intraoperative positioning or management of physiologic factors.<sup>4</sup>

Viruses have been associated with central as well as peripheral neuropathies that develop in the perioperative period. As noted earlier, immunosuppression is present in a fairly significant proportion of patients undergoing major surgical procedures. This immunosuppression may provide opportunities for existing viruses or newly introduced viruses to activate, particularly in neural tissues. For example, the onset of shingles may be more frequent in surgical compared to general populations.<sup>7</sup>

Positioning can, of course, cause tissue damage. Stretch of neural tissue may be an important factor in the development of peripheral and central neuropathies. Stretch of many mammalian nerves to 5% greater than their normal resting length has been shown repeatedly to lead to ischemia by reducing both arteriole and venule blood flow. The kinking of the arterioles and venules associated with neuronal stretch leads to ischemia.<sup>8</sup> If the ischemia is prolonged, it may result in permanent neural damage. The impact of stretch on other soft tissues is less well documented and would be highly dependent on the type of tissue and amount of stretch.

**Figure 29-1** **A:** Supine adult with minimal gradients in the horizontal vascular axis. Pulmonary blood volume is greatest dorsally. Viscera displace the diaphragm cephalad. Cerebral circulation is slightly above heart level if the head is on a small pillow. **B:** Head-down tilt aids blood return from lower extremities but encourages reflex vasodilation, congests vessels in the poorly ventilated lung apices, and increases intracranial blood volume. **C:** Elevation of the head shifts abdominal viscera away from the diaphragm and improves ventilation of the lung bases. According to the gradient above the heart, pressure in arteries of the head and neck decreases; pressure in

accompanying veins may become subatmospheric.

Point pressure on any soft tissue may reduce local blood flow and cause ischemia. There are many ways to reduce point pressure, but the most commonly used involve padding. Although there may be distinct differences in mechanical properties of various padding materials (e.g., gels, foam, textiles, and others), none have been proven to be significantly better than the others in reducing the frequency or severity of nerve or soft tissue damage perioperatively. The basic principle is to use any of these materials to protect nerves and soft tissues from point pressure.

## Supine Positions

### *Variations of Supine Positions*

#### **Horizontal**

In the traditional supine position, the patient lies on his or her back with a small pillow beneath the head (Fig. 29-1A). The arms are either comfortably padded and restrained alongside the trunk or abducted on well-padded arm boards. Either arm (or both) may be extended ventrally and the flexed forearm secured to an elevated frame in such a way that perfusion of the hand is not compromised, no skin-to-metal contact exists to cause electrical burns if cautery is used, and the brachial neurovascular bundle is neither stretched nor compressed at the axilla. The lumbar spine may need padded support to prevent a postoperative backache (see “Complications of Supine Positions”). Bony contact points at the occiput, elbows, and heels should be padded. Fortunately, most modern surgical tables have mattress pads that are sufficiently buoyant and thick to allow dispersion of point pressure.

Although the horizontal supine posture has a long history of widespread use, it does not place hip and knee joints in neutral positions and is poorly tolerated for prolonged periods by an immobilized, awake patient.

#### **Contoured**

A contoured supine posture (Fig. 29-2) has been termed the *lawn chair position*. It is established by arranging the surface of the operating table so that the trunk–thigh hinge is angulated approximately 15 degrees and the thigh–knee hinge is angulated a similar amount in the opposite direction. Alternatively, a rolled towel, pillow, or blanket can be placed beneath the patient’s knees to keep them flexed. The patient of average height then lies comfortably with hips and knees flexed gently.

## Lateral Uterine or Abdominal Mass Displacement

With a patient in the supine position, a mobile abdominal mass, such as a very large tumor or a pregnant uterus, can rest on the great vessels of the abdomen and compromise circulation. This is known as the *aortocaval syndrome* or the *supine hypotensive syndrome*. A significant degree of perfusion can be restored if the compressive mass is rolled toward the left hemiabdomen by leftward tilt of the tabletop or by a wedge under the right hip.

## Lithotomy

### *Standard*

In the standard lithotomy position (Fig. 29-3), the patient lies supine, typically with one or both arms extended laterally to less than 90 degrees on arm boards. Each lower extremity is flexed at the hip and knee, and both limbs are simultaneously elevated and separated so that the perineum becomes accessible to the surgeon. For many gynecologic and urologic procedures, the patient's thighs are flexed approximately 90 degrees on the trunk and the knees are bent sufficiently to maintain the lower legs nearly parallel to the floor. More acute flexion of the knees or hips can threaten to angulate and compress major vessels at either joint. In addition, hip flexion to greater than 90 degrees on the trunk has been shown to increase stretch of the inguinal ligaments.<sup>8</sup> Branches of the lateral femoral cutaneous nerves often pass directly through these ligaments and can be impinged and become ischemic within the stretched ligament.

Numerous devices are available to hold legs that are elevated during obstetric delivery or perineal operations. Each device should be fitted to the stature of the individual patient. Care should be taken to ensure that angulations or edges of the padded holder do not compress the popliteal space or the upper dorsal thigh. Compartment syndromes of one or both lower extremities have resulted from prolonged use of the lithotomy position with various types of support devices.

**Figure 29-2** Establishment of the contoured supine (lawn chair) position. **A:** Traditional flat supine tabletop. **B:** Thighs flexed on trunk. **C:** Knees gently flexed in final body position. **D:** Trunk section leveled to stabilize floor-supported arm board.

**Figure 29-3** Standard lithotomy position with “candy cane” extremity support. Thighs are flexed approximately 90 degrees on the abdomen; knees are flexed enough to bring the lower legs grossly parallel to the torso section of the tabletop. Arms are retained on the boards, crossed on the abdomen, or snugged at the sides of patient.

### Low

For most urologic procedures and for many procedures that require simultaneous access to the abdomen and perineum, the degree of thigh elevation in the lithotomy position is only approximately 30 to 45 degrees (Fig. 29-4). This reduces perfusion gradients to and from the lower extremities and improves access to a perineal surgical site for members of the

operating team who may need to stand at the lateral aspect of either leg.

**Figure 29-4** Low lithotomy position for perineal access, transurethral instrumentation, or combined abdominoperineal procedures.

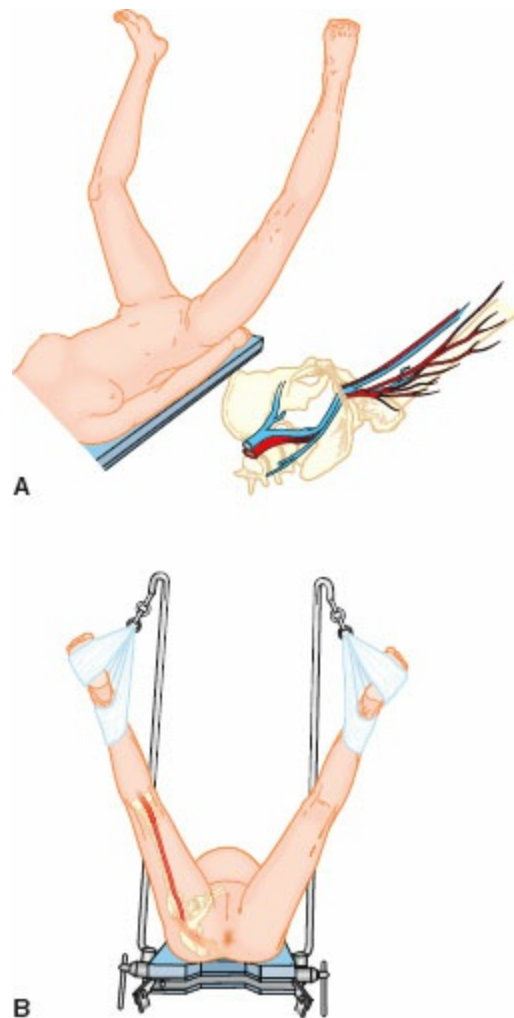

### *High*

Some surgeons prefer to improve access to the perineum by suspending the patient's feet from high poles. The effect is to have the patient's legs almost fully extended on the thighs (Fig. 29-5) and the thighs flexed 90 degrees or more on the trunk. The posture produces a significant uphill gradient for arterial perfusion into the feet, requiring careful avoidance of systemic hypotension. There is considerable variation in lower extremity perfusion pressure in volunteers placed in high lithotomy positions; they all tend to have low perfusion pressures, however.<sup>9,10</sup> Less mobile patients may tolerate this posture poorly because of angulation and compression of the contents of the femoral canal by the inguinal ligament (Fig. 29-5A), or stretch of the sciatic nerve (Fig. 29-5B), or both.

### *Exaggerated*

Transperineal access to the retropubic area requires that the patient's pelvis be flexed ventrally on the spine, the thighs almost forcibly flexed on the trunk, and the lower legs aimed skyward so they are out of the way (Fig. 29-6). The result places the long axis of the symphysis pubis almost parallel to the floor. This exaggerated lithotomy position stresses the lumbar spine, produces a significant uphill gradient for perfusion of the feet, and may restrict ventilation because of abdominal compression by bulky thighs. If pre-existing painful lumbar spine disease is present, an alternative surgical position may need to be chosen beforehand to avoid severely accentuating the lumbar distress after surgery. This position has been associated with a very high frequency of lower extremity compartment syndrome.<sup>11</sup> Maintenance of

adequate perfusion pressure in the legs is important.

**Figure 29-5** High lithotomy position. Note potential for angulation and compression/obstruction of contents of femoral canal (**A**, *inset*) or stretch of sciatic nerve (**B**). (**A**) Adapted from McLeskey CH, ed. *Geriatric Anesthesiology*. Baltimore, MD: Williams & Wilkins; 1997:146.

## Complications of Supine Positions

### Brachial Plexus Neuropathy

#### Root Injuries

**1** Shoulder braces placed tight against the base of the neck can compress and injure the roots of the brachial plexus when steep head-down positions are used. Braces, if needed at all, are considered less harmful when placed more laterally over the acromioclavicular joint. In general, the use of shoulder braces should be discouraged. The same is true of straps or tape criss-crossed from above the shoulders to keep patients from sliding cephalad.

Supine positions do not usually threaten structures in the patient's neck unless considerable lateral displacement of the head occurs or if steep head-down tilt is added. When lateral displacement of the head occurs, the roots of

the brachial plexus on the side of the obtuse head–shoulder angle can be stretched and damaged. If the upper extremity is fixed to the operating table at the wrist (e.g., by wrist wrap or a sheet or towel used to tuck the arm), the stretch injury of the plexus can be accentuated as the head moves laterally away from the anchoring point of the wrist. Similarly, exaggerated rotation of the head away from an extended arm may be associated with a brachial plexus injury.

**Figure 29-6** The exaggerated lithotomy position. Shoulder support may be needed to stabilize the torso. If used, it should be placed over the acromioclavicular area to minimize compression of the brachial plexus and adjacent vessels.

### *Sternal Retraction*

Frequently, the patient undergoing a median sternotomy has both arms padded and secured alongside the torso. An alternative is to have both arms abducted.<sup>12</sup> Vander Salm et al.<sup>13,14</sup> described first-rib fractures and brachial plexus injuries associated with median sternotomies. They related the extent of the injury to the amount of retractor displacement of the rib, with the most severe injury being caused by displacement sufficient to produce a first-rib fracture. Roy et al.,<sup>15</sup> in a study of 200 consecutive adults scheduled for cardiac surgery via a median sternotomy, positioned the left arm either abducted and padded on an arm board with the palm supinated or secured by a draw sheet alongside the trunk; the right arm was always placed alongside the trunk. They found a 10% incidence of upper extremity nerve injury that was not influenced by internal mammary artery harvest, internal jugular vein

catheterization, or left arm position. Surgical manipulation was more contributory than extremity positioning in producing trauma to the brachial plexus. Jellish et al.<sup>12</sup> reported that there is less slowing of somatosensory evoked potentials (SSEPs) of the ulnar nerve during sternotomy when both arms are abducted instead of tucked at the sides. However, they found no differences in perioperative symptoms between patients in the arm-abducted versus arm-at-side groups.

### **Long Thoracic Nerve Dysfunction**

A number of lawsuits have centered on postoperative serratus anterior muscle dysfunction and winging of the scapula (Fig. 29-7) alleged to be the result of position-related injuries to the long thoracic nerve, a nerve arising from nerve roots C5, C6, and C7. Because C5 and C6 fibers of the nerve course through the middle scalene muscle and emerge from its lateral border to join the fibers from C7, it has been proposed that neuropathies of the long thoracic nerve are traumatic in origin.<sup>16,17</sup> Because the nerve is not routinely involved in a stretch injury of the brachial plexus and because the plexus is not routinely involved when long thoracic nerve dysfunction occurs, the relationship between postoperative long thoracic neuropathy and patient positioning remains speculative. Based on evidence of Foo and Swann<sup>18</sup> plus data from various litigations, Martin<sup>17</sup> concluded that in the absence of demonstrable trauma, postoperative dysfunctions of the long thoracic nerve were quite likely the result of coincidental neuropathies, possibly of viral or inflammatory origin.

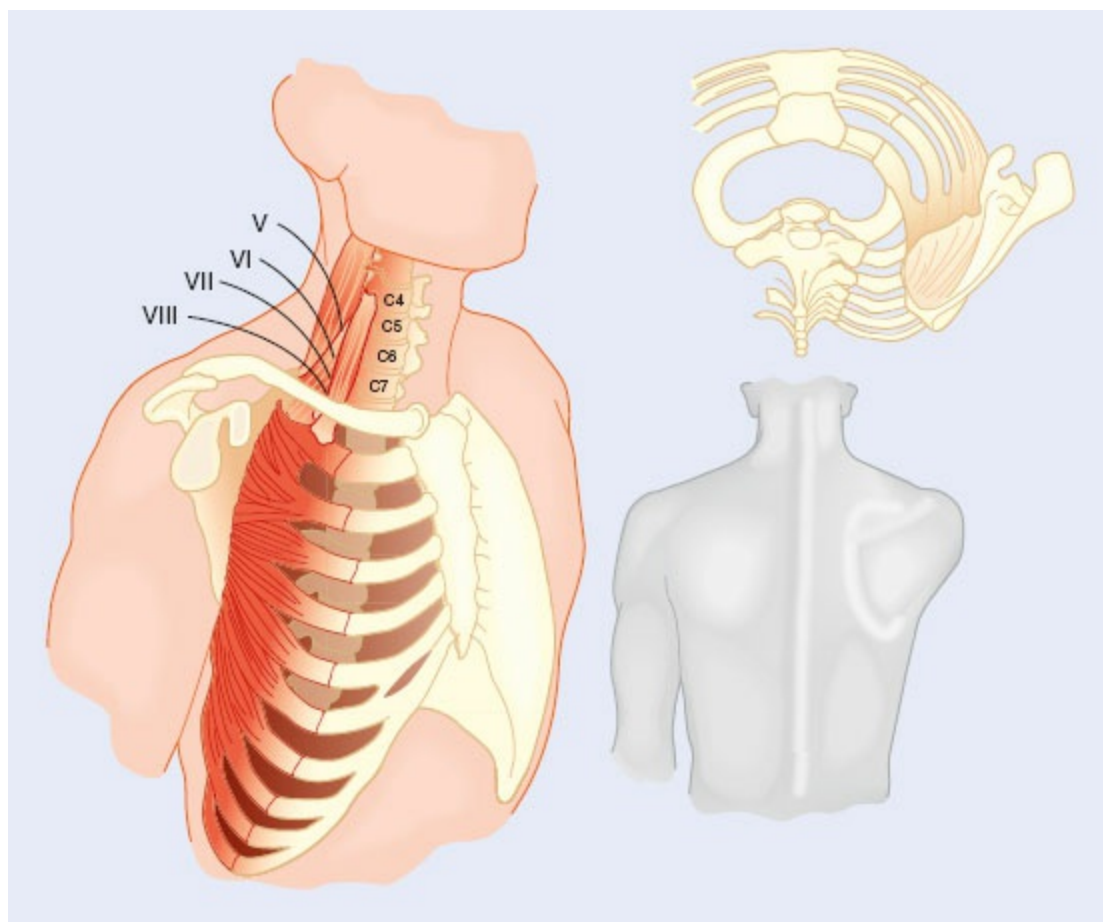

### **Axillary Trauma from the Humeral Head**

Abduction of the arm on an arm board to greater than 90 degrees may thrust the head of the humerus into the axillary neurovascular bundle. This bundle typically lies on the flexion side of the shoulder joint. However, when the arm is abducted to greater than 90 degrees, the bundle is now on the extension side of the joint. The bundle is both compressed and stretched at that point, and its neural structures may be damaged. In the same manner, vessels can be compressed or occluded and perfusion of the extremity can be jeopardized.

### **Radial Nerve Compression**

The radial nerve, arising from roots C6–8 and T1, passes dorsolaterally around the middle and lower portions of the humerus in the musculospiral groove. At a point on the lateral aspect of the arm, approximately three fingerbreadths proximal to the lateral epicondyle of the humerus, the nerve can be compressed against the underlying bone and injured. Pressure from the

vertical bar of an anesthesia screen or a similar device against the lateral aspect of the arm, excessive cycling of an automatic blood pressure cuff, and compression at the midhumerus level by restrictive sheets or towels used to tuck the arms have been implicated in causing damage to the radial nerve. Other support devices, including arm boards and slings used when patients are positioned laterally, can directly compress the radial nerve as it wraps around the musculospiral groove.

**Figure 29-7** Scapular winging. The serratus anterior muscle (*upper right*) is supplied solely by the long thoracic nerve that branches immediately from C5, C6, C7, and sometimes C8 (*left figure*). Arising on the lateral ribs and inserting on the deep surface of the scapula, the muscle keeps the shoulder girdle approximated to the dorsal rib cage. Long thoracic nerve palsy allows dorsal protrusion of the scapula (*lower right*). See text for details.

## Median Nerve Dysfunction

Isolated perioperative injuries to the median nerve are uncommon and the mechanism is usually obscure.<sup>19,20</sup> A potential source of injury is iatrogenic trauma to the nerve during access to vessels in the antecubital fossa, as might occur during venipuncture. Anecdotally, this problem appears to occur primarily in men 20 to 40 years of age who cannot easily extend their elbows completely. Forced elbow extension after administration of muscle relaxants

and while positioning the arms, with resultant stretch of the median nerve, has been suggested as one potential mechanism for this problem.

## Ulnar Neuropathy

Improper anesthetic care and patient malpositioning have been implicated as causative factors in the development of ulnar neuropathies since reports by Büdinger<sup>21</sup> and Garriques<sup>22</sup> in the 1890s. These factors likely play an etiologic role for this problem in some surgical patients. Other factors, however, may contribute to the development of postoperative ulnar neuropathies. In a series of 12 inpatients with newly acquired ulnar neuropathy, Wadsworth and Williams<sup>23</sup> determined that external compression of an ulnar nerve during surgery was a factor in only two patients. Ulnar neuropathies develop in medical as well as surgical patients.<sup>24</sup> Thus, the mechanisms of ulnar neuropathy are unclear.

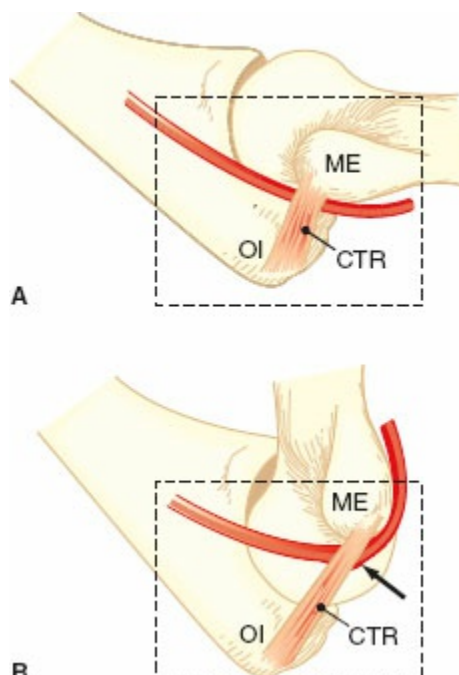

Typically, anesthesia-related ulnar nerve injury is thought to be associated with external nerve compression or stretch caused by malpositioning during the intraoperative period. Although this implication may be true for some patients, three findings suggest that other factors may contribute. First, patient characteristics (e.g., male gender, high body mass index, and prolonged postoperative bed rest) are associated with these ulnar neuropathies.<sup>25</sup> Various reports suggest that 70% to 90% of patients who have this problem are men.<sup>19,20,23–25</sup> Second, many patients with perioperative ulnar neuropathies have a high frequency of contralateral ulnar nerve conduction dysfunction.<sup>26</sup> This finding suggests that many of these patients likely have asymptomatic but abnormal ulnar nerves before their anesthetics, and these abnormal nerves may become symptomatic during the perioperative period. Finally, many patients do not notice or complain of ulnar nerve symptoms until more than 48 hours after their surgical procedures.<sup>25,26</sup> A prospective study of ulnar neuropathy in 1,502 surgical patients found that none of the patients had symptoms of the neuropathy during the first 2 postoperative days.<sup>27</sup> It is not clear whether onset of symptoms indicates the time that an injury has occurred to the nerve. Prielipp et al.<sup>28</sup> found that 8 of 15 awake volunteers who had notable alterations in their ulnar nerve SSEP signals from direct ulnar nerve pressure did not perceive a paresthesia, even when the SSEP waveforms decreased as much as 72%.

Elbow flexion can cause ulnar nerve damage by several mechanisms. In some patients, the ulnar nerve is compressed by the aponeurosis of the flexor carpi ulnaris muscle and cubital tunnel retinaculum when the elbow is flexed by greater than 110 degrees (Fig. 29-8).<sup>29,30</sup> In other patients, this fibrotendinous roof of the cubital tunnel is poorly formed and can lead to

anterior subluxation or dislocation of the ulnar nerve over the medial epicondyle of the humerus during elbow flexion. This displacement has been observed in approximately 16% of cadavers in whom the flexor muscle aponeurosis and supporting tissues have not been dissected.<sup>31,32</sup> Ashenhurst<sup>32</sup> has speculated that the ulnar nerve may be chronically damaged by recurrent mechanical trauma as the nerve is in subluxation over the medial epicondyle.

External compression in the absence of elbow flexion also may damage the ulnar nerve.<sup>33,34</sup> Although compression within the medial epicondylar groove may be possible if the groove is shallower than normal, the bony groove usually is deep and the nerve is well protected from external compression.<sup>35</sup> External compression may occur distal to the medial epicondyle, where the nerve and its associated artery are relatively superficial. In an anatomic study, Contreras et al.<sup>36</sup> observed that the ulnar nerve and posterior recurrent ulnar artery pass posteromedially to the tubercle of the coronoid process, where they are covered only by skin, subcutaneous fat, and a thin distal band of the aponeurosis of the flexor carpi ulnaris.

There are several anatomic differences between men and women that may increase the likelihood of perioperative ulnar neuropathy developing in men. First, two anatomic differences may increase the chance of ulnar nerve compression in the region of the elbow. The tubercle of the coronoid process is approximately 1.5 times larger in men than women.<sup>36</sup> In addition, there is less adipose tissue over the medial aspect of the elbow of men compared with women of similar body fat composition.<sup>36–38</sup> Second, men may be more likely to have a well-developed cubital tunnel retinaculum than women, and the retinaculum, if present, is thicker. A thicker cubital tunnel retinaculum may increase the risk of ulnar nerve compression in the cubital tunnel when the elbow is flexed.

**Figure 29-8** Medial-to-lateral view of right elbow. The cubital tunnel retinaculum (CTR) is lax in extension (**A**) as it stretches from the medial epicondyle (ME) to the olecranon (OI). The retinaculum tightens in flexion (**B**) and can compress the ulnar nerve (*arrow*). (Adapted from O’Driscoll SW, Horii E, Carmichael SW, et al. The cubital tunnel and ulnar neuropathy. *J Bone Joint Surg Br.* 1991;73:615.)

Clinical manifestations of ulnar nerve dysfunction vary with the location and extent of the lesion.<sup>39</sup> Nearly all patients have numbness, tingling, or pain in the sensory distribution of the ulnar nerves once they become symptomatic. However, there can be considerable ulnar nerve dysfunction before symptoms appear. Prielipp et al.<sup>28</sup> found that only 8 of 15 male volunteers with significant ulnar nerve conduction slowing noted any symptoms. More studies are needed to better understand the mechanism and natural history of ulnar neuropathy.

Perioperative ulnar neuropathy is relatively common.<sup>19,20,27</sup> Also, a significant proportion of patients have symptoms of bilateral ulnar nerve dysfunctions both before and after surgery.<sup>27</sup> Therefore, some have speculated that it might be helpful during the preanesthetic interview to inquire about a history of ulnar neuropathies (“crazy bone” problems) or previous surgery at the elbow. If such a history is indicated, the finding must be recorded and a discussion with the patient or family should present the possibility of a postoperative recurrence despite special precautions of padding and positioning.

The time of recognition of digital anesthesia associated with ulnar nerve dysfunction may be quite important in establishing the origin of the postoperative syndrome. If ulnar hypesthesia or anesthesia is noted promptly after the end of anesthesia, as in the recovery facility, the condition is likely to be associated with events that occurred during anesthesia or surgery. If the recognition is delayed for many hours, the likelihood of cause shifts from the intra-anesthetic period to postoperative events. In a review of closed claims, Cheney et al.<sup>20</sup> commented that postoperative ulnar dysfunction can occur as a result of events in the postanesthetic period and that nerve injury may develop in certain susceptible patients “despite conventionally accepted methods of positioning and padding.”

Opioids may mask postoperative dysesthesias and pain, but even strong analgesics do not appear to mask a loss of sensation as a result of nerve dysfunction. It may be helpful to assess ulnar nerve function and record these observations before discharging the patient from the recovery room.

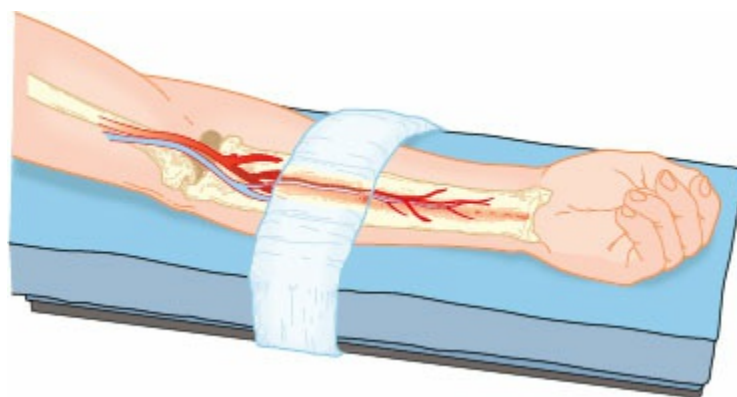

## **Other Supine Position Problems**

### *Arm Complications*

Arm boards should be securely attached to the operating table to prevent accidental release. An arm that is not properly secured can slip over the edge of the table or arm board, resulting in injury to the capsule of the shoulder joint by excessive dorsal extension of the humerus, fracture of the neck of an osteoporotic humerus, or injury to the ulnar nerve at the elbow. Conversely, in the unlikely event that the retaining strap or other holding device or cloth is excessively tight across the supinated forearm (Fig. 29-9), the potential exists for pressure to compress the anterior interosseous nerve, a branch of the median nerve in the upper forearm that courses with its artery along the volar surface of the tough interosseous membrane. The result is an ischemic injury to the distribution of the nerve and artery that resembles a compartment syndrome in the lower extremity and may require prompt surgical decompression.<sup>40-42</sup>

### *Backache and Paraplegia*

Lumbar backache can be worsened by the ligamentous relaxation that occurs with general, spinal, or epidural anesthesia. Loss of normal lumbar curvature in the supine position is apparently the issue. As a general rule, when possible prior to induction of anesthesia, patients should be placed in positions that are **4** comfortable while they are awake. Padding placed under the lumbar spine before the induction of anesthesia may help retain lordosis and make a patient with known lumbar distress more comfortable. Hyperlordosis should be avoided, however. Hyperextension of the lumbar spine, especially to an angulation of greater than 10 degrees at the L2-3 apex of the lumbar spine, may result in ischemia of the spinal nerves.<sup>43</sup> Multiple patients undergoing pelvic procedures have been reported to have developed paraplegia. In these patients, hyperlordosis was induced by retroflexing the operating room tables maximally, elevating kidney rests fully, and adding padding (e.g., towels, rolls, pillows, and even liter bags of crystalloid) under the lumbar spine to maximize hyperlordosis.

**Figure 29-9** Arm restraint, if excessively tight, can compress the anterior interosseous nerve and vessel against the interosseous membrane in the volar forearm to produce an ischemic neuropathy. (Adapted from McLeskey CH, ed. *Geriatric Anesthesiology*.)

### *Compartment Syndrome*

If, for whatever reason, perfusion to an extremity is inadequate, a compartment syndrome may develop. Characterized by ischemia, hypoxic edema, elevated tissue pressure within fascial compartments of the leg, and extensive rhabdomyolysis, the syndrome produces extensive and potentially lasting damage to the muscles and nerves in the compartment.

Causes of a compartment syndrome that may be associated with positioning factors while a patient is in any of the dorsal decubitus positions include (1) systemic hypotension and loss of driving pressure to the extremity (augmented by elevation of the extremity); (2) vascular obstruction of major leg vessels by intrapelvic retractors, by excessive flexion of knees or hips, or by undue popliteal pressure from a knee crutch; and (3) external compression of the elevated extremity by straps or leg wrappings that are too tight, by the inadvertent pressure of the arm of a surgical assistant, or by the weight of the extremity against a poorly supportive leg holder. A tight strap on an arm as well as tight “draw sheets” for maintaining arms at the patient’s sides may compress the anterior interosseous neurovascular bundle and may be associated with an anterior interosseous neuropathy or a forearm or hand compartment syndrome.<sup>41,42</sup>

Several clinical characteristics seem to be associated with perioperative compartment syndrome. Prolonged lithotomy posture in excess of 5 hours has been a common factor in literature anecdotes of postlithotomy compartment syndromes. For lengthy procedures in the lithotomy position, well-padded holders that immobilize the limb by supporting the foot without compressing the calf or popliteal fossa seem to be the least threatening choice. There is considerable variability in the perfusion pressure of the lower extremity in elevated legs. Halliwill et al.<sup>9</sup> and Pfeffer et al.<sup>10</sup> found significant blood pressure variation at the ankle in volunteers placed in various lithotomy positions. Several volunteers had mean pressures of greater than 20 mmHg when positioned in the high lithotomy position. This pressure is less than intracompartment pressures commonly measured in many lithotomy positions.

Warner et al.<sup>44</sup> have shown that perioperative compartment syndromes occur in patients in positions other than lithotomy. The frequency of this problem appears to occur as often (approximately 1 in 9,000 patients studied retrospectively) in anesthetized patients who are positioned laterally as in similar patients who are positioned in lithotomy. The difference between compartment syndromes in these two groups is that patients in a lateral decubitus position tend to have compartment syndromes of either arm, whereas those in a lithotomy position have compartment syndromes of the

lower extremities.

## Lateral Positions

There are several general positioning concepts to consider when placing a patient into a lateral decubitus position. Wrapping the legs and thighs in compressive bandages has been commonly used to combat venous pooling. Marked flexion of the lower extremities at knees and hips can partially or completely obstruct venous return to the inferior vena cava either by angulation of vessels at the popliteal space and inguinal ligament or by thigh compression against an obese abdomen. A small support placed just caudad of the downside axilla can be used to lift the thorax enough to relieve pressure on the axillary neurovascular bundle and prevent disturbed blood flow to the arm and hand. However, this chest support (inappropriately called an *axillary roll* by some) has not been proven to reduce the frequency of ischemia, nerve damage, or compartment syndrome to the downside upper extremity. It may, however, decrease shoulder discomfort postoperatively. Any padding should support only the chest wall and it should be periodically observed to ensure that it does not impinge on the neurovascular structures of the axilla.

### *Variations of Lateral Positions*

#### **Standard Lateral Position**

In the standard lateral position ([Fig. 29-10](#)), the patient is rolled onto one side on a flat table surface and stabilized in that posture by flexing the downside thigh. The downside knee is bent to retain the leg on the table and improve stabilization of the trunk. The common peroneal nerve of that side is padded to minimize compression damage caused by the weight of the legs. The upside thigh and leg are extended comfortably, and pillows are placed between the lower extremities. The head is supported by pillows or a headrest so that the cervical and thoracic spines are properly aligned. A small pad, thick enough to raise the chest wall and prevent excessive compression of the shoulder or entrapment/compression of the neurovascular structures of the axilla, is placed just caudad to the downside axilla. This padding may support adequate perfusion of the downside hand and minimize circumduction of the dependent shoulder, which might stretch its suprascapular nerve.

Arms may be extended ventrally and retained on a single arm board with suitable padding between them, or they may be individually retained on a padded two-level arm support that can also help to stabilize the thorax. An alternate method of arm arrangement is to flex each elbow and place the arms on suitable padding on the table in front of the patient's face.

The patient is stabilized in the lateral position by the use of one or more retaining tapes or straps stretched across the hip and fixed to the underside of the tabletop. Care must be taken to see that the hip tapes or straps lie safely between the iliac crest and the head of the femur rather than over the head of the femur. An additional restraining tape or strap may be used across the thorax or shoulders if needed. Other methods, such as the use of “bean bag” or vacuum-supported retention devices, are commonly used. As with any such devices, it is essential to ensure that point pressure on bony prominences is minimized and body structures are appropriately supported.

**Figure 29-10** The standard lateral decubitus position. Proper head support, chest support, and leg pillow arrangements are shown on the *lower figure*. The downside leg is flexed at the hip and knee to stabilize the torso. Retaining straps and pad for the downside peroneal nerve are not shown.

## Semisupine and Semiprone

Semi-lateral postures are designed to allow surgeons to reach anterolateral (semisupine) and posterolateral (semiprone) structures of the trunk. In the semisupine position, the upside arm must be carefully supported so that it is not hyperextended and no traction or compression is applied to the brachial and axillary neurovascular bundles (Fig. 29-11). The supporting bar should be well wrapped to prevent electrical grounding contact (Fig. 29-11A). Sufficient noncompressible padding should be placed under the torso and hip to prevent the patient from rolling supine and stretching the anchored extremity. The pulse of the restrained wrist should be checked to ensure adequate circulation in the elevated arm and hand (Fig. 29-11B).

## Flexed Lateral Positions

### *Lateral Jackknife*

The lateral jackknife position places the downside iliac crest over the hinge

between the back and thigh sections of the table (Fig. 29-12). The tabletop is angulated at that point to flex the thighs on the trunk laterally. After the patient has been suitably positioned and restrained, the chassis of the table is tipped so that the uppermost surface of the patient's flank and thorax becomes essentially horizontal. As a result, the feet are below the level of the atria, and significant amounts of blood may pool in distensible vessels in each leg.

The lateral jackknife position is usually intended to stretch the upside flank and widen intercostal spaces as an asset to a thoracotomy incision. However, in terms of lumbar stress, restriction by the taut flank of upside costal margin motion, and pooling of blood in depressed lower extremities, the position has the potential to impose a significant physiologic insult. Actually, its usefulness to the surgeon is brief, and its use should be limited. Once the rib-spreading retractor is placed in the incision, the position has reduced value for the rest of the operation.

### *Kidney*

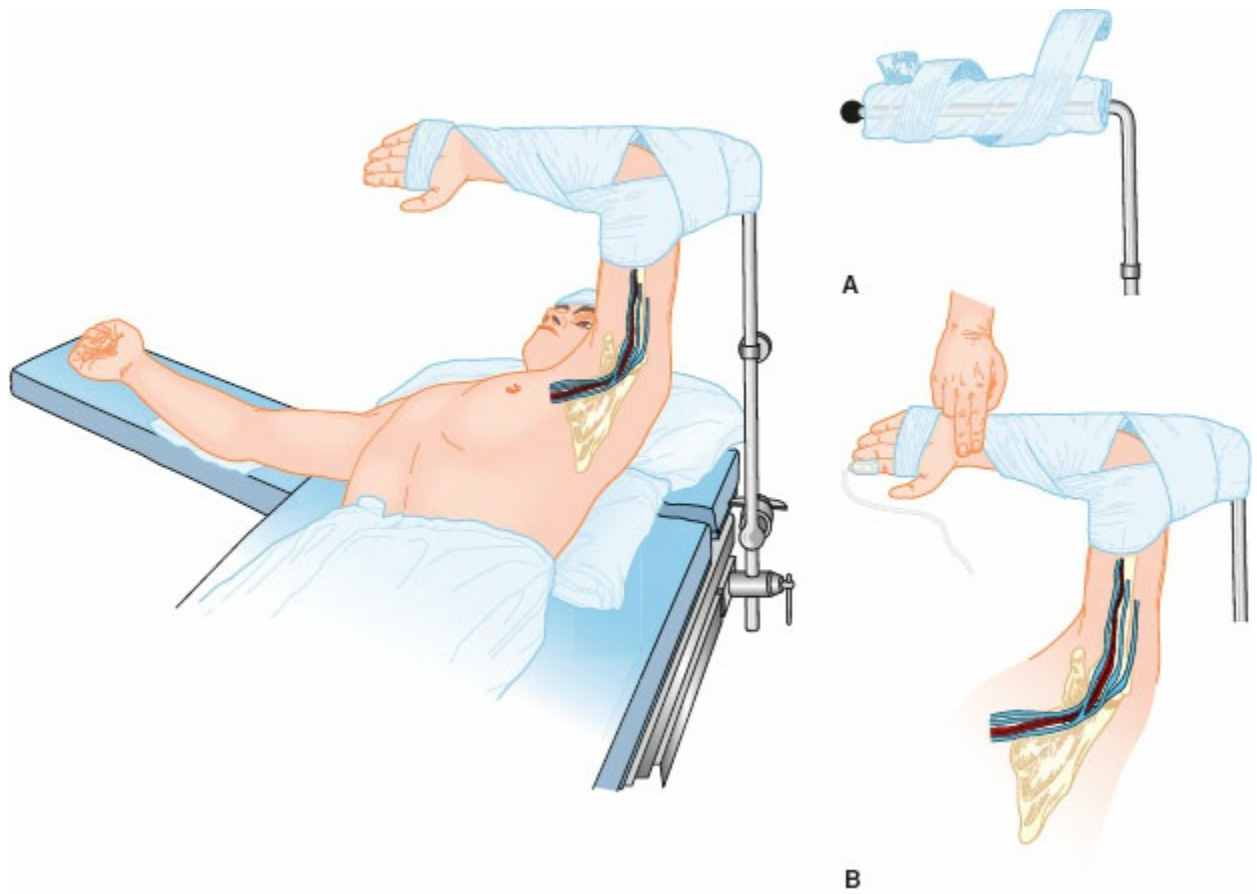

The kidney position (Fig. 29-13) resembles the lateral jackknife position, but it adds the use of an elevated rest (the *kidney rest*) under the downside iliac crest to increase the amount of lateral flexion and improve access to the upside kidney under the overhanging costal margin. Unlike the lateral jackknife position, the kidney position does not have a useful alternative for a flank approach to the kidney. Thus, the physiologic insults associated with the posture need to be limited by vigilant anesthesia and, hopefully, rapid surgery. Strict stabilizing precautions should be taken to prevent the patient from subsequently shifting caudad on the table in such a manner that the elevated rest relocates into the downside flank and becomes a severe impediment to ventilation of the dependent lung.

## **Complications of Lateral Positions**

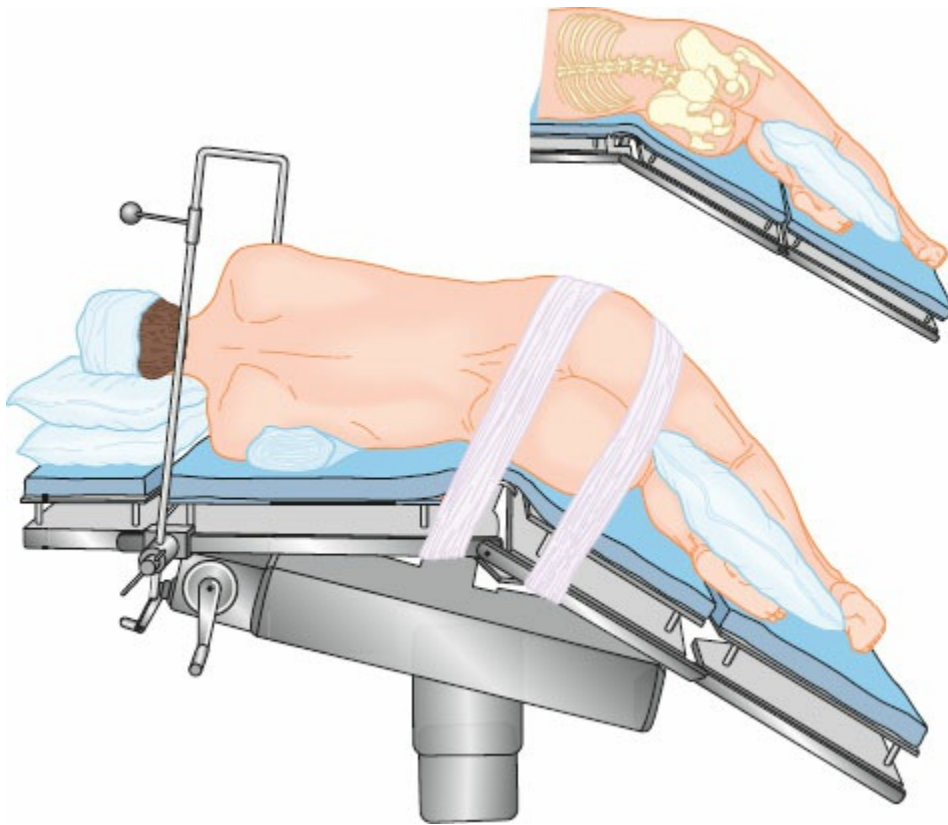

### **Eyes and Ears**

Injuries to the dependent eye are unlikely if the head is properly supported during and after the turn from the supine to the lateral position. If the patient's face turns toward the mattress, however, and the lids are not closed or the eyes otherwise protected, abrasions of the ocular surface can occur. Direct pressure on the globe can displace the crystalline lens, increase intraocular pressure or, particularly if systemic hypotension is present, cause ischemia. 

**Figure 29-11** The semisupine position with dorsal pads supporting the torso, the extended arm padded at the elbow, and the elevated arm restrained on a well-cushioned, adjustable overhead bar (**A**). Axillary contents (**B**) are not under tension and are not compressed by the head of the humerus, and a pulse oximeter ensures that the digital circulation is not compromised. The position is safe only if the arm does not become a hanging mechanism to support the torso. (Adapted from Collins VJ, ed. *Principles of Anesthesiology*, 3rd ed. Philadelphia, PA: Lea & Febiger; 1993:176.)

**Figure 29-12** The lateral jackknife position, intended to open intercostal spaces. Note the properly placed restraining tapes (*large figure*) thrusting cephalad to retain the iliac crest at the flexion point of the table and prevent caudad slippage, which compresses the downside flank (*inset*).

**Figure 29-13** The flexed lateral (kidney) position. Upper panels show improper locations of the elevated transverse rest, the flexion point of the table, in the flank (**A**) or at the lower costal margin (**B**) to impede ventilation of the downside lung. The iliac crest at the proper flexion point (**C**), allowing the best possible expansion of the downside lung. Restraining tapes deleted for clarity.

In the lateral position, the weight of the head can press the downside ear against a rough or wrinkled supporting surface. Careful padding with a pillow or a foam sponge is usually sufficient protection against contusion of the ear. The external ear should also be palpated to ensure that it has not been folded over in the process of placing support beneath the head.

## Neck

Lateral flexion of the neck is possible when the head of a patient in the lateral position is inadequately supported. If the cervical spine is arthritic, postoperative neck pain can be troublesome. Pain from a symptomatic protrusion of a cervical disk can be intensified unless the head is carefully positioned so that lateral or ventral flexion, extension, or rotation is avoided.

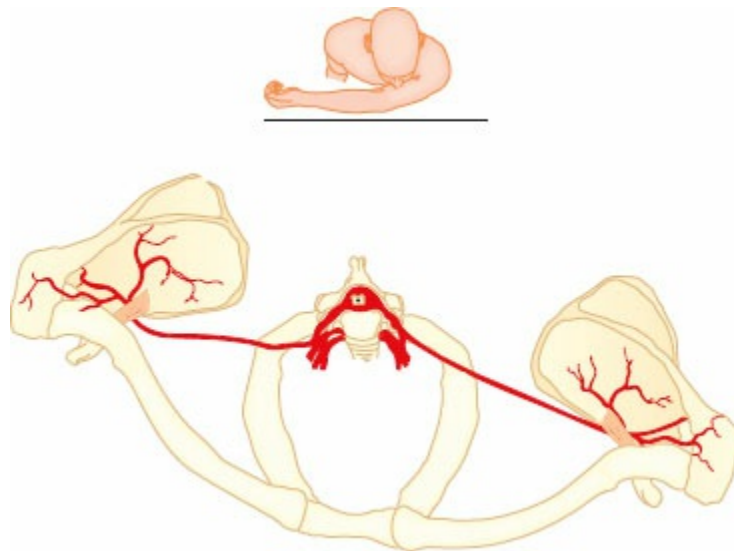

## Suprascapular Nerve

Ventral circumduction of the dependent shoulder can rotate the suprascapular notch away from the root of the neck (Fig. 29-14). Because the suprascapular nerve is fixed both paravertebrally and at the notch, circumduction can stretch the nerve and produce troublesome, diffuse, dull shoulder pain. The diagnosis is established by blocking the nerve at the notch and producing pain relief. Treatment may require resecting the ligament over the notch to decompress the nerve. A supporting pad placed under the thorax caudad of the axilla and thick enough to raise the chest off the shoulder may prevent a circumduction stretch injury to the nerve.

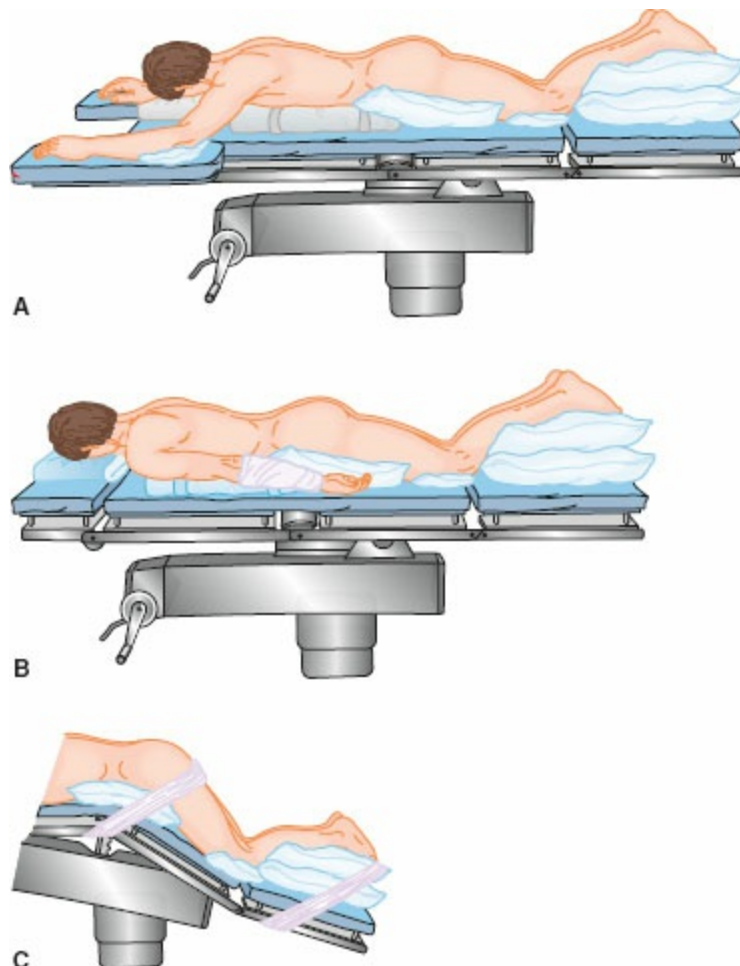

## Prone Positions

### Full Prone

In the so-called *full prone position* (Fig. 29-15), the requirement to elevate the trunk off the supporting surface so that the ventral abdominal wall is freed of compression almost always results in the head and lower extremities being below the level of the spine. If the tabletop is angulated at the trunk–thigh hinge to remove the lumbar lordosis and separate the lumbar spinous processes, and if the chassis is then rotated head-up sufficiently to level the patient’s back, a significant perfusion gradient may develop between the legs and the heart. Wrapping the legs in compressive bandages, or the use of full-length elastic hosiery, minimizes pooling of blood in distensible vessels and supports venous return.

**Figure 29-14** Circumduction of the arm displacing the scapula and stretching the suprascapular nerve between its anchoring points at the cervical spine and the suprascapular notch.

**Figure 29-15** The classic prone position. **A:** Flat table with relaxed arms extended alongside the patient's head. Parallel chest rolls extended from just caudad of the clavicle to just beyond the inguinal area, with a pillow over the pelvic end. Elbows and knees are padded, and legs are bent at the knees. The head is turned onto a C-shaped pad, gel, or foam sponge that frees the downside eye and ear from compression. **B:** The same posture with arms snugly retained alongside the torso. **C:** Table flexed to reduce lumbar lordosis; subgluteal area straps placed after the legs are lowered to

provide cephalad thrust and prevent caudad slippage.

When this position results in the head being lower than the heart, the pressure gradient can result in venous and lymphatic stasis in the head. This position may result in facial and airway edema, making extubation of intubated patients challenging, especially after prolonged procedures such as spine fusions. In addition, over the past decade or two, long spine surgical procedures have resulted in a surprising number of patients who experience severe vision loss. This vision loss is primarily related to ischemic optic neuropathy. Although the etiology of the ischemic optic neuropathy is not entirely clear, Lee et al.<sup>45</sup> suggest that prone positions with the head lower than the heart may lead to venous and lymphatic congestion in the optic canal. This congestion, added to the effect of gravity on the suspended globe of the eye, can result in optic nerve stretch and possibly the development of ischemic neuropathy (see later).<sup>46</sup>

Various pelvic, abdominal, and chest supports, including parallel rolls of tightly packed sheets, gels, padded and adjustable metal frames, and four-pillar frames, have been devised to free the abdomen from compression. Of these, the Wilson frame is particularly concerning in that its use results in the head being lower than the heart, potentially contributing to optic nerve congestion.<sup>45</sup> The use of frames may also produce opportunities for point pressure and if they are used, careful padding of contact points should be considered. The choice of equipment is based on the physique of the patient, the requirements of the surgical procedure, and availability.

Pronated patients with limited mobility of the neck, a history of postural neck pain, or a history suggesting a symptomatic cervical disk should have their heads retained in the sagittal plane, either with a skull-pin head clamp or with a face rest. Face rests have fluctuating popularity. Excessive periocular pressure must be considered and avoided if a face rest is used. If the neck is pain-free and its mobility is satisfactory, the head can be turned laterally and supported to prevent pressure on the downside eye and ear. However, forced rotation of the pronated head should be carefully avoided lest it induce postoperative neck pain or cervical nerve root or vascular compression. In addition, most patients described in the American Association of Anesthesiologists (ASA) Closed Claims database as having developed cervical neuropathies while positioned prone were found to have their heads rotated for greater than 3 hours. This information suggests that it may be reasonable to maintain the head in a neutral position when patients are anticipated to be positioned prone for greater than 3 hours.

When a patient is scheduled to be pronated after induction of anesthesia, it is worthwhile during the preanesthetic interview to obtain and record information about any limitations that may exist in his or her ability to raise

the arms overhead during work or sleep. If the patient is symptomatic, it may be prudent to place the arms alongside the torso after pronation (see Thoracic Outlet Syndrome). If the arms are placed alongside the head (i.e., extended ventrally at the shoulder, flexed at the elbow, and abducted onto arm boards; the “surrender” position), the musculature about the shoulders should be under no tension, neither humeral head should stretch or compress its axillary neurovascular bundle (i.e., shoulders should be abducted <90 degrees), ulnar nerves at the elbow should be padded, and the pulses at the wrists should remain full. Anterior (forward) flexion of the shoulders may reduce tension on the neurovascular structures of the axilla.

## **Complications of Prone Positions**

### **Eyes and Ears**

The eyes and ears may sustain injury in the prone position. The eyelids should be closed, and each eye should be protected in some manner so that the lids cannot be accidentally separated and the cornea scratched. Instillation of lubrication in the eyes should be considered, although the value of this treatment is being debated. The eyes should also be protected against the head turning after positioning and pressure being exerted on the globe. Monitoring wires and intravenous tubing should be checked after 5 pronation to see that none has migrated beneath the head. If the head is retained in the sagittal plane, the eyes should be checked after positioning to ensure that they are safe from compression by any headrest.

Conjunctival edema usually occurs in the eyes of the pronated patient if the head is at or below the level of the heart. It is usually transient, inconsequential, and requires only reestablishment of the normal tissue perfusion gradients of the supine position, or of a slight amount of head-up tilt, to be redistributed. There does not appear to be any connection between this edema and the occurrence of posterior ischemic optic neuropathy.

### **Blindness**

Permanent loss of vision can occur after nonocular surgical procedures, 5 especially those performed in a prone position.<sup>45</sup> The occurrence of this devastating complication is associated particularly with extensive surgical procedures done in the prone position, such as reconstructive spine surgery, where there is associated blood loss, anemia, and hypotension.

Lee et al.<sup>45</sup> used data from the American Society of Anesthesiologists Visual Loss Registry to study ischemic optic neuropathy in spine fusion patients. Using a 1:4 case-control methodology, the authors found six risk factors, half of which strongly support their speculation that acute venous

congestion of the optic canal is a potential etiology of ischemic optic neuropathy in this setting. The use of a Wilson surgical bed frame with its elevated curvature resulting in the head being lower than the heart, obesity with its potential elevation of intra-abdominal pressure in prone-positioned patients, and long anesthetic durations can all contribute to elevated venous congestion in the optic canal and potentially reduce optic nerve perfusion pressure. The authors also found that increased estimated blood loss, male gender, and lower percent of colloid administration were independently associated with the development of ischemic optic neuropathy after spinal fusion surgery.

These results suggest that the ASA's 2012 Practice Advisory on this issue is relevant.<sup>46</sup> Basically, it is prudent to attempt to reduce venous congestion in the optic canal. That is, consideration should be given to using positions that allow the patients' heads to be level with or higher than their hearts. It may be helpful to use colloids as well as crystalloids to maintain intravascular volume. Intraoperative positioning that helps reduce intra-abdominal pressure and, therefore, venous congestion, may be useful. The use of the Wilson frame and other positioning devices should be assessed carefully, with a goal to reduce pressure on the abdomen and to keep the head level with or higher than the heart. Since the authors found duration of anesthesia to be an independent risk factor for ischemic optic neuropathy in this population, it may be prudent to work with the spine surgeons to determine if there is merit to limiting the duration of surgeries that are anticipated to be prolonged, especially 6 hours or longer. Staging these procedures may be helpful.

## **Neck Problems**

Anesthesia impairs reflex muscle spasm that protects the skeleton against motion that would be painful if the patient were alert. Lateral rotation of the head and neck of an anesthetized, pronated patient, particularly one with an arthritic cervical spine, can stretch relaxed skeletal muscles and ligaments and injure articulations of cervical vertebrae. Postoperative neck pain and limitation of motion can result. The arthritic neck is usually best managed by keeping the head in the sagittal plane when the patient is prone.

Extremes of head and neck rotation can also interfere with flow in either the ipsilateral or contralateral vessels to and from the head. Excessive head rotation can reduce flow in both the carotid<sup>47</sup> and vertebral systems.<sup>48</sup> Impaired cerebral perfusion is the obvious consequence.

## **Brachial Plexus Injuries**

Stretch injuries to the roots of the brachial plexus ([Fig. 29-16A](#)) on the side contralateral to the turned face are possible if the contralateral shoulder is

held firmly caudad by a wrist restraint. If an arm is placed on an arm board alongside the head, care must be taken to ensure that the head of the humerus is not stretching and compressing the axillary neurovascular bundle (Fig. 29-16B,C).

When an arm is placed on an arm board alongside the head, the forearm naturally pronates. As a result, the ulnar nerve, lying in the cubital tunnel (the groove between the olecranon process and the medial epicondyle of the humerus), is vulnerable to being compressed by the weight of the elbow (Fig. 29-16D). Consequently, the medial aspect of the elbow must be well padded and its weight borne across a large area to avoid point pressure.

Asking patients about their ability to work or sleep with arms elevated overhead may identify patients with *thoracic outlet obstruction*. A useful preoperative test if the history is in question is to have the patient clasp hands behind the occiput during the interview. If the patient describes dysesthesias, it may be prudent to keep the arms alongside the trunk in the prone position. Agonizing, debilitating, and unremitting postoperative pain has been known to follow overhead arm placement in pronated patients who have had prior discomfort in their arms in that position.

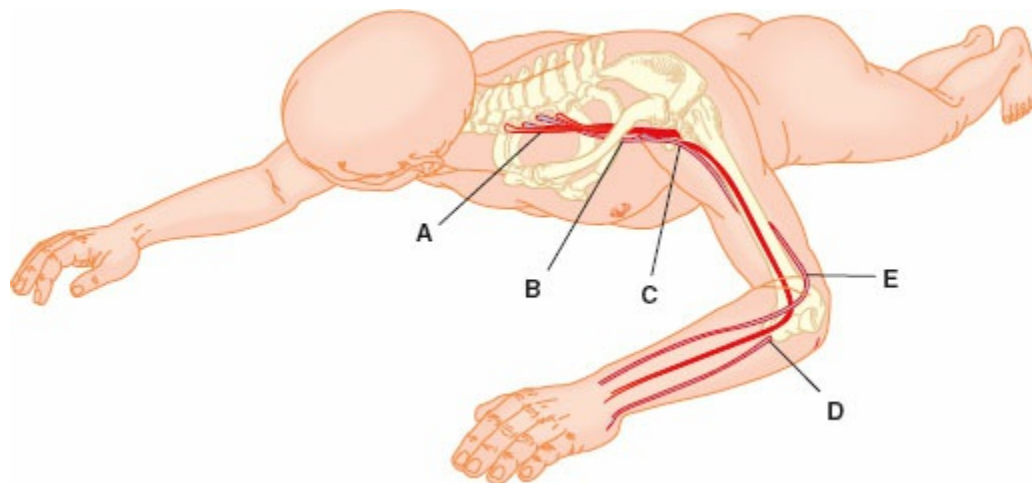

## **Breast Injuries**

The breasts of a pronated woman, if forced laterally or medially by chest and abdominal wall supports, can be stretched and injured along their sternal borders. Direct pressure on breasts (particularly if breast prostheses are present) can cause ischemia to breast tissue and should be avoided. Multiple cases of breast tissue ischemia have been reported, often resulting in mastectomy and the need for reconstruction.

## **Abdominal Compression**

Compression of the abdomen by the weight of the prone patient's trunk can cause viscera to force the diaphragm cephalad enough to impair ventilation. If intra-abdominal pressure approaches or exceeds venous pressure, return of blood from the pelvis and lower extremities is reduced or obstructed. Because the vertebral venous plexuses communicate directly with the abdominal veins, increased intra-abdominal pressure is transmitted to the perivertebral and intraspinal surgical field in the form of venous distention and increased difficulty with hemostasis. All of the various supportive pads and frames, when properly used, are designed to remove pressure from the abdomen and avoid these problems.

**Figure 29-16** Sources of potential injury to the brachial plexus and its peripheral components when the patient is in the prone position. **A:** Neck rotation, stretching roots of the plexus. **B:** Compression of the plexus and vessels between the clavicle and first rib. **C:** Injury to the axillary neurovascular bundle from the head of the humerus. **D:** Compression of the ulnar nerve before, beyond, and within the cubital tunnel. **E:** Area of vulnerability of the radial nerve to lateral compression proximal to the elbow.

## Stoma and Genitals

Stoma that drain visceral contents through the abdominal wall are at risk in the prone position if they lie against a part of any supporting frame or pad.

**6** Compressive ischemia of the stomal orifice can cause it to slough. The same issue is present for genitals, especially the penis and scrotum of men turned prone.

## Head-elevated Positions

### Variations of Head-elevated Positions

#### Sitting

 The classic *sitting position* for surgery places the patient in a semireclining posture on an operating table, with the legs elevated to approximately the level of the heart and the head flexed ventrally on the neck (Fig. 29-17). Head flexion should not be sufficient to force the chin into the suprasternal notch (see “Midcervical Tetraplegia”). Elastic stockings or compressive wraps around the legs reduce pooling of blood in the lower extremities. The head often is held in place by some type of a face rest or by a three-pin skull fixation frame.

#### Supine—Tilted Head Up

A supine recumbent position with the head of the patient elevated is used for many operations involving the ventral and lateral aspects of the head (Fig.

29-18) and neck, and occasionally with the neck flexed, for transcranial access to the top of the brain. Its purpose is to improve access to the surgical target for the operating team as well as to drain blood and irrigation solutions away from the wound. The back section of the surgical table can be elevated as needed to produce a low sitting position (Fig. 29-18A) or the entire table can be rotated head-high with the patient's extended legs supported by a foot rest (Fig. 29-18B). Although the degree of tilt typically is not great, small pressure gradients are created along the vascular axis that can pool blood in the lower extremities or entrain air in patulous vessels that are incised above the level of the heart.

For operations around the shoulder joint, the patient may be placed in a head-elevated semisupine position (Fig. 29-19). The upper trunk typically is moved laterally until the raised surgical shoulder extends beyond the edge of the operating table. The torso is supported so that the hips are on the table, the surgical shoulder is off and above the table edge, and the head rests on either a pillow (Fig. 29-19A) or a headrest (Fig. 29-19B). Access is thereby provided to both the dorsal and ventral aspects of the shoulder girdle. The surgical arm remains on the front of the torso and is prepared and draped to be mobile in the surgical field.

### **Lateral—Tilted Head Up**

The lateral position with the head somewhat elevated, a means of access to occipitocervical lesions, has also been referred to as the *park bench position*. All the stabilizing requirements needed for the usual lateral position apply. The head may be held firmly in a three-pin skull fixation holder, which can be readjusted as needed during surgery, or supported by pillows or padding. Although the degree of head elevation used typically is less than 15 degrees, the position does not completely remove the threat of air embolization. The anesthesiologist has good access to the patient's face and thorax for purposes of monitoring, manipulation, and resuscitation. Considerable attention should be directed to avoiding compression of neck veins, which can lead to an increase in intracranial pressure and to edema of the tongue.

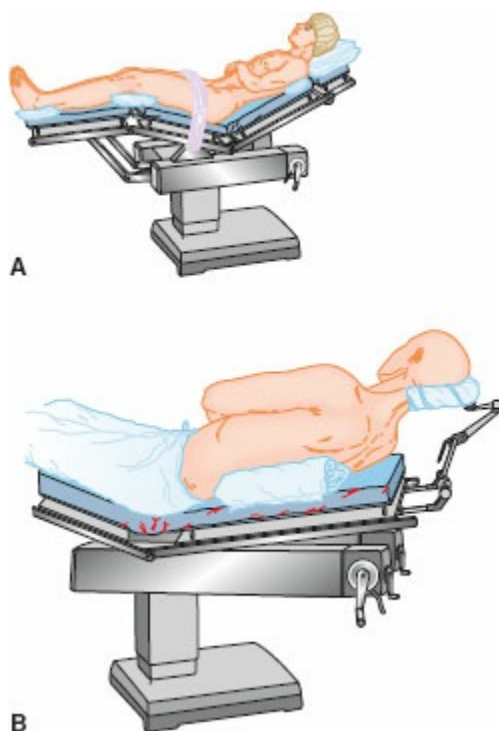

**Figure 29-17** **A:** Conventional neurosurgical sitting position. The legs are at approximately the level of the heart and gently flexed on the thighs; the feet are supported at right angles to the legs; subgluteal padding protects the sciatic nerve. The frame of the head holder is *properly* clamped to the side rails of the back section in the event of hemodynamically significant air embolism. **B:** *Improper* attachment of the head frame to the table side rails at the thigh section. In this position, the patient's head could not be quickly lowered because it would require disengaging the skull clamp.

**Figure 29-18** Head-elevated positions often used for operations about the ventral and

ventrolateral aspects of the head, face, neck, and cervical spine. **A:** The legs are at approximately heart level and the gradient into the head is appreciable but slight. **B:** The flat table and foot rest are useful when a thyroidectomy is planned under regional anesthesia.

**Figure 29-19** **A:** The lawn chair position for surgery around the shoulder joint. **B:** The upper torso is rotated toward the nonsurgical shoulder and supported with a firm roll or pad.

## *Complications of Head-elevated Positions*

### **Postural Hypotension**

In the anesthetized patient, establishing any of the head-elevated positions is frequently accompanied by some degree of reduction in systemic blood pressure. The normal protective reflexes are inhibited by drugs used during anesthesia. Measuring mean arterial pressures at the level of the circle of Willis is recommended by many to assess cerebral perfusion pressures more accurately. This recommendation, however, is controversial.<sup>49–53</sup>

### **Air Embolus**

Air embolization is potentially lethal. In the bloodstream, air migrates to the heart, where it creates a compressible foam that destroys the propulsive efficiency of ventricular contraction and irritates the conduction system. Air can also move into the pulmonary vasculature, where bubbles obstruct small vessels and compromise gas exchange, or it can cross through a patent foramen ovale to the left side of the heart and the systemic circulation.

The potential for venous air embolization increases with the degree of elevation of the operative site above the heart. Although the occurrence of air emboli is a relatively frequent phenomenon in head-elevated positions, most of the emboli are small in volume, clinically silent, and recognizable only by sophisticated Doppler detection or echocardiographic (e.g., transesophageal) techniques. Nevertheless, the potential for dangerous accumulations of entrained air requires immediate detection of the embolization, a careful search for its portal of entry, and prompt treatment of its clinical effects.

### **Edema of the Face, Tongue, and Neck**

Severe postoperative macroglossia, apparently because of venous and lymphatic obstruction, can be caused by prolonged, marked neck flexion. Postoperative need for a tracheostomy has been reported. Try to avoid placing the patient's chin firmly against the chest and use an oral airway to protect the endotracheal tube. Extremes of neck flexion, with or without head rotation, have been widely used to gain access to structures in the posterior fossa and cervical spine, but their potential for damage should be understood and excessive flexion-rotation avoided if possible. Moore et al.<sup>54</sup> have suggested that the primary mechanism may be neurologically determined rather than being the result of either vascular obstruction or local trauma. This problem also has been described with the use of transesophageal echocardiography probes.

### **Midcervical Tetraplegia**

This devastating injury occurs after hyperflexion of the neck, with or without rotation of the head, and is attributed to stretching of the spinal cord with resulting compromise of its vasculature in the midcervical area. An element of spondylosis or a spondylotic bar may be involved.<sup>55,56</sup> The result is paralysis below the general level of the fifth cervical vertebra. Although most reports in the literature have described the condition as occurring after the use of the sitting position, midcervical tetraplegia has also occurred after prolonged, nonforced head flexion for intracranial surgery in the supine position.

### **Sciatic Nerve Injury**

Stretch injuries of the sciatic nerve can occur in some seated patients if the hips are markedly flexed without bending the knees. Prolonged compression of the sciatic nerve as it emerges from the pelvis is possible in a thin seated patient if the buttocks are not suitably padded. Foot drop may be the result of injuries to either the sciatic nerve or the common peroneal nerve and can be

bilateral.

## Head-down Positions

The introduction of robotic procedures has resulted in an increased use of head-down positions. The great majority of robotic procedures early in the introduction of the technology have involved prostatectomies, colorectal, and gynecologic procedures. Thus, most of these initial procedures and the experience gained with robotic procedures have been performed in the pelvis and lower abdomen. As with any introduction of new technology, there is a steep learning curve for the operators. Typically, early adopters of robotic technology have requested steep head-down positions of supine patients. These steep head-down positions have resulted in a variety of complications that challenge anesthesia providers and patients.

### *Complications of Head-down Positions*

#### **Head and Neck Injury**

During the years coincident with the introduction of robotic surgery techniques, several patients have suffered severe injury and have even died from body shifts on operating room tables that have been tilted severely head-down. There are several anecdotes from medicolegal actions involving patients who slid off operating tables with resulting neck injuries. In one instance, a patient in a supine and very steep head-down position apparently somersaulted heels over head off of the operating room table and subsequently died from a massive intracranial bleed. Steep head-down tilt is not often warranted and should be actively discouraged when appropriate. Skilled operators often find that they need less steep head-down tilt as they gain experience and expertise with robotic procedures.

#### **Brachial Plexopathy**

There is a risk of brachial injuries associated with cephalad movement of the patient while the arms or shoulders are secured to the table with retention materials or shoulder braces. Cephalad movement when arms are fixated or when shoulder restraints with braces, tape, “bean bag” devices, or other torso restraints are used may result in stretch of the middle and lower divisions of the brachial plexus. If the cephalad movement results in a relative hyperabduction of the shoulder to greater than 90 degrees, the brachial plexus can be stretched as it courses distally around the hyperabducted head of the humerus.

Depending on the degree of head depression, the addition of tilt to the

lithotomy position combines the worst features of both the lithotomy and the head-down postures. The weight of abdominal viscera on the diaphragm adds to whatever abdominal compression is produced by the flexed thighs of an obese patient or of one placed in an exaggerated lithotomy position. Ventilation should be assisted or controlled. Because elevation of the lower extremities above the heart produces an uphill perfusion gradient, systemic hypotension and compressive leg wrapping may limit perfusion to the periphery, and both can be factors in the development of compartment syndromes in the legs of patients in the lithotomy position. This perfusion gradient often is unpredictable and exaggerated, potentially increasing the risk of compartment syndrome.<sup>9,10</sup>

Cephalad displacement of the diaphragm and obstruction of its caudad inspiratory stroke accompany a head-down position because of gravity-shifted abdominal viscera. Consequently, the work of spontaneous ventilation is increased for an anesthetized patient in a posture that already worsens the ventilation–perfusion ratio by gravitational accumulation of blood in the poorly ventilated lung apices. During controlled ventilation, higher inspiratory pressures are needed to expand the lung.

Cranial vascular congestion and increased intracranial pressure can be expected to result from head-down tilt. For patients with known or suspected intracranial disease, the position should be used only in those rare instances in which a surgically useful alternate posture cannot be found. Maintenance of the position should then be as brief as possible.<sup>57,58</sup>

Steep head-down tilt positions (e.g., 30 to 45 degrees of head-down tilt) may require some means of preventing the patient from sliding cephalad out of position. The use of bent knees is occasionally used to retain the tilted patient in position (Fig. 29-20). Historically, shoulder braces, straps, or tape also have been used to prevent cephalad sliding in steep head-down tilt positions. These are best tolerated if placed over the acromioclavicular joints, but care must be taken to see that the shoulder is not forced sufficiently caudad to trap and compress the subclavian neurovascular bundle between the clavicle and the first rib. If they are placed medially against the root of the neck, they may easily compress neurovascular structures that emerge from the area of the scalene musculature. For these and other reasons, the use of shoulder braces and other retaining approaches have waned in popularity. In general, the use of steep head-down positions should be limited to only those portions of procedures in which their use is most important.<sup>57,58</sup>

**Figure 29-20** Head-down tilt. *Lower figure* shows traditional steep (30- to 45-degree) tilt. Leg restraints and knee flexion stabilize the patient, avoiding the need for wristlets or shoulder braces that threaten the brachial plexus. *Upper figure* shows 10 to 15 degrees of head-down tilt.

## Summary

There are many ways that patients can be injured during surgical procedures. Careful consideration of intraoperative and postoperative positioning may help reduce the frequency and severity of perioperative positioning-related events. Although many problems that appear to be related to perioperative positioning may seem simple and preventable, the etiologic mechanisms of many of these problems are not readily apparent. Much work still remains to determine the role of other potential etiologies, such as perioperative inflammatory responses, immunosuppression, and virus activation, on the development of these problems.

## Conclusion

### KEY POINTS

- 1 The standards for preoperative evaluation, intraoperative monitoring, and the continuous presence of a member of the anesthesia care team are no different from those for general or regional anesthesia.
- 2 As a general principle, to avoid excessive levels of sedation, drugs should be titrated in small increments or by adjustable infusions rather than administered in larger doses according to predetermined notions of efficacy.
- 3 At the present time, no single drug can provide all the components of monitored anesthesia care (i.e., analgesia, anxiolysis, and hypnosis) with an acceptable margin of safety or ease of titratability.
- 4 Excessive sedation leading to respiratory compromise is the most common cause of death or central nervous system injury during MAC.
- 5 The important mechanisms whereby respiratory function may be compromised during monitored anesthesia care include the effects of sedatives and opioids on respiratory drive, upper airway patency, and protective airway reflexes.
- 6 Burns, particularly around the head and neck, are an important cause of patient injury during MAC. The combination of electrocautery, supplemental oxygen, alcohol prep, and flammable drapes is particularly dangerous.
- 7 If anesthesiologists are not willing or able to provide MAC or sedation/analgesia services, others, who are less qualified, are prepared to assume that role.

Monitored anesthesia care is a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure and includes all the usual aspects of anesthetic care—a preprocedure evaluation, intraprocedure care, and postprocedure management. *Monitored anesthesia care does not describe the continuum of depth of sedation.* During monitored anesthesia care, the continuous attention of the anesthesiologist is directed at optimizing patient comfort and safety. Monitored anesthesia care usually (but not always) involves the administration of drugs with anxiolytic, hypnotic, analgesic, and

amnestic properties, either alone or as a supplement to a local or regional technique. Monitored anesthesia care is provided by a Physician Anesthesiologist, thus can safely encompass the complete spectrum of sedation from light sedation/analgesia to conversion to general anesthesia if required. The American Society of Anesthesiologists (ASA) has published several position statements, guidelines, and advisories on various topics that relate to monitored anesthesia care and moderate sedation. These are listed in [Table 30-1](#) and are a well worth reviewing.

## Terminology

It is important to distinguish between the terms “monitored anesthesia care” and “moderate sedation/analgesia.” In October 2013, the ASA House of Delegates reaffirmed the statement titled “Distinguishing Monitored Anesthesia Care from Moderate Sedation/Analgesia.”<sup>1</sup>

Moderate sedation/analgesia is the term used by the ASA in their published *Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists*.<sup>2</sup> During moderate sedation (conscious sedation), care need not be provided by an anesthesiologist and a full anesthetic preoperative evaluation is typically not performed. Sedation/analgesia provided by nonanesthesia providers should not intend to attain a level of sedation in which the patient is unresponsive. Monitored anesthesia care implies the potential for a deeper level of sedation than that provided by **1** sedation/analgesia and is always administered or medically directed by an anesthesiologist. The provider of MAC is prepared and qualified to convert to a general anesthetic if and when necessary. The standards for preoperative evaluation, intraoperative monitoring, and the continuous presence of a member of the anesthesia care team are no different from those for general or regional anesthesia.<sup>3</sup>

Title of ASA Statement, Guideline, or Advisory	Date of Publication
Position on Monitored Anesthesia Care	October 2013
Statement on Anesthesia Care for Endoscopies	October 2014
Statement on Granting Privileges to Non-anesthesiologist Physicians for Personally Administering or Supervising Deep Sedation	October 2012
Statement on Granting Privileges for Administration of Moderate Sedation to Practitioners who are not Anesthesiologists	October 2011
Advisory on Granting Privileges for Deep Sedation to Non-anesthesiologist Sedation Practitioners	October 2010
Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists	April 2002
Continuum of Depth of Sedation: Definition of General Anesthesia and levels of Sedation/Analgesia	October 2014
Statement on Safe Use of Propofol	October 2014
Distinguishing Monitored Anesthesia Care (MAC) from Moderate Sedation/Analgesia (Conscious Sedation)	October 2013
Guidance for Directors of Anesthesia Services for Computer-Assisted Personalized Sedation Devices	January 2014

Conceptually, monitored anesthesia care utilizing sedation rather than general anesthesia is attractive because it should invoke less physiologic disturbance and allow a more rapid recovery than general anesthesia. It is instructive to review the ASA position statement that defines monitored anesthesia care<sup>3</sup>:

*Monitored anesthesia care is a specific anesthesia service for a diagnostic or therapeutic procedure. Indications for monitored anesthesia care include the nature of the procedure, the patient's clinical condition, and/or the potential need to convert to a general or regional anesthetic.*

*Monitored anesthesia care includes all aspects of anesthesia care—a preprocedure visit, intraprocedure care, and postprocedure anesthesia management. During monitored anesthesia care, the anesthesiologist provides or medically directs a number of specific services, including but not limited to:*

- *Diagnosis and treatment of clinical problems that occur during the procedure*
- *Support of vital functions*
- *Administration of sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary for patient safety*
- *Psychological support and physical comfort*
- *Provision of other medical services as needed to complete the procedure safely.*

*Monitored anesthesia care may include varying levels of sedation, analgesia, and anxiolysis as necessary. The provider of monitored anesthesia care must be prepared and qualified to convert to general anesthesia when necessary. If the patient loses consciousness and the ability to respond purposefully, the anesthesia care is a general anesthetic, irrespective of whether airway instrumentation is required.*

*Monitored anesthesia care is a physician service provided to an individual*

*patient. It should be subject to the same level of payment as general or regional anesthesia. Accordingly, the ASA Relative Value Guide provides for the use of proper base procedural units, time units, and modifier units as the basis for determining payment. \**

The ASA also states that monitored anesthesia care should be requested by the attending physician and be made known to the patient, in accordance with accepted procedures of the institution. In addition, the ASA states that the service must include the following:

- Performance of a preanesthetic examination and evaluation
- Prescription of anesthetic care
- Personal participation in, or medical direction of, the entire plan of care
- Continuous physical presence of the anesthesiologist or, in the case of medical direction, of the resident or nurse anesthetist being medically directed
- Proximate presence, or in the case of medical direction, availability of the anesthesiologist for diagnosis and treatment of emergencies

Furthermore, the ASA states that all institutional regulations pertaining to anesthesia services shall be observed, and all the usual services performed by the anesthesiologist shall be furnished, including but not limited to:

- Usual noninvasive cardiocirculatory and respiratory monitoring
- Oxygen administration, when indicated
- Administration of sedatives, tranquilizers, antiemetics, narcotics, other analgesics,  $\beta$ -blockers, vasopressors, bronchodilators, antihypertensives, or other pharmacologic therapy as may be required in the judgment of the anesthesiologist

## **Preoperative Assessment**

The preoperative evaluation is an essential prerequisite to monitored anesthesia care and should be as comprehensive as that performed prior to any general or regional anesthetic (see [Chapter 23](#)). However, in addition to the usual evaluation for the patient who is scheduled to undergo general anesthesia, there are additional considerations unique to the monitored anesthesia care that may ultimately determine the success or failure of the procedure. It is important to evaluate the patient's ability to remain motionless and, if necessary, actively cooperate throughout the procedure. Thus, it is important to evaluate the patient's psychological preparation for the planned procedure. It is also important to elicit the presence of coexisting sensorineural or cognitive deficits. These factors or the inability to communicate with the patient may occasionally make general anesthesia a more appropriate alternative. Verbal communication between physician and

patient is very important for three reasons: as a monitor of the level of sedation and cardiorespiratory function, as a means of explanation and reassurance for the patient, and as a mechanism of communication when the patient is required to actively cooperate. Although cardiorespiratory disease is often cited as an indication to perform a procedure using monitored anesthesia care rather than general anesthesia, there are occasions when cardiorespiratory disease may reduce the utility of monitored anesthesia care. For example, the presence of a persistent cough may make it very difficult for the patient to remain immobile, which can be particularly dangerous during ophthalmologic or awake neurosurgical procedures. Attempts to attenuate coughing with sedation techniques are likely to be unsuccessful and potentially harmful because a significant level of anesthesia is required to abolish the cough reflex. Similarly, some patients with significant cardiovascular or pulmonary disease may be unable to lie flat for an extended period.

## **Techniques of Monitored Anesthesia Care**

A variety of medications are commonly administered during monitored anesthesia care with the desired end points to provide patient comfort, maintain cardiorespiratory stability, improve operating conditions, and prevent recall of unpleasant perioperative events. It is helpful to delineate and individualize the goals for each patient in order to formulate an appropriate regimen, which frequently involves the administration of either individual or combinations of analgesic, amnestic, and hypnotic drugs. There should be a minimal incidence of side effects, such as cardiorespiratory depression, nausea and vomiting, delayed emergence, and dysphoria, and there should be a rapid and complete recovery. Ideally, the patient should be able to communicate during the procedure. Clinical experience suggests that a level of sedation that allows verbal communication is optimal for the patient's comfort and safety. If the level of sedation is deepened to the extent that verbal communication is lost, the risks of the technique approach those of general anesthesia with an unprotected and uncontrolled airway. However, because monitored anesthesia care is provided by anesthesiologists, the range of sedation may include deeper sedation techniques than those provided by nonanesthesiologists during sedation/analgesia.

The preanesthetic evaluation and plan should identify specific causes and provide specific therapy for pain, anxiety, and agitation. Pain may be treated by local or regional analgesia, systemic analgesics, or removal of the painful stimulus. Anxiety may be reduced by the use of an anxiolytic such as a benzodiazepine and reassurance by the anesthesiologist. Patient agitation may be a result of pain or anxiety or life-threatening factors such as hypoxia,

hypercarbia, impending local anesthetic toxicity, and cerebral hypoperfusion. Other causes of pain and agitation include a distended bladder, hypothermia, hyperthermia, pruritus, nausea, positional discomfort, uncomfortable oxygen masks and nasal cannulae, intravenous (IV) cannulation site infiltration, a member of the surgical team leaning on the patient, and prolonged pneumatic tourniquet inflation.

## Pharmacologic Basis of Monitored Anesthesia Care Techniques: Optimizing Drug Administration

The ability to predict the effects of the drugs in our armamentarium demands an understanding of their pharmacokinetic and pharmacodynamic properties. This understanding is a fundamental prerequisite for the design of an effective sedation regimen and greatly increases the probability of producing the desired therapeutic effect. Context-sensitive half-time, effect site equilibration time, and anesthetic/sedative drug interactions are fundamental concepts that are particularly useful in the context of monitored anesthesia care and are discussed in more detail in other chapters of this book.

The ultimate objective of any dosing regimen is to deliver a therapeutic concentration of drug to its site of action, which is determined by the unique pharmacokinetic properties of that drug in that particular patient. The therapeutic response to a particular drug concentration is described by the pharmacodynamics of that particular patient–drug combination. There is a large degree of pharmacokinetic and pharmacodynamic variability, producing a significant variability in the dose–response relationship in clinical practice. Excessive sedation may result in cardiac or respiratory depression. Inadequate sedation may result in patient discomfort and potential morbidity from 2 lack of cooperation. As a general principle, to avoid excessive levels of sedation, drugs should be titrated in small increments or by adjustable infusions rather than administered in larger doses according to predetermined notions of efficacy.<sup>4</sup> In an ideal dosing regimen, an effective concentration of drug is achieved and then adjusted according to the magnitude of the noxious stimulus. If the noxious stimulus is increased or decreased, the concentration is increased or decreased accordingly. By the end of the procedure, the drug concentration should have decreased to a level compatible with rapid recovery. This approach requires the easily titratable drugs such as propofol. When using drugs such as propofol, adjustable-rate continuous infusions ▶ 1 are the most logical method of maintaining a desired therapeutic concentration. If intermittent bolus administration is used, significant fluctuations in drug concentration occur. Under these circumstances, the plasma concentrations are either above or below the desired therapeutic range for a significant proportion of the procedure (Fig. 30-1). Continuous

infusions are generally superior to intermittent bolus dosing because they produce less fluctuation in drug concentration, thus reducing the number of episodes of inadequate or excessive sedation. Administration of drugs by continuous infusion rather than by intermittent dosing also reduces the total amount of drug administered and facilitates a more prompt recovery.<sup>5</sup>

## Distribution, Elimination, Accumulation, and Duration of Action

Following the administration of IV anesthetic drugs, the immediate distribution phase causes a brisk decrease in plasma levels as the drug is transported to the rapidly equilibrating vessel-rich group of tissues. There is a simultaneously occurring distribution of drug to the less well-perfused tissues such as muscle and skin. Over time, the drug is also distributed to the poorly perfused tissues such as bone and fat. Although the latter compartments are poorly perfused, they may accumulate significant amounts of lipophilic drugs during prolonged administration. This peripheral depot may contribute to a delayed recovery when the drug is eventually released back into the central compartment after its administration is discontinued. Redistributive factors are important determinants of drug effect and influence the plasma concentration of a drug in a time-dependent fashion.

**Figure 30-1** The changes in drug concentration during differing administration techniques. The *green line* represents a continuous infusion of a drug. In this situation the drug is maintained within the therapeutic range for most of the procedure. The *orange line* represents the drug concentration resulting from intermittent bolus administration. The drug concentration is significantly above or below the desired therapeutic level for most of the procedure.

### Elimination Half-life

Until recently, the elimination half-time was the predominant

pharmacokinetic parameter used as the predictor of an anesthetic drug's duration of action. In everyday clinical practice, however, this parameter does not greatly enhance our ability to predict anesthetic drug disposition. Only in single-compartment models does the elimination half-time actually represent the time required for a drug to reach half of its initial concentration after administration. In a single-compartment model, elimination is the only process that can alter drug concentration. Intercompartmental distribution cannot occur because there are no other compartments for the drug to be distributed to and from. Most drugs in the anesthesiologist's armamentarium are lipophilic and are, therefore, more suited to multicompartmental modeling than single-compartment modeling. Similarly, other pharmacokinetic parameters, such as distribution half-time, distribution volume, intercompartmental rate constants, and so forth, do not provide us with a practical means of predicting drug disposition. In multicompartmental models, the metabolism and excretion of some IV anesthetic drugs may have only a minor contribution to the changes in plasma concentration when compared with the effects of intercompartmental distribution.

### ***Context-sensitive Half-time***

The concept of context-sensitive half-time was developed to improve the description and understanding of anesthetic drug disposition.<sup>6</sup> This concept has greatly improved our understanding of anesthetic drug disposition and is clinically applicable. The effect of distribution on plasma drug concentration varies in magnitude and direction over time and depends on the drug concentration gradients that exist between the various compartments. For example, during the early part of an infusion of a lipophilic drug, distributive factors will tend to decrease plasma concentrations as the drug is transported to the unsaturated peripheral tissues. Later, after the infusion is discontinued, drug will return from the peripheral tissues and re-enter the central circulation. The relative effect on plasma concentrations of distributive processes versus elimination varies over time and from drug to drug. The context-sensitive half-time describes the time required for the plasma drug concentration to decline by 50% after terminating an infusion of a particular duration.<sup>7</sup> This parameter is calculated by using computer simulation of multicompartmental models of drug disposition (Fig. 30-2). The context-sensitive half-time reflects the combined effects of distribution and metabolism on drug disposition. There are several interesting aspects of these data. First, the data confirm the clinical impression that as the infusion duration increases, the context-sensitive half-time of all the drugs increases; this phenomenon is not described in any way by the elimination half-life. The increase in context-sensitive half-time is particularly marked with fentanyl

and thiopental. In the case of fentanyl, drug that is irreversibly eliminated from the plasma by hepatic clearance is immediately replaced by drug returning from the peripheral compartments. Thus, although fentanyl has a shorter *elimination* half-life than that of sufentanil (462 vs. 577 minutes), its *context-sensitive* half-time is much greater than that of sufentanil after an infusion of longer than 2 hours. The storage and later release of fentanyl from peripheral binding sites delay the decline in plasma concentration that would otherwise occur. *The context-sensitive half-times of all the drugs bear no constant relationship to their elimination half-times.* For example, compare also the context-sensitive half-times of propofol and thiopental (Fig. 30-2). Although the context-sensitive half-times of propofol and thiopental are comparable following a brief infusion, the context-sensitive half-time of thiopental increases rapidly following all but the shortest infusions. This finding confirms the clinical impression that thiopental is not an ideal drug for continuous infusion during ambulatory procedures. The context-sensitive half-time of propofol is prolonged to a minimal extent as the infusion duration increases. After an infusion of propofol, the drug that returns to the plasma from the peripheral compartments is rapidly cleared by metabolic processes and is, therefore, not available to retard the decay in plasma levels. This difference between thiopental and propofol is attributable to (1) the high metabolic clearance of propofol compared with thiopental, and (2) the relatively slow rate at which propofol returns to the plasma from peripheral compartments.

**Figure 30-2** Context-sensitive half-time as a function of infusion duration. These data were generated from the computer model of Hughes et al.<sup>5</sup> It can be seen that the context-sensitive half-time of propofol demonstrates a minimal increase as the duration of the infusion increases. Also note that for infusions of short duration, sufentanil has a shorter half-time than alfentanil. (Reproduced with permission from Hughes MA, Glass PSA, Jacobs JR. Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology*. 1992;76:334, with permission.)

Alfentanil is the opioid that was, until the introduction of remifentanil, frequently studied, described, and promoted in the context of ambulatory techniques. Alfentanil has a very short elimination half-time, one-fifth that of sufentanil (111 vs. 577 minutes). However, despite the longer elimination half-time of sufentanil, its context-sensitive half-time is actually less than that of alfentanil for infusions up to 8 hours in duration. This phenomenon is explained in part by the huge distribution volume of sufentanil. After termination of a sufentanil infusion, the decay in plasma drug concentrations is accelerated not only by elimination but also by the continued redistribution of sufentanil into peripheral compartments. On the other hand, the small distribution volume of alfentanil equilibrates rapidly; therefore, peripheral distribution of drug away from the plasma is not a significant contributor to the decay in plasma concentration after an infusion. The data derived from computer simulation by Hughes et al.<sup>6</sup> show that the plasma decay of alfentanil is slower than that of sufentanil following infusions of similar duration to those used during conscious sedation. Thus, despite its short elimination half-time, alfentanil may not necessarily be superior to sufentanil.<sup>8</sup>

### **How Does the Context-sensitive Half-time Relate to the Time to Recovery?**

Although the context-sensitive half-time represents a significant advance in our ability to describe drug disposition, this parameter does not directly describe how long it will take the patient to recover from monitored anesthesia care. The context-sensitive half-time merely describes how long it will take for the plasma concentration of the drug to decrease by 50%. The time to recovery depends on other additional factors. The difference between the plasma concentration at the end of the infusion and the plasma concentration below which awakening can be expected is an obvious factor in determining time to recovery. For example, if the drug concentration is maintained at a level just above that required for awakening, the time to recovery will be more rapid than after an infusion during which the drug concentration is much greater than that required for awakening (Fig. 30-3). Furthermore, although context-sensitive half-time is a reflection of plasma drug decay, awakening from anesthesia is actually a function of effect site (i.e., brain) concentration decay. Changes in effect site concentration demonstrate a variable time lag behind changes in plasma drug concentration. Effect site equilibration is a concept that is particularly relevant to IV sedation. When a drug is administered intravenously by bolus or infused rapidly, there is a delay before the onset of clinical effect. This delay occurs because the plasma is not usually the site of action but is merely the route by

which the drug reaches its effect site. If some parameter of drug effect can be measured (e.g., power spectrum electroencephalographic [EEG] analysis in the case of opioids), the half-time of equilibration between drug concentration in the blood and the drug effect can then be determined.<sup>9</sup> This parameter is abbreviated  $t_{1/2ke0}$ . Drugs with a short  $t_{1/2ke0}$  will equilibrate rapidly with the brain and have a shorter delay in onset than drugs that have a longer  $t_{1/2ke0}$ . Thiopental, propofol, and alfentanil have short  $t_{1/2ke0}$  values compared with midazolam, sufentanil, and fentanyl.

**Figure 30-3** The context-sensitive half-time is not the sole determinant of the time it takes for the patient to awaken. This parameter merely reflects the time taken for the plasma concentration of a drug to decrease by 50%. The time to awakening is determined in addition by the difference in concentration at the end of the procedure and the concentration below which awakening will occur.

The  $t_{1/2ke0}$  allows predictions to be made of the time course of equilibration of the drug between the blood and the brain. A distinct time lag between the peak serum fentanyl concentration and the peak EEG slowing can be seen. In contrast, following alfentanil administration, the EEG changes closely parallel serum concentrations. The  $t_{1/2ke0}$  for fentanyl is 6.4 minutes compared with a  $t_{1/2ke0}$  of 1.1 minutes for alfentanil. Therefore, if an opioid is required to blunt the response to a single brief stimulus, alfentanil might represent a logical choice over fentanyl. The  $t_{1/2ke0}$  is an important determinant of bolus spacing when titrating drugs to clinical effect. In the case of drugs like midazolam and propofol, boluses of drug should be spaced far enough apart to allow the full peak effect to be clinically appreciated before further drug administration in order to avoid inadvertent overdosing.<sup>10-12</sup> For example, even if the shortest quoted equilibration half-time for midazolam (0.9 minutes) is used, it will take 2.7 (i.e., three half-times) minutes for effect site concentrations to be 87.5% equilibrated. Other factors are also important determinants of bolus size and spacing. For

example, a low cardiac output will markedly delay drug arrival at the site of action. If sufficient time is not given for the drug to take effect before giving additional drug increments, significant cardiorespiratory compromise may occur. Furthermore, the effects of initial doses of most drugs in anesthetic practice are terminated by redistribution, which depends on blood flow to redistribution sites. If there is reduced blood flow to redistribution sites because of pre-existing and iatrogenic decreases in cardiac output, the dangerous adverse effects of these drugs are likely to be both delayed and markedly prolonged. An example of this scenario is the patient with a hemodynamic compromise caused by a tachydysrhythmia who requires sedation for cardioversion. Careful, well-spaced, small boluses of drug should be given to induce the appropriate level of sedation, bearing in mind that it may take several minutes for the full effect of a small bolus dose to become apparent.

## Drug Interactions

At the present time, no single drug can provide all the components of monitored anesthesia care (i.e., analgesia, anxiolysis, and hypnosis) with an acceptable margin of safety or ease of titratability. Therefore, patient comfort is usually maintained with a combination of drugs. By acting synergistically, combinations of drugs enable reductions in the dose requirements of individual drugs. For example, the combination of propofol and fentanyl by infusion has been shown to produce a more rapid recovery and better stress response abolition than the use of propofol alone.<sup>13–15</sup> In addition, lower doses of each drug may reduce the untoward side effects associated with higher doses leading to increased patient satisfaction and decreased times to discharge. However, synergistic interaction may also extend to the undesirable interactions of the drugs such as cardiorespiratory depression.

Drug interactions may have both a pharmacodynamic and a pharmacokinetic basis and may vary depending on the combination of drugs being coadministered, the dose range over which these drugs are administered, and the specific clinical effect that is measured. For example, because fentanyl is primarily an analgesic rather than a hypnotic, it reduces propofol requirements for suppression of response to skin incision to a much greater degree than it reduces propofol requirements for induction of anesthesia.<sup>16</sup> On the other hand, because midazolam has significant hypnotic properties, it displays significant synergism with propofol or thiopental when used to induce hypnosis for prevention of movement in response to a painful stimulus.<sup>17–19</sup>

The plasma concentration of a drug at steady state that is required to abolish purposeful movement at skin incision in 50% of patients ( $C_{pss50}$ ) is a

measure of potency that is analogous to the familiar parameter of minimum alveolar concentration (MAC) of the volatile inhaled anesthetics. IV anesthetic interactions may be evaluated by their effect on the  $C_{pss50}$  in a manner analogous to the expression of the effects of opioids on volatile anesthetic requirements in terms of MAC reduction.<sup>20</sup> For example, during general anesthesia, opioid requirements to suppress the responses to noxious stimuli are tenfold higher when used as the sole agent compared with when they are used in conjunction with a nitrous oxide/potent inhaled vapor technique. This interaction persists at the lighter levels of anesthesia encountered during monitored anesthesia care. Therefore, it is likely that a rapid recovery would be facilitated by using opioids in combination with other agents (e.g., propofol/midazolam) rather than as the sole drug.

Drug interactions are dose dependent. For example, when fentanyl is combined with isoflurane, the greatest reduction in isoflurane MAC occurs within the analgesic concentration range of fentanyl (i.e., 1 to 2 ng/mL). At a fentanyl concentration of 1.7 ng/mL, the MAC of isoflurane is reduced by 50%.<sup>21</sup> Once the fentanyl concentration is increased beyond 3 ng/mL, there appears to be minimal further reduction with the largest MAC reduction of 80%. Likewise, the MAC of desflurane is reduced by approximately 50%, 25 minutes after a 3- $\mu$ g/kg IV bolus of fentanyl.<sup>22</sup> However, when the fentanyl bolus is increased to 6  $\mu$ g/kg, there is no significant further decrease in the MAC of desflurane. Studies with other opioids have yielded similar results.<sup>23–25</sup> The interactions between propofol and opioids are important because these agents are frequently used during monitored anesthesia care. When analgesic concentrations of fentanyl (0.6 ng/mL) are used in combination with propofol for anesthesia, the  $C_{pss50}$  of propofol is reduced by 50% compared with when propofol is used as the sole agent.<sup>17</sup> However, when the dose of fentanyl is increased, there is no significant further reduction of the  $C_{pss50}$  for propofol beyond a fentanyl concentration of 3 ng/mL.

Although the data presented here pertain to patients under general anesthesia, these findings have important implications for monitored anesthesia care. These studies demonstrate that the potentiating effects of opioids on coadministered sedatives are pronounced within the dose range commonly used during monitored anesthesia care. Furthermore, the data suggest that the dose–response curve is likely to be steep within this dose range, thus supporting the clinical impression that significant increases in depth of sedation can occur with only modest increments in opioid or hypnotic/sedative dosage. The following clinical recommendations can be made: During monitored anesthesia care, the maximum benefit of opioid supplementation, in terms of potentiation of other administered sedatives, will accrue when the opioid is used in the analgesic dose range. **3**

Within this dose range there is great potential for adverse cardiorespiratory interaction.

Opioid and benzodiazepine combinations are frequently used to achieve the components of hypnosis, amnesia, and analgesia. This drug combination displays marked synergism in producing hypnosis. Approximately 25% of the median effective dose for each individual drug is required in combination to induce hypnosis in 50% of patients.<sup>26</sup> If the combination were simply additive, hypnosis would be induced in only approximately 25% of patients. Even subanalgesic doses of alfentanil (3 µg/kg) produce a profound reduction in midazolam requirements for hypnosis.<sup>27</sup> This synergism also extends to the unwanted effects of these drugs, producing the life-threatening complications of respiratory and cardiac depression. Several fatalities have been reported after the use of midazolam, the majority of these being related to adverse respiratory events.<sup>28</sup> In many of these cases, midazolam was used in combination with an opioid. The effects of midazolam and fentanyl on respiratory function in healthy volunteers have been examined by Bailey et al.<sup>29</sup> Whereas midazolam produced no significant respiratory effects alone, and fentanyl alone produced hypoxemia (oxyhemoglobin saturation  $\leq 95\%$ ) in half of the subjects, the combination of midazolam 0.05 µg/kg and fentanyl 2 µg/kg resulted in hypoxemia in 11 of 12 subjects and apnea (no spontaneous respiratory effort for 15 seconds) in 6 of 12 subjects. The combination of midazolam and fentanyl places patients at high risk for developing hypoxemia and apnea. The respiratory depressant effects of this drug combination are likely to be even more significant in the patient with coexisting respiratory or central nervous system disease or at the extremes of age. In clinical practice, the clinical advantages of the synergy between opioids and benzodiazepines for the maintenance of patient comfort should be carefully weighed against the disadvantages of the potentially adverse effect of this drug combination on the cardiovascular and respiratory systems.

## Specific Drugs Used for Monitored Anesthesia Care

### *Propofol*

Propofol has become a popular choice for monitored anesthetic care due to its side effect profile and ease of titratability. Propofol has many of the ideal properties of a sedative–hypnotic for use in monitored anesthesia care. Its pharmacokinetic profile, that is, a context-sensitive half-time that remains short even after infusions of prolonged duration and a short effect site equilibration time, makes it an easily titratable drug with an excellent recovery profile. The quality of recovery and the low incidence of nausea and vomiting make propofol particularly well suited to ambulatory monitored

anesthesia care procedures. A significant body of experience with the use of propofol for monitored anesthesia care has emerged.

Propofol has significant advantages compared with benzodiazepines when used as the hypnotic component of a monitored anesthesia care technique. Although midazolam has a relatively short elimination half-time, its context-sensitive half-time is approximately twice that of propofol. Whereas propofol is noted for the rapid return to clear-headedness, midazolam is often associated with prolonged postoperative sedation and psychomotor impairment, particularly in the elderly. Propofol in typical moderate sedation doses (25 to 75  $\mu\text{g}/\text{kg}/\text{min}$ ) has minimal analgesic properties. On the other hand, the use of propofol as a component of general anesthesia has been associated with less postoperative pain and narcotic use when compared to isoflurane.<sup>30</sup> However, the unique advantages of propofol can be exploited to the maximum when propofol is used to provide sedation when the analgesic component is provided by a local or regional analgesic technique. The use of propofol (50 to 70  $\mu\text{g}/\text{kg}/\text{min}$ ) to provide sedation (defined as sleep with preservation of the eyelash reflex and purposeful reaction to verbal or mild physical stimulation) as an adjunct to spinal anesthesia for lower limb surgery has been examined.<sup>31-33</sup> After termination of infusions of approximately 100 minutes, patients regained consciousness in approximately 4 minutes. The authors also noted the ease with which general anesthesia could be induced if necessary by increasing the propofol infusion. The same group also compared propofol (60.5  $\mu\text{g}/\text{kg}/\text{min}$ ) with midazolam (4.3  $\mu\text{g}/\text{kg}/\text{min}$ ) as an adjunct to spinal anesthesia. The propofol group had faster immediate recovery than the midazolam group (2.3 vs. 9.2 minutes to spontaneous eye opening). Furthermore, psychomotor function was comparable with baseline values following propofol sedation but did not return to baseline until 2 hours after midazolam administration. Several studies comparing propofol and midazolam sedation for local and regional anesthesia demonstrated that propofol produced less postoperative sedation, drowsiness, confusion, and clumsiness than midazolam but the discharge times varied.<sup>34,35</sup>

General anesthesia with propofol is generally associated with less nausea and vomiting than most other anesthetic techniques.<sup>36-41</sup> There is growing evidence that even subhypnotic doses of propofol also possess direct antiemetic properties particularly when combined with an antiemetic in patients at risk for nausea and vomiting.<sup>42-45</sup> Thus, it is likely that the beneficial effects of propofol upon nausea and vomiting will be a feature of monitored anesthesia care techniques using this drug. On the other hand, even during low-dose infusions used for sedation, pain during injection of propofol may be troublesome in 33% to 50% of patients.<sup>35-46</sup> Several strategies for reducing the pain of propofol administration are described in [Table 30-2](#).<sup>47</sup>

## Fospropofol

Fospropofol, a prodrug of propofol, was approved in 2008 by the FDA for use during monitored anesthetic care in adults; however, this drug was not extensively used or studied and has now been withdrawn from the market in the United States. This phosphate ester prodrug is metabolized by endothelial cell alkaline phosphatases to propofol, formaldehyde, and phosphate.<sup>48–55</sup> The major advantage of fospropofol was a reduction in pain on injection compared to propofol. Other purported advantages were the lack of need for an infusion pump and avoidance of the lipid-emulsion related drug shortages seen with propofol. Theoretically, during a propofol shortage, fospropofol could be used for MAC sedation cases in adults, thus preserving the limited propofol supply for other cases. Unfortunately, the metabolism of fospropofol to its active metabolite, propofol, takes several minutes, resulting in a prolonged time to peak effect (1 to 8 minutes) compared to propofol and a slower recovery, making the optimal dosing technique somewhat different to that of propofol. The standard dosing regimen recommended by the manufacturer was an initial IV bolus dose of 6.5 mg/kg followed by supplemental doses of 1.6 mg/kg as needed. The initial dose should not exceed 16.5 mL; no supplemental bolus should exceed 4 mL. Supplemental doses should only be administered after patients can demonstrate movement upon command (verbal or tactile stimulation) and not more frequently than every 4 minutes to avoid dose stacking. The most common adverse effects reported included paresthesias described as a burning sensation in the perineal and perianal area, pruritus, hypoxemia, hypotension, and abdominal pain. These side effects occurred approximately 4 minutes after administration and may have been related to the phosphate metabolite.

**Table 30-2** Published Strategies for Reducing the Pain on Intravenous Injection of Propofol

- Using larger veins in antecubital fossa
- Decreasing the speed of injection
- Injection into a fast-running intravenous line
- Diluting with 5% glucose or 10% intralipid
- Adding lidocaine to propofol
- Pretreating with lidocaine and venous occlusion
- Pretreatment with opioid
- Pretreatment with pentothal
- Cooling propofol to 4°C prior to injection
- Injecting cooled saline (4°C) prior to injection
- Discontinuing intravenous fluid administration during injection
- Formulation in medium chain rather than long chain triglyceride

## Benzodiazepines

Benzodiazepines are commonly used during monitored anesthesia care for their anxiolytic, amnestic, and hypnotic properties. Patients presenting for diagnostic and surgical procedures frequently request some form of anxiolytic. Midazolam is usually administered prior to the start of the surgical or diagnostic procedures to facilitate amnesia and reduce the patient's level of anxiety. Compared to other benzodiazepines, midazolam's relatively short elimination half-life and decreased likelihood of concomitant drug interactions makes this a superior choice to other benzodiazepines. The important differences between midazolam and diazepam are listed in [Table 30-3](#).<sup>56</sup> Although midazolam has a short elimination half-time, there is often significant and prolonged psychomotor impairment following sedation techniques using midazolam as a significant component. With the recent availability of propofol, midazolam may be better used in a modified role by using lower doses prior to the start of a propofol infusion to provide the specific amnestic and perhaps anxiolytic component of a "balanced" sedation technique rather than as the major hypnotic component.<sup>57</sup> A study in healthy volunteers demonstrated that propofol reduced the distribution and clearance of midazolam in a concentration-dependent manner. The group reported increased plasma levels of midazolam ranging from 5% to 25% during increasing doses of propofol for monitored anesthesia care. This strategy allows the more evanescent and titratable propofol to provide the desired level of deep sedation in an adjustable manner according to the specific stimulus. The analgesic component, if required, of a balanced monitored anesthesia care technique may be provided by regional/local techniques or opioids. Again, when using opioids with benzodiazepines, the potential for significant respiratory impairment should be considered.

**Table 30-3** Comparison of the Important Properties of Midazolam and Diazepam

Midazolam	Diazepam
Water-soluble, does not require propylene glycol for solubilizing	Lipid-soluble, requires propylene glycol for solubilizing
Nonvenoirritant, usually painless	Venoirritant, pain on injection
Thrombophlebitis rare	Thrombophlebitis common
Short elimination half-time (1–4 h)	Long elimination half-time (>20 h)
Clearance unaffected by H <sub>2</sub> antagonists	Clearance reduced by H <sub>2</sub> antagonists
Inactive metabolites (1-hydroxymidazolam)	Active metabolites (desmethyldiazepam, oxazepam)
Resedation unlikely	Resedation more likely

The age of the patient should be taken into consideration when administering benzodiazepines. The dose of a particular benzodiazepine required to reach a desired clinical end point is reduced in elderly compared with younger patients.<sup>58</sup> This difference in dosing requirements in elderly patients is mainly related to pharmacodynamic factors. As demonstrated by the threefold decrease in plasma concentration of midazolam, 50% of patients would be expected not to respond to verbal command (Cp50) in an 80-year-old patient compared with a 40-year-old patient (Fig. 30-4).<sup>59</sup>

Benzodiazepines are valuable components of monitored anesthesia care techniques because they enhance patient comfort, improve operating conditions, and provide amnesia. However, recovery of psychomotor and cognitive function may be significantly prolonged following benzodiazepine sedation, especially when compared with sedative-hypnotic techniques using propofol as the major component.<sup>60</sup> The specific benzodiazepine antagonist flumazenil provides the potential to improve the recovery profile of benzodiazepines by permitting the active termination of their sedative and amnestic effects without invoking adverse side effects. However, the potential for re sedation remains an obstacle to the routine use of benzodiazepine reversal, particularly in patients undergoing ambulatory procedures. The effects of midazolam may recur up to 90 minutes following the administration of flumazenil.<sup>46</sup> Thus, it is possible that patients could be discharged prematurely to a less well-monitored area, or even out of the hospital in the case of ambulatory surgery, and later experience recurrence of benzodiazepine effects. Typical dose requirements for use of flumazenil are listed in Table 30-4.

**Figure 30-4** Midazolam Cp50 (the concentration at which 50% of subjects will fail to respond to a verbal command) as a function of age. There is a marked decrease in midazolam requirements as patient age increases. (Reproduced with permission from Jacobs JR, Reves JG, Marty J, et al. Aging increases pharmacodynamic sensitivity to the hypnotic effects of midazolam. *Anesth Analg*. 1995;80:143, with permission.)

## Opioids

Opioids are administered in the context of monitored anesthesia care to provide the specific analgesic component of a “balanced” technique. Opioids are indicated when regional or local anesthetic techniques are inappropriate or ineffective, and are typically administered immediately prior to the painful or invasive portion of the procedure. In addition, opioids may be indicated to blunt untoward hemodynamic and physiologic responses, a desirable effect in patients with significant cardiac disease. Pain relief may be required for factors other than the procedure itself, such as uncomfortable positioning, propofol injection, pneumatic tourniquet pain, or other pain not relieved by the local anesthetic technique. The choice of a particular opioid depends on several factors including cost, availability, time of onset, duration, and potential side effects. Opioids frequently administered during monitored anesthesia care include alfentanil, fentanyl, and remifentanyl. Their adverse effects include respiratory depression, muscle rigidity, and nausea and vomiting, all of which are undesirable in the spontaneously breathing patient with an unprotected airway. A complicating issue is that the ability to predict the effect of a given dose of opioid in a particular patient is limited by significant interpatient pharmacokinetic and pharmacodynamic variability. Furthermore, the coadministration of sedative agents increases the risk of serious adverse events, particularly respiratory arrest. This problem is usually overcome in practice by the cautious incremental administration of small, carefully titrated boluses or by titrating infusions to the desired effect.

**Table 30-4** Recommended Regimen for the Use of Flumazenil to Antagonize Benzodiazepine Effects

Initial recommended dose of 0.2 mg  
If desired level of consciousness is not achieved in 45 sec,  
repeat 0.2-mg dose  
0.2-mg doses may need to be repeated every 60 sec until a  
maximum of 1 mg is administered  
Be aware of the potential for re sedation

An example in which the patient must briefly cooperate and remain motionless is during the placement of a retrobulbar block prior to ophthalmic procedures. Patient movement during block placement may increase the incidence of complications such as damage to the globe, retrobulbar hemorrhage, optic nerve injury, total spinal anesthesia, and cardiac arrest.<sup>61,62</sup> Retrobulbar block placement affords an excellent opportunity to study the effects of drugs on the response to a standardized, ethically acceptable, brief painful stimulus. The ideal drug for block placement would provide a brief period of intense analgesia, yet allow the patient to be awake and cooperative

without causing cardiorespiratory depression or nausea and vomiting. Alfentanil appears to have a pharmacokinetic advantage for the treatment of discrete stimuli because of its short effect site equilibration time, which allows rapid access of the drug to the brain and facilitates titration. Yee et al.<sup>63</sup> studied the effect of the addition of alfentanil to propofol for sedation during placement of a retrobulbar block. The authors found that the addition of alfentanil improved the conditions of block placement although increased doses of alfentanil were associated with oxygen desaturation. In addition, the total amount of propofol for sedation decreased proportional to the increasing concentration of alfentanil. Other opioids, including fentanyl and remifentanil, have been successfully administered for ophthalmic surgery without significant side effects.<sup>64–66</sup> In a study conducted by Ahmad et al.,<sup>67</sup> a bolus of 1 µg/kg of remifentanil over 30 seconds was administered 90 seconds prior to block placement. More than three-quarters of patients receiving remifentanil did not report any pain during subsequent block placement. However, 15% of the patients given a single bolus alone had significant respiratory depression (respiratory rates <8 breaths per minute), and 19% of those given a bolus followed by an infusion had significant respiratory depression. The group also noted that remifentanil provided superior analgesia compared to alfentanil administered at a dose of 7 µg/kg.

The well-described phenomenon of patient awareness and subsequent recall of intraoperative events following high-dose opioid anesthesia is taken as evidence that opioids lack significant amnestic properties. However, when the effects of low-dose fentanyl on memory were specifically examined in volunteers, it was found that although the subjects appeared to be awake during the fentanyl infusion, there was significant memory impairment.<sup>68</sup> In this study, the degree of stimulation was probably less than that experienced by a patient undergoing a painful surgical procedure. Recall for a painful stimulus during an invasive procedure may not be impaired to the same degree as recall for the less noxious stimuli experienced by the subjects of this study. Aydin et al.<sup>69</sup> noted that the addition of fentanyl to local anesthesia during cataract surgery provided a significant difference in sedation levels; however, it was of brief duration. If amnesia is desired as part of a balanced technique, a sedative–hypnotic agent should be administered and the dose of both agents decreased to avoid any cardiorespiratory events.

## **Remifentanil**

Remifentanil is a potent, ultrashort-acting opioid used during monitored anesthesia care to provide analgesia during brief, painful procedures. Remifentanil is typically administered by a bolus to achieve therapeutic analgesia followed by a continuous infusion. If the situation permits, the bolus

should be avoided to decrease the incidence of adverse cardiorespiratory effects. It has been suggested that the administration of continuous infusions during monitored anesthesia care improves the operative conditions for the proceduralist.<sup>70,71</sup>

Remifentanyl has pharmacodynamic properties similar to those of other potent  $\mu$ -opioid receptor agonists such as fentanyl and alfentanil. However, remifentanyl is predominantly metabolized by nonspecific esterases, generating an extremely rapid clearance and termination of effect and making it an attractive choice for patients with significant hepatic or renal disease.<sup>72,73</sup> Another major advantage is the intense analgesia of limited duration, which is advantageous to prevent respiratory depression after the stimulating portion of the procedure is completed. The context-sensitive half-time of remifentanyl is consistently short, 3 to 5 minutes, increasing to a minimal degree with the duration of the infusion.<sup>74,75</sup> Furthermore, remifentanyl has a short effect site equilibration time ( $t_{1/2ke0}$ ) of 1 to 1.5 minutes. This  $t_{1/2ke0}$  is slightly longer than that of alfentanil (0.6 to 1.2 minutes) but much shorter than that of fentanyl (4 to 5 minutes) and morphine (approximately 20 minutes), and makes the onset of effect after drug administration very rapid, thus facilitating titration of effect during monitored anesthesia care.

In clinical practice, remifentanyl has been used successfully as the analgesic component of sedation techniques for regional and local anesthesia. Its unique pharmacokinetic profile makes it well suited for monitored anesthesia care techniques. Published experience with the use of remifentanyl suggests that it is possible to titrate remifentanyl administration to provide effective analgesia with minimal respiratory depression. The published data can be used to generate some practical clinical guidelines,<sup>76</sup> which are discussed here.

1. The most desirable therapeutic end point for remifentanyl administration is effective analgesia and patient comfort rather than sedation. Sedative drugs such as propofol or midazolam can be used in combination with remifentanyl to provide the hypnotic–amnestic component of the sedation technique, remembering that the concomitant administration of midazolam decreases remifentanyl dose requirements by up to 50%.<sup>77</sup>
2. Published data suggest that bolus administration of remifentanyl is associated with an increased incidence of respiratory depression and chest wall rigidity. Because these side effects are likely to be related to high peak concentrations of drugs, it is recommended that remifentanyl boluses be administered slowly (over 30 to 90 seconds) or avoided completely by using a pure infusion technique. If respiratory depression is promptly recognized and the remifentanyl administration is reduced or discontinued, it should resolve within approximately 3

minutes. Despite the pharmacokinetic advantages of remifentanyl, the level of vigilance required for its administration should be no different from that for any other potent opioid. Although the offset time of remifentanyl is rapid, it still requires the recognition of respiratory depression to trigger a downward adjustment in dosage. Similarly, the short  $t_{1/2ke0}$  of remifentanyl suggests that sudden respiratory depression may occur in response to upward adjustments in dosage. Despite the potential for respiratory depression, the efficacy of remifentanyl boluses during monitored anesthesia care has been investigated by several groups.<sup>66,78–80</sup>

3. The effects of coadministration of benzodiazepines and opioids are well documented. The addition of midazolam to provide the anxiolytic–sedative and amnestic components of a sedation technique has been shown to increase patient satisfaction and significantly reduce remifentanyl dose requirements. Even relatively low-dose midazolam (2 mg IV) produces significant reductions in remifentanyl requirements and patient anxiety. During breast or lymph node biopsy, remifentanyl infusion requirements were 0.065  $\mu\text{g}/\text{kg}/\text{min}$  when preceded by midazolam compared with 0.123  $\mu\text{g}/\text{kg}/\text{min}$  when used alone.<sup>77</sup> The advantages of coadministration of small doses of midazolam include increased patient satisfaction, increased amnesia, decreased nausea and vomiting, and decreased anxiety. The disadvantages include a tendency toward increased respiratory depression, apnea, and excessive sedation.
4. Because most painful stimuli are of unpredictable duration and because the risk of adverse respiratory events is increased following bolus administration, the most logical method for the administration of remifentanyl during monitored anesthesia care is by an adjustable infusion. This should ideally be preceded by a small bolus of midazolam. Most investigators have used infusion rates that start at 0.1  $\mu\text{g}/\text{kg}/\text{min}$  approximately 5 minutes prior to the first painful stimulus. This initial “loading” infusion is then weaned to approximately 0.05  $\mu\text{g}/\text{kg}/\text{min}$  to maintain patient comfort. The maintenance infusion is adjusted upward in response to pain or hemodynamic response or downward in response to excessive sedation, respiratory depression, or apnea. A typical incremental change in infusion rate is 0.025  $\mu\text{g}/\text{kg}/\text{min}$ . The use of remifentanyl infusions of 0.2  $\mu\text{g}/\text{kg}/\text{min}$  is associated with an increased incidence of respiratory depression that is not necessarily associated with superior analgesia. As in the case of propofol administration, inadvertent interruption of remifentanyl administration will result in abrupt offset of effect, which may result in patient discomfort, hemodynamic

instability, and even morbidity due to patient movement. It is therefore very important to ensure that the drug delivery system is monitored carefully during the procedure. Remifentanyl is supplied as a powder that must be reconstituted prior to use. It is particularly important when administering this drug to patients with an unsecured airway to ensure that there are no errors in drug dilution that would result in inadvertent dosing errors.

Typical adult dose recommendations for opioids and other drugs discussed in the text are listed in [Table 30-5](#).

## **Ketamine**

Ketamine, a phencyclidine derivative, is an intense analgesic frequently used as a component of pediatric sedation techniques and is rapidly gaining popularity in the adult population, particularly in the opioid tolerant patient.<sup>81–83</sup> When used in small doses (0.25 to 0.5 mg/kg), its use is associated with minimal respiratory and cardiovascular depression. Ketamine produces a dissociative state in which the eyes remain open with a nystagmic gaze. However, as the dose of ketamine increases, or when used in combination with other sedatives, a state of deep sedation and/or general anesthesia may be inadvertently achieved. It is often stated that increased oral secretions make laryngospasm more likely. The fear of laryngospasm is the underlying rationale for the frequent administration of an antisialagogue such as atropine or glycopyrrolate. Ketamine is frequently combined with a benzodiazepine to reduce the incidence of hallucinations associated with its use. However, this practice is controversial.<sup>84</sup> There are increasing reports in the emergency medicine literature of replacing benzodiazepines and/or opioids with propofol when ketamine is administered for sedation. Advantages of the administration of “ketofol” are predominately due to the ability of these drugs to balance the negative side effects of the other. For example, the analgesic effect of ketamine reduces the dosage of propofol required in order to complete an invasive or painful procedure. Frequent advantages cited included preserved hemodynamic stability, decreased nausea and vomiting, improved procedural conditions, and decreased airway complications.<sup>85–89</sup> Problems may arise when repeated doses or prolonged administration of the drug combinations are required due to differences in half-life. The effect of ketamine may outlast the effects of propofol under these conditions. Patient movement may make ketamine less than ideal for procedures requiring a completely motionless patient. Ketamine can elevate intracranial and intraocular pressure and is thus relatively contraindicated in patients with increased intracranial pressure and with glaucoma or open-globe injuries.<sup>90</sup> Although it has been suggested that airway reflexes are relatively

preserved with ketamine, there is no convincing evidence to support this notion.

**Table 30-5** Typical Dose Ranges of Sedative, Hypnotic, and Analgesic Drugs

Drug	Typical Adult Intravenous Dose Range (Titrated to Effect in Small Increments)
<b>Benzodiazepines</b>	
Midazolam	1–2 mg prior to propofol or remifentanyl infusion
Diazepam	2.5–10 mg as the major component of sedation technique
<b>Opioid Analgesics</b>	
Alfentanil	5–20 µg/kg bolus 2 min prior to stimulus
Fentanyl	0.5–2 µg/kg bolus 2–4 min prior to stimulus
Remifentanyl	Infusion 0.1 µg/kg/min 5 min prior to stimulus Wean to 0.05 µg/kg/min as tolerated Adjust up or down in increments of 0.025 µg/kg/min Reduce dose accordingly when co-administered with midazolam or propofol Avoid boluses
<b>Hypnotics</b>	
Propofol	250–500 µg/kg boluses 25–75 µg/kg/min infusion
Dexmedetomidine	Loading infusion: 0.5–1 µg/kg over 10–20 min Maintenance infusion: 0.2–0.7 µg/kg/h

Ketamine can be also administered orally or intramuscularly. The oral dose of ketamine is 4 to 6 mg/kg. The onset of action typically occurs within 20 to 30 minutes and the duration of effect is between 60 and 90 minutes. The intramuscular dose is 2 to 4 mg/kg with an onset of action of 5 to 10 minutes and typically has a duration of effect of 30 to 120 minutes. When administered via the IV route, ketamine should be given in small (0.25 to 1 mg/kg) increments, titrating to effect with an onset of action of 1 to 2 minutes and an approximate duration of 20 to 60 minutes.

### Dexmedetomidine

Dexmedetomidine is a selective  $\alpha_2$ -receptor agonist that depresses central sympathetic function and produces sedation and analgesia. The  $\alpha_2$ -agonists potentiate opioid-induced analgesia, benzodiazepine-induced hypnosis, and have potent MAC-sparing effects when administered with volatile agents.

Compared with other sedative and analgesic drugs, dexmedetomidine appears to have relatively minor effects on respiratory function when used in the typical dose range.<sup>91-93</sup> Of note, unlike during opioid-induced sedation, the hypercapnic arousal response, a feature of natural sleep, appears to be preserved during dexmedetomidine sedation. When compared to propofol, use of dexmedetomidine to facilitate sedation may be associated with improved airway patency,<sup>94</sup> particularly in patients with suspected obstructive sleep apnea. This consideration is ever important given the increasing prevalence of obesity and associated sleep disordered breathing in our current practice. However, occasional airway intervention to relieve obstruction and apnea may be required during dexmedetomidine administration, particularly when used in combination with other respiratory depressants.<sup>95</sup> Dexmedetomidine has been used for sedation during instrumentation of the difficult airway. Patients undergoing fiberoptic intubation who are sedated using dexmedetomidine are generally comfortable yet cooperative.<sup>96-100</sup> Administration of  $\alpha_2$ -agonist is associated with a reduction of sympathetic outflow and an increase in cardiac vagal activity; therefore, it is not surprising that hypotension and bradycardia may occur during dexmedetomidine administration. Clinically significant episodes of bradycardia and sinus arrest have been associated with dexmedetomidine administration in young, healthy volunteers with high vagal tone, particularly during rapid IV or bolus administration.<sup>101,102</sup> The  $\alpha_2$ -agonists do have peripheral vasoconstrictive effects that can occasionally precipitate hypertension. Despite this phenomenon, the incidence of hypertensive episodes requiring intervention is lower when compared with an equivalent propofol-based technique.<sup>103</sup>

Dexmedetomidine has been used successfully in both adult and pediatric patients for monitored anesthesia care during the awake portions of craniotomies requiring patient cooperation for cortical speech mapping.<sup>104,105</sup> Dexmedetomidine has been used as sedative supplementation to regional anesthesia during carotid endarterectomy. Under these circumstances, there were fewer fluctuations from the desired sedation level when compared with the combination of midazolam, fentanyl, and propofol.<sup>106</sup> Dexmedetomidine tends to decrease cerebral blood flow both directly via  $\alpha_2$ -mediated constriction of cerebral blood vessels and indirectly via its effect on systemic pressure. However, there appears to be a concomitant decrease in cerebral metabolic rate.<sup>107</sup> To add further reassurance, the use of dexmedetomidine does not appear to be associated with an increase in the need for intracarotid shunting in patients undergoing awake carotid endarterectomy.<sup>108</sup>

The lack of pain on injection and its analgesic and minimal adverse respiratory properties would seem to make dexmedetomidine a useful alternative to propofol in certain circumstances. However, when compared

with propofol, the target sedation level takes longer to achieve with dexmedetomidine (25 vs. 10 minutes).<sup>109</sup> Furthermore, if loading boluses of dexmedetomidine are used to accelerate the onset of sedation, bradycardia and hypotension may occur. Although the use of dexmedetomidine may result in greater sedation, lower blood pressure, and improved analgesia in the recovery room when compared with propofol, the time to postanesthesia care unit discharge is not significantly different.<sup>110</sup> Dexmedetomidine is most often delivered as an initial bolus followed by a continuous infusion. Initial bolus doses range from 0.5 to 1  $\mu\text{g}/\text{kg}$  over 10 to 20 minutes, followed by a continuous infusion of 0.2 to 0.7  $\mu\text{g}/\text{kg}/\text{hr}$ .

Two large retrospective observational studies from a single children's hospital suggest that dexmedetomidine may be used for sedation for pediatric magnetic resonance imaging and computed tomography studies.<sup>110,111</sup> In these studies, the loading dose of dexmedetomidine was 2 to 3  $\mu\text{g}/\text{kg}$  over 10 minutes, followed by an infusion of between 1 and 2  $\mu\text{g}/\text{kg}/\text{hr}$ . However, approximately 15% of patients required a second bolus in order to achieve satisfactory conditions to complete the scan. The analgesic properties of dexmedetomidine may make it a useful alternative to the use of propofol as a sole agent during painful procedures. However, the time taken to deliver the loading dose, the occasional need to rebolus, hypotension, bradycardia, and the relatively long recovery time may limit the utility of dexmedetomidine for very brief procedures such as computed tomography studies. On the other hand, the pain on injection of propofol and the legislative constraints on the administration of propofol by nonanesthesia-trained providers may make dexmedetomidine advantageous in certain circumstances.

### *Amnesia during Sedation with Dexmedetomidine or Propofol*

Drugs with sedative–hypnotic properties reduce attention to stimuli as a direct consequence of depression of consciousness. Therefore, all sedative–hypnotics have the potential to impair memory formation because attention to stimuli is a crucial element of explicit memory formation. However, like benzodiazepines, propofol has significant amnestic effects at subhypnotic doses, suggesting an additional amnestic mechanism that is separate from its sedative effect.<sup>112</sup> In the case of propofol, drug-induced amnesia appears to be a consequence of lack of retention of information that was already successfully stored into long-term memory.<sup>113</sup> In contrast to propofol and benzodiazepines, it is unlikely that dexmedetomidine has amnestic properties at subhypnotic doses.<sup>114</sup> If amnesia is desired for a procedure performed during dexmedetomidine administration, loss of consciousness would be necessary if dexmedetomidine is used as the sole agent. Alternatively, amnestic doses of propofol or a benzodiazepine may be used to supplement

dexmedetomidine. The properties of propofol and dexmedetomidine are compared in [Table 30-6](#).

### ***Patient-controlled Sedation and Analgesia***

Techniques that allow the direct patient control of the level of sedation may positively affect patient satisfaction.<sup>115</sup> The degree of sedation desired by the patient varies significantly and the individual response to drugs is variable. Patient-controlled sedation appears to be an attractive solution to this problem. One approach to patient-controlled sedation has been to use a conventional patient-controlled analgesia (PCA) delivery system set to deliver 0.7-mg/kg boluses of propofol with a 3-minute lockout period.<sup>116</sup> Other approaches include fixed-dose combinations of 0.5-mg midazolam and 25- $\mu$ g fentanyl with a 5-minute lockout interval between doses.<sup>117</sup> The pharmacokinetic profile of alfentanil is ideal for the treatment of short, discrete episodes of pain. These properties have been exploited during vaginal ovum retrieval procedures, when ultrasonically guided needles are passed through the vaginal wall under monitored anesthesia care. To this end, Zelcer et al.<sup>118</sup> used a PCA delivery system to allow self-administration of alfentanil during this procedure. After midazolam premedication and a loading dose of alfentanil, patients received 5- $\mu$ g/kg boluses of alfentanil via the PCA pump with a mandatory 3-minute lockout period. Patient acceptability, alfentanil dosage, respiratory variables, and pain scores were similar to those obtained with physician-controlled analgesia. From the limited data that are available, intraoperative PCA during monitored anesthesia care appears to be an effective alternative to physician-administered analgesia.

**Table 30-6** A Comparison of Some Important Properties of Propofol and Dexmedetomidine

	<b>Propofol</b>	<b>Dexmedetomidine</b>
Pain on injection	Yes	Minimal
Analgesic properties in subhypnotic doses	Minimal	Yes
Amnestic properties in subhypnotic doses	Significant	Insignificant
Time of onset with typical administration	Rapid	5–10 min
Restrictive regulations on use by nonanesthesia-trained providers	Yes	No
Potential for significant bradycardia	Minimal	Significant

## **Respiratory Function and Sedative–Hypnotic Drugs**

During monitored anesthesia care, there is significant potential for respiratory compromise, as highlighted by the American Society of Anesthesiologists Closed Claims Database Study that examined claims related to MAC.<sup>119,120</sup> In that study, excessive sedation leading to respiratory compromise was the most common cause of death or central nervous system injury during MAC. An accompanying editorial noted that MAC is no less risky than general anesthesia in terms of occurrences of permanent brain injury and death for patients undergoing predominantly elective procedures in outpatient settings. The adverse respiratory effects of sedation administration include adverse effects on respiratory drive, airway patency, and loss of airway protective reflexes. These effects result either directly as a result of sedative–hypnotic or opioid administration or indirectly as a consequence of brain stem hypoperfusion resulting from hypotension. There may also be a marked increase in the work of breathing because of increased upper airway resistance<sup>121</sup> and adverse effects on respiratory system mechanics resulting from a decline in functional residual capacity.<sup>122,123</sup>

### *Sedation and Upper Airway Patency*

The upper airway is located outside the thorax. During inspiration, the pressure within the upper airway is subatmospheric; thus, there is a tendency for the upper airway to collapse under the influence of the surrounding atmospheric pressure. However, in the normal subject this tendency for airway collapse is opposed by upper airway dilator muscle tone. These muscles increase the diameter and reduce the compliance of the upper airway. An increase in upper airway dilator muscle tone occurs during inspiration, commencing just prior to diaphragmatic contraction.<sup>124</sup> The coordinated activation of the diaphragmatic and upper airway respiratory muscles are critical in maintaining airway patency. However, upper airway dilator muscle control appears to be extremely sensitive to sedative–hypnotic drug administration.<sup>125</sup> For example, sedative doses of benzodiazepines have been reported to increase inspiratory subglottic airway resistance by three- to fourfold<sup>126</sup> and to selectively suppress genioglossal muscle activity to a greater degree than diaphragmatic activity; furthermore, this effect is exaggerated in elderly patients. The response to this obstruction is a significant increase in intercostal and accessory muscle activity. However, this response is only partially effective because the increase in inspiratory force will further decrease intraluminal upper airway pressure, thus predisposing to further airway collapse. It is likely that these effects will be of greatest significance in patients with pre-existing respiratory compromise, such as elderly patients or those with chronic obstructive pulmonary disease. These patients often have limited respiratory reserve and are unable to increase

their respiratory muscle activity in response to the increased work of breathing induced by sedation and may become hypercarbic, acidotic, and hypoxic. Not surprisingly, the aforementioned ASA Closed Claims Database Study showed that MAC-related adverse respiratory outcomes were overrepresented in the elderly and ASA class 3 and 4 populations.

### *Sedation and Protective Airway Reflexes*

Competent laryngeal and upper airway reflexes are required to protect the lower airway from aspiration. Protective laryngeal and pharyngeal reflexes are depressed by anesthesia and sedation. Furthermore, it is also well documented that protective airway reflexes are compromised by advanced age and debilitation. Therefore, it is likely that significant further impairment of airway reflexes occurs during sedation in the elderly or debilitated patient. Aspiration of gastric contents can potentially occur any time during the perioperative period, particularly if oral intake is allowed before the return of adequate upper airway protective reflexes. The time required for the return of protective reflexes varies considerably. Complete recovery of the swallowing reflex occurs approximately 15 minutes after the return of consciousness following propofol anesthesia.<sup>127</sup> However, the IV administration of 15 mg of diazepam has been shown to depress the swallowing reflex for up to 4 hours.<sup>128</sup> The swallowing reflex is significantly depressed for up to 2 hours following the administration of midazolam despite the return to a normal state of consciousness.<sup>129</sup> In otherwise healthy adult male volunteers, the inhalation of 50% nitrous oxide was associated with marked depression of the swallowing reflex.<sup>130</sup>

It is apparent from the sources previously quoted that the protective airway reflexes alone cannot be relied on to protect the lower airway from aspiration during sedation. Thus, patients who are deemed to be at risk from aspiration of gastric contents should be maintained at the lightest level of sedation possible. Ideally, the patient should be awake enough to recognize the regurgitation of gastric contents and be able to protect his or her own airway. If the ability of the patient to protect his or her own airway cannot be reliably guaranteed and regurgitation/aspiration is thought to be a significant risk, placement of a cuffed endotracheal tube under general anesthesia should be seriously considered. Propofol has a particularly potent suppressive effect upon upper airway protective reflexes.<sup>131</sup> This property of propofol is exploited by anesthesiologists in our daily clinical practice. We use propofol to facilitate LMA insertion, to prevent and treat laryngospasm, and to facilitate endotracheal intubation without the use of muscle relaxants. However, the obvious downside to propofol-induced protective reflex suppression is that propofol-based techniques with an unprotected airway

might be associated with a greater likelihood of aspiration. There is some evidence to support this supposition. A large Medicare database–based study (>100,000 patients) retrospectively examined whether receiving anesthesia for screening colonoscopy was associated with an increase in complications, including aspiration pneumonia, requiring hospitalization within 30 days of colonoscopy.<sup>132</sup> Aspiration occurred more frequently in those patients receiving anesthesia services versus those who did not (0.14% vs. 0.1%).

### ***Sedation and Respiratory Control***

Clinical experience would lead most anesthesiologists to predict that the administration of sedative–hypnotic drugs is associated with the depression of respiratory drive. However, the findings of scientific studies in this area are often conflicting and confusing. On occasion they show minimal effects of sedative drugs, if any,<sup>134–136</sup> on ventilatory responsiveness. However, it is important to note that in many cases the methods used to measure respiratory drive may affect the outcome of the study by stimulating the subject, thus attenuating the negative effect of the drug on respiratory drive. In clinical practice, it is likely that during regional anesthesia there is a degree of deafferentation that will potentiate the respiratory depressant effects of sedative–hypnotic drugs.<sup>137</sup> Most studies have demonstrated that opioids depress the ventilatory response to hypercapnia and hypoxia.<sup>138–142</sup> Reports of the effects of sedative doses of benzodiazepines on carbon dioxide responsiveness have shown variable results, including no significant effect and clinically significant depression.<sup>143–146</sup> However, when opioids and benzodiazepines are used in combination, there appears to be a consistent and marked negative effect on respiratory responsiveness.<sup>142</sup> Although the addition of sedative doses of propofol to opioids showed little potentiation of the respiratory effects of opioids, caution is still warranted when combinations of sedative–hypnotics are used.

### **Supplemental Oxygen Administration**

Hypoxia as a result of alveolar hypoventilation is a relatively common occurrence following the administration of sedatives, analgesics, and hypnotics. In the absence of significant lung disease, the administration of only modest concentrations of supplemental oxygen is frequently effective in restoring the patient's oxygen saturation to an acceptable level. This concept is well illustrated by reference to the familiar alveolar gas equation. An extreme example illustrates the point: An otherwise healthy adult male breathing room air receives a dose of an opioid that causes marked alveolar hypoventilation such that his alveolar PCO<sub>2</sub> is increased to 80 mmHg. The

alveolar gas equation predicts that his arterial PO<sub>2</sub> will fall to approximately 40 mmHg as shown here:

$$\begin{aligned} \text{PAO}_2 &= \text{PiO}_2 - \text{PACO}_2/\text{R} \\ \text{PiO}_2 &= \text{FiO}_2 \times (\text{P}_B - \text{PH}_2\text{O}) \\ \text{PiO}_2 &= 0.21 \times (760 - 47) = 150 \text{ mmHg} \\ \text{PAO}_2 &= 150 - 80/0.8 \\ \text{PAO}_2 &= 50 \text{ mmHg} \end{aligned}$$

where PAO<sub>2</sub> is alveolar partial pressure of oxygen, PiO<sub>2</sub> is inspired partial pressure of oxygen, PACO<sub>2</sub> is alveolar partial pressure of carbon dioxide, R is respiratory quotient, P<sub>B</sub> is barometric pressure, and PH<sub>2</sub>O is water vapor pressure at body temperature.

Assuming a normal alveolar to arterial (A–a) gradient, his PAO<sub>2</sub> will be 40 mmHg, corresponding to an arterial oxygen saturation of 75%. If while initiating definitive therapy for hypoventilation this patient were to receive only a modest increase in inspired oxygen, a marked improvement in arterial saturation would be achieved:

$$\begin{aligned} \text{FiO}_2 &\text{ increased to 28\%} \\ \text{PiO}_2 &= 0.28 \times (760 - 47) = 200 \text{ mmHg} \\ \text{PAO}_2 &= 200 - 80/0.8 \\ \text{PAO}_2 &= 100 \text{ mmHg} \end{aligned}$$

This theoretical example serves to highlight an important point. First, in isolated hypoventilation modest increases in inspired oxygen are remarkably effective at restoring oxygen saturation to acceptable levels. On the other hand, *a patient who is receiving minimal supplemental oxygen and has an acceptable oxygen saturation may have significant undetected alveolar hypoventilation.* The necessity to administer oxygen supplementation is controversial. Deitch et al.<sup>143</sup> reported that the use of supplemental oxygen (2 L/min) during sedation with midazolam and fentanyl did not reduce the occurrence of hypoxia compared to patients on room air. The investigators conducted a similar study evaluating the effect of 3 L/min of oxygen in patients receiving propofol and reported that patients on oxygen had a lower incidence of desaturations compared to patients on room air (18% vs. 28%, respectively) although it was not found to be significant.<sup>144</sup> The authors claimed that physician recognition and correction of an obstructed airway was of greater significance than supplemental oxygen. It should be noted that the data from the ASA closed claims analysis shows that respiratory depression associated with monitored anesthesia care accounted for over one-third of

closed-claim injuries in remote locations.<sup>145</sup> We recommend that before discharging patients, it is useful to measure their oxygen saturation while breathing room air.

### **Head and Neck Fires with the Use of Supplemental Oxygen**

From the ASA closed-claims study of Bhananker et al.,<sup>119</sup> we learned that the leading cause of death and severe nervous system injury during MAC is hypoxia due to suppression of spontaneous respiration by sedative-hypnotic drugs. Although administration of supplemental oxygen is generally prudent, the authors of that study also note the surprising finding that the second most common cause of injury was cautery fires, particularly around the head and neck. Thus, caution should be used when supplemental oxygen is administered to patients undergoing surgery in the head and neck. The combination of supplemental oxygen, electrocautery, alcoholic prep solution, and flammable drapes is particularly dangerous, especially when a tent of drapes around the patient's head creates a pocket of increased oxygen concentration. Recommendations to prevent fires in this situation are listed in [Table 30-7](#).

**Table 30-7** Recommendations to Prevent Burn Injuries during MAC

Open face draping techniques; that is, avoiding tent of drapes  
Supplemental oxygen at lowest acceptable flows guided by SpO<sub>2</sub>  
Use of compressed air rather than oxygen to prevent CO<sub>2</sub> accumulation  
Stopping oxygen flow 60 sec prior to use of electrocautery  
Avoidance of alcohol-based prep solutions  
Awareness of the causes and prevention of surgical fires

## **Monitoring during Monitored Anesthesia Care**

### **American Society of Anesthesiologists Standards**

The ASA standards for basic anesthetic monitoring are applicable to all levels of anesthesia care, including monitored anesthesia care. It is useful to review the components of the ASA standards that are pertinent to monitored anesthesia care as approved by the House of Delegates in October 2010.<sup>146</sup>

### **Communication and Observation**

A conscientious and well-trained anesthesia caregiver is the single most vital monitor in the operating room. However, his or her effectiveness will be markedly enhanced by the use of the basic quantitative and qualitative monitoring devices, which should be readily available in all operating rooms. It is important that the anesthesiologist continually evaluates the patient's response to verbal stimulation to effectively titrate the level of sedation and to allow the earlier detection of neurologic or cardiorespiratory dysfunction. Continuous visual, tactile, and auditory assessment of physiologic function could include observation of the rate, depth, and pattern of respiration; palpation of the arterial pulse; and assessment of peripheral perfusion by extremity temperature and capillary refill. In addition, the patient should be continually observed for diaphoresis, pallor, shivering, cyanosis, and acute changes in neurologic status.

### **Auscultation**

Auscultation of heart and breath sounds has long been a vital component of monitoring during anesthesia. Placement of a precordial stethoscope near the sternal notch of a nonintubated patient provides important information concerning upper airway patency as well as a continuous monitor of heart sounds and ventilation. Continuous precordial auscultation is an inexpensive, effective, and essentially risk-free process that serves as an additional important purpose by bringing the anesthesia care provider closer to the patient.

### **Pulse Oximetry**

No monitor of oxygen transport has had a greater impact on the practice of anesthesiology than the pulse oximeter.<sup>147</sup> Pulse oximetry is noninvasive, safe, and comfortable to the awake patient; it is also technically simple to apply and interpret, and allows continuous real-time monitoring of arterial oxygenation. The use of a quantitative measure of oxygenation is specifically mandated by the ASA standards for intraoperative monitoring. The important mechanisms whereby respiratory function may be compromised during monitored anesthesia care include the effects of sedatives and opioids on respiratory drive, upper airway patency, and protective airway reflexes. Additional important risk factors for arterial desaturation include obesity, pre-existing upper airway obstruction and respiratory disease, increased metabolic rate, general anesthesia, the extremes of age, surgical site, and patient positioning.<sup>148–150</sup> The fundamental importance of monitoring oxygenation during monitored anesthesia care can be appreciated from the closed-claim study of Caplan et al.<sup>133</sup> who examined 14 cases of sudden cardiac arrest in

otherwise healthy patients who received spinal anesthesia. These major anesthetic mishaps occurred before the routine adoption of pulse oximetry. One of the major findings of this study was that cyanosis frequently heralded the onset of cardiac arrest, suggesting that unappreciated respiratory insufficiency may have played an important role. Further support for the use of pulse oximetry comes from the ASA Committee on Professional Liability analysis of closed anesthesia claims, which reveals that respiratory events constitute the single largest source of adverse outcome. Furthermore, review of these cases suggests that pulse oximetry in combination with capnometry would have prevented the adverse outcome in most cases.

## Capnography

Although capnography is most effective in the intubated patient, useful information may be obtained from a spontaneously breathing, nonintubated patient. Capnography may be used to monitor respiratory rate and aid in the detection and management of airway obstruction. There are numerous methods to monitor end-tidal carbon dioxide. In addition, it may be able to detect hypoventilation during the administration of supplemental oxygen.<sup>151</sup> Sidestream capnographs have been adapted for use with face masks, nasal airways, and nasal cannulae and have been used successfully during monitored anesthesia care.<sup>152,153</sup> Nasal cannulae for oxygen delivery have been modified to provide an integral port for respiratory gas sampling and are available commercially. Alternatively, capnograph sampling lines can be attached to shortened IV catheters and inserted inside nasal oxygen probes. There is growing evidence that capnography may reduce risk associated with sedation/analgesia or monitored anesthesia care in both the pediatric and adult population.<sup>151,154,155</sup> Waugh et al.<sup>156</sup> conducted a meta-analysis to determine if the addition of capnography identified more respiratory complications than standard monitoring alone. They reported that cases of respiratory depression were 17.6 times more likely to be detected if monitored with capnography. Currently, capnography is not a standard of care; however, because of the low cost and enhanced patient safety, we recommend routine use for all patients receiving sedation/analgesia or monitored anesthesia care.

## Cardiovascular System

At a minimum, the electrocardiogram must be continually displayed and the blood pressure measured and recorded at least every 5 minutes during monitored anesthesia care. The pulse should be monitored by palpation, oximetry, or auscultation. The selection of additional hemodynamic

monitoring is usually determined more by the cardiovascular status of the patient than the magnitude of the procedure. Most procedures performed under monitored anesthesia care do not involve major hemorrhage, fluid shifts, or major physiologic trespass. Decisions concerning choice of monitoring for myocardial ischemia and other adverse hemodynamic events will need to be individualized on a case-by-case basis.

### ***Temperature Monitoring and Management during Monitored Anesthesia Care***

The value of temperature monitoring is well established during general anesthesia, the perioperative period being frequently complicated by hypothermia and hyperthermia. Although sedation techniques used during monitored anesthesia care do not generally trigger malignant hyperthermia, there is potential for significant inadvertent hypothermia, particularly during neuraxial anesthesia. Even monitored anesthesia care techniques unaccompanied by regional anesthesia are associated with hypothermia at the extremes of age, both the old and very young having impaired thermoregulatory mechanisms. The elderly also have markedly reduced muscle mass and therefore basal heat production. Although the anesthesiologist may be able to exert some control over the ambient temperature in the operating room, he or she may be unable to influence the temperature at remote anesthetizing locations. Radiology suites are often maintained at lower temperatures to accommodate the computer systems that are used to reconstruct images. Radiant heating lamps, forced-air heaters, fluid warmers, or warming blankets, all common items in operating rooms, may be unavailable and unsuitable for use at remote locations. Forced-air heating has been shown to be an effective means of maintaining normothermia, and can be combined with IV fluid warming.<sup>157,158</sup> Even mild perioperative hypothermia (i.e., 1°C to 2°C) accompanying general anesthesia is associated with adverse myocardial outcomes, increased bleeding tendency and transfusion requirements, wound infections, and delayed wound healing and hospital discharge.<sup>159-164</sup> At this time, there is no evidence suggesting that the morbidity associated with perioperative hypothermia is any less during monitored anesthesia care than during general anesthesia. The morbidity associated with perioperative hypothermia is well described in high-risk patients; this is a group of patients who are very likely to undergo procedures under monitored anesthesia care. When hypothermia is significant, shivering may interfere with the planned procedure and markedly increase oxygen requirements and predispose susceptible patients to myocardial ischemia or respiratory insufficiency. The major thermoregulatory defenses against hypothermia include vasoconstriction, shivering, and behavior.

Vasoconstriction and shivering are impaired during major conduction anesthesia. Behavioral thermoregulation is impaired even in the conscious patient. Regional anesthesia has major effects on thermoregulation.<sup>165</sup> Lower extremity vasodilatation causes central cooling via a redistribution of heat from the core to the periphery. Afferent input to the hypothalamus from the warm peripheral compartment counteracts conflicting input from the cooling central compartment, thus delaying the initiation of compensatory thermoregulation. In the absence of reliable temperature monitoring, it is possible that the first indication of hypothermia would be the onset of shivering, by which time considerable central cooling may have occurred.

Frank et al.<sup>166</sup> have examined the issue of temperature monitoring and management during neuraxial anesthesia and found that temperature monitoring is significantly underused, with only one-third of patients being monitored. Furthermore, the method that was most frequently used to monitor temperature may not accurately reflect core temperature, the most important determinant of thermoregulatory response and perioperative morbidity. Forehead skin surface was the most commonly monitored site. The accuracy of these devices for perioperative temperature monitoring remains controversial; they do not reliably detect malignant hyperthermia and are not sufficiently accurate for fever screening purposes in children.<sup>167</sup> Sessler<sup>168</sup> recommends the use of a properly positioned axillary probe or intermittent oral temperature monitoring during neuraxial anesthetics.

Patients will frequently complain of feeling too warm when covered by heavy drapes. Although malignant hyperthermia is rare during monitored anesthesia care, hyperthermia is still possible as a result of thyroid storm or malignant neuroleptic syndrome. The subjective sensation of hyperthermia may also be the first indicator of important adverse events in evolution such as hypoxia, hypercarbia, cerebral ischemia, local anesthetic toxicity, and myocardial ischemia.

### ***Bispectral Index Monitoring during Monitored Anesthesia Care***

The bispectral index (BIS) is a processed EEG parameter that was developed specifically to evaluate patient response during drug-induced anesthesia and sedation. Sedation monitoring is attractive because of the potential to titrate drugs more accurately, avoiding the adverse effects of both over- and underdosing. BIS monitoring has some potential advantages over conventional intermittent techniques of patient assessment. Conventional assessment involves patient stimulation at frequent intervals to determine the level of consciousness, requires patient cooperation, and is subject to testing fatigue. An example of a conventional assessment tool is the Observer's Assessment of Alertness/Sedation Scale ([Table 30-8](#))<sup>169</sup> and the ASA Continuum of Depth of

Sedation Definition (Table 30-9).<sup>170</sup> The BIS has been shown to be a useful monitor of drug-induced sedation and recall in volunteers and has been shown to correlate with Observer’s Assessment of Alertness/Sedation Scale scores during propofol-induced sedation in patients undergoing surgery with regional anesthesia.<sup>169</sup> An increasing depth of sedation was associated with a predictable decrease in the BIS. Absence of recall was associated with BIS values below 80. These findings correspond with those of Kearse et al.<sup>171</sup> who found no intraoperative recall at BIS values below 79 during midazolam-, isoflurane-, and propofol-induced sedation. However, the inability to recall a nonnoxious stimulus such as a picture, as used in the previously mentioned studies, may not necessarily correspond to amnesia to noxious events such as surgical stimulation. Despite this caveat, Liu et al.<sup>172</sup> suggest that using a combination of propofol and midazolam to achieve a BIS value below 80 will minimize the possibility of intraoperative recall. Although the use of BIS to monitor sedation is appealing, conventional assessment of sedation is an important mechanism whereby continuous patient contact is maintained. Ideally, BIS monitoring will be employed in the future as an adjunct to clinical evaluation rather than as the primary monitor of consciousness.

**Table 30-8** Observer’s Assessment of Alertness/Sedation Scale

Responsiveness	Speech	Facial Expression	Eyes	Composite Score
Responds readily to name spoken in normal tone	Normal	Normal	Clear, no ptosis	5 (alert)
Lethargic response to name spoken in normal tone	Mild slowing or thickening	Mild relaxation	Glazed or mild ptosis (less than half the eye)	4
Responds only after name is called loudly or repeatedly	Slurring or prominent slowing	Marked relaxation (slack jaw)	Glazed and marked ptosis (half the eye or more)	3
Responds only after mild prodding or shaking	Few recognizable words			2
Does not respond to mild prodding or shaking				1 (asleep)

### *Preparedness to Recognize and Treat Local Anesthetic Toxicity*

Monitored anesthesia care is often provided in the context of regional or local anesthetic techniques. It is vitally important that the anesthesiologist responsible for the patient have a high index of suspicion and be fully prepared to recognize and treat local anesthetic toxicity immediately (see Chapter 22). This point deserves special emphasis, particularly in view of the fact that monitored anesthesia care is often provided to the elderly or debilitated patient who has been deemed “unfit” for general anesthesia; these are the patients most likely to suffer adverse reactions to local anesthetic drugs. Even if the anesthesiologist does not perform the block personally, he

or she is in a unique position to fulfill an important “preventive” role by advising the surgeon about the most appropriate volume, concentration, and type of local anesthetic drug or technique to be used.

Systemic local anesthetic toxicity occurs when plasma concentrations of drug are excessively high. Plasma concentrations will increase when the rate of entry of drug into the circulation exceeds the rate of drug clearance from the circulation. The clinically recognizable effects of local anesthetics on the central nervous system are concentration dependent. At low concentrations, sedation and numbness of the tongue and circumoral tissues and a metallic taste are prominent features. As concentrations increase, restlessness, vertigo, tinnitus, and difficulty focusing may occur. Higher concentrations result in slurred speech and skeletal muscle twitching, which often herald the onset of tonic-clonic seizures.

The conduct of monitored anesthesia care may modify the individual’s response to the potentially toxic effects of local anesthetic administration and adversely affect the margin of safety of a regional or local technique. For example, a patient with compromised cardiovascular function may experience a further decline in cardiac output during sedation. The resultant reduction in hepatic blood flow will reduce the clearance of local anesthetics that are metabolized by the liver and have a high hepatic extraction ratio, thereby increasing the likelihood of achieving toxic plasma concentrations. A patient receiving sedation may experience respiratory depression and a subsequent increase in arterial carbon dioxide concentration. Hypercarbia adversely affects the margin of safety in several ways. By increasing cerebral blood flow, hypercarbia will increase the amount of local anesthetic that is delivered to the brain, thereby increasing the potential for neurotoxicity. By reducing neuronal axoplasmic pH, hypercarbia increases the intracellular concentration of the charged, active form of local anesthetic, thus also increasing its toxicity. In addition, hypercarbia, acidosis, and hypoxia all markedly potentiate the cardiovascular toxicity of local anesthetics. Furthermore, the administration of sedative-hypnotic drugs may interfere with the patient’s ability to communicate the symptoms of impending neurotoxicity. However, the anticonvulsant properties of benzodiazepines and barbiturates may attenuate the seizures associated with neurotoxicity. In both of these circumstances, it is possible that the symptoms of cardiotoxicity will be the first evidence that an adverse reaction has occurred. Thus, appropriate treatment is delayed or inadvertent intravascular injection is continued because of the absence of any clinical evidence of neurotoxicity. Cardiovascular toxicity usually occurs at a higher plasma concentration than neurotoxicity, but when it does occur, it is usually much more difficult to manage than neurotoxicity. Although cardiotoxicity is usually preceded by neurotoxicity, it may on occasion be the initial presenting feature.

**Table 30-9** Continuum of Depth of Sedation

	Minimal Sedation Anxiolysis	Moderate Sedation/Analgesia ("Conscious Sedation")	Deep Sedation/ Analgesia	General Anesthesia
<b>Responsiveness</b>	Normal response to verbal stimulation	Purposeful <sup>a</sup> response to verbal or tactile stimulation	Purposeful response following repeated or painful stimulation	Unarousable, even with a painful stimulus
<b>Airway</b>	Unaffected	No intervention required	Intervention may be required	Intervention often required
<b>Spontaneous ventilation</b>	Unaffected	Adequate	May be inadequate	Frequently inadequate
<b>Cardiovascular function</b>	Unaffected	Usually maintained	Usually maintained	May be impaired

<sup>a</sup>Reflex withdrawal from a painful stimulus is not considered a purposeful response.

Adapted with permission from ASA House of Delegates. Continuum of depth of sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia, 2014. ## *Sedation and Analgesia by Nonanesthesiologists*

Although anesthesiologists have specific training and expertise to provide sedation and analgesia, in clinical practice minimal and moderate sedation **7** services are frequently provided by nonanesthesiologists. Deep sedation is occasionally delivered by trained specialists, including emergency department physicians and intensivists. The specific reasons for nonanesthesiologist involvement differ from institution to institution and from case to case and include convenience, availability, and scheduling issues; perceived lack of anesthesiologist availability; perceived increased cost; and a perceived lack of benefit concerning patient satisfaction and safety when sedation and analgesia are provided by anesthesiologists. Despite our frequent noninvolvement in these cases, anesthesiologists are indirectly involved in the care of these patients by being required to participate in the development of institutional policies and procedures for sedation and analgesia, as mandated by the Joint Commission. To assist anesthesiologists in this process, an ASA task force has developed practice guidelines for sedation and analgesia by nonanesthesiologists.<sup>173,174</sup>

Four levels of sedation are defined in the ASA practice guidelines and include minimal sedation, moderate sedation, deep sedation, and general anesthesia. The practice guidelines emphasize that sedation and analgesia represent a continuum of sedation wherein patients can easily pass into a level of sedation deeper than intended. The ASA House of Delegates issued a statement on this continuum of depth of sedation originally in October 1999, and most recently amended it in October 2014. This statement contains a chart representing the clinical progression along this continuum ([Table 30-9](#)).<sup>172</sup> When monitoring a sedated patient during a procedure, it is important to recognize when a patient becomes more deeply sedated than intended so that the care team can act appropriately to prevent cardiorespiratory compromise.

The sedation guidelines emphasize the importance of preprocedure patient evaluation, patient preparation, and appropriate fasting periods. The importance of continuous patient monitoring is discussed—in particular, the response of the patient to commands as a guide to the level of sedation. The appropriate monitoring of ventilation, oxygenation, and hemodynamics is also discussed, and recommendations are made for the contemporaneous recording of these parameters. The task force strongly suggests that an individual other than the person performing the therapeutic or diagnostic procedure be available to monitor the patient's comfort and physiologic status. Education and training of providers is recommended. Specific educational objectives include the potentiation of sedative-induced respiratory depression by concomitantly administered opioids, adequate time intervals between doses of sedative/analgesics to avoid cumulative over-dosage, and familiarity with sedative/analgesic antagonists. The routine administration of supplemental oxygen is recommended. At least one person with Basic Life Support training should be available during moderate sedation, with immediate availability (1 to 5 minutes) of personnel trained in Advanced Life Support. For procedures requiring Deep Sedation, the ASA recommends ACLS trained personnel be present in the procedure room. This individual should have the ability to recognize airway obstruction, establish an airway, and maintain oxygenation and ventilation. The practice guidelines recommend that appropriate patient-size emergency equipment be readily available, specifically including equipment for establishing an airway and delivering positive pressure ventilation with supplemental oxygen, emergency resuscitation drugs, and a working defibrillator. The presence of reliable IV access until the patient is no longer at risk for cardiorespiratory depression will improve safety. Adequate postprocedure recovery care with appropriate monitoring must be provided until discharge. Certain high-risk patient groups (e.g., unco-operative patients, extremes of age, severe cardiac, pulmonary, hepatic, renal, or central nervous system disease, morbid obesity, sleep apnea, pregnancy, and patients who abuse drug or alcohol) will be encountered, and the guidelines recommend that preprocedure consultation with anesthesiologists, cardiologists, pulmonologists, and so forth be performed *before* administration of sedation and analgesia by nonanesthesiologists.

Controversy exists regarding the level of training required for nonanesthesiologists to be credentialed to provide moderate and deep sedation. The ASA released a statement in October 2005, amended in 2011, suggesting a framework for granting privileges that will help ensure competence of individuals who administer or supervise the administration of moderate sedation.<sup>174</sup> This statement suggests that the practitioner should complete formal training in (1) the safe administration of sedative and analgesic drugs used to establish a level of moderate sedation, and (2) rescue

of patients who exhibit adverse physiologic consequences of a deeper-than-intended level of sedation. The ASA released an advisory in October 2010 on granting privileges for deep sedation to nonanesthesiologist sedation practitioners.<sup>174</sup>

Recently, the Centers for Medicare and Medicaid Services (CMS) published revised hospital anesthesia services interpretive guidelines requiring hospitals to establish policies and procedures that address whether specific clinical situations involve “anesthesia” versus “analgesia” services. The CMS document places general anesthesia, monitored anesthesia care, deep sedation, and regional anesthesia under “anesthesia” services. These “anesthesia” services must be provided by: A qualified anesthesiologist; a doctor of medicine or osteopathy, a dentist, oral surgeon, or podiatrist who is qualified to administer anesthesia under state law; an appropriately supervised Certified Registered Nurse Anesthetist or Anesthesia Assistant, all who are separate from the practitioner performing the procedure. Moderate sedation and minimal sedation fall under “analgesia” services.<sup>175</sup> The statement released by the ASA on the safe use of propofol, most recently amended in 2014, is explicit that the drug should be administered only by “persons trained in the administration of general anesthesia, who are not simultaneously involved in these surgical or diagnostic procedures.... Failure to follow these recommendations could put patients at increased risk of significant injury or death.”<sup>176</sup>

### ***Computer-assisted Personalized Sedation—SEDASYS***

Although the SEDASYS device has now been withdrawn from the US market, it is worthwhile to briefly review the circumstances prompting its development and its design features. In December 2009, the American College of Gastroenterology (ACG) released a position statement which suggested that nonanesthesiologist administered propofol is more cost-effective than standard sedation for routine endoscopic GI procedures; and that the utilization of anesthesiologist-administered sedation for “healthy, low risk patients results in higher cost with no proven benefit in terms of patient safety.”<sup>177</sup> Although the professional cost of anesthesia services is only a small fraction (3%) of the total physician services, the recent increase in spending on monitored anesthesia care for esophagogastroduodenoscopy and colonoscopy is significant. Given the ACG stance on the cost-effectiveness of nonanesthesiologist administered propofol, the cost associated with anesthesiologist-administered sedation, and the increasing demand for large numbers of patients to receive sedation for endoscopic procedures, it is not surprising that alternatives to anesthesiologist-administered sedation might be considered attractive. Recent advances in technology have allowed the

development of computer-assisted personalized sedation (CAPS) devices. These devices integrate patient monitoring variables with the programmed delivery of propofol. The most publicized of these systems, SEDASYS (SEDASYS Computer-Assisted Personalized Sedation System, Ethicon Endo-Surgery, Inc. Cincinnati, Ohio) integrated information extracted from standard ASA monitors (including pulse oximetry, capnography, electrocardiography, and blood pressure surveillance) with dosing algorithms to deliver a titratable infusion of propofol in order to achieve and maintain minimal-to-moderate sedation. The manufacturer of this system required that it should only be used in facilities where an anesthesia professional is immediately available to assist or consult as needed. The ASA recommends that in this particular context, that at a minimum, “immediate availability” could be a code or rapid response team that includes an anesthesia professional.

SEDASYS primarily achieved sedation with propofol. However, the device worked in conjunction with a single administered dose of fentanyl given 3 minutes prior to the start of a propofol infusion in an attempt to yield some analgesic effect.<sup>2,3</sup> Patients less than 65 years of age received a 50 to 100 µg IV bolus of fentanyl, whereas patients 65 years of age and older were limited to 25 to 50 µg. Initial propofol infusion rates varied between 25 and 75 µg/kg/min. After a maintenance infusion rate escalation, further increases were limited by a 3-minute lockout period.<sup>178,179</sup> If patient variables suggested a need for increased sedation, a maximum infusion rate of 200 µg/kg/min could be achieved over the course of 12 minutes. There were several safety mechanisms in place to ensure both adequate depth of sedation, and prevention of oversedation. An automated responsiveness monitor actuated by the patient assessed his/her responsiveness by requiring interaction with a hand-held device when prompted by vibratory or auditory stimulation. Oxygen delivery was also automatically titrated as determined by oxygen saturation measurement. There were alarm systems to alert the provider to low respiratory rate, low oxygen saturation or apnea events. Triggering these alarms resulted in the discontinuation of the propofol infusion. Although the aforementioned safety features were effective in generally healthy adults, some patients were not considered to be suitable candidates for sedation with SEDASYS, including age under 18 years, ASA IV or V classification, BMI over 35, abnormal airway anatomy or evidence of obstructive sleep apnea, chronic pain patient utilizing a fentanyl patch, gastroparesis, patients undergoing both colonoscopy and EGD in the same procedure, emergent colonoscopy or EGD. Although SEDASYS was withdrawn from the market, it seems likely that other CAPS devices will be developed. In 2014, the ASA issued a guidance document with recommendations on sedation with regard to the integration of CAPS devices into medical practices

in the safest and most efficient way. The ASA statement notes that it is important when working with new technology to investigate ways to ensure it is used safely. Highlights of the recommendations are that Directors of Anesthesia Services should be familiar with the manufacturer's recommendations and the FDA labeling information on the operation and safe use of the device, and that quality and safety programs in procedural sedation should be revised to include data collection on all sedation including these devices. The Anesthesia Quality Institute (AQI) publishes guidelines for quality metrics for procedural sedation. These guidelines now include metrics for patients receiving sedation via CAPS.<sup>180</sup>

## Conclusion

Through the use of monitored anesthesia care, an often terrifying and painful procedure can be made safe and comfortable for the patient. Monitored anesthesia care presents an opportunity for our patients to observe us at work. For the anesthesiologist, monitored anesthesia care presents an opportunity to provide a more prolonged and intimate level of care and reassurance to our patients that is in contrast to the more limited exposure that occurs during and after general anesthesia. Our airway management skills and our daily practice of applied pharmacology make us uniquely qualified to provide this service. Monitored anesthesia care presents us with an opportunity to display these skills and increase our recognition in areas outside the operating room. The availability of drugs with a more favorable pharmacologic profile allows us to tailor our techniques to provide the specific components of analgesia, sedation, anxiolysis, and amnesia with minimal morbidity and to facilitate a prompt recovery. As the population ages, increasing numbers of patients will become candidates for monitored anesthesia care. Significant advances in nonsurgical fields (e.g., interventional radiology) will increase the number of procedures that are ideally performed under monitored anesthesia care. It is our responsibility to clearly demonstrate to our nonanesthesia colleagues that anesthesiologist-provided monitored anesthesia care contributes to the best outcome for our patients. If anesthesiologists are not willing or able to provide these services, others, who are less well qualified, are prepared to assume that role.

# 31 Ambulatory Anesthesia

J. LANCE LICHTOR • PETER MANCINI

## Place, Procedures, and Patient Selection

### Preoperative Screening

Upper Respiratory Tract Infection

Restriction of Food and Liquids Prior to Ambulatory Surgery

Anxiety Reduction

### Managing the Anesthetic: Premedication

Benzodiazepines

Opioids and Nonsteroidal Analgesics

### Intraoperative Management: Choice of Anesthetic Method

Regional Techniques

Spinal Anesthesia

Epidural and Caudal Anesthesia

Nerve Blocks

Sedation and Analgesia

General Anesthesia

### Management of Postanesthesia Care

Reversal of Drug Effects

Nausea and Vomiting

Pain

Preparation for Discharging the Patient

## Acknowledgments

## KEY POINTS

- 1 Procedures appropriate for ambulatory surgery are those associated with low rates of postoperative complications that do not require intensive physician or nursing management.
- 2 Medically stable ASA physical status III or IV patients may be appropriate candidates for ambulatory surgical procedures.
- 3 ASA, Society for Ambulatory Anesthesia, and American College of Chest Physicians agree that a procedure typically performed as an ambulatory procedure with local or regional anesthesia can also be performed as an ambulatory procedure in patients with obstructive sleep apnea (OSA).
- 4 Airflow obstruction in adults may persist for up to 6 weeks after viral

infections. For that reason, many agree that surgery should be delayed for 6 weeks. For children, whether surgery should be delayed for that length of time is questionable.

- 5 The most recent ASA revised practice guidelines for preoperative fasting was published in 2011. The guidelines allow a light meal up to 6 hours before an elective procedure and support a fasting period for clear liquids of 2 hours for all patients.
- 6 Most premedicants do not prolong recovery when given in appropriate doses for appropriate indications, although drug effects may be apparent even after discharge.
- 7 Regional and general anesthesia in the ambulatory setting are equally safe. However, even for experienced anesthesiologists, there is a failure rate associated with regional anesthesia.
- 8 Nerve blocks improve postoperative patient satisfaction and decrease postoperative nausea and vomiting (PONV) and postoperative pain.
- 9 Two primary concerns for ambulatory anesthesia are speed of wake-up and incidence of PONV.
- 10 It is important to distinguish between wake-up time and discharge time. Patients may emerge from anesthesia with desflurane and nitrous oxide significantly faster than after propofol or sevoflurane and nitrous oxide, though the ability to sit up, stand, and tolerate fluids and the time to fitness for discharge may be no different.
- 11 Nausea, with or without vomiting, is probably the most important factor contributing to a delay in discharge and an increase in unanticipated admissions after ambulatory surgery.
- 12 In addition to the postanesthesia care unit (PACU), most ambulatory surgery centers (ASCs) in the United States have Phase II Recovery, which may be located within or separate from the PACU. Patients remain in Phase II Recovery until they are able to tolerate liquids, walk, and (depending on the operation) void.

Ambulatory anesthesia for ambulatory surgery may seem to be a recent phenomenon, although it has been around for over 100 years. The Society for Ambulatory Anesthesia (SAMBA) in the United States and the British Association of Day Surgery roughly 30 years ago helped to bring together those who practice ambulatory anesthesia to provide education and stimulate research. The International Association for Ambulatory Surgery (<http://www.iaas-med.com>) was formed in 1995, is designed to promote worldwide development of ambulatory surgery, has a peer reviewed journal, *Ambulatory Surgery*, and currently has members from 18 nations.

The U.S. National Library of Medicine (USNLM) defines the term “ambulatory surgical procedure” as “Surgery performed on an outpatient

basis. It may be hospital-based or performed in an office or surgicenter.” USNLM groups office-based and ambulatory surgery together. Hospital-based ASCs in the United States and Canada can receive accreditation through The Joint Commission (TJC), DNV-GL, and Healthcare Facilities Accreditation Program (HFAP). In the United States, they can be accredited through a state survey agency or the Centers for Medicare and Medicaid Services. Freestanding US ASCs and offices receive accreditation through the Accreditation Association for Ambulatory Health Care, Inc., The American Association for Accreditation of Ambulatory Surgery Facilities, Inc., or TJC.

## Place, Procedures, and Patient Selection

Place: Ambulatory surgery occurs in a variety of settings. Some centers are within a hospital or in a freestanding satellite facility affiliated with or independent from a hospital. The independent facilities are often for-profit and not located in rural or inner-city areas. Some private companies acquire or build ambulatory facilities and then work with local surgeons who become the company’s affiliated staff. Procedures might also be performed in a physician’s office (see also [Chapter 32](#)). Freestanding, independent facilities continue to grow in number and popularity, although some consumers prefer care in units affiliated with hospitals or health-care systems.

A major concern of freestanding ambulatory surgery growth is that the surgery centers may force some hospitals out of business. This issue can be particularly problematic in areas in which population density or median income are low. Freestanding ambulatory facilities usually do not provide charity or government-subsidized care. Some surgeons may work exclusively in a freestanding facility and not be on the staff of a hospital since a requirement for hospital staff privileges frequently is that a physician provides coverage for the hospital’s emergency department. Some hospitals have lost emergency department coverage for an entire surgical specialty because that surgical specialty works exclusively in a freestanding facility.

Costs are lower for ASCs. Scheduling can be more predictable because the variety of cases is low. Turnaround times are also usually lower. The profits, particularly for freestanding facilities, do not have to subsidize more costly areas of the hospital. Yet some hospitals own ASCs. ASCs also tend to serve mostly insured patients. Medicare pays ASCs at a lower percent than what they pay hospitals for the same procedure. Medicare can then save money, though the payment system may force some ambulatory facilities to decide whether they accept Medicare patients.

Procedures: What case is appropriate for an ambulatory surgical procedure? Some centers use maximum duration of surgery time, for example, 4 hours, as a criterion for allowing a procedure to take place in an

ambulatory care facility. Others consider an ambulatory procedure as one that does not pose a significant safety risk or require an overnight stay. Generally, procedures appropriate for ambulatory surgery are those associated with **1** postoperative care that is easily managed at home, have low rates of postoperative complications, and do not require intensive physician or nursing management. Establishing a low rate of postoperative complication depends on the relative aggressiveness of the facility, surgeon, patient, and payer. For example, procedures that postoperatively result in intense pain may be treated with continuous regional techniques that are continued at home, whereas in other settings, the same procedures are limited to inpatients. Quite a bit of variability exists between facilities concerning rates of postoperative complications after ambulatory surgery (Fig. 31-1).<sup>1</sup>

Patients undergoing longer procedures should have their operations earlier in the day, primarily because resources are more efficiently managed during regular working hours. The need for transfusion is also not a contraindication for ambulatory procedures. Some patients undergoing outpatient liposuction, for example, receive autologous blood. Because of blood bank proximity, procedures that require the use of a blood bank are more commonly performed in larger facilities. Freestanding dialysis facilities commonly receive blood shipped from a blood bank located elsewhere and the same can be set up with freestanding ambulatory surgery facilities. The key is to have proper procedures established.

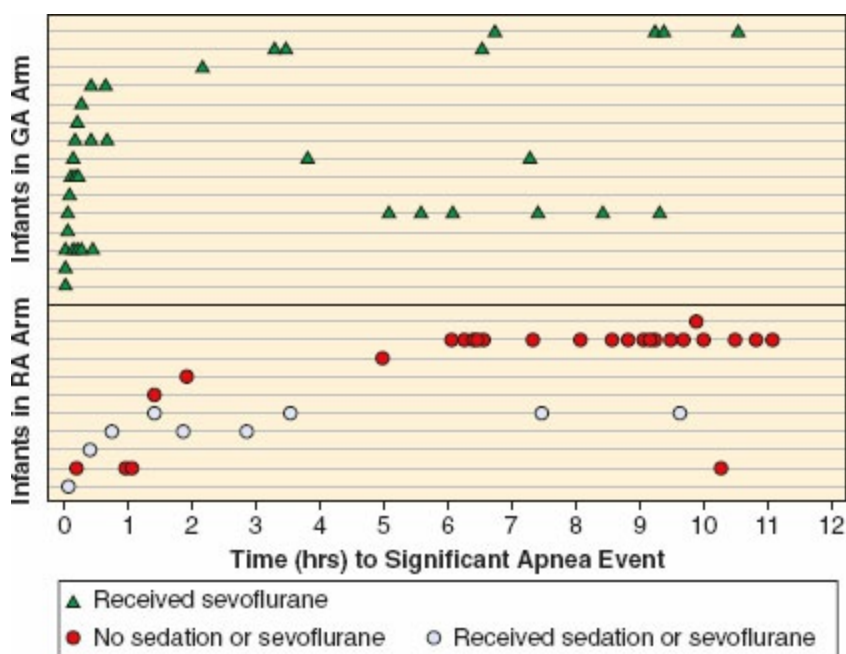

Some have questioned the safety of office-based procedures, in part because of reports of deaths in Florida (see also Chapter 32). A 2012 analysis revealed 46 deaths and 263 procedure-related complications and hospital transfers in Florida, and 3 deaths and 49 complications or hospital transfers in Alabama over several years.<sup>2</sup> An accompanying editorial notes that liposuction on awake patients using tumescent local anesthesia is safe; however, liposuction performed in conjunction with abdominoplasty under general anesthesia is problematic and should be avoided.<sup>3</sup>

Patient selection: Age is an important consideration in patient selection. Term infants whose postconceptual age is less than 46 weeks, or preterm infants whose postconceptual age (PCA) is less than 60 weeks should be monitored for 12 hours after their procedure. They are at risk of developing postoperative apnea even without a history of apnea (Fig. 31-2; Table 31-1).<sup>4</sup> In one series of over 700 patients who underwent inguinal hernia surgery, the overall incidence of postoperative apnea was 6.1% in prematurely born infants and 0.3% in full-term infants. There was no difference in the incidence of apnea in patients who received either regional or general anesthesia.<sup>4</sup> However, the incidence and severity of apnea, 0 to 30 minutes in the postanesthesia care unit (PACU), was less in those infants who received regional anesthesia. Two infants in that study experienced apnea 6 to 7 hours

after their procedures; they were 29 weeks of gestation and 43 weeks PCA, and 30 weeks of gestation and 42 weeks PCA.

**Figure 31-1** Admission rates after ambulatory surgery among 635 California outpatient surgery facilities, studied between 2005 and 2015. On average, 30-day admission rate was 1.2%; 18 facilities were statistically significant outliers; and 79 facilities had no patients that needed hospital admission. (Adapted with permission from Parina R, Chang D, Saad AN, et al. Quality and safety outcomes of ambulatory plastic surgery facilities in California. *Plast Reconstr Surg.* 2015;135:791–797.)

**Figure 31-2** Apnea after regional and general anesthesia in infants. Regional anesthesia (RA) group further divided into those who received only regional anesthesia without sedation or general anesthesia (*closed circles*) and those who received spinal anesthesia and sedation or general anesthesia (*closed squares*). (Adapted with

permission from Davidson AJ, Morton NS, Arnup SJ, et al. General anesthesia compared to spinal anesthesia (GAS) consortium: apnea after awake regional and general anesthesia in infants: the general anesthesia compared to spinal anesthesia study-comparing apnea and neurodevelopmental outcomes, a randomized controlled trial. *Anesthesiology*. 2015. Copyright © 2015, Wolters Kluwer Health.)

At the other extreme of life, advanced age alone is not a reason to disallow surgery in an ambulatory setting. In a study of over 500 patients, postoperative outcome was no different when patients 65 years and older undergoing inguinal hernia repair were compared to patients less than 54 years old.<sup>5</sup> Based on another series, older patients had less chronic post herniorrhaphy pain.<sup>6</sup> Increasing age, however, does affect the pharmacokinetics of drugs (see also [Chapter 11](#)). Even short-acting drugs such as midazolam and propofol have decreased clearance in older individuals. Increased age may increase the likelihood of unanticipated admission, but, by itself, does not contraindicate ambulatory surgery.

Hospital admission is not necessarily a failure if it results in a better quality of care. With proper patient selection for typically elective ambulatory procedures, the incidence of hospital admission should be very low. Most medical problems that older individuals experience after ambulatory procedures are not related to patient age, but to specific organ dysfunction. For that reason, all individuals, whether young or old, should receive a careful preoperative history and physical examination.

Patients of ASA physical status III or IV are appropriate candidates for **2** some ambulatory surgical procedures if their systemic diseases are medically stable. In a review of over 10,000 patients who underwent ambulatory orthopedic surgical procedures between June 1993 and June 2012, no major complications were reported. Of the 14 patients who needed overnight admission, the majority were ASA III.<sup>7</sup> That very low rate of major complications resulted from selecting patients whose medical problems were well controlled.

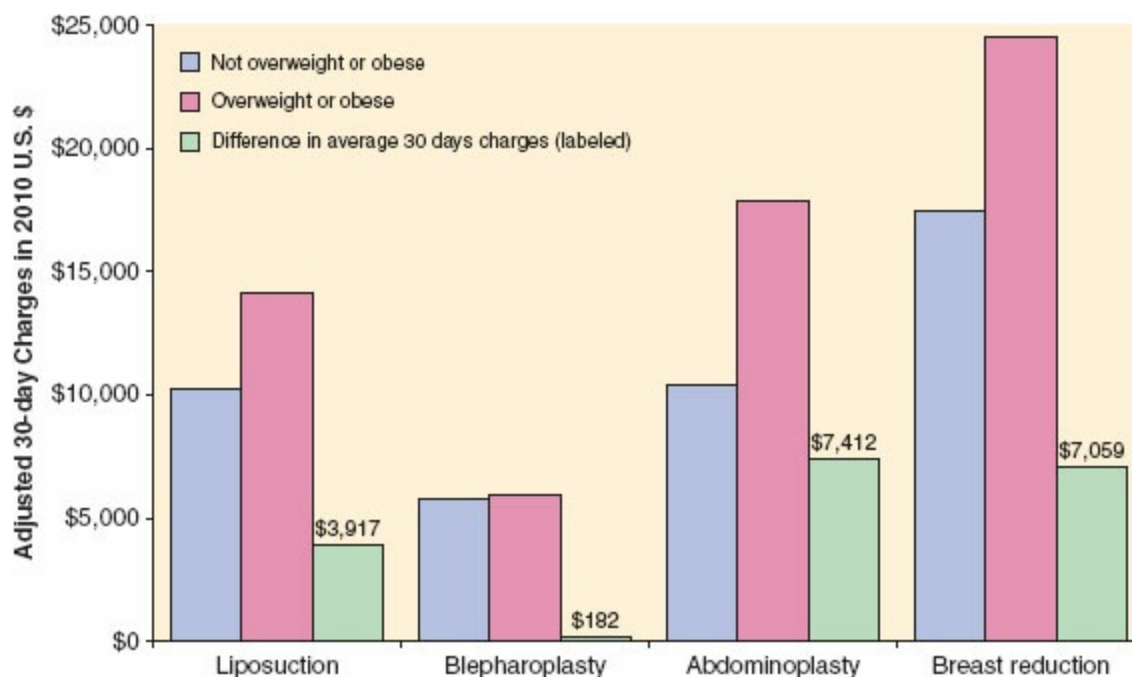

Obese patients represent a special situation. Obese patients are more likely to have adverse outcomes, and they have a higher incidence of obstructive sleep apnea (OSA). One review of over 47,000 discharges from almost 1,000 ASCs for patients undergoing outpatient blepharoplasty, abdominoplasty, breast reduction, and liposuction included 4.3% who were obese. The obese patients more often had at least one hospital-based, acute care encounter within 30 days of discharge and because of that had higher health-care charges ([Fig. 31-3](#)).<sup>8</sup> In a meta-analysis of patients undergoing nonupper airway surgery, patients with or at high risk of OSA were more prone to adverse perioperative outcomes including respiratory, cardiac, and neurologic complications, and unplanned ICU transfer. Further, patients with sleep apnea

had higher risk of hypoxemia postoperatively.<sup>9</sup> Some feel that patients with OSA who need more opioids may be at greater risk for apnea and should be observed for a longer period after their procedure. The ASA, SAMBA, and American College of Chest Physicians published practice guidelines for the perioperative management of patients with OSA.<sup>10-12</sup> For patients with OSA, if a procedure is typically performed as an outpatient procedure and local or regional anesthesia is used, the procedure can also be performed as an ambulatory procedure. Conversely, those patients with OSA who are undergoing major surgery, or who are undergoing a procedure with an increased risk for perioperative complications, should not have their procedure performed as an ambulatory procedure (Table 31-2).

**Table 31-1** Guide to Determine Length of Stay for Infants after Surgery

Born (Weeks Postconception)	Age at Time of Surgery (Weeks Postconception)	Other Factors	Disposition
<37	<60		Admit overnight
>36	<46		Admit overnight
	<60	Still in PACU @ 9 PM	Admit overnight

PACU, postanesthesia care unit

**Figure 31-3** Overweight or obese patients had higher health-care charges, when adjusted for presence of medical comorbidity. (Adapted with permission from Sieffert MR, Fox JP, Abbott LE, et al. Obesity is associated with increased health care charges in patients undergoing outpatient plastic surgery. *Plast Reconstr Surg.* 2015;135:1396–1404.)

Patients who undergo ambulatory surgery should have an adult take them home and stay with them afterward until the next morning to provide care.

Before the procedure, the patient should receive information about the procedure, where it will be performed, laboratory studies that will be ordered, and dietary restrictions. The patient must understand before the procedure that an overnight stay is not intended. The patient, or some responsible person, must ensure all instructions are followed. Once at home, the patient must be able to tolerate the pain from the procedure, assuming adequate pain therapy is provided. The majority of patients are satisfied with early discharge, although a few prefer a longer stay in the facility. Patients for certain procedures such as laparoscopic cholecystectomy or transurethral resection of the prostate should live close to the ambulatory facility because postoperative complications may require their prompt return. “Reasonable” distance and time for the patient to get care if problems arise are not easily defined. This issue must be addressed by each facility for individual patients based on the planned procedure.

**Table 31-2** An Example of a Scoring System That Can Be Used to Determine Whether a Patient Is at Increased Risk for Complications due to OSA

	Points
<b>A. Severity of sleep apnea based on a sleep study or clinical indicators:</b>	
None	0
Mild	1
Moderate	2
Severe	3
Mild or moderate OSA (obstructive sleep apnea) has resting PaCO <sub>2</sub> > 50 mmHg	1
Uses CPAP (continuous positive airway pressure) or NIPPV (noninvasive positive pressure ventilation) before surgery and will continue the appliance consistently postoperatively	-1
<b>B. Invasiveness of surgery and type of anesthesia:</b>	
Superficial surgery, local or peripheral block, no sedation	0
Superficial surgery with moderate sedation or general anesthesia	1
Peripheral surgery, spinal or epidural anesthesia, at most moderate sedation	1
Peripheral surgery with general anesthesia	2
Airway surgery with moderate sedation	2
Major surgery, general anesthesia	3
Airway surgery, general anesthesia	3
<b>C. Postoperative opioid requirement:</b>	
None	0
Low-dose oral opioids	1
High-dose oral opioids, parenteral or neuraxial opioid	3

Perioperative risk: A plus (B or C, whichever greater).

Score = 4: increased perioperative risk from OSA

Score = 5: significantly increased perioperative risk from OSA

## Preoperative Screening

Each outpatient facility should develop its own method of preoperative screening. The patient may visit the facility, or the staff members may telephone to obtain necessary information about the patient, including a complete medical history of the patient and family, the medications the

patient is taking, and the problems the patient or the patient's family may have had with previous anesthetics. At some facilities, experienced nurses make those telephone calls. Regardless of who performs screening, screened patients are less likely to cancel surgery.<sup>13</sup> Screening may uncover the need for transportation to the facility or the need for childcare. The process also provides the staff with an opportunity to remind patients of arrival time, suitable attire, and dietary restrictions (e.g., when to stop eating and drinking, no jewelry or makeup). Staff members can determine whether a responsible person is available to escort the patient to and from the facility and care for the patient at home after surgery. The screening is the ideal time for the anesthesiologist to talk to the patient, but if that is not possible, the anesthesiologist may review the screening record to determine whether additional evaluation by other consultants is necessary and whether laboratory tests are needed.

### *Upper Respiratory Tract Infection*

**4** Following viral upper respiratory infections (URIs) in adults, airflow obstruction persists for up to 6 weeks. For that reason, many agree that surgery should be delayed if an adult presents with an URI until 6 weeks have elapsed. In the case of children, whether surgery should be delayed for that length of time is questionable. In a year-long survey of almost  10,000 children who underwent surgery, URI was associated with an increased risk for perioperative respiratory adverse events only when symptoms were present or had occurred within the 2 weeks before the procedure.<sup>14</sup> This Swiss study included children who were febrile or who had mucopurulent airway secretions and nevertheless had surgery. Of interest, children with these symptoms in the United States would have had their operations cancelled. Although a case may be cancelled because a child is symptomatic, the child may develop another URI when the procedure is rescheduled. Independent risk factors for adverse respiratory events in children with URIs include use of an endotracheal tube (vs. use of a laryngeal mask airway [LMA] or face mask), history of prematurity, history of reactive airway disease, history of parental smoking, surgery involving the airway, presence of copious secretions, and nasal congestion. Generally, if a patient with a URI has a normal appetite, does not have a fever or an elevated respiratory rate, and does not appear toxic, it is probably safe to proceed with the planned procedure.

### *Restriction of Food and Liquids Prior to Ambulatory Surgery*

To decrease the risk of aspiration of gastric contents, we routinely ask

patients not to eat or drink anything (*non per os* [NPO] or “nothing by mouth”) for at least 6 to 8 hours before surgery. Prolonged fasting could be detrimental to a patient. Yet, hydration, as measured by urine osmolality, does not correlate with intraoperative hypotension.<sup>15</sup> In children, there is no correlation between hunger, thirst, and gastric volume; nor do hunger and thirst correlate with duration of fasting.<sup>16</sup> Shorter fasting times are correlated with increased patient satisfaction.<sup>17</sup> The most recent ASA revised practice guidelines for preoperative fasting were published in 2011 (Table 31-3).<sup>18</sup> The guidelines allow a patient to eat a nonfat meal up to 6 hours before an elective procedure and support a fasting period for clear liquids of 2 hours for all patients. Coffee and tea are considered clear liquids. Coffee and tea drinkers should follow fasting guidelines but should be encouraged to drink coffee prior to their procedure because physical signs of caffeine withdrawal (headache) can occur. It is not clear if the more liberal NPO guidelines should apply to patients with diabetes or dyspepsia. There is some evidence that shorter periods of preoperative fasting are accompanied by less postoperative nausea and vomiting (PONV).

To ensure patients are optimally medically managed before their outpatient surgery, patients should have clear instructions concerning what chronic medications they should take before surgery and when (Table 31-4).

### **Anxiety Reduction**

Most patients are anxious before scheduled surgery, and they are probably anxious long before they come to the outpatient area. Anxiety may begin as soon as the surgeon states the patient needs an operation and may not end even after discharge from the outpatient facility. Reasons for anxiety include concerns about family, worry about pain after the procedure, fear of complications, and lack of social support. Preoperative reassurance from nonanesthesia staff, use of booklets or audiovisual instruction with information about the procedure, or a preoperative visit by the anesthesiologist can all help reduce preoperative anxiety. However, not all outpatients are anxious and whether it is necessary to give every patient a preoperative drug to decrease anxiety is not clear. If in doubt about patient anxiety, ask the patient; do not assume every patient needs a drug to reduce anxiety.

**Table 31-3** Fasting Guidelines before Surgery

Food/Drink	Time to Fast Prior to Surgery (h)
Clear liquids (e.g., water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee)	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Light meal (toast and clear liquids)	6
Meals that include fried or fatty foods or meat	8

**Table 31-4** A Guide to Medications Appropriate to Take Prior to Surgery

<b>Medications that should be taken on the day of surgery:</b> β-Blockers Statins Antiarrhythmics Antihypertensives (except ACE I, ARB, diuretics) Pulmonary inhalers Pain medications (except NSAIDs) Antiseizure medications Hyperthyroid medications
<b>Medications that should be avoided on the day of surgery:</b> ACE I/ARB (angiotensin-converting-enzyme inhibitor/angiotensin II receptor blockers)—risk of profound hypotension unresponsive to traditional treatments Diuretics—hypokalemia and dehydration Anticoagulants/antiplatelet—depending on surgery, surgeon and underlying medical conditions—we leave these decisions up to surgeon and prescribing physician Oral hypoglycemic agents Vitamins which affect platelets (vitamin E) Herbal supplements which may affect bleeding
<b>Nonessential medications that can be continued on the day of surgery:</b> Hypothyroid medications Antidepressants

Source: Jill Zafar, Yale University Department of Anesthesiology.

Like adults, children should have some idea of what to expect during a procedure. Certainly some of a child's anxiety before surgery concerns separation from a parent or parents. A child is more likely to demonstrate problematic behavior from the time of separation from parents to induction of anesthesia if the procedure has not been explained preoperatively. Parents

and children need to be involved in some preoperative discussions together so that the parents do not transmit their anxiety to the child. If the parents are calm and can effectively manage the physical transfer to a warm and playful anesthesiologist or nurse, premedication is not necessary.

Whether having the parent present during induction reduces a child's anxiety is unclear, though the practice of parental presence during anesthesia induction is widespread. Certain parental behaviors are more helpful than are others. Some parents can become upset when they see their anesthetized child, who appears to be dead, albeit breathing, and with a beating heart. Separation anxiety on the part of the parents is probably no different if the child is awake or asleep.

## Managing the Anesthetic: Premedication

The outpatient is not that different from the inpatient undergoing surgery. In both, premedication is useful to control anxiety, postoperative pain, nausea and vomiting, and to reduce the risk of aspiration during induction of anesthesia. Because the outpatient is going home on the day of surgery, the drugs given before anesthesia should not hinder recovery. Most premedicants do not prolong recovery when given in appropriate doses for appropriate indications, although drug effects may be apparent even after discharge. 6

### *Benzodiazepines*

Midazolam, a benzodiazepine, is currently the drug most commonly used to reduce preoperative anxiety and induce sedation. It can be administered intravenously and orally. In adults, it can be used to control preoperative anxiety and, during a procedure alone or in combination with other drugs, for intravenous sedation. For children, oral midazolam in doses as small as 0.25 mg/kg produces effective sedation and reduces anxiety (Fig. 31-4).<sup>19</sup> With this dose, most children can be effectively separated from their parents after 10 minutes and satisfactory sedation can be maintained for 45 minutes. Some children, particularly younger and more anxious children, even when they receive midazolam 0.5 mg/kg, show signs of distress.<sup>20</sup> Discharge may be delayed when midazolam is given before a short procedure. Oral diazepam is useful to control anxiety in adult patients, either the day before surgery or the day of surgery and before intravenous line insertion.

Sleepiness associated with the effects of anxiolytics may delay or prevent the discharge of patients on the day of surgery, although more frequently patients are admitted because of the effects of the operation. With regard to anesthesia effects, patients more frequently stay in the facility not because they are too sleepy but because they are nauseous. In adults, particularly

when midazolam is combined with fentanyl, patients can remain sleepy for up to 8 hours. Although children may be sleepier after oral midazolam, discharge times are not affected.

**Figure 31-4** The very smallest dose (0.25 mg/kg) of oral midazolam syrup was equally as effective as the two higher doses when commercially prepared oral midazolam syrup was used. Onset was faster with the larger dose. (Adapted with permission from Coté CJ, Cohen IT, Suresh S, et al. A comparison of three doses of a commercially prepared oral midazolam syrup in children. *Anesth Analg*. 2002;94:37–43.)

At proper doses, neither midazolam nor diazepam place patients at any additional risk for cardiovascular and respiratory depression. Decreased oxygen saturation has been reported after injection of midazolam. Routine administration of supplemental oxygen with or without continuous monitoring of arterial oxygenation is recommended whenever benzodiazepines are given intravenously. This precaution is important not only when midazolam is given as a premedicant but also when it is used alone or with other drugs for conscious sedation. The potential for amnesia after premedication is another concern, especially for patients undergoing ambulatory surgery. Anterograde but probably not retrograde amnesia occurs. For benzodiazepines, the effects on memory are separate from the effects on sedation. In addition, amnesia is not simply an effect of drug administration but, among other factors, it is also a function of stimulus intensity.

### Opioids and Nonsteroidal Analgesics

Opioids can be administered preoperatively to sedate patients, control hypertension during tracheal intubation, and decrease pain before surgery. Meperidine (but not morphine or fentanyl) is sometimes helpful in controlling

shivering in the OR or the PACU. Treatment for shivering is usually instituted at the time of shivering, not in anticipation of the event. Other drugs, including clonidine, tramadol, and ketamine can also help control shivering.<sup>21</sup>

Opioids are useful in controlling hypertension during tracheal intubation. Opioid premedication prevents increases in systolic pressure in a dose-dependent fashion. After tracheal intubation, systolic, diastolic, and mean arterial blood pressures sometimes decrease below baseline values.

It would seem that preoperative administration of opioids or nonsteroidal anti-inflammatory drugs (NSAIDs) may be useful for controlling pain in the early postoperative period. The term “preventive analgesia” (as opposed to “preemptive analgesia”) is used to mean treatment of postoperative pain for a longer duration than the effect of the target drug (e.g., at least 5.5 half-lives of the drug), so that the effect of the drug is more than its analgesic effect.<sup>22,23</sup> The drug then does not necessarily have to be administered before surgery. Laparoscopic cholecystectomy is less painful than open cholecystectomy, though patients undergoing the laparoscopic procedure also have postoperative pain. Based on a Cochrane review, pain is less after NSAIDs plus opioids, and anticonvulsant analgesics, 4 to 8 hours and 9 to 24 hours, respectively after surgery. Anticonvulsant analgesics are more effective than NSAIDs plus opioids though it is unclear if pain control is any different if the drugs are given pre- or intraoperatively.<sup>24</sup> Children undergoing cleft-lip repair who received acetaminophen before surgery had similar pain relief postoperatively as compared to patients who received the acetaminophen intraoperatively.<sup>25</sup> Ibuprofen or acetaminophen can be given orally preoperatively, or administered rectally to children around the time of induction. In children, an initial rectal loading dose of 40 mg/kg is appropriate. When preoperative rectal acetaminophen is combined with an NSAID, particularly for more painful procedures, postoperative pain is less than when either drug is given alone.<sup>26</sup>

Not every patient needs preoperative sedation. However, for those whose anxiety is not relieved by a reassuring preoperative clinic visit, we recommend oral diazepam 2 to 5 mg/70 kg body weight, prescribed for the night before and at 6 AM on the day of surgery (even if surgery is scheduled for 1 PM or later). For patients seen for the first time in the preoperative holding area, midazolam 0.01 mg/kg is administered intravenously. For anxious children, oral midazolam, 0.25 mg/kg, can be administered in the preoperative holding area (Table 31-5).

**Table 31-5** A Guide to Premedication

A patient is seen least 24 hours before a scheduled procedure, expresses a desire for medication to relieve anxiety or has anxiety that cannot be relieved with comforting: oral diazepam, 2 to 5 mg per 70 kg body weight the night before and at 6 AM on the day of surgery, even if surgery is scheduled for 1 PM or later.

A patient is seen for the first time in the preoperative holding area and seems to need medication: midazolam, 0.01 mg/kg intravenously, or in the OR, propofol, 0.7 mg/kg, intravenously.

For an anxious child, oral midazolam, 0.25 mg/kg, administered in the preoperative holding area.

## Intraoperative Management: Choice of Anesthetic Method

There are several choices among anesthetic methods: general anesthesia, regional anesthesia, and local anesthesia. Regional and local anesthesia can be used with or without sedation. Except for obstetric cases, for which regional anesthesia may be safer than general anesthesia, all three types are otherwise equally safe. However, even for experienced anesthesiologists, there is a failure rate associated with regional anesthesia. **7**

Certainly, some procedures are possible only with a general anesthetic. For others, the preference of patients, surgeons, or anesthesiologists may determine selection. The cost of sedation is usually less than the cost of a general or regional anesthetic. In one study using New York's ambulatory surgery databases, the authors analyzed patients undergoing inguinal hernia repair. They found that hospital cost was less if open inguinal hernia repair with local/regional anesthesia was used (\$6,845) compared to general anesthesia (\$7,839) and laparoscopic repair (\$11,340).<sup>27</sup> The different types of anesthesia and surgery, though, are not an option for all operations. Another study that compared groin hernia repair after either general, regional, or local infiltration, found that medical complications were more common, particularly in patients of 65+ years after regional versus general anesthesia and urologic complications were more common after regional versus local infiltration.<sup>28</sup> Lower cost may not always accompany improved quality. In a retrospective study, authors compared spinal anesthesia to general anesthesia for patients undergoing hip or knee replacement procedures. They found that hospital treatment costs and length of stay were less for patients who received spinal anesthesia.<sup>29</sup>

The choice of anesthetic method may also influence time to recovery. In a review of peripheral regional anesthesia and outcome, the authors note that outcome studies of peripheral regional analgesia have yet to be published. However, postoperative mobilization and upper limb analgesia are generally better following regional anesthesia.<sup>30</sup> In one retrospective study of patients

undergoing ambulatory surgery at a large tertiary center, regional anesthesia use was associated with shorter PACU length of stay compared to general anesthesia; in addition, when regional anesthesia was used in conjunction with general anesthesia, PACU length of stay was shorter than when general anesthesia was used alone.<sup>31</sup> Patients who receive spinal anesthesia for ambulatory surgery may take longer to be discharged if micturition is required, though discharge instructions do not necessarily have to require a patient to micturate prior to discharge. Generally, pain and PONV are greater after general anesthesia compared to regional anesthesia. When applying studies of regional anesthesia to everyday practice, remember that the studies arise from centers where the authors are experienced in performing regional anesthesia and there are good systems to support the practice. Note also that anesthesiologists who are more experienced performing regional anesthesia are more likely to provide regional anesthesia.

With regional anesthesia or sedation, some of the side effects of general anesthesia can be avoided. Whenever drugs that affect memory are given, patients might complain that they do not remember events that occurred after the procedure. Performing a block may take longer than inducing general anesthesia, and the incidence of failure is higher. However, performing the block beforehand in a preoperative holding area can obviate unnecessary delays that may prompt surgeons to discourage regional anesthetics for their cases despite the evidence that postoperative pain control is best with regional techniques. Surgeons might feel that regional anesthesia is beneficial, but the potential delay in establishing a block and perceived unpredictable success might detract from their enthusiasm for regional anesthesia.

One adverse effect associated with spinal anesthesia is postdural puncture headache, although patients also experience headaches after general anesthesia. The incidence of headache after either technique is similar when smaller spinal needles are used. Patients may experience backache after spinal anesthesia, but sore throat and nausea are higher after general anesthesia than spinal anesthesia.

## *Regional Techniques*

Local anesthesia and regional anesthesia have long been used for ambulatory surgery. As early as 1963, for example, 56% of ambulatory procedures were performed with the use of these techniques.<sup>32</sup> Regional techniques commonly used for ambulatory surgery, in addition to spinal and epidural anesthesia, include local infiltration, brachial plexus and other peripheral nerve blocks, and intravenous regional anesthesia. General anesthesia can also be supplemented with regional nerve blocks.

An occasional patient may experience syncope when the needle for the

regional block is inserted. This event is alarming to patient and providers. Needle phobia can be minimized by using oral premedication with benzodiazepines or intravenous sedation before starting the block, monitoring patients during the procedure, and having available atropine and vasopressors.<sup>33</sup> After a regional block, patients may still have a numb extremity (e.g., after a brachial plexus block) but otherwise meet all criteria for discharge. In such instances, the extremity must be well protected (e.g., with a sling for an upper extremity procedure) and patients must be cautioned to protect against injury because they are without normal sensations that would warn them of vulnerability. Reassurance that sensation will return should be provided.

## **Spinal Anesthesia**

### **Children**

Some centers use spinal anesthesia most commonly for ex-premature infants undergoing hernia repair because the risk of postoperative apnea is reduced and because neurodevelopmental outcome is likely less affected by spinal anesthesia compared to general. When planning spinal anesthesia, general anesthesia should be available as a backup because spinal anesthesia failure rates for this population is as high as 20%.<sup>4</sup> The authors found that though apnea in the immediate postoperative period may be lower with spinal anesthesia, it does not reduce the risk of apnea seen up to 12 hours after surgery. Furthermore, premature infants and those who have postoperative apnea within 30 minutes after surgery are more likely to have apnea up to 12 hours after surgery. A bloody tap on the first attempt at lumbar puncture is the only predictor of spinal anesthesia failure.<sup>34</sup> Interestingly, in that study, such factors as experience of the anesthesiologist were not predictive of success.

### **Adults**

Spinal anesthesia is suitable for pelvic, lower abdominal, lower extremity, and even laparoscopic cholecystectomy surgery. Motor block of the legs may delay a patient's ability to walk. However, the use of a short-acting local anesthetic will minimize this problem. Nausea is much less frequent after epidural or spinal anesthesia than after general anesthesia. Though not a comparison of patients receiving general anesthesia, in one Danish study of patients undergoing total hip or knee arthroplasty, more than 85% of patients who received low-dose spinal anesthesia were ready for discharge from the PACU 15 minutes after arrival, and the median PACU stay was 25 minutes.<sup>35</sup>

Different drugs and drug concentrations have been used for spinal

anesthesia. Though any intrathecal local anesthetic can cause transient neurologic symptoms, lidocaine use is particularly problematic because of its high association with transient neurologic symptoms. Bupivacaine can be problematic for ambulatory surgical procedures because of its longer duration of action. In one study where spinal anesthesia was compared with either 0.75% hyperbaric bupivacaine 7.5 mg (n = 53) or 2% preservative-free 2-chloroprocaine 40 mg (n = 53), discharge readiness was 76 minutes faster with chloroprocaine.<sup>36</sup>

Although headache is a common complication of lumbar puncture, smaller-gauge needles result in a lower incidence of postdural puncture headache. For those patients who do receive spinal anesthesia, it is incumbent on the anesthesiologist and the facility to have follow-up with telephone calls to ensure no disabling symptoms of headache have developed (see also [Chapter 35](#)). If the headache does not respond to bed rest, analgesics, and oral hydration, the patient must return to hospital for a course of intravenous caffeine therapy or an epidural blood patch. Instructions regarding postdural puncture headache should be included in the preoperative consent process.

Spinal anesthesia should not be avoided in ambulatory surgery patients simply because they may be more active postoperatively than inpatients. Bed rest does not reduce the frequency of headache. Indeed, early ambulation may decrease the incidence.

### *Epidural and Caudal Anesthesia*

Epidural anesthesia (see also [Chapter 35](#)) takes longer to perform than spinal anesthesia. Onset with spinal anesthesia is more rapid, although recovery may be the same with either technique. When spinal anesthesia and epidural anesthesia are combined, the initial onset of block is faster than with epidural anesthesia alone. Epidural anesthesia is particularly advantageous for procedures where duration of surgery is unclear. Another advantage of the epidural block is that it can be performed outside the OR and avoids the problem of postdural puncture headache provided there is no “wet tap.”

Caudal anesthesia is a form of epidural anesthesia commonly used in children having infraumbilical operations as a supplement to general anesthesia and to control postoperative pain. In a 2012 review of patients recorded in the Pediatric Regional Anesthesia Network (PRAN) database, almost 19,000 received a caudal block. The authors found that the incidence of complications, consisting mostly of block failure, blood aspiration, and intravascular injection, was about 2% and there were no permanent sequelae.<sup>37</sup> Nearly 25% of patients in the database received bupivacaine higher than 2 mg/kg, a seemingly large dose, though it was unclear if the larger doses included epinephrine in the caudal drug mix. Two patients who

had signs of systemic toxicity received a bupivacaine dose lower than 2 mg/kg. Different adjuvants have been used to increase the duration of analgesia such as opioids, ketamine, and clonidine, though the potential toxicity of different additives is not clear. *Anesthesia & Analgesia* (A&A) includes a link in their Guide for Authors concerning the status of drugs for neuraxial or perineural administration ([Table 31-6](#)).<sup>38</sup> A&A will not publish studies that involve the administration of drugs not included on the list in neuraxial or perineural locations. Caudal blocks may be more difficult in children, particularly those who weigh more than 10 kg and in obese children if landmarks for the block are difficult to locate. The block is usually administered after the induction of general anesthesia. After the caudal block, the depth of general anesthesia can be reduced. Because of better pain control after a caudal block, children can usually ambulate earlier and be discharged sooner than without a caudal block. Pain control and discharge times are no different whether the caudal block is administered before or after the operation.

**Table 31-6** Status of Drugs Used for the Neuraxial or Perineural Human Research

Drug	Intrathecal Status	Epidural Status	Perineural	Notes
Adenosine	IND required	IND required	—	—
Alfentanil	IND required	IND required	—	—
Baclofen	Approved	—	"50 µg, 500 µg, or 2,000 µg/mL"	—
Buprenorphine	IND required	IND required	—	—
Chloroprocaine	IND required	Approved	2–3%	—
Clonidine	Widely accepted	Approved	100 µg/mL or 500 µg/mL	—
Dexamethasone	IND required	Widely accepted	IND required	—
Diazepam	IND required	IND required	—	—
Droperidol	IND required	IND required	—	—
Ephedrine	IND required	IND required	—	—
Epinephrine	Approved	Approved	—	—
Fentanyl	Widely accepted	—	Widely accepted	50 µg/mL
Hydromorphone	Widely accepted	—	Widely accepted	2 mg/mL
Ketamine	IND required	IND required	—	—
Ketorolac	IND required	IND required	—	—
Lidocaine	Approved	—	Approved	5%
Liposomal morphine	Not approved	Approved	—	10 mg/mL
Magnesium	IND required	IND required	IND required	—
Meperidine	—	Widely accepted	—	50 mg/mL
Midazolam	IND required	IND required	—	—
Morphine	Approved	Approved	"0.5 mg/mL, 1 mg/mL, 10 mg/m, 25 mg/mL"	—
Neostigmine	IND required	IND required	—	—
Parecoxib	IND required	IND required	—	—
Phenylephrine	IND required	IND required	—	—
Remifentanyl	IND required	IND required	—	—
Sufentanil	—	Widely accepted	Approved	50 µg/mL
Tramadol	IND required	IND required	—	—
Triamcinolone	IND required	IND required	—	—

Notes

1. Use of approved agents is based on the use of concentrations approved for human use.
2. No intrathecal agent should be considered if it contains preservative or other adjuvants not prescribed for human intrathecal use.
3. None of these agents have been officially approved for neonatal or pediatric use.
4. Blank entries indicate drugs and routes of delivery that have not been considered. It should be assumed that they are not approved.
5. Triamcinolone is no longer acceptable for epidural injection, as particulates have caused injury if intra-arterial injection.

## Nerve Blocks

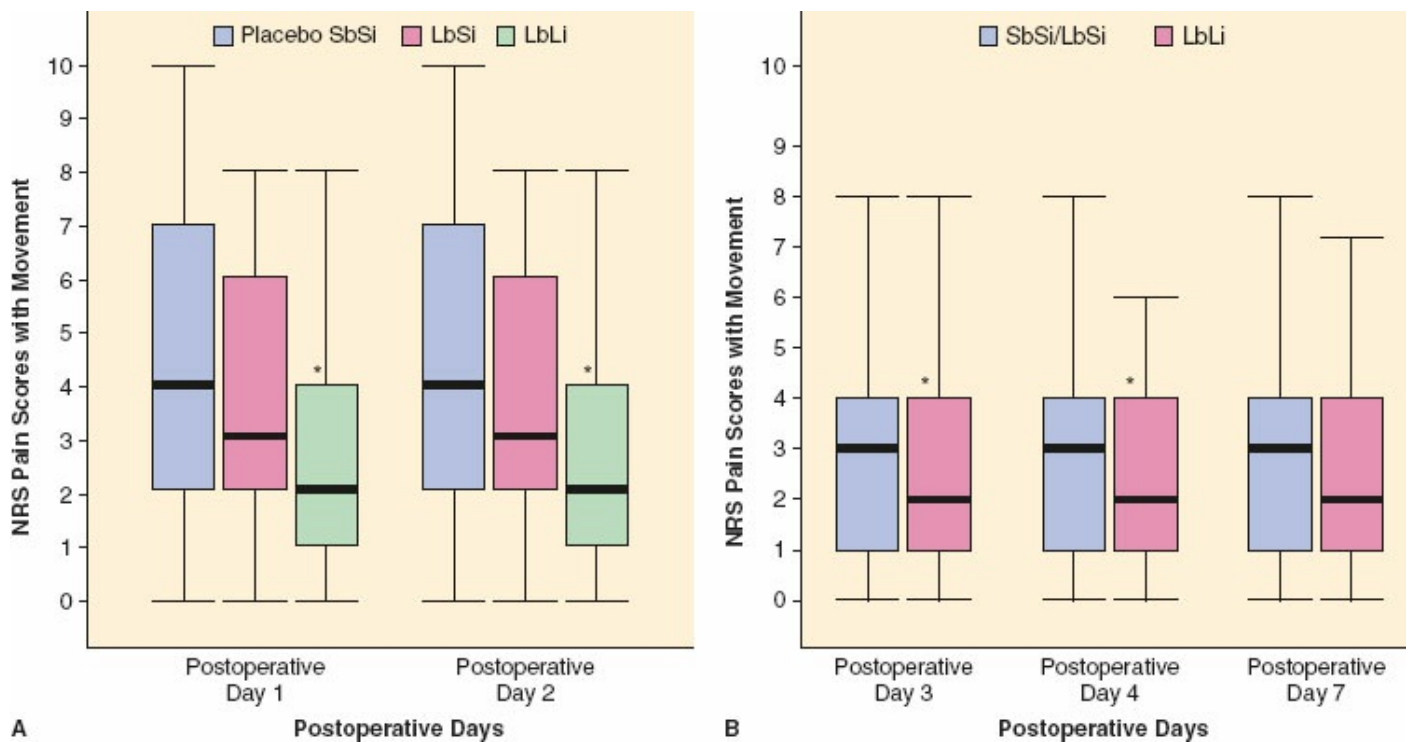

**8** Nerve blocks are an important technique in ambulatory anesthesia (see also [Chapter 36](#)). They improve patient satisfaction and reduce both PONV and postoperative pain. In a study of patients undergoing arthroscopic rotator cuff repair surgery, most patients in the continuous interscalene brachial plexus block group had pain scores less than 4 compared to patients in the single injection interscalene brachial plexus block group or the general anesthesia group whose pain scores were more than 4. These findings were observed on postoperative days 1, 2, and 7.<sup>39</sup> A designated room where regional anesthesia can be performed far enough in advance of the OR such that the block is effective by the time the patient enters the OR will reduce

turnover time.<sup>40</sup> Counterintuitively, there was no difference in PACU times between with regional anesthesia and with or without general anesthesia; but PACU length of stay was shorter with regional anesthesia compared to general anesthesia alone.<sup>31</sup>

Certain procedures can be quite painful, and hospitalization may be required to control pain. Nerve blocks with catheters intended to provide postoperative analgesia can be placed preoperatively. Recent examples of their use in ambulatory surgery include posterior insertion of transverse abdominis blocks kept in place for 2 days after inguinal hernia repair,<sup>42</sup> use of a continuous infraclavicular nerve block with a portable infusion pump for patients undergoing total elbow arthroplasty,<sup>43</sup> continuous popliteal sciatic nerve block for outpatient foot surgery in adults<sup>44</sup> and children,<sup>45</sup> and paravertebral somatic nerve block for breast surgery, followed by a continuous perineural infusion of local anesthetic at home for 24 to 48 hours.<sup>46</sup> Femoral nerve catheters left in for 2 days after discharge following anterior cruciate ligament reconstruction had decreased postoperative pain up to 4 days after surgery (Fig. 31-5).<sup>47</sup> Interscalene perineural catheters, kept in for 4 days after surgery, have been used for patients undergoing moderately painful shoulder surgery.<sup>48</sup> Patients who are discharged with interscalene perineural catheters and ropivacaine infusion pumps are discharged earlier on the first postoperative day and require less opioids at home than those treated with single-shot regional techniques. The same techniques have been used in children and adolescents; except for two patients who required hospital readmission, over 1,200 patients remained comfortable at home with only oral opioids after major orthopedic surgery (Fig. 31-6).<sup>49</sup>

Patients who go home with catheters inserted must be taught about pump function, understand signs of local anesthesia toxicity, and have someone else at home who can provide assistance. Patients must be able to communicate with someone by phone. There should also be a catheter removal protocol. The number of patients who have been sent home with catheters is increasing but is not large. More study is needed in order to demonstrate patient safety. The use of these catheters has recently been reviewed.<sup>50</sup>

**Figure 31-5** When a continuous femoral perineural infusion, spinal anesthesia, and multimodal analgesia, are used together, pain scores are less, when compared with the same spinal anesthetic technique and multimodal analgesia plan coupled with a placebo femoral nerve catheter. Box plots show numeric pain score differences (NRS) after anterior cruciate ligament reconstruction. The *thick black line* inside the box represents the median NRS value; the lowest bar on the y-axis represents the 10th percentile, the bottom and top of the boxes represent the interquartile range (25th and 75th percentiles), and the top bar represents the 90th percentile. Placebo SbSi is the placebo treatment group receiving a saline bolus and saline infusion through the femoral nerve block catheter, whereas treatment group LbSi received a levobupivacaine bolus and saline infusion, and LbLi received both a bolus and infusion containing levobupivacaine. **A:** On both days 1 and 2, the LbLi treatment group had significantly lower pain scores when compared with the other two nerve block treatment groups (\*). **B:** On postoperative days 3 and 4, the LbLi treatment group had significantly lower pain scores when compared with the other two nerve block treatment groups (\*) but by day 7, no differences are seen. (Adapted with permission from Williams BA, Kentor ML, Vogt MT, et al. Reduction of verbal pain scores after anterior cruciate ligament reconstruction with 2-day continuous femoral nerve block: a randomized clinical trial. *Anesthesiology*. 2006;104:315–327.)

**Figure 31-6** Number of patients with a continuous peripheral nerve block (CPNB) per year by discharge status (inpatient vs. outpatient) placed at one children’s hospital from 2005 to 2011. Shown in each column are patients discharged home with a CPNB versus patients who stayed in the hospital until the CPNB was removed. During the last 5 years, the percentage of patients discharged home with a CPNB has increased to approximately 80%. (Adapted with permission from Gurnaney H, Kraemer FW, Maxwell L, et al. Ambulatory continuous peripheral nerve blocks in children and adolescents: a longitudinal 8-year single center study. *Anesth Analg.* 2014;118:621–627.)

### Sedation and Analgesia

Many patients who undergo surgery with local or regional anesthesia prefer to be sedated and to have no recollection of the procedure. Sedation is important, in part, because injection with local anesthetics can be painful and lying on a hard OR table can be uncomfortable. Levels of sedation vary from light, during which a patient’s consciousness is minimally depressed, to very deep, in which protective reflexes are partially blocked and response to physical stimulation or verbal command may not be appropriate.

### General Anesthesia

The drugs selected for general anesthesia determine how long patients stay in the PACU after surgery, and for some patients, whether they can be discharged to go home.

### Induction

Though in previous editions of this chapter, propofol and Pentothal has been compared, Pentothal is no longer available for use in humans in this country. Though the effect of drugs given for induction may seem to be transient, they can depress psychomotor performance for several hours. Propofol’s half-life is 1 to 3 hours, and after an induction dose of propofol, impairment is apparent

for only 1 hour compared to methohexital which has a half-life of 6 to 8 hours.

Pain on injection can be a problem with propofol. Pain is more likely when injected into dorsal hand veins and is minimized if forearm or larger antecubital veins are used. Some individuals, though, experience pain if the drug is injected into proximal larger veins. Nonetheless, thrombophlebitis does not appear to be a problem after intravenous administration of this agent. As noted in one meta-analysis, the most effective technique to decrease pain related to propofol injection is to use IV lidocaine (0.5 mg/kg), given with a rubber tourniquet on the forearm, 30 to 120 seconds before injection of propofol.<sup>51</sup> As the authors of a review published in 2014 noted, when comparing manuscripts published after the review by Picard et al.,<sup>51</sup> “Firstly, although the systematic review had identified a simple, effective, and low cost intervention and strongly suggested that additional trials on this specific issue were no longer necessary, the publication of trials has not decreased. Secondly, although the systematic review provided a clear research agenda, its influence on the design of further trials has remained poor. Thirdly, the proportion of subsequently published trials that could have had an impact on clinical practice has remained low. Finally, citing the systematic review had no clear influence on the design or relevance of subsequently published research.”<sup>52</sup> Whether patients remember the pain of injection with propofol after the procedure is unclear.

Most children and some adults prefer not to have an intravenous catheter inserted before the start of anesthesia. Sevoflurane has a relatively low blood–gas partition coefficient and the speed of induction is only slightly slower than propofol. Induction with sevoflurane can be hastened when the patient is told to breathe out to residual volume, take a vital capacity breath through a primed anesthesia circuit, and then hold the breath.

For short procedures, some patients may not require neuromuscular-blocking drugs; others may need brief paralysis (e.g., with succinylcholine) to facilitate tracheal intubation. Nondepolarizing drugs can be used to facilitate intubation and for paralysis during the procedure. Large doses of rocuronium have rapid onset times that are similar to those with succinylcholine. Of course, paralysis is not needed to insert an endotracheal tube; drug combinations such as propofol, alfentanil, or remifentanil, with or without lidocaine obviate the need for paralysis. Succinylcholine should be used with caution in children because of the possibility of cardiac arrest related to malignant hyperthermia or unsuspected muscular dystrophy, particularly Duchenne disease. Indeed, patients can experience painful myalgias after receiving succinylcholine.

## Maintenance

Although many factors affect the choice of agents for maintenance of anesthesia, two primary concerns for ambulatory anesthesia are speed of wake-up and incidence of PONV. 9

### *Anesthesia Maintenance and Wake-up Times*

Time to recovery may be measured by various criteria; however, for an ambulatory center, a patient may be considered awake only when he or she is able to leave the center. Actual discharge from an ambulatory center, though, may depend on administrative issues such as a written order from a surgeon or anesthesiologist. The time necessary before a patient can be taken from the OR after completion of surgery, or a patient's ability to skip the PACU and go directly to Phase II recovery (see also [Chapter 54](#)), may be directly related to the anesthetic and may result in cost savings for an institution.

Does choice of maintenance agent affect recovery after anesthesia? Propofol, desflurane, and sevoflurane have characteristics that make them ideal for maintenance of anesthesia for ambulatory surgery. Propofol has a short half-life and, when used as a maintenance agent, results in rapid recovery and few side effects. Desflurane and sevoflurane, halogenated ether anesthetics with low blood-gas partition coefficients, seem to be ideal for general anesthesia for ambulatory surgery. Sevoflurane, unlike desflurane, facilitates a smooth inhalation induction of anesthesia and is the preferred technique to ensure rapid recovery of children in ASCs.

**10** It is important to distinguish between wake-up time and discharge time. Patients may emerge from anesthesia with desflurane and nitrous oxide significantly faster than after propofol or sevoflurane and nitrous oxide, although the ability to sit up, stand, and tolerate fluids and the time to fitness for discharge may be no different. Fast wake-up times may translate to bypass of phase I, which can result in cost savings.

### *Intraoperative Management of Postoperative Nausea and Vomiting*

**11** Nausea, with or without vomiting, is probably the most important factor contributing to a delay in discharge of patients and an increase in unanticipated admissions of both children and adults after ambulatory surgery. Patients often fear PONV more than postoperative pain. Reducing risk factors can significantly decrease the incidence of PONV ([Table 31-7](#)). To decrease the risk of PONV:

- Use regional anesthesia.
- If general anesthesia is necessary, use a propofol infusion instead of an inhalation agent (propofol is now generic so the decision to use the drug should not be based on cost).
- Avoid nitrous oxide.

- Minimize use of perioperative opioids.
- Try to avoid paralysis.
- Provide adequate hydration.

The incidence of emesis may be greater after nitrous oxide than after potent inhalation agents. Although many studies have shown that nitrous oxide can be used successfully for ambulatory anesthesia, there is evidence that when nitrous oxide is used for less than 1 hour, the risk of PONV is not increased.<sup>53</sup>

Women have a higher incidence of PONV as do those with a previous history of PONV or motion sickness. Patients who undergo certain procedures, such as laparoscopy; lithotripsy; major breast surgery; and ear, nose, or throat surgery are at increased risk for PONV. The greater the number of risk factors, the greater the risk for nausea or vomiting after surgery.

There are also specific genotypes that are associated with more susceptibility to PONV. A recent review suggests that there may be a genetic relationship to PONV since some patients have resistance to antiemetic prophylaxis and/or therapy, some patients have PONV in several generations of families, and there is PONV concordance in monozygotic twins.<sup>54</sup> Pharmacogenetic research focused on 5HT<sub>3</sub> receptor antagonists, metabolic pathways of 5HT<sub>3</sub> antagonists, and other genes associated with PONV and chemotherapy-induced nausea and vomiting. Sensitivity is probably multifactorial and may include several genomic pathways; more study relating genetic makeup and possible treatment implications is needed.

PONV treatment has been based on sites and pathways in the brain that are associated with PONV. Receptor antagonists, specifically selective serotonin antagonists (ondansetron, dolasetron, and granisetron), have been shown to have similar efficacy to help alleviate nausea and vomiting. Dopamine antagonists, antihistamines, and anticholinergic drugs are useful and are generally less expensive, but are associated with extensive side effects. Neurokinin (NK1) receptor antagonists may also be useful to control PONV. Two types of drug are better than one. For example, when aprepitant is combined with ondansetron, PONV reduction is more effective than when each is used alone.<sup>55</sup> Dexamethasone has an additive effect when included with ondansetron and droperidol.<sup>56</sup> Dexamethasone, even when used alone, has been shown to effectively help prevent PONV, though its routine use is controversial due to the possible risk of cancer and hyperglycemia. Yet, as summarized in an editorial, both cancer recurrence and perioperative hyperglycemia are not related to low-dose dexamethasone when used to help prevent PONV.<sup>57</sup> Other therapies useful in controlling PONV include acupuncture or acupressure,<sup>58</sup> supplemental fluid therapy, and clonidine (perhaps in part because it decreases anesthesia requirement). If,

intraoperatively, leads to monitor patient paralysis are placed at the P6 acupuncture point and tetanus monitoring is used as the neuromuscular monitoring mode, PONV is reduced.<sup>59</sup>

**Table 31-7** Techniques to Decrease Postoperative Nausea and Vomiting Risk

Use regional anesthesia alone if possible  
If general anesthesia is needed, use a propofol infusion instead of an inhalation agent (propofol is now generic so the decision to use the drug should not be based on cost)  
Avoid use of nitrous oxide for anesthesia maintenance, particularly for procedures longer than 1 hour  
Minimize use of perioperative opioids  
Try to avoid paralysis if clinically indicated  
Consider adequate hydration

Though much work has been focused on PONV, postdischarge nausea and vomiting (PDNV) is also an issue. In one study, the overall incidence of PDNV was almost 60%, and PDNV continued until day 7 for 2% of patients. Those who had a history of motion sickness, previous PONV, migraine headaches, and pain on activity postdischarge were more likely to have PDNV. Nitrous oxide and the use of a regional block as an adjunct to inhalation anesthesia was not associated with PDNV.<sup>60</sup> Another group found a relationship between patients with high pain and PDNV for all of the first 6 postoperative days. It was not until postoperative day 6 that PDNV scores in the high and low pain groups were the same (Fig. 31-7).<sup>61</sup>

### *Paralysis*

Muscle paralysis for ambulatory anesthesia extends beyond the time of paralysis for intubation, particularly when nondepolarizing drugs are used. The duration of action of rocuronium, vecuronium, rapacuronium, and cisatracurium ranges from 25 to 40 minutes. Reversal agents must be used unless there is no doubt that muscle relaxation is fully reversed. Patient safety is optimized when acceleromyography is used to monitor the extent of paralysis and the adequacy of reversal.<sup>62</sup> Furthermore, when quantitative monitoring of neuromuscular block depth guides neostigmine dosing, respiratory complications can be minimized (Fig. 31-8).<sup>63</sup>

### *Intraoperative Management of Postoperative Pain*

Intraoperative opioid administration provides analgesia for both the intraoperative and postoperative course. Fentanyl is probably the most popular drug, although all other available opioids have been tried. All opioids can cause nausea, sedation, and dizziness, which can delay a patient's discharge. Nonsteroidal analgesics are not effective as supplements during

general anesthesia, although they are useful in controlling postoperative pain, particularly when given before skin incision. To control postoperative pain, combination therapy is most useful. (See also the earlier discussion on opioids and nonsteroidal analgesics in this chapter.)

### Airway Adjuncts

The use of supraglottic airways, such as the LMA, provides several advantages for allowing a patient to return to baseline status quickly. Muscle relaxants are generally avoided. Coughing is less than with tracheal intubation. Anesthetic requirements, hoarseness, and sore throat are all reduced. Overall, cost savings result with the use of LMAs. Because of gastric insufflation, though, nausea and vomiting may be greater. After an LMA is inserted, there is a 1% failure rate requiring endotracheal tube insertion.<sup>64</sup> In the study of almost 16,000 patients, risk factors for failure included surgical table rotation, male gender, poor dentition, and increased body mass index. Patients for whom LMA failed had a three-fold increase of difficult mask ventilation, unplanned admission rate was almost 14%, and almost 6% needed ICU admission due to persistent hypoxemia.

**Figure 31-7** Mean differences in daily nausea scores between high-pain and low-pain groups, with 95% confidence intervals from day of surgery (DOS) to postoperative day 7. The largest difference was seen on the second day after surgery, followed by a gradual decrease. Differences on days 6 and 7 were not significant. (Adapted with permission from Odom-Forren J, Rayens MK, Gokun Y, et al. The relationship of pain and nausea in postoperative patients for 1 week after ambulatory surgery. *Clin J Pain*. 2015;31:845–851.)

## Management of Postanesthesia Care

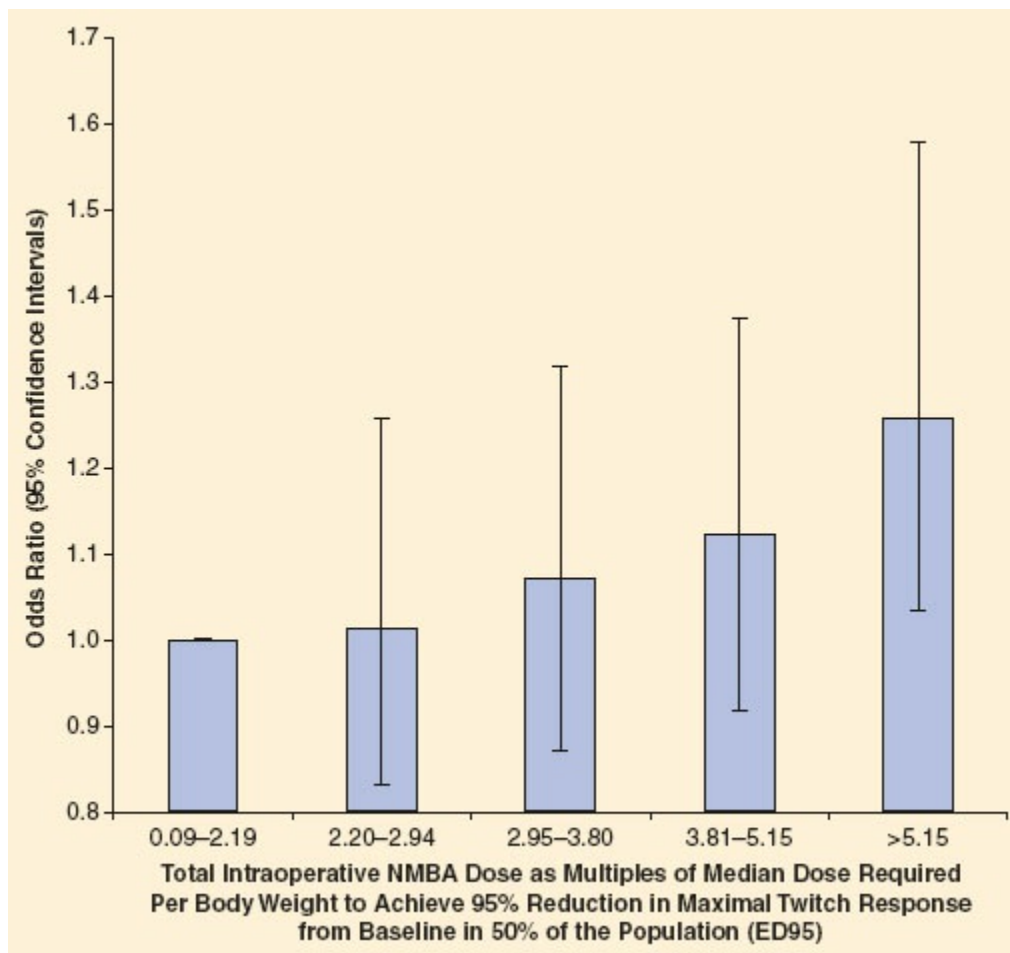

Many recovery challenges are part of patient selection and perioperative management and must be considered before the patient enters the PACU (see also [Chapter 54](#)). Managing common problems in the PACU quickly and

effectively is as important as appropriate patient selection and choice of anesthetic technique if the patient is to return home on the day of surgery. The three most common reasons for delay in patient discharge from the PACU are drowsiness, nausea and vomiting, and pain. All three are a function of intraoperative management, but nausea, vomiting, and pain can be treated in the PACU.

### *Reversal of Drug Effects*

Reversal of muscle relaxants is not unique to the ambulatory surgery patient and is not discussed here (see also [Chapter 21](#)). Reversal of opioids may sometimes be necessary. Flumazenil, a benzodiazepine receptor antagonist, has primarily been used to reverse the effects of sedation after endoscopy and spinal anesthesia. Reversal of psychomotor impairment with flumazenil is not complete, and the subjective experience of sedation is not necessarily attenuated. Reversal of amnesia with flumazenil is only partial, and the duration of the reversal effect may not be long enough to be clinically significant. Flumazenil should not be used routinely as a benzodiazepine antagonist, but may be used when sedation appears to be excessive. In addition, reversal of benzodiazepine-induced sedation by flumazenil should not replace appropriate ventilation assistance and, if necessary, placement of an endotracheal tube.

**Figure 31-8** As the dose of neuromuscular blocking agent (intraoperative dose of atracurium, cisatracurium, rocuronium, or vecuronium) increases, the likelihood of respiratory complications increases. (Adapted with permission from McLean DJ, Diaz-Gil D, Farhan HN, et al. Dose-dependent association between intermediate-acting neuromuscular-blocking agents and postoperative respiratory complications. *Anesthesiology*. 2015;122:1201–1213.)

## Nausea and Vomiting

**1** Nausea and vomiting are the most common reasons both children and adults have protracted stays in the PACU or unexpected hospital admission due to anesthesia. Nausea and vomiting are also the most common adverse effect in patients in the PACU. Much research has been undertaken to study prophylactic treatment of this problem before surgery, as well as techniques in the OR that can minimize nausea and vomiting in the PACU. The treatment of this problem, once it occurs in the PACU, has not received as much study. Yet, there are a variety of drugs that are effective in treating the problem. The 5-HT<sub>3</sub> antagonists seem particularly effective. Dexamethasone, 8 mg, given with other antiemetics can enhance treatment of established PONV in the PACU.<sup>56</sup>

Midazolam and propofol, although more commonly used for sedation, have antiemetic effects that are longer in duration than their effects on

sedation. Acupressure bands or acupressure stimulation in the region of the P6 acupuncture point can help reduce PONV. If patients have already received ondansetron prophylaxis in the OR, and then are nauseous in the PACU, another dose might not be effective. Based on a retrospective analysis of patients with nausea after receiving prophylactic ondansetron, established PONV was more effectively treated with promethazine than ondansetron; and promethazine, 6.25 mg intravenously, rather than higher doses was most effective.<sup>65</sup> More work is obviously needed to study effective therapies for treatment of PONV in the PACU. Finally, because pain may be associated with nausea, treatment of pain frequently decreases nausea. For a more complete discussion, consider the review by Gan et al.<sup>66</sup>

## **Pain**

Postsurgical pain must be treated quickly and effectively. It is important for the practitioner to differentiate postsurgical pain from the discomfort of hypoxemia, hypercapnia, or a full bladder. Medications for pain control should be given in small intravenous doses (e.g., morphine 1 to 3 mg/70 kg or fentanyl 10 to 25 µg/70 kg). Intramuscular injection of opioid for pain control in the PACU is usually not necessary. Onset of action of drugs is faster after intravenous catheter administration than after oral administration. Control of postoperative pain may include administration of opioid analgesics or NSAIDs, which are not associated with respiratory depression, nausea, or vomiting. Fentanyl is the opioid frequently used to control postoperative pain that ambulatory surgery patients experience, although the effects of morphine and hydromorphone last longer. Patients who receive fentanyl for pain control may require additional injections and go home no sooner compared with patients who receive morphine. Oral tramadol/paracetamol (TP 37.5/325 mg) given after surgery and then as 1 tablet four times daily for 48 hours is an effective fixed drug combination for treating pain after discharge.<sup>67</sup> Nonsteroidal medications, such as ketorolac or ibuprofen, can also effectively control postoperative pain<sup>68</sup> and, compared with opioids, can give pain relief for a longer period and are associated with less nausea and vomiting. NSAIDs can increase bleeding, although there is no evidence at this time of such a danger for most ambulatory surgery procedures. When swelling and pain are problematic postoperatively, NSAIDs can be more effective than opioids in relieving both.

Though acetaminophen was used clinically late in the nineteenth century, it was not until early in the twenty-first century that the drug has been available intravenously. Unlike opioids, acetaminophen is not associated with PONV or respiratory depression, and unlike NSAIDs, it is not associated with platelet dysfunction, gastritis, or renal toxicity. When given intravenously,

first-pass hepatic exposure is limited, and the risk of hepatic injury is reduced. When given before surgical incision,<sup>69</sup> or postoperatively,<sup>70</sup> opioid need is reduced. Total daily dose of acetaminophen should not exceed 4 g/day and 2 g/day or less for patients with impaired liver or kidney function.

We manage pain in both adults and children initially either with a short-acting opioid analgesic such as fentanyl (25 µg/70 kg for pain on a scale of 3-5 out of 10 and 50 µg/70 kg for pain on a scale of 6-10 out of 10), or with an injection of ketorolac, 30 to 60 mg/70 kg intravenously or acetaminophen 650 mg (12.5 mg/kg for children 2 to 12 years or adults <50 kg). Fentanyl is repeated at 5-minute intervals until pain is controlled. For children, we also use an elixir of acetaminophen containing codeine (120 mg acetaminophen and 12 mg codeine, in each 5 mL of solution). Five milliliters is administered to children between the ages of 3 and 6, and 10 mL to children between the ages of 7 and 12. Children are returned to parental care as soon as they are awake. We find frequently that infants younger than 6 months of age usually need to be reunited with their mothers for nursing or bottle feeding after a procedure not associated with severe pain. For older infants and young children in the PACU, acetaminophen, 60 mg per year of age (given orally or rectally), is commonly used to relieve mild pain. Meperidine (0.5 mg/kg) and codeine (1 to 1.5 mg/kg) can be given intramuscularly if an intravenous route has not been established.

### *Preparation for Discharging the Patient*

In addition to the PACU, most ASCs in the United States have Phase II **12** Recovery. Patients remain in Phase II Recovery until they are able to tolerate liquids, walk, and/or (depending on the operation) void. With the anesthetics that are typically used in ambulatory surgery ORs, patients who are awakened in the OR and are evaluated as 9 or 10 according to the modified Aldrete scoring system (see also [Chapter 54](#)) may be transferred directly to Phase II Recovery from the OR. Patients who undergo procedures under monitored anesthesia care can usually go straight to Phase II Recovery from the OR. After procedures using sedation, fast-tracking to Phase II Recovery should take place but often does not, usually because of uninformed departmental policy or personnel.<sup>71</sup> Though it may seem that time and money are saved when a patient can bypass the PACU, nursing workload in Phase II recovery might be greater and overall hospital costs may be no different than if a patient first recovers in the PACU.

Some criteria for discharge to home were created without scientific basis. One criterion is the ability to tolerate oral liquids before being discharged. Postoperative nausea may be greater if patients are required to drink liquids prior to discharge. Even though it is warranted after spinal or epidural

anesthesia, the requirement that low-risk patients void before discharge may only lengthen stay in the facility where the patient underwent surgery, particularly if patients are willing to return to a medical facility if they are unable to void. Practical criteria for patient discharge from the OR, from the PACU, and from Phase II Recovery are needed such that there is no compromise in patient safety. The value of psychomotor tests to measure different phases of recovery, except for research purposes, is questionable.

Although scoring systems may be used to guide transfer from the PACU to the Phase II Recovery and from Phase II Recovery to home, they do little to test higher levels of function, such as the ability to use one's hands, to drive a car, or to remain alert long enough to drive. Patients may feel fine after they leave the hospital, but they should be advised against driving for at least 24 hours after a procedure. Patients and responsible parties should be reminded that the patient should not operate power tools or be involved in major business decisions for up to 24 hours. Once the patient leaves the medical facility, supervision may not be as good as it was in the hospital. Therefore, before a patient is discharged, dressings should be checked. It is wise to include the responsible person in all discharge instructions.

Patients should also be informed that they may experience pain, headache, nausea, vomiting, or dizziness and, if succinylcholine was used, muscle aches and pains apart from the incision for at least 24 hours. A patient will be less stressed if the described symptoms are expected in the course of a normal recovery. Written instructions are important. The addition of written and oral education techniques at discharge has a significant impact on improving compliance.

When discussing discharge planning, it is also important to consider where a patient should return in case of a problem. Unlike a hospital, most ambulatory centers are not open around the clock. As ambulatory procedures are becoming more prevalent, patients are traveling farther distances.<sup>72</sup> Whether this is associated with increased risk is yet to be determined.

For patients with a language barrier, consent forms, procedural explanation, and discharge information may have to be written in languages other than English and the services of an interpreter may be necessary. Nursing staff should assess the adult who will take the patient home to determine whether he or she is a responsible person. A responsible person is someone who is physically and intellectually able to take care of the patient at home. Facilities should develop a method of follow-up after the patient has been discharged. At some facilities, staff members telephone the patient the next day to determine the progress of recovery; others use follow-up postcards.

Whenever we become innovative in the management of our outpatients, we must assess how a cost-effective, "no frills" approach to care affects

patient safety. We must determine what we can do for the patient who lives alone, for the patient whose responsible person is unable to manage his or her needs, for the patient without means of transportation, and for the patient with limited insurance coverage. Hospital beds can be set aside for patients who require observation. Patients in these beds after an ambulatory surgical procedure are still considered outpatients. They are charged for the hours spent in the observation area. Some hospitals have joined with management firms to build a hospital hotel or medical motel close to the hospital itself. The hotel, usually a nonmedical facility, offers the outpatient a comfortable, inexpensive, and convenient place to recuperate while being cared for by family or nurses. Home health-care nursing may be appropriate after surgical procedures such as reduction mammoplasty, abdominoplasty, vaginal hysterectomy, and major open ligament repairs of the knee. The various services for management and/or observation of outpatients after surgery stand today where techniques for management of outpatients during surgery stood in the health-care delivery system 20 years ago. Prospective studies are needed to assess the quality of care and the effect that these innovative approaches have on patient safety.

Patient, procedure, availability and quality of aftercare, and anesthetic technique must be individually and collectively assessed to determine acceptability for ambulatory surgery. A delicate balance must be maintained between the physical status of the patient, the proposed surgical procedure, and the appropriate anesthetic technique, to which must be added the expertise level of the anesthesiologist caring for a patient.

Anesthesia for ambulatory surgery is a rapidly evolving specialty. Patients who were once believed to be unsuitable for ambulatory surgery are now considered appropriate candidates. Operations once believed unsuitable for outpatients are now routinely performed in the morning, so patients can be discharged in the afternoon or evening. The appropriate anesthetic management before these patients come to the OR, during their operation, and then afterward is the key to success. The availability of both shorter-acting anesthetics and longer-acting analgesics and antiemetics enables us to care for patients in ambulatory centers effectively.

# 32 Office-based Anesthesia

LAURENCE M. HAUSMAN • MEG A. ROSENBLATT

## Brief Historical Perspective of OBA

## Advantages and Disadvantages of Office-based Surgery and Anesthesia

## Office Safety

## Patient Selection

## Surgeon Selection

## Office Selection and Requirements

### Accreditation

## Procedure Selection

### Specific Procedures

## Anesthetic Techniques

### Anesthetic Agents

## Postanesthesia Care Unit

## Regulations

### Business and Legal Aspects

## Conclusions

## KEY POINTS

- 1 An office-based anesthetic is one that is performed in an outpatient venue such as a freestanding medical or surgical office or procedure room that is not accredited as either an ambulatory surgery center (ASC) or a hospital.
- 2 Cost containment and patient convenience are the two major advantages of office-based procedures over traditional hospital-based procedures.
- 3 The disadvantages of office-based procedures are related to patient safety, reporting, quality improvement, and peer review. Thus, great care must be taken concerning these issues.
- 4 Office-based morbidity and mortality are usually the result of inadequate perioperative patient monitoring, oversedation, and thromboembolic events.
- 5 The injuries that occur in offices tend to be of greater severity than those that occur in ambulatory surgical centers. Twenty-one percent of the reported injuries sustained in offices were temporary and nondisabling in

nature and 64% were permanent or led to death, whereas 62% of the injuries sustained in ambulatory surgical centers were temporary and nondisabling and only 21% were permanent or led to death.

- 6 The American Society of Plastic Surgeons acknowledged that the ideal patient for an office-based procedure has an ASA physical status of 1 or 2. They recommended that American Society of Anesthesiology (ASA) physical status 3 patients undergo an office-based procedure only after an anesthesia consultation and only have an office-based procedure performed under local anesthesia without sedation.
- 7 Pulmonary embolism arising from deep vein thrombosis remains an important risk of an office-based procedure.
- 8 When formulating a quality improvement program, there should be random chart reviews as well as key sentinel events that trigger a case review.
- 9 The anesthesiologist should function as a zealous patient advocate in assuring that an anesthetic only is performed in a safe anesthetizing location. Issues that must be sorted out and codified include equipment, monitoring in conformance with ASA standards, emergency drugs and equipment, controlled substance handling and storage, medical director and governance, plan for hospital admission if needed, fire prevention and preparedness, and accreditation.
- 10 Nonfatal injuries occurring during monitored anesthesia care were more likely to be permanent than the nonfatal injuries occurring during general anesthesia, which were more frequently temporary. Of all injuries occurring during monitored anesthesia care, 34% were fatalities.
- 11 In terms of smooth operation of an office-based anesthesia practice and patient satisfaction, prevention of postoperative nausea and vomiting and pain are paramount.

Office-based anesthesia (OBA) is a subset of both nonoperating room anesthesia (NORA) and ambulatory anesthesia. NORA refers to any anesthetic that takes place outside of the traditional operating room (OR) but often performed within a fully licensed hospital. NORA locations include endoscopy suites, invasive radiology suites, magnetic resonance imaging (MRI) machine or an area in which electroconvulsive therapy (ECT) takes place. An ambulatory anesthetic is defined as one in which the patient arrives to the surgical venue on the day of the procedure, is anesthetized, and is discharged home later that same day.

**1** An office-based anesthetic is one that is performed in an outpatient venue such as a freestanding medical or surgical office or procedure room that is not accredited as either an ambulatory surgery center (ASC) or a hospital. The surgical/medical office often provides practitioners with the

space for other activities such as consultation with new patients, the performance of routine history and physicals, and office administration. Office-based practices are generally confined to one specialty such as urology, gastroenterology, plastic surgery, or dentistry,<sup>1,2</sup> but some surgical offices provide OR space for a number of surgical and procedural subspecialties.

Although an OBA practice may be an exciting alternative to the traditional hospital-based one, it requires the anesthesiologist to expand his or her role within the health-care delivery system. Along with providing safe anesthetics across the spectrum of young to old, and healthy to medically challenged patients undergoing increasingly complex procedures, the anesthesiologist must understand office safety and policy, legal and financial issues such as antitrust laws, state laws or regulations that may exist, the need for possible accreditation and billing and collection issues.<sup>3,4</sup> These are relatively new responsibilities for the anesthesiologist, who historically has worked as a member within a hospital department either in the private or academic setting, where these responsibilities are given to hospital administrators, lawyers, nurses, and other medical professionals. A further challenge to the office-based practitioner is that presently he or she has received little to no training in OBA within the anesthesia residency curriculum.<sup>5</sup>

## **Brief Historical Perspective of OBA**

There have been reports of office-based surgery and anesthesia since the mid-nineteenth century. In 1856, John Snow documented his experience in providing anesthesia with chloroform for 867 dental patients, and approximately 3,021 teeth were extracted in private dental offices under his care.<sup>6</sup> In addition to dental care, the family physician often performed house calls where numerous small surgical procedures such as the lancing of boils and repair of wounds were conducted within the comfort of the patient's home. The physician's private medical office was, likewise, utilized in the service of this type of surgical care.

As surgery became more invasive, the need for intensive perioperative physiologic monitoring became increasingly necessary. The capacity to administer blood products and the development of an extensive array of pharmaceutical agents began to play a role in patient care, fostering the growth of larger health-care delivery teams to assist in patient care. Thus, over time, the inpatient hospital became the primary setting in which surgery would be performed.

Over the past several decades, as a result of both surgical and anesthetic advances, the surgical experience has again changed. Through innovations such as laparoscopic and endoscopic surgical capabilities, surgery has become increasingly less invasive and less painful. In addition, newer anesthetics have

the benefit of a “fast-acting” profiles (associated with quick onsets and rapid termination of effect) and with fewer hemodynamic side effects, lending increasing numbers and types of procedures to be suitable for performance in outpatient venues.<sup>7-9</sup>

During the 1970s, less than 10% of all surgical and diagnostic procedures were performed on an ambulatory basis and, virtually all of these were performed in hospitals. By 1987, approximately 25 million, or 40% of all procedures, were performed on an ambulatory basis. In the United States, between 1984 and 1990, the number of office-based procedures increased from 400,000 to 1.2 million, and by 1994, 8.5% of all procedures were performed in offices.<sup>10</sup> In 1994, a landmark survey of the membership of the American Society of Plastic Surgeons (ASPS) revealed that 55% of the respondents performed the majority or all of their procedures in an office.<sup>11</sup> By the year 2000, approximately 75% of all procedures were performed on an outpatient basis; 17% in freestanding ASCs, and 14% to 25% (approximately 8 to 10 million) in physicians’ offices.<sup>12-16</sup> By 2005, the American Hospital Association reported that although 82% of all procedures were performed on an ambulatory basis, 16% of all these ambulatory procedures were performed in private offices.<sup>17</sup> Even more recent data confirm that presently, 17% to 24% of all surgical procedures (approximately 10,000,000 procedures) are performed in private surgical offices annually.<sup>18</sup>

## Advantages and Disadvantages of Office-based Surgery and Anesthesia

**2** There are many advantages to an office-based procedure when compared to a traditional hospital-based one, with one of the most obvious being cost containment.<sup>19</sup> Several components make up the actual cost of a given surgical procedure. In addition to the professional fees of both the proceduralist and the anesthesiologist (which are usually negotiated prior to an elective procedure), there is a facility fee charged by the hospital or ASC. This fee generally covers the associated costs to the specific site, and includes overhead such as maintenance, equipment, and staffing. It often constitutes a large component of the patient’s overall charge. In an office, this amount can easily be predicted and is often significantly less. The reason for this discrepancy is that although the overhead costs in a small office are usually quite reasonable and managed, the comparable costs in a large tertiary care hospital can be both enormous and unforeseen.<sup>12,13,20,21</sup>

To get a historical perspective of cost analysis, in 1994, Schultz determined the cost of an inhospital laparoscopic inguinal hernia repair to be \$5,494. When the same procedure was performed in an office, the price was decreased to \$1,534. Similarly, the average cost of an inhospital open inguinal

hernia repair that same year was found to be \$2,237, whereas only \$894.79 when performed in a private office.<sup>22</sup> More recently, it has been reported that office-based ocular surgeries, performed under monitored anesthesia care (MAC), can cost 70% less than similar procedures performed in a hospital.<sup>23</sup> A recent study, found that when dental rehabilitation is performed in an office the cost is approximately 13 times less than when done in a hospital.<sup>21</sup> This change resulted in an average savings of \$6,800 per case. It is understandable that insurance companies now offer incentives to surgeons who utilize an office location as their preferred surgical venue.<sup>24</sup>

Other clear advantages of office-based procedures include ease of scheduling (often with less paperwork), patient and surgeon convenience, decreased patient exposure to nosocomial infections, and both improved patient privacy and continuity of care, since an office is usually staffed by a small consistent group of personnel.<sup>3,13,25,26</sup>

There are potential disadvantages to an office-based procedure. These usually relate to patient safety, reporting, quality improvement, and peer review.<sup>27</sup> In some parts of the country, no regulations governing office-based surgery and OBA exist. Therefore, there may be little to no oversight regarding the certification/qualification of either the surgeon or anesthesiologist to perform the intended procedures, the surgical office's policy regarding peer review, performance and quality improvement, documentation, general policies and procedures, and the reporting of adverse outcomes. However, the number of such states without regulation and oversight is rapidly decreasing (Table 32-1).<sup>28</sup> It is therefore imperative that the practicing anesthesiologist be familiar with all and any regulations that may be in place in his/her state.<sup>29</sup>

**Table 32-1** States That Have Regulations Regarding Office-based Surgery and Anesthesia

Alabama	New Hampshire
Arizona	New Jersey
California	New Mexico
Colorado	New York
Connecticut	North Carolina
Delaware	Ohio
District of Columbia	Oklahoma
Florida	Oregon
Georgia	Pennsylvania
Illinois	Rhode Island
Indiana	South Carolina
Kansas	Tennessee
Montana	Texas
Nebraska	Utah
Nevada	Virginia

Media reports and newspaper articles raised the earliest questions regarding the safety of office-based procedures.<sup>30</sup> These exposés in the lay press may be legitimate. In fact, the remote location of an office may specifically confer an increased risk of injury during an office-based anesthetic.<sup>31</sup>

Data reveal that injuries and deaths occurring in offices are often multifactorial in causation. Reasons include toxicity of local anesthetics; prolonged surgery with occult blood loss; pulmonary embolism; and accumulation of multiple anesthetics resulting in oversedation, hypovolemia, hypoxemia, and the use of reversal drugs with short half-lives.<sup>32–34</sup> Both the Anesthesia Patient Safety Foundation and the American Society of Anesthesiologists (ASA) have emerged as leaders in the field of OBA safety and have advocated that the quality of care in office-based practice be no less than that of a hospital or ASC.<sup>35,36</sup> Thus, it is imperative to ensure that all safety precautions one may take for granted in a hospital be present in the surgical office.

In 1990, the mortality rate from anesthesia was approximately 1/100,000. By the year 2000, the rate had decreased to 1/250,000 in hospitals and 1/400,000 in freestanding ASCs.<sup>37</sup> Although the interpretation of these figures is open to debate, the decrease in mortality can be attributed, in part, to improvements in the training of the anesthesia providers, the safety profiles of the newer anesthetics, enhanced perioperative monitoring capabilities, and intrinsic safety mechanisms in place within the anesthetizing location. Since the majority of office-based patients are young and healthy, one would expect that anesthetics performed in offices would be at least equally as safe as those performed in hospitals, if not safer. However, reports of morbidity and mortality within office-based practices exist. In 1997, Morello et al. conducted a survey querying 418 accredited plastic surgeons' offices. They had a 57% response rate and found that over a 5-year period, 400,675 office procedures were performed; of these, 63.2% were cosmetic and 36.8% were reconstructive. Several outcomes were reviewed including hemorrhage, hypertension, hypotension, wound infection, and need for hospital admission and reoperation. There was an overall complication rate of 0.24%, and seven mortalities occurred, which were secondary to both surgery and anesthesia. They included two myocardial infarctions (MI) (one following an augmentation mammoplasty, the other 4 hours after a rhinoplasty), one case of cerebral hypoxia during an abdominoplasty, one tension pneumothorax during a breast augmentation, one cardiac arrest during carpal tunnel surgery, one stroke 3 days after a rhytidectomy and brow lift, and one unexplained death.<sup>38</sup> This information represented an overall mortality rate of 1 in 57,000. A later report by Hoefflin et al.,<sup>39</sup> however, found no complications after 23,000 plastic surgical procedures that occurred in a single office under general anesthesia (GA). Similarly, Sullivan et al. retrospectively reviewed

the results in an office performing over 5,000 surgical procedures by five independent plastic surgeons. The primary anesthetic technique during this time period consisted of deep sedation in conjunction with local anesthesia or regional block, which was performed by an anesthesiologist supervising a certified registered nurse anesthetist (CRNA). No mortalities occurred over the 5-year period.<sup>40</sup> Bitar et al. retrospectively studied adverse outcomes in 3,615 consecutive patients undergoing 4,778 plastic surgery procedures in offices between 1995 and 2000. The anesthetics were MAC with midazolam, propofol, and an opioid, and again, no deaths were reported. Dyspnea occurred in 0.05% of patients, nausea and vomiting in 0.2%, and there was a 0.05% rate of hospital admissions.<sup>41</sup> When analyzing these outcomes, it must be appreciated that since the mortality rate from anesthesia is so low, an extremely large cohort group would be necessary to provide real data regarding the relative risk of an office-based anesthetic.

A close look at the more recent data again supports the supposition that an office-based procedure is as safe as a procedure done in a more traditional setting. Keyes et al. looked at adverse events in offices accredited by the American Association for Accreditation of Ambulatory Surgical Facilities (AAAASF) between 2001 and 2002. This group found no increase in morbidity and mortality in patients who had procedures with OBA, when compared to those having surgery in a freestanding ASC.<sup>42,43</sup> The group then analyzed the charts of 1,000,000 patients undergoing ambulatory procedures between 2001 and 2006. They found an overall mortality rate of 0.002% (with more than half the deaths being caused by a pulmonary embolism). They concluded that there is no increase in mortality for an ambulatory setting when compared to a freestanding hospital.<sup>43</sup> Similar results were reported by Soltani et al.<sup>44</sup> when looking at 5,500,000 patients undergoing outpatient surgery.

One important caveat when looking at safety records for office-based surgery is that there are no prospective randomized studies. All data are from retrospective chart reviews. When examining the literature, it becomes clear that there have been several studies that report a poor outcome for patients undergoing office-based procedures. According to closed malpractice claims in Florida, Rao et al. reported 830 deaths and 4,000 injuries associated with OBA between 1990 and 1999. These claims accounted for 30% of all malpractice claims in that state. Some more recent data have shown that office-based morbidity and mortality are usually the result of inadequate **4** perioperative patient monitoring, oversedation, and thromboembolic events.<sup>31,33,45</sup> The challenge of acquiring accurate morbidity and mortality data for OBA is complicated by the fact that many offices are not required to report adverse events. In addition, although an anesthesiologist may not even be administering the anesthetic in an office, many complications may still be reported as anesthetic-related.

Why should the surgical venue affect the safety of a particular procedure? Again, the difference may be multifactorial. For example, traditional credentialing procedures, such as board certification and the granting or renewing of hospital privileges based on competency and proof of continuing medical education, may not be required or enforced in an office. Within and among offices, providers of anesthesia may also have varying degrees of both education and expertise. The provider may be an anesthesiologist, a nurse anesthetist, a dental anesthetist, or a surgeon with little or no training in anesthesia. Furthermore, safety within an anesthetizing location also depends on the perioperative patient monitoring capabilities. Although hospital patients are mandated by the accrediting organizations to have defined standards of care for monitoring in the ORs and postanesthesia care units (PACUs), these may be lacking in inadequately prepared and nonaccredited surgical offices.<sup>41</sup> There have been patient injuries reported during office-based procedures resulting from the use of obsolete and/or malfunctioning anesthesia machines, as well as from alarms that have not been serviced and/or are not functioning properly.<sup>46</sup> The ASA created guidelines for defining obsolete anesthesia machines which prohibit the use of any anesthesia machine that lacks essential safety features (e.g., oxygen ratio device, oxygen pressure failure alarm), has the presence of unacceptable features (e.g., copper kettles, or vaporizers with rotary concentration dials that increase vapor concentration when the dial is turned clockwise), or for which routine maintenance is no longer possible.<sup>46</sup>

Without prospective data regarding injuries occurring during office-based surgery, anesthesia databases offer the most reliable approximation. A review of ASA Closed Claims Project data, which incorporates information from the 35 liability insurers that indemnify approximately 50% of the practicing anesthesiologists in the United States, reveals safety concerns in office-based practices are more than theoretical.<sup>32,47</sup> As of 2001 there were 753 (13.7%) claims for ambulatory procedures and 14 (0.26%) for office-based ones. This small number of claims is most likely due to the 3- to 5-year time lag in reporting to the database.<sup>37</sup> ASA physical status 1 or 2 females who had undergone elective surgery under GA make up most of the claims filed. This

**5** statistic parallels the profiles of trends seen in ORs and freestanding ASCs. The injuries that occur in offices tend to be of greater severity than those that occur in ASCs. Twenty-one percent of the reported injuries sustained in offices were temporary and nondisabling in nature and 64% were permanent or led to death, while 62% of the injuries sustained in ASCs were temporary and nondisabling and only 21% were permanent or led to death.<sup>37</sup> A study by Coté et al.<sup>48,49</sup> concluded that the causes for injuries in offices ranged from human error to machine and equipment malfunction ([Table 32-2](#)).

The Closed-Claims Project database reveals that injuries during office-

based procedures occur throughout the perioperative period, and are multifactorial in etiology. The majority, 64%, occurred intraoperatively, while 14% occurred in the PACU and 21% after discharge.<sup>37</sup> Half of these adverse events were respiratory and included airway obstruction, bronchospasm, inadequate oxygenation and ventilation, and unrecognized esophageal intubation. The second most common group of events were considered to be drug-related, occurring 25% of the time. These included incorrect agents or doses, allergies, and malignant hyperthermia (MH). Cardiovascular and equipment-related injuries each occurred in 8% of incidents.<sup>37</sup>

An important point to consider when looking at adverse events is whether or not they were preventable. Again, according to the information in the Closed-Claims Project database, only 13% of the events that occurred in ASCs were considered preventable, whereas 46% of the office-based ones were deemed so. Furthermore, all of the adverse respiratory events that occurred in the PACUs of offices could have been prevented, had pulse oximetry, and capnography been used. Care was considered to be substandard in 50% of OBA claims and in 34% of ASC ones. In 2001, claims originating from an office-based procedure resulted in a monetary award 92% of the time, with a median payment of \$200,000 (ranging between \$10,000 and \$2,000,000), whereas claims originating from ASC-based procedures were compensated only 59% of the time with a median payout of \$85,000 (ranging between \$34 and \$14,700,000).<sup>37</sup>

**Table 32-2** Causes of Injury in the Office-based Practice<sup>48,49</sup>

- Inadequate resuscitation equipment
- Inadequate monitoring (most commonly lack of pulse oximetry)
- Inadequate preoperative or postoperative evaluation
- Human error
  - Slow recognition of an event
  - Slow response to an event
  - Lack of experience
  - Drug overdosage

Ensuring office-based practice safety is critical. After several highly publicized office liposuction injuries and deaths in August 2000, the State of Florida attempted to address this problem by placing a 90-day moratorium on all office-based procedures that utilized anesthetic depths greater than conscious sedation. During that time a safety panel comprised of surgeons, anesthesiologists, and other health-care professionals was formed and charged with the task of developing recommendations to improve the safety record of office-based procedures. The panel's recommendations focused on factors including patient selection, preoperative evaluation and testing, procedures to

be excluded, surgeon qualification, and facility standards.<sup>26,50</sup> Other major organizations that played a leading role in developing standards for the office-based practitioner include the ASA, ASPS, the American Association of Nurse Anesthetists (AANA), and the American Medical Association (AMA).<sup>35,50–52</sup>

## Patient Selection

Prior to presenting for an office-based procedure, the patient's medical condition should be optimally managed.<sup>53</sup> He or she should have a preoperative history and physical examination documented within 30 days prior to the procedure, and all pertinent laboratory tests as well as any medically indicated specialist consultation(s) must be readily available. Consent for the procedure and the anesthetic must also be in the chart. The anesthesiologist should have access to all of this information preoperatively and, when possible, contact the patient prior to the scheduled procedure. If a patient's ASA physical status is 1 or 2, the surgeon's office should arrange the surgery as per office protocol. However, if a patient has significant comorbid conditions, a preoperative anesthesiology consultation should be obtained before scheduling the patient for office-based surgery. A protocol regarding the scheduling of patients with significant comorbidities has become increasingly important in OBA. As OBA has become more commonplace, the medical/surgical community began to include older and sicker patients in this venue. There are many office-based practices that perform procedures on ASA 3 patients and several on ASA physical status 4 patients.<sup>54</sup>

Patient selection has always been a controversial topic among anesthesiologists practicing OBA because little morbidity and mortality data exist to support the inclusion or exclusion of specific populations. In 1982, Meridy<sup>55</sup> reported that patients should not be excluded from undergoing ambulatory procedures based solely on their age, the type of procedure, or the duration of the planned procedure. Conflicting recommendations do exist. The ASPS acknowledged that the ideal patient for an office-based **6** procedure has an ASA physical status of 1 or 2. They recommended that ASA physical status 3 patients undergo an office-based procedure only after an anesthesia consultation and only have an office-based procedure performed under local anesthesia without sedation. The ASA also has developed recommendations regarding patient selection.<sup>56</sup> It is important to realize that the office is often remote, and the anesthesiologist may be unable to get assistance should it be required. Thus, groups of patients in whom anticipated anesthetic problems may develop should be avoided ([Table 32-3](#)). Individual anesthesiologists should therefore consider excluding certain patients with significant comorbid conditions in order to avoid unanticipated problems. Again, these are recommendations that are not based on evidence.

Morbidly obese patients and those with obstructive sleep apnea (OSA) syndrome present unique and increasingly frequent challenges to the office-based practitioner.<sup>57</sup> Indeed, they are usually the same population, with estimates of 60% to 90% of all OSA patients being obese (body mass index  $\geq 30$  kg/m<sup>2</sup>).<sup>58,59</sup> Confounding this problem is that the majority of the patients with OSA syndrome have yet to be formally diagnosed.<sup>60,61</sup> In patients who have not been diagnosed with OSA syndrome, the STOP-Bang (snoring, tiredness, observed apnea, high blood pressure, BMI, age, neck circumference, male gender) questionnaire is a helpful and highly sensitive tool.<sup>62-64</sup>

**Table 32-3** Unsuitable Candidates for an Office-Based Procedure

- Poorly controlled diabetes
- History of substance abuse
- Seizure disorder
- Malignant hyperthermia susceptibility
- Potential difficult airway
  - Morbid obesity
  - Severe obstructive sleep apnea syndrome
- NPO (solid foods) < 8 h
- No escort
- Previous adverse outcome from anesthesia
- Significant drug allergies
- Aspiration risk

Patients with OSA syndrome are often difficult to ventilate and intubate. One of the first steps in the ASA algorithm for management of the difficult intubation is to call for help, which, in an office, is usually not possible. Assuming an airway is secured during surgery, patients with OSA syndrome are likely to experience major anesthetic problems after extubation of the trachea.<sup>65</sup> These patients tend to be exquisitely sensitive to the respiratory depressant effects of even small dosages of sedation and/or narcotics.<sup>51</sup> They are prone to respiratory distress after extubation or may suffer from respiratory arrest with postoperative sedation or analgesia.<sup>49,66</sup> Although perhaps clinically unimportant, transient hypoxia is often seen during the recovery phase of patients with OSA syndrome.<sup>67</sup> Furthermore, respiratory depression may not be reversible with pharmacologic antagonism.<sup>68</sup> Some recommend that a postoperative observational unit with close monitoring of oxygen saturation or an intensive care unit setting be used for monitoring the OSA syndrome patient postoperatively.<sup>69</sup> It may thus be prudent to avoid performing GA in which narcotics are required during the perioperative period on any patient with severe OSA syndrome in an office-based venue.<sup>70</sup> An alternative would be to completely avoid administering any anesthetic in an office to a patient with severe OSA syndrome.

Pulmonary embolism has long been known to be a significant cause of

perioperative morbidity and mortality from office-based surgical procedures.<sup>71,72</sup> Recent studies have revealed that this risk has not dissipated with time.<sup>43,44</sup> Even in 1998, Reinisch found that 0.39% (37/9,493) of patients who underwent rhytidectomy developed a deep vein thrombosis (DVT). Of these, 40.5% (15/37) went on to form a pulmonary embolism. Although GA had only accounted for 43% of the anesthetic techniques used for the procedure, 83.7% of the embolic events were associated with the patient having received a general anesthetic.<sup>73</sup> Studies by Keyes et al.<sup>43</sup> and **7** Soltani et al.<sup>44</sup> confirm that pulmonary embolism (PE), in 2014, remains an important risk of an office-based procedure. Risk factors for the development of DVT appear in [Table 32-4](#).<sup>74</sup> The ASPS recommends that patients be stratified according to risk and the prophylactic treatment be guided by risk ([Table 32-5](#)).

As more subspecialties begin to perform office-based procedures, and as the population ages, older and sicker patients will present for surgery and anesthesia.<sup>75</sup> The anesthesiologist must be the patient's advocate in the matter of safety. This advocacy can only result from a true understanding of how to adequately select appropriate patients for this unique surgical venue.

**Table 32-4** Risk Factors for the Development of Deep Vein Thrombosis (DVT)

- Age > 40
- Antithrombin III deficiency
- Central nervous system disease
- Family history of DVT
- Heart failure
- History of a DVT
- Hypercoagulable states
- Lupus anticoagulant
- Malignancy
- Obesity
- Oral contraceptive use
- Polycythemia
- Previous miscarriage
- Radiation therapy for pelvic neoplasms
- Severe infection
- Trauma
- Venous insufficiency

## Surgeon Selection

The relationship between the surgeon and anesthesiologist must be one of mutual trust and understanding. Since the surgeon performing the procedure may also own the office, he or she must not put pressure on the anesthesiologist to perform an anesthetic if he or she believes that the patient or procedure is not appropriate.

**Table 32-5** Recommended Treatment for Prevention of Deep Vein Thrombosis in Patients, Stratified by Risk<sup>73,74</sup>

Cohort	Treatment
<b>Low Risk</b> No risk factors Uncomplicated surgery Short duration	<ul style="list-style-type: none"> <li>• Comfortable position</li> <li>• Knees flexed at 5 degrees</li> <li>• Avoid constriction and external pressure</li> </ul>
<b>Moderate Risk</b> Age >40 with no other risks Procedure >30 min Oral contraceptive use	<ul style="list-style-type: none"> <li>• Proper positioning</li> <li>• Intermittent pneumatic compression of calf or ankle (prior to sedation and continued until patient is awake and moving)</li> <li>• Frequent alterations of the OR table</li> </ul>
<b>High Risk</b> Age >40 with concomitant risk factors Procedure >30 min	<ul style="list-style-type: none"> <li>• Treatment as per patients with moderate risk</li> <li>• Preoperative hematology consultation with consideration of perioperative antithrombotic therapy</li> </ul>

The surgeon must have a valid medical license, registration, and Drug Enforcement Administration (DEA) certificate. He or she should be either board eligible or board certified by a recognized member of the American Board of Medical Specialties, and either have privileges to perform the proposed procedure in a local hospital, or have training and documented competency comparable to a practitioner who does have such privileges in a hospital. Although this requirement may sound intuitive, there have been cases reported of surgeons performing procedures for which they have little or no training.<sup>13</sup> In addition, the surgeon must have adequate liability insurance, at least equal to that carried by the anesthesiologist. If a lawsuit should arise and the surgeon is inadequately insured, the anesthesiologist may be held financially responsible and become the “deep pocket.” Similarly, the facility itself should have adequate liability insurance.

In addition, there should be a system in place for monitoring continuing medical education as well as peer review and ongoing quality improvement for the surgeon/proceduralist, anesthesiologist, and nursing staff. This provision is often not the case in an office-based practice.<sup>13</sup> If an anesthesia group provides care at more than one office, an overall peer review for the practice may be used; it need not be specific to each individual office-site. Solo anesthesia practitioners should not be exempt from this process. Anesthesiologists should only align themselves with the offices which have ongoing processes, or help organize one. The peer review committee should include surgeons, anesthesiologists, and nursing staff. It should meet regularly

and maintain a written record of minutes and recommendations. Similarly, continuing medical education should also be documented and at a minimum should be sufficient to meet relicensing requirements.

**8** When formulating a quality improvement program, there should be random chart reviews as well as key sentinel events that trigger a case review (Table 32-6). It is imperative that this review be an open forum to ensure continued quality improvement of care, and not be biased or hindered by fear of litigation. Legal counsel should be sought to determine whether information disclosed at these meetings is discoverable in a court of law, should a malpractice claim arise.

**Table 32-6** Sentinel Events That Should Trigger a Case Review and Be Presented at a Performance Improvement/Quality Assurance Meeting

- Death
- Neurologic injury
- Perioperative MI or stroke
- Aspiration
- Reintubation/unanticipated intubation postop
- Return to the operating room
- Peripheral nerve injury
- Adverse drug reaction
- Uncontrolled pain or nausea/vomiting
- Unexpected hospital admission
- Cardiac arrest
- Dental injury
- Incomplete charts
- Controlled substance discrepancy
- Patient complaints
- Corneal abrasion

## Office Selection and Requirements

The anesthesiologist should function as a zealous patient advocate in **9** assuring that an anesthetic only is performed in a safe anesthetizing location. The office needs to be appropriately equipped, stocked, and maintained to perform GA (Table 32-7). All supplies must be age and size appropriate for the patient population. If an anesthesia machine or ventilator is present, it must be regularly serviced and calibrated. If potent inhaled volatile agents or N<sub>2</sub>O is used, there must be a functioning waste gas scavenging system. This system may be exhausted via a window or roof vent. However, the exhaust must not be situated such that there is a possibility that it will be vented back into the office or into any other inhabited space. Further, it must be in accordance with Occupational Safety and Health Administration (OSHA), as well as state and federal standards. Portable scavenging systems presently available can be safely used. Air testing should be done on a regular basis. In an office without an exhaust system, total

intravenous anesthesia (TIVA) techniques should be employed.

All offices, even those without ventilators or anesthesia machines, require a means to deliver positive pressure ventilation to the patient's lungs. This ventilation can be achieved by using a self-inflating resuscitation device. An adequate supply of compressed oxygen must be present as well as a back-up supply for use in an emergency. In offices that do not have a pipeline supply of oxygen, H cylinders are usually used and several E cylinders should be available in reserve. A policy must be in place describing the transport, storage, and disposal of medical gases, consistent with state and local laws. All equipment described in the ASA algorithm for management of the difficult airway should be present.<sup>76</sup> A readily available means to create an emergency surgical airway and jet ventilation capability may be lifesaving.

**Table 32-7** Equipment Required for Safe Delivery of Office-based Anesthesia

Monitors
Noninvasive blood pressure with an assortment of cuff sizes
Heart rate/electrocardiogram
Pulse oximeter
Temperature
Capnography
Airway supplies
Nasal cannulas
Oral airways
Face-masks
Self-inflating bag-mask ventilation device
Laryngoscopes multiple sizes and styles (Mac and Miller)
Handles
Various sizes of tracheal tubes
Stylettes
Emergency airway equipment (laryngeal mask airways, cricothyrotomy kit, transtracheal jet ventilation equipment)
A video laryngoscope
Suction catheters and suction equipment
Cardiac defibrillator
Emergency drugs
Advanced cardiac life support drugs
Dantrolene and malignant hyperthermia supplies
Intravenous lipid infusion if nerve blocks are being performed
Anesthetic drugs
Vascular cannulation and IV equipment

Perioperative monitoring must adhere to the ASA standards for basic anesthetic monitoring.<sup>77</sup> These monitors include continuous monitoring of heart rate and oxygen saturation, intermittent noninvasive blood pressure monitoring, end-tidal carbon dioxide (EtCO<sub>2</sub>) monitoring and the capacity for both temperature monitoring and continuous ECG. Monitors must be routinely serviced, calibrated, and repaired as per manufacturers' recommendations (preventive maintenance is usually performed annually). All monitors should have a back-up battery supply and there should be an

extra monitor available for an emergency. It is of interest to note that the ASA only requires EtCO<sub>2</sub> monitoring to be used if sedation is performed by an anesthesiologist; if sedation is performed by a nonanesthesiologist, the ASA has no such requirement. However, in 2014, the American Association of Oral and Maxillofacial Surgeons Board of Trustees mandated the use of capnography by all of its members for deep sedation and GA.<sup>78</sup>

All emergency drugs appearing on the American Heart Association Advanced Cardiac Life Support (ACLS) protocol should be immediately available. The expiration dates for these agents should be checked on a regular basis, and outdated drugs replaced. A cardiac defibrillator with a battery back-up must be immediately available and routinely checked and maintained, as should a source of suction including pharyngeal suction catheters. Having an “MH” cart containing at least 12 bottles of dantrolene is a requirement, if triggering agents are stocked in an office. A complete listing of MH supplies is available online at [www.mhaus.org](http://www.mhaus.org).<sup>79</sup> The office-based anesthesiologist should be familiar with the signs and symptoms of MH and be prepared to initiate treatment. It is recommended that the published MH algorithm be displayed in all areas where triggering agents are used. The office staff should undergo MH drills at least annually.

A protocol for the delivery and secure storage of controlled substances must be in place. A licensed anesthesiologist may supply these drugs in accordance with DEA regulations, as can any licensed physician with a current DEA registration certificate. Instead of transporting drugs, it is often more convenient to store them in the surgical office. In this situation, they must be stored in a double-locked storage cabinet installed in a secure location, in accordance with state and local regulations. The office in which the controlled substances will be dispensed must also be properly registered with the DEA. Drug accounting must be performed in accordance with state and federal regulations. Individual states have different provisions and regulations regarding the dispensing of controlled substances, and it is the responsibility of the dispensing physician to assure that the office-based practice is in compliance.

A medical director and a governing body, responsible for overall operations and ensuring high quality patient care, should be identified for every office. This provision even applies to solo practitioner offices. The governing body should meet regularly and amongst other duties, be responsible for the credentialing and privileging of all health-care providers. There must also be a policy and procedures manual that outlines the responsibilities of the governing body, each staff member including nurses (circulating/scrub and postop), physician assistants, surgical technicians, and office staff and administrators. The manual should include a description of the infection control policy, risk management, safety issues, anesthesia policies,

and so forth. All nurses should be licensed by the state and have training and education consistent with their responsibilities. Basic cardiac life support (BCLS) certification should be mandatory and ACLS certification is preferable for nurses. In addition, either the anesthesiologist or the physician who supervises the anesthesia care provider must be ACLS or pediatric advanced life support (PALS) certified, depending on the patient population. There should always be at least one member of the health-care team with ACLS/PALS certification present in the office until the last patient has been physically discharged from the unit.

**Table 32-8** Emergencies That Require Contingency Plans

- Fire
- Bomb/bomb threat
- Power loss
- Equipment malfunction
- Loss of oxygen supply pressure
- Cardiac or respiratory arrest in the waiting room, operating room, or postanesthesia care unit
- Earthquake
- Hurricane
- External disturbance such as a riot
- Malignant hyperthermia
- Massive blood loss
- Emergency transfer of patient to a hospital

Emergencies such as cardiac arrest, earthquakes, hurricanes, and fires can and do occur in office-based settings (Table 32-8). Each office must have a plan in place delineating the responsibilities of each staff member, in the event of such an occurrence. The physical structure of the office is an important consideration. There should be a clear egress that would easily accommodate a stretcher carrying a mechanically ventilated patient. Adequate clearance and room for transport in an elevator must also be considered.

Destinations for a patient in need of hospital admission must be identified. Developing an office-hospital relationship is challenging, as hospitals may be reluctant to be involved in office mishaps. However, it is of utmost importance to have a formal written transfer agreement in place with a local hospital. Telephoning the emergency services number (911) is an acceptable plan for transportation, provided the response time is rapid. If 911 is unavailable in a specific city, or has a slow response time, the office should have a contractual agreement with a local ambulance company.

The office must be prepared to respond to an intraoperative fire. The ASA has published an advisory on the prevention and management of such an emergency.<sup>80</sup> Fire requires three components known as the “fire triad”: an oxidizer (oxygen and nitrous oxide [N<sub>2</sub>O]), an ignition source (electrocautery, laser, drill, etc.), and fuel (sponges, drapes, endotracheal tubes, solutions

containing alcohol or other volatile compounds, etc.). The modern OR contains all three in great supply. The first step in fire prevention is education. All members of the surgical and anesthesia team must be educated on how fires are started, sustained, and prevented. There must be regularly scheduled fire drills that include all employees, even those with nonclinical duties. These drills should highlight the responsibilities of each staff member. A yearly meeting with the local fire marshal is often helpful.

Fire prevention is of the utmost importance. The ASA recommends that if flammable materials are used to prep the skin they should be allowed to completely dry prior to draping the surgical field. The field should then be draped in a manner that does not allow for oxygen to accumulate. These accumulated pockets of oxygen may flow into the surgical field, where there is a source of ignition such as electrocautery. There must be communication between the surgeon and anesthesiologist when an oxygen-rich environment is being created near a surgical site. This scenario is common during facial plastic surgery. Medical air insufflation or suctioning can be used to reduce oxygen accumulation and the use of N<sub>2</sub>O avoided. When using an ignition source in an oxygen-rich environment, the ASA recommends reducing the oxygen flow as low as possible without creating hypoxia, and waiting several minutes to allow the oxygen to dissipate.<sup>74</sup>

The management of a fire will require recognizing the early signs, stopping the procedure and ignition source, extinguishing the fire, and delivering care to the patient. It may even be necessary to evacuate the building. In any case, it is imperative that all these steps be reviewed regularly and drills performed. The office should have at least a 1-hour firewall present to help prevent in the spread of the fire.

There must be contingency plans in the event of a power supply interruption or electrical failure. Each office should have an emergency generator capable of running necessary equipment and monitors; monitors should have battery back-up power that is routinely checked. Battery reserve power will usually last for 1.5 hours, but this duration needs to be verified for each piece of electrically powered equipment.

The office should keep patient records (including anesthesia records) in accordance with local laws, which is usually for a minimum of 5 to 7 years. Clinical records must be stored in a secure location, with access limited to medical professionals who are privileged to review these records. Similarly, the anesthesiologist should maintain his or her own records, which include the preanesthesia history and physical, informed consent, intraoperative documentation and postoperative care record, as well as discharge orders.

## **Accreditation**

One way to objectively evaluate an office is to have it be accredited by a nationally recognized accrediting agency. The ASA has developed a classification of offices that stratifies them by the level of anesthetic depth that may be administered (Table 32-9).<sup>56</sup> Presently many states require offices to be accredited and more are following suit. In states that do not require accreditation, there are benefits to voluntarily obtaining it. Often accreditation will allow the facility fee to be reimbursed by a third-party payer in medically necessary procedures.<sup>81</sup> It should be noted that presently Medicare and Medicaid will not pay a facility fee for an office-based procedure. Another benefit of accreditation is that the patient may feel more comfortable undergoing a procedure in an office that has been accredited. Finally, as more states require accreditation, if a surgeon's office proactively becomes accredited in a state that subsequently requires it, there would be no interruption of services.

**Table 32-9** American Society of Anesthesiology Classification of Surgical Procedures<sup>56</sup>

<b>Class A</b>
Minor surgical procedures Local, topical, or infiltration of local anesthetic No sedation preoperatively or intraoperatively
<b>Class B</b>
Minor or major surgical procedures Sedation via oral, rectal, or intravenous sedation Analgesic or dissociative drugs
<b>Class C</b>
Minor or major surgical procedures General anesthesia Major conduction block anesthesia

Currently there are three major accrediting bodies for office-based surgery offices, although several other agencies are also recognized. The Accreditation Association for Ambulatory Health Care (AAAHC) was the first major accrediting body, offering certification since 1998. The AAAASF, originally the Accreditation Association for Ambulatory Plastic Surgical Facilities (AAAAPSF), was the second, followed by The Joint Commission (TJC). To date, the most active organization in the accreditation of surgical offices is the AAAASF. Although its requirements are similar to those of AAAHC and TJC, the accreditation process is occasionally less expensive. Changes are currently underway to allow AAAHC and TJC to be more competitive.<sup>3</sup> Each agency has different criteria for eligibility and different accreditation cycles pertaining to the time limit of a certificate.<sup>82</sup> The agencies deal with the entire perioperative spectrum of running a surgical office, ranging from the actual facility through patient issues, governance, risk management, safety, infection, clinical record keeping, and administration (Table 32-10). Each

agency has a workbook available to the practitioners to review all requirements of accreditation. Of note, the AAAHC can accredit not only the surgical office but also an anesthesia group that provides OBA.

**Table 32-10** Factors Considered in Accrediting an Office for Surgical Procedures

- Governance
- Administration
- Clinical records
- Credentialing and privileging
- Safety
- Infection control
- Physical layout of the office
- Laboratory values
- Quality improvement
- Personnel records
- Surgeon qualification
  - Training
  - Local hospital privileges (surgical and admission)
- Peer review
- Anesthesiologist requirements
- Staffing intraoperatively and postoperatively
- Monitoring capabilities both intraoperatively and postoperatively
- Ancillary care
- Equipment
- Drugs (emergency, controlled substances, routine medications)
- Basic, advanced cardiac, and pediatric life support certification
- Temperature
- Neuromuscular functioning
- Patient positioning
- Pre- and postanesthesia care/documentation
- Quality assurance/peer review
- Liability insurance
- Postanesthesia care unit evaluation
- Discharge evaluation
- Emergency preparedness (fire/admission/transfer, etc.)
- A complete listing of criteria can be obtained from the individual agencies

The accrediting agencies were developed, in part, to reduce some of the variability that exists among offices in regard to safety and administrative issues. Several professional societies are encouraging their members to perform procedures only in accredited facilities. The Society for Aesthetic Plastic Surgeons mandates that all of its members perform procedures only in offices that have been accredited by one of the nationally recognized accrediting agencies, or have been certified to participate in the Medicare program under title XVIII, or are licensed by the state. The actual improvement in safety conferred by performing surgery in an accredited office has yet to be determined, and there are those who suggest that it provides no advantage.<sup>83</sup> As long as there is no mandatory reporting system in place, it will be impossible to determine true incidence of morbidity associated with office-based practice. Presently, the only accrediting agency

that requires reporting of all adverse outcomes in the AAAASF. In addition, several states have similar reporting mandates. Clearly though, safety in an office depends upon more than just accreditation; there must be constant vigilance by all members of the health-care team.

## Procedure Selection

Early in the development of office-based surgery, procedures were generally noninvasive and of short duration. However, as newer surgical and anesthetic techniques have evolved, longer and more invasive procedures have been successfully performed.<sup>84–91</sup> Suitable office-based procedures range the gamut from superficial incision and drainage of abscesses to more invasive microlaparoscopies.

Duration of procedure has long been correlated with the need for hospital admission, with procedures lasting more than 1 hour being associated with a higher incidence of unplanned admission.<sup>92</sup> Other data have shown that longer procedures are also often associated with an increased incidence of postoperative nausea and vomiting (PONV), postoperative pain, and bleeding,<sup>93,94</sup> which may warrant hospital admission. For these reasons the ASPS has recommended that procedures be limited to 6 hours and be completed by 3 PM, thus allowing for a full patient recovery with maximum office staffing.<sup>50</sup> In addition, when determining the suitability of a procedure one must consider the possibility of hypothermia, blood loss, or significant fluid shifts.<sup>50</sup>

## Specific Procedures

### Liposuction

Liposuction is the most commonly performed cosmetic procedure performed primarily by plastic surgeons and dermatologists.<sup>95,96</sup> It is accomplished by inserting hollow rods into small incisions in the skin, and suctioning subcutaneous fat into an aspiration canister. Superwet and tumescent techniques, introduced in the mid-1980s, utilize large volumes (1 to 4 mL) of infiltrate solution (0.9% saline or Ringer lactate with epinephrine 1:1,000,000 and lidocaine 0.025% to 0.1%) for each 1 cc of fat to be removed. Blood loss is generally 1% of the aspirate with these techniques.<sup>97</sup> The peak serum levels of lidocaine occur 12 to 14 hours after injection and decline over the subsequent 6 to 14 hours.<sup>98,99</sup> Although the maximum dose of lidocaine has been traditionally limited to 7 mg/kg, 35- to 55-mg/kg doses have been used safely because the tumescent technique results in a single compartment clearance similar to that of a sustained-release medication.<sup>100</sup>

Liposuction is not a benign procedure.<sup>101</sup> In 2000, a census survey of the 1,200 members of the ASAPS, revealed an overall mortality rate of 19.1 per 100,000 liposuction procedures, with pulmonary embolism the diagnosis in 23.1% of deaths. Other etiologies of mortality included abdominal viscous perforation, anesthesia causes, fat embolism, infection, and hemorrhage; 28.5% of all deaths in this study were reported as of unknown or confidential etiology.<sup>102</sup> Risk factors identified included the use of multiliter wetting solution infiltration, mega-volume aspiration causing massive third spacing, multiple concurrent procedures, anesthetic sedative effects yielding hypoventilation, and permissive discharge policies. The management of the postoperative period, with attention to fluid and electrolyte balance and pain control, is critical to an optimal outcome after liposuction. The patient's fluid deficit, maintenance, intraoperative loss, and third spacing should guide fluid management throughout the perioperative period. Generally, an office liposuction should be limited to 5,000 mL of total aspirant which includes supernatant fat and fluid.<sup>50</sup> It is also recommended that large volume liposuction not be performed in conjunction with other procedures.

Iverson et al. developed the following considerations and recommendations regarding office-based liposuction<sup>26,50</sup>:

- Plastic surgeons should follow the current ASA Guidelines for Sedation and Analgesia.
- GA can be used safely in the office setting.
- GA has advantages for more complex liposuction procedures that include precise dosing of sedatives, controlled patient movement, and airway management.
- Epidural and spinal anesthesia in the office setting are discouraged because of the possibility of vasodilatation, hypotension, and fluid overload.
- Moderate sedation/analgesia augments the patient's comfort and is an effective adjunct to the anesthetic infiltrate solutions.

In 2002, 261 respondents to a survey sent to the membership of The American Society for Dermatologic Surgery reported no mortalities among 66,570 liposuction procedures performed in hospitals, ASCs, and offices. The authors reported adverse events, which mirrored those of the ASAPS. They found that serious adverse events occurred more frequently with procedures performed in hospital and ASCs than in offices. This difference may be due to the fact that, in hospitals, liposuction is performed on sicker patients or that the procedures are associated with removal of a larger amount of fat. Interestingly, 71% of the offices surveyed were nonaccredited. Further, the authors reported that morbidity correlated better with the area of the body suctioned (abdomen and buttocks as compared to extremities, which has lower associated morbidity), than the facility in which the procedure took

place.<sup>103</sup>

## **Aesthetics**

Many facial aesthetic procedures such as blepharoplasty, rhinoplasty, and meloplasty are routinely performed in offices, usually under varying depths of MAC, but occasionally with GA. Facial plastic procedures that require use of a laser or even routine electrocautery, pose a problem for the anesthesiologist. Supplemental nasal oxygen in patients receiving sedation presents a fire hazard. Any supplemental oxygen must be turned off during periods of laser or electrocautery use about the face, and this requires vigilance by the anesthesiologist who must be in constant communication with the surgeon. Methods for delivering supplemental oxygen to a patient having a facial procedure include nasal cannula, an oxygen hood, or placement of oxygen tubing in an oral/nasal airway. The latter usually requires a deeper level of sedation. The avoidance of supplemental oxygen when medically appropriate is ideal.

## **Breast**

Procedures such as breast biopsy or augmentation, implant exchange, or completion of transverse rectus abdominal muscle (TRAM) flap (i.e., nipple construction or revisions) are routinely performed in office settings. Breast augmentation entails separating the pectoralis muscles from the chest wall, which is painful and usually requires GA and can be accomplished by using either a laryngeal mask airway (LMA) or tracheal tube. The use of regional anesthesia with paravertebral nerve blocks has also been reported.<sup>104</sup> Breast surgery is associated with a high incidence of PONV; thus, it is likely that patients undergoing breast surgery will require antiemetic medication in addition to postoperative analgesics.<sup>105</sup>

## **Gastrointestinal Endoscopy**

Procedures performed by gastroenterologists include esophageal, gastric and duodenal endoscopies (EGD) and colonoscopies. This patient population tends to be older, with significant comorbid conditions. Upper GI procedures rarely require endotracheal intubation because, although many of these patients have gastroesophageal reflux, the stomach is emptied under direct visualization. The endoscopist requires patient participation to aid in insertion of the endoscope, which can usually be accomplished with sedation using small doses of propofol with or without midazolam.

Colonoscopy is uncomfortable secondary to the insertion and manipulation of the endoscope, and may be associated with cardiovascular effects,

including dysrhythmias, bradycardia, hypotension, hypertension, myocardial infarction, and death. The mechanism of these cardiovascular effects is not known, but there is evidence that they may be mediated by the autonomic nervous system when stimulated by anxiety or discomfort.<sup>106</sup> Adding an opioid to midazolam during colonoscopy has been shown to improve patient tolerance of the procedure and decrease pain without increasing the frequency of respiratory events.<sup>107</sup> Interestingly, anesthetic techniques consisting of midazolam,<sup>108</sup> remifentanyl/propofol, and fentanyl/propofol/midazolam<sup>109</sup> lower the number of episodes of heart rate variability which reflects sympathetic activation as seen on continuous electrocardiography, and may contribute to the number of cardiovascular events that occur during colonoscopy.

Recently the gastroenterology community has sought to be able to provide moderate or even deep sedation with propofol without the assistance of a trained anesthesiologist.<sup>110</sup> However, due to safety concerns propofol may still only be given by an anesthesiologist as indicated in the product insert. In addition, the Institute for Safe Medical Practices has indicated that propofol may only be administered by individuals who are “trained in the administration of drugs that cause deep sedation and GA,” dedicated to only providing the sedation (not also performing the procedure) and proficient at tracheal intubation.<sup>111</sup> The AAAASF has, likewise, indicated that anesthesia professionals are best qualified to administer propofol sedation. Every office should clearly delineate who is privileged and credentialed to administer propofol.

## **Dentistry and Oral and Maxillofacial Surgery**

N<sub>2</sub>O has been used for most of the world’s office-based dental anesthetics since 1884, when Horace Wells, himself a dentist, had N<sub>2</sub>O administered for a wisdom tooth extraction by a colleague. It was Harry Langa, another dentist, who pioneered the concept of using lower concentrations of N<sub>2</sub>O in combination with local anesthetics. This idea of “relative analgesia” was the forerunner of “conscious sedation.”<sup>112</sup>

The American Association of Oral and Maxillofacial Surgeons studied a prospective cohort of patients who underwent oromaxillofacial surgery (OMS) surgery between January and December 2001. Of the 34,191 patients included, 71.9% received deep sedation or GA, 15.5% conscious sedations, and 12.6% local anesthesia. The operating surgeon provided anesthesia services in 96% of cases, and anesthesia-specific hospitalization rate was 4 per 100,000, with no reported mortalities. The authors attributed this safety level to the use of pulse oximetry, blood pressure and ventilation monitoring, as well as administration of

supplemental oxygen.<sup>113</sup> Newer studies found that most patients are satisfied with the use of office-based sedation and GA.<sup>115</sup> Patients' biggest concerns and reason for dissatisfaction continue to be pain, nausea and vomiting, or being "awake" during the procedure.<sup>114</sup> Because office-based OMS procedures are so commonplace and patients are presenting with more comorbidities, it is likely that anesthesiologists will increase their presence in this arena.

## **Orthopedics and Podiatry**

Orthopedic offices provide excellent locations for anesthesiologists who practice regional anesthesia. Although knee arthroscopies can be performed with intra-articular local anesthesia and MAC, an adductor canal block with bupivacaine or ropivacaine, supplementing the intra-articular local anesthetic in an arthroscopically assisted anterior cruciate ligament repair will provide long-acting postoperative analgesia. Interscalene, supraclavicular, infraclavicular, and axillary blocks avoid airway manipulations in patients undergoing upper extremity procedures, whereas ankle blocks or blocks of the sciatic nerve in the popliteal fossa provide anesthesia for operations on the lower extremity. All of these blocks can be supplemented with short-acting anxiolytic agents.

Spinal anesthetics in the office-based setting must be of short duration secondary to limited PACU space. Lidocaine, which provides reliable short-acting analgesia, may be associated with an increased risk of transient neurologic symptoms in the ambulatory patient population,<sup>115</sup> whereas using procaine–fentanyl spinals are associated with nausea and vomiting as well as pruritus.<sup>116</sup> When the neuraxial anesthetic wears off, postoperative pain may arise; therefore, the patient must be discharged with oral analgesics as well as contact information for both the surgeon and the anesthesiologist.

## **Gynecology and Genitourinary**

Many procedures, such as cervical dilation and curettage, vasectomy, and cystoscopy have been routinely performed in offices, often with local anesthesia and no sedation.<sup>117</sup> Recently there has been an increase in more invasive procedures (on older patients) such as minilaparoscopies, ovum retrieval, prostate biopsies, and lithotripsy, necessitating an anesthesiologist's expertise.<sup>118</sup> A variety of anesthetic options are available for these procedures and the anesthetic choice is dependent upon the surgeon, patient, and anesthesiologist's preferences.

## **Ophthalmology and Otolaryngology**

Ophthalmologic procedures suitable for the office include cataract extractions,

lacrimal duct probing, and ocular plastics. Topical anesthesia and periorbital or retrobulbar blocks are frequently used to provide analgesia. Supplemental sedation may be required. Otolaryngology procedures include endoscopic sinus surgery, turbinate resection, septoplasty, and myringotomy.<sup>119</sup> Again, combinations of topical and regional nerve blocks with supplemental sedation are commonly employed, but occasionally GA is used.<sup>120,121</sup>

## **Pediatrics**

Although no minimum age requirement for a child to undergo an office-based anesthetic has been established, patients greater than 6 months of age and ASA physical status 1 or 2 may be reasonable candidates.<sup>20</sup> Appropriate OBA pediatric cases are usually dental, and chloral hydrate with N<sub>2</sub>O has historically been the anesthetic choice of many dentists. The use of these agents is however associated with significant morbidity. Ross et al.<sup>20</sup> found that in children between the ages of 1 and 9 years, 70 mg/kg of chloral hydrate with 30% N<sub>2</sub>O resulted in hypoventilation in 94% of patients, which increased to 97% of patients when the chloral hydrate was combined with 50% N<sub>2</sub>O. This increase is significant in view of the findings of Coté et al., who reviewed 95 adverse sedation-related events in pediatric patients. In the 93% of these cases that resulted in permanent neurologic injury or death, the anesthetic was delivered by an oral surgeon, periodontist, or CRNA supervised by a dentist.<sup>48,49</sup>

There are increasing numbers of ophthalmologic (examination under anesthesia, lacrimal duct probing), otolaryngology (myringotomy), cast/dressing changes, and minor plastics procedures being performed on children in offices. The American Academy of Pediatrics, Section on Anesthesiology has developed guidelines for the pediatric perioperative environment, which should be adhered to in the office setting (Table 32-11).<sup>122</sup>

**Table 32-11** Considerations for the Pediatric Perioperative Anesthesia Environment

<b><i>Patient Care Facility and Medical Staff Policies</i></b>
Designation of operative procedures
Categorization of pediatric patients undergoing anesthesia
Annual minimal case volume to maintain clinical competence
<b><i>Clinical Privileges of Anesthesiologists</i></b>
Regular privileges
Special clinical privileges
Pain management
<b><i>Patient Care Units</i></b>
Preoperative evaluation and preparation units
Operating room
Anesthesiologists
Other health-care providers involved in perioperative care
Clinical laboratory and radiologic services availability and capabilities
Pediatric anesthesia equipment and drugs including resuscitation cart
PACU
Nursing staff
Anesthesiologist/physician staff
Pediatric anesthesia equipment and drugs
<b><i>Postoperative Intensive Care</i></b>
Availability of transfer to local hospital intensive care unit, with arranged admissions through the emergency department

## Anesthetic Techniques

The ASA recommends that anesthetics be provided or supervised by a fully licensed anesthesiologist.<sup>56</sup> If an anesthesiologist is directing anesthesia care, he or she must be immediately available throughout the entire perioperative period. Regulations in several states have questioned the need for this level of anesthesia training in the delivery of OBA. Some states allow for an anesthetic to be performed by a nonphysician anesthesia provider supervised by a licensed physician. In this situation, the supervising physician must be qualified to perform a preanesthetic focused history and physical examination as well as be immediately available throughout the perioperative period. He or she must know how to handle anesthetic-related emergencies and complications. The supervising physician must be ACLS certified.

OBA requires many levels of anesthesia ranging from moderate sedation through regional and GA.<sup>123</sup> Anesthesia is, however, a continuum and it is often impossible to predict how a patient will react. The ASA has developed definitions regarding depths of anesthesia (Table 32-12). Patients will routinely drift between the anesthetic depths; thus it is imperative that the anesthesia provider or supervisor be able to rescue a patient from a deeper level of anesthetic than was anticipated.

**Table 32-12** Definitions of Levels of Sedation/Analgesia by the American Society of Anesthesiology

<b>Minimal Sedation (Anxiolysis)</b>	
Drug-induced sedation	
Patient responds normally to verbal commands	
Cognitive and motor function may be impaired	
Ventilatory and cardiovascular function maintained normally	
<b>Moderate Sedation/Analgesia (Conscious Sedation)</b>	
Drug-induced sedation	
Patient responds purposefully to verbal commands either alone or with light tactile stimulation	
Patient maintains a patent airway and spontaneous ventilation	
Cardiovascular function maintained	
<b>Deep Sedation/Analgesia</b>	
Drug-induced sedation	
Patient cannot be easily aroused but can respond purposefully to repeated or painful stimulation	
Ventilatory function may be impaired, requiring assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate	
Cardiovascular function is usually maintained	
<b>General Anesthesia</b>	
Drug-induced loss of consciousness	
Patients are not arousable by painful stimulation	
Ventilatory function is often impaired; patient may require assistance in maintaining a patent airway	
Spontaneous ventilation may be impaired as well as neuromuscular functioning	
Positive pressure ventilation is often required	
Cardiovascular function may be impaired	

Adapted from American Society of Anesthesiologists. Continuum of depth of sedation: definition of general anesthesia and levels of sedation/analgesia. Blue Cross and Blue Shield of Tennessee website. [http://www.bcbst.com/mpmanual/American\\_Society\\_of\\_Anesthesiologists\\_Definitions\\_.htm](http://www.bcbst.com/mpmanual/American_Society_of_Anesthesiologists_Definitions_.htm). Accessed June 6, 2106.

**Table 32-13** Distribution of Types of Patient Injury during MAC Recorded in ASA Closed Claims Project Database during 1990s<sup>125</sup>

Injury	Occurrence
Death	34%
Brain damage	19%
Nerve damage	7%
Eye damage	12%
Myocardial infarction	4%
Stroke	4%
Burn	4%
Emotional distress	4%
Aspiration	4%

When formulating an anesthetic plan, one must consider that all agents and techniques used should be short acting, and patients should be ready for discharge home soon after the completion of the procedure. Furthermore, any

agents used should have a high safety profile, few side effects, and be cost-effective. One must not be under the false impression that sedation is inherently safer than GA. Cohen et al.<sup>124</sup> reviewed the data from 100,000 anesthetics and found that the group with the greatest number of mortalities had undergone procedures with sedation, whereas sedation constituted only 2% of all cases. The complication rate related to MAC anesthetics is increasing, as its use expands.

The ASA Closed Claims Project database reveals that in the 1970s sedation (often referred to as MAC) cases accounted for 1.6% of the claims; in the 1980s, 1.9%; and by the 1990s, 6% of the cases were MAC. The injuries sustained in patients receiving MAC ranged from emotional distress to death (Table 32-13). The percentage of claims resulting from mortality was 10 identical for both MAC and GA cases. In the 1990s, when injuries other than death occurred during MAC anesthetics, they were more likely to be permanent, whereas injuries occurring during GA were more frequently temporary.<sup>125</sup> MAC anesthetics also tend to lead to litigation. Suits were filed in 90% of the MAC claims; 65% were settled, 20% went to judgment, and 15% were discontinued. The range of payout was \$2,000 to \$6,300,000, with a median of \$75,000.<sup>125</sup>

## *Anesthetic Agents*

Intravenous sedation (propofol, barbiturates, midazolam, fentanyl) is the most often used anesthetic technique in the OBA setting. When selecting an anesthetic for an office-based procedure, one must consider factors such as duration of action, cost-effectiveness, and safety/side effects profile; drugs should have a short half-life, be inexpensive, and not be associated with undesirable side effects such as nausea and vomiting.

Because of its desirable pharmacokinetics and pharmacodynamics, propofol, a di-isopropyl phenol molecule, has long been a mainstay of ambulatory anesthesia. It has a rapid onset (approximately 1 arm-brain circulation time), and because of rapid redistribution, has a short clinical duration of action (approximately 15 minutes). Its short context-sensitive half-time causes propofol's clinical effect to be terminated relatively quickly, even after relatively long infusion times (8 hours).<sup>126</sup> In addition to its hypnotic properties, it has an intrinsic antiemetic effect. Propofol may cause a burning sensation on injection or elicit an allergic reaction. It is also associated with bradycardia and respiratory depression, and it supports microbial growth. It can be used alone or in combination with other agents by intermittent boluses or continuous infusion.

Fentanyl has long been the gold standard for "short-acting" narcotics, but recently the use of remifentanyl has also increased in popularity. Remifentanyl,

an ultra–short-acting opioid, when combined with propofol for conscious sedation, has been shown to provide discharge readiness within 15 minutes after colonoscopy. This time frame is a marked reduction from the 48 to 80 minutes reported after the traditional meperidine/midazolam technique.<sup>127</sup> Remifentanil is also an ideal drug for use during many office-based procedures such as facial cosmetic procedures, which can be quite painful while the local anesthetic is being injected after which are relatively painless. An important caveat to the use of remifentanil is that it may cause nausea and vomiting as well as apnea. Infusions of remifentanil are also associated with acute tolerance and hyperalgesia during the recovery phase, which may limit its utility.<sup>128–131</sup> In addition, it often requires the use of an infusion pump.

Ketamine, a phencyclidine derivative, has experienced a resurgence in popularity over the past several years in the OBA practice. The use of ketamine–propofol sedation has been described as an excellent way to provide a relaxed surgical field in a quiet, immobile patient, often eliminating the need for supplemental oxygen.<sup>132</sup> Ketamine functions as both an anesthetic and an analgesic. It does not depress respiration, and will increase laryngeal reflexes, thus decreasing the risk of aspiration. Furthermore, it is not associated with nausea and vomiting. Ketamine can, however, cause an increase in secretions as well as cause hallucinations. The latter can be decreased or eliminated by adding propofol or midazolam.<sup>133–136</sup> Glycopyrrolate can be used as an antisialagogue. Another advantage of ketamine is that it is relatively inexpensive.

Clonidine has been found to be useful in an office. Since it is an  $\alpha_2$ -agonist, clonidine will help control blood pressure throughout the perioperative period, thus potentially minimizing blood loss.<sup>137,138</sup> In addition it may decrease the total propofol usage.<sup>113</sup> Its use may however precipitate hypotension and oversedation.

Dexmedetomidine has also recently become a mainstay infusion drug for an office-based anesthetic.<sup>139</sup> It is a short-acting,  $\alpha_2$ -adrenergic receptor agonist with sedative qualities. Dexmedetomidine permits patients to retain their respiratory drive and does not cause nausea and vomiting. It is however associated with hypotension.

TIVA is a common choice for non-OR anesthetics. TIVA usually consists of propofol as the hypnotic component used in conjunction with fentanyl, remifentanil, or ketamine as the analgesic component. All of these drugs can be given by intermittent bolus or infusion. Mathews found that remifentanil 0.085  $\mu\text{g}/\text{kg}/\text{min}$  can substitute for 66%  $\text{N}_2\text{O}$ .<sup>140</sup> Advantages of TIVA over inhalation anesthesia include the avoidance of the need for gas scavenging and a reduced incidence of PONV. Since the availability of the newer less soluble inhalation agents (e.g., desflurane and sevoflurane), many authors have compared recovery times from these agents with the recovery time after

a total intravenous anesthetic using a propofol infusion.<sup>141,142</sup> Recently, Gupta conducted a meta-analysis of all such publications and reported an overall more rapid recovery from desflurane when compared to either isoflurane- or propofol-based anesthetics. Recovery was also found to be faster with sevoflurane when compared to isoflurane. However, there was more PONV as well as postdischarge nausea and vomiting in the isoflurane groups as compared to the propofol ones; for these considerations isoflurane may not be the best choice of inhalation agent in non-OR locations. Overall, the inhalation agent groups required more antiemetic treatment than did the propofol groups.<sup>143</sup>

Depth of anesthesia monitoring has been shown to decrease the time to extubation and discharge readiness.<sup>144–146</sup> A depth of anesthesia monitor has been described as useful in the office during MAC procedures, resulting in a possible decrease in total propofol usage.<sup>147</sup> Whether this type of monitoring will prove to be cost-effective or not, in office-based settings, remains to be seen.

Any type of anesthesia from sedation through GA and regional anesthesia can be administered in an office setting safely but it is vital that the office be adequately equipped and staffed to rescue a patient from a deeper stage of anesthesia. Thus, if MAC is planned, GA must be anticipated.

## Postanesthesia Care Unit

Following an office-based procedure, a patient should be able to sit in a chair, or ambulate to an examination room to dress almost immediately postoperatively, and be free of pain and PONV. All vital signs should be within 10% of baseline. A formal PACU may not be present, and the patient may be required to recover in the surgical suite. Regardless of where the patient recovers, it is important to adhere to all the ASA standards for monitoring and documentation throughout the postoperative period. Staffing in the recovery area must be adequate, and the use of a pulse oximeter is imperative.<sup>148</sup> It is recommended that there be at least one ACLS/PALS certified member of the health-care team present until the last patient has left the office.

Since PACU space in an office is often limited and the anesthesiologist may **11** have multiple locations to attend in a single day, patient satisfaction and prevention of PONV and pain are paramount. The effect of these physiologic occurrences may also have a profound economic impact on an office surgical unit.<sup>149</sup> It is imperative that every anesthetic administered be designed to maximize postoperative patient alertness and mobility and minimize the risks of the need for a prolonged PACU stay. Twersky has recommended that the postanesthesia discharge scoring system and clinical

discharge criteria used in ambulatory surgery also be used in the office-based setting.<sup>150</sup> Interestingly, there is a trend to discharge patients, particularly after colonoscopy, without escorts. This practice has been sanctioned in some states. In New York, regulations require that all patients undergoing a procedure with anesthesia be “discharged in the company of a responsible adult, unless exempted by a physician.”<sup>151</sup> Specific data confirming the enhanced safety of this practice do not exist.

Local anesthesia alone, minimal to moderate and deep sedation supplemented by wound infiltration with local anesthetics, or peripheral nerve blocks, often form the basis for a multimodal strategy for postoperative pain management. These effective pain relief techniques not only decrease the anesthetic and analgesic requirements during surgery but also reduce the need for opioid analgesics in the postoperative period, thus facilitating the recovery process.<sup>152</sup> Nonopioid analgesics (e.g., acetaminophen) and nonsteroidal anti-inflammatory drugs (e.g., ketorolac) are routinely used. Ketorolac decreases the incidence of PONV and patients tolerate oral fluids and meet discharge criteria sooner than those receiving opioids.<sup>153</sup> In an effort to minimize the potential for postoperative bleeding and risk of gastrointestinal (GI) complications, more specific COX-2 inhibitors are being increasingly used as nonopioid adjuvants for minimizing postoperative pain.<sup>154</sup>

An optimal antiemetic regimen for OBA has yet to be established. However, since the etiology of PONV is multifactorial, combination prophylactic therapies may be beneficial in high-risk patients.<sup>155</sup> Many of the older first-line therapies are associated with sedation, drowsiness, and extrapyramidal side effects, and have been supplanted by 5-HT<sub>3</sub> antagonists such as ondansetron, dolasetron, and granisetron.<sup>156</sup> Dexamethasone has been shown to improve the efficacy of both 5-HT<sub>3</sub> antagonists<sup>157</sup> as well as dopamine antagonists when used for the prevention of PONV.<sup>156</sup> Dexamethasone has no utility as a rescue drug for PONV.<sup>158</sup> Routine prophylaxis of all patients, though, has not been shown to offer any advantage over symptomatic treatment<sup>159</sup> and has associated costs. Prophylaxis should be considered for all patients with a high risk of PONV. Such patients include, young women having breast or gynecologic surgery, nonsmokers, or patients with a history of PONV. Ensuring adequate hydration (up to 20 mL/kg of crystalloid), to avoid orthostatic hypotension and, thus, to prevent the release of emetogenic chemicals by decreasing blood flow to the midbrain emetic centers is an intervention that may be successful in the prevention of PONV.<sup>156</sup>

## Regulations

Governmental oversight of office-based surgery varies among states; currently regulations exist in the majority of states with others following. A complete list of regulations in each of the states is available online.<sup>28</sup> Whereas accreditation is often a voluntary certification of an office, in some states, regulations, which are governmental mandates imposed by the local or state government, exist. It is imperative that anesthesiologists embarking on an office-based practice familiarize themselves with any rules and regulations that govern practice in his/her particular state.

In 1994, California was the first state to adopt legislation regarding OBA, and was soon followed by New Jersey. A closer look at these two states provides an example of the varied requirements being enforced by states throughout the country. California's regulations pertain to patients undergoing a GA, and do not address procedures performed under local, peripheral nerve block, or sedation/anxiolysis administered in doses that do not affect a patient's life-preserving reflexes.<sup>160</sup> The regulations deal with issues ranging from office policy and mandatory reporting of adverse outcomes, to surgeon and anesthesia provider qualifications.<sup>160</sup> California Health and Safety Code 1248-1248.85 mandates that surgical procedures occur only in offices that have been accredited or have been certified to participate in the Medicare Program under Title XVIII (42 U.S.C. Sec. 1395 et seq.), with very few exceptions.<sup>161</sup> In addition, offices must have a written plan in place that deals with issues regarding emergency admissions. Surgeons must have admitting privileges at a local licensed or accredited acute care hospital or have a written transfer agreement with a physician who does have such privileges. Offices must have an agreement with the hospital for the admission, in accordance with the hospital's system of quality assurance and peer review. California law also requires that offices have adequate patient monitoring throughout the perioperative period, and have a system in place for the storage and maintenance of patient records. Any office that fails to comply with these regulations risks sanctions ranging from reprimand with or without monetary penalties to criminal prosecution.

New Jersey's administrative Code 13:35-4A.1-13:35-4A.18 develops criteria for patient selection. Only ASA physical status 1 and 2 patients may undergo GA or regional anesthesia. ASA physical status 3 patients can undergo only conscious sedation. Providers of GA must be credentialed to do so by a hospital, and only appropriately credentialed physicians may supervise CRNAs. New Jersey law establishes guidelines regarding mandatory monitoring, emergency supplies that must be present, physician credentialing, and peer review. In contrast to California, New Jersey's regulations pertain to all patients undergoing surgical procedures regardless of the anesthetic depth. However, similar to California, violations may result in fines ranging from reprimand to license revocation and criminal prosecution.<sup>162</sup>

In states that have no regulations regarding office-based surgical procedures any physician who holds a valid medical license may perform any procedure that he/she so chooses, within his/her office without oversight. A surgeon may perform a procedure for which he/she may have had little to no training, and may sedate a patient without any training in anesthesia or airway management. In fact, there have been reported cases of patients undergoing procedures without any preoperative evaluation, pertinent laboratory tests, informed consent, intraoperative or postoperative monitoring or operative report, and without regard for sterile technique.<sup>13</sup> It is therefore imperative that the anesthesiologist continues to maintain the role of a zealous patient advocate, and help to educate the surgeon as to what constitutes a safe anesthetizing location.

### ***Business and Legal Aspects***

It is in the anesthesia provider's best interest to seek legal counsel and to create a valid business model before embarking on a career in OBA. This model must consider the overhead costs associated with staffing and running a safe surgical office as well as the potential and probable case load and patient insurance mix. An OBA division within a department may provide benefits to an academic practice, in addition to the monetary ones. There may be an intangible benefit to the community it serves, as well enhancing the anesthesia training program.<sup>5</sup> It would however become necessary to involve the American Board of Anesthesiology (ABA) as well as the American College of Graduate Education (ACGME) to ensure that any resident rotation outside the ACGME-approved hospital setting is acceptable.

Many OBA groups have formed either professional corporations or limited liability companies. Although not eliminating the need for liability insurance, both of these arrangements serve to protect the private assets of the anesthesiologists in the case of a malpractice claim.<sup>3</sup> Legal counsel may also prove to be beneficial in creating business plans that follow all state and federal laws regarding billing/collection and antitrust.<sup>163</sup>

It is imperative to have an aboveboard and legal relationship with every office in which anesthesia services are being delivered. Billing strategies must be legal and ethical. In this complex environment of third-party payers it is quite easy to make legal errors. Ignorance of the law offers no protection or excuse, and one should seek the advice of expert billing agencies, even if one chooses not to outsource this responsibility. In calculating pricing one must include all overhead charges such as drugs, equipment, time, and business expenses including malpractice insurance. A pricing structure with the surgeon must exist before embarking on a clinical relationship. One must outline specifically what will be provided by the office (intravenous

equipment, antibiotics, monitors, etc.) and what the anesthesiologist will supply. These decisions take on further legal implications when the office is receiving a facility fee.

## Conclusions

OBA continues to rapidly expand and pose unique challenges to anesthesiologists, who must not only provide medical care in remote environments but also have a solid business sense and an extensive understanding of OR management. Although regulations have not kept pace with the growth of OBA, it is imperative that anesthesiologists make it their responsibility to help ensure that every possible safety measure is afforded to their patients. Decisions about appropriate patient/procedure selection and equipping anesthetizing locations must be made in conjunction with surgeons. All clinical decisions and anesthetic choices must take into consideration the need for rapid turnover and limited PACU availability. Any depth of anesthesia from minimal sedation through regional anesthesia and GA may be delivered as long as the proper safeguards are in place.

The many advantages afforded by office-based surgery are fueling its evolution and as more complex procedures are performed on patients with increasing numbers of comorbidities. The anesthesiologist's role in providing care and serving as their patients' advocate is both complex and vital.

# 33 Nonoperating Room Anesthesia

KAREN J. SOUTER • ANDREW J. PITTAWAY • CARLY PETERSON

## General Principles

### Three-step Approach to Nonoperating Room Anesthesia

- The Patient
- The Procedure
- The Environment

### Patient Safety in Nonoperating Room Anesthesia

- Adverse Events
- Preprocedural Checklists
- Standards of Care for Nonoperating Room Anesthesia

### Sedation and Anesthesia

- Definition of Sedation and Anesthesia
- The Continuum of Anesthesia

### Environmental Considerations for Nonoperating Room Anesthesia

- X-rays and Fluoroscopy
- Intravenous Contrast Agents

### Specific Nonoperating Room Procedures

- Angiography
- Interventional Neuroradiology
- Computed Tomography
- Radiofrequency Ablation
- Transjugular Intrahepatic Portosystemic Shunt
- Magnetic Resonance Imaging
- Pediatric Sedation and Anesthesia for MRI and CT Scans
- Radiation Therapy
- Positron Emission Tomography
- Gastroenterology
- Cardiology and Interventional Cardiology
- Electroconvulsive Therapy

## Summary

## KEY POINTS

- 1 Nonoperating room (NOR) locations are remote from a hospital's main operating room sites.

- 2 A three-step approach that considers the patient, the procedure, and the environment is useful in considering any anesthetic in the NOR setting.
- 3 All significant patient comorbidities must be carefully assessed, and the appropriate level of sedation, general anesthesia, and level of monitoring determined by the anesthesiologist caring for the patient.
- 4 Procedural considerations are both general (e.g., duration, position, and level of discomfort) and specific to individual specialties.
- 5 Patients must receive the same standard of care at a NOR site as they do in the operating room and the American Society of Anesthesiologists (ASA) has defined guidelines to be applied to the administration of anesthesia in NOR locations.<sup>1</sup>
- 6 The anesthetic and monitoring equipment used for nonoperating room anesthesia (NORA) must meet the same standards as equipment provided in the operating room.
- 7 Following NORA, the patient should be transported to an appropriate postanesthesia care unit, accompanied and monitored by anesthesia-trained personnel.
- 8 Environmental considerations in NOR locations include hazards such as radiation, magnetic resonance imaging, and the side effects of intravenous contrast agents.

## General Principles

Nonoperating room anesthesia (NORA) refers to anesthesia that is provided at **1** any location remote from the traditional operating room.<sup>1</sup> These locations include radiology departments, endoscopy suites, magnetic resonance imaging (MRI), and computerized tomography (CT) scanners. This chapter will consider the care of the patient undergoing procedures in these locations. Discussion of anesthesia in stand-alone ambulatory centers, or offices, is addressed in [Chapters 31](#) and [32](#). Anesthesia and analgesia provided for labor and delivery is discussed in [Chapter 41](#).

Examination of data from the National Anesthesia Clinical Outcomes Registry (NACOR)<sup>2</sup> between 2010 and 2013 has estimated that NORA accounts for about 30% of anesthesia cases, and although the number of OR anesthesia cases remains static, the number of NORA cases has steadily increased recently, the highest rate of increase being in gastroenterologic procedures.<sup>3</sup>

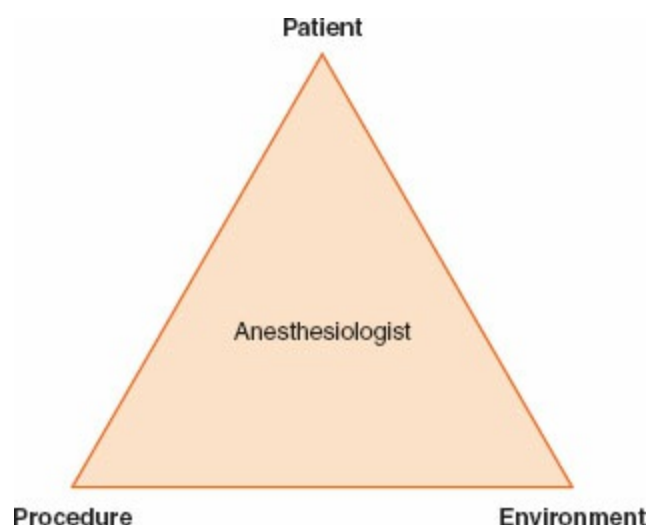

## Three-step Approach to Nonoperating Room Anesthesia **2**

Away from the operating room, the anesthesiologist may lack familiar equipment and staff experienced in the care of the anesthetized patient. NORA

therefore presents unique challenges and a systematic approach using the simple three-step paradigm “the PATIENT, the PROCEDURE, and the ENVIRONMENT” is recommended (Fig. 33-1).

## The Patient

Patients presenting for NOR procedures tend to be older (above 50 years) and in the case of gastroenterologic, cardiology, and radiologic procedures, of higher ASA status than patients cared for in the standard operating rooms. Patients presenting for NOR procedures are also more likely to receive monitored anesthesia care (MAC) or sedation than those undergoing OR procedures.<sup>3</sup> Patients may require sedation or anesthesia to tolerate NOR procedures for a number of reasons (Table 33-1). Children commonly require sedation or anesthesia for diagnostic and therapeutic procedures.<sup>4</sup> Palliative, less-invasive procedures are increasingly being offered to patients too ill to tolerate a major surgical procedure representing a continuing challenge for the NOR anesthesiologist. All patients presenting for NORA require a thorough preanesthetic assessment, standard preanesthesia care,<sup>5</sup> the development of a sound anesthetic plan with appropriate levels of monitoring,<sup>6</sup> and the appropriate postanesthesia care.<sup>7</sup>

**Figure 33-1** A three-step paradigm for nonoperating room anesthesia.

## The Procedure

Common NOR procedures for which the patient may require anesthesia or sedation are listed in Table 33-2. The anesthesiologist must understand the nature of the procedure, including the position of the patient, how painful the procedure will be, and how long it will last. The optimum anesthesia plan provides safe patient care and facilitates the procedure. Discussions with the proceduralist must include contingencies for emergencies and adverse

outcomes.

## The Environment

**5** The American Society of Anesthesiologists (ASA) has developed standards for NORA.<sup>1</sup> Prior to the anesthetic, the presence and proper functioning of all equipment needed for safe patient care must be established; this is described in [Table 33-3](#). The location of immediately available resuscitation equipment should be noted and protocols developed with the local staff for dealing with emergencies, including cardiopulmonary resuscitation and the management of anaphylaxis.

**Table 33-1** Patient Factors Requiring Sedation or Anesthesia for Nonoperating Room Procedures

Claustrophobia, anxiety, and panic disorders  
Cerebral palsy, developmental delay, and learning difficulties  
Seizure disorders, movement disorders, and muscular contractures  
Pain, both related to the procedure and other causes  
Acute trauma with unstable cardiovascular, respiratory, or neurologic function  
Raised intracranial pressure  
Significant comorbidity and patient frailty (American Society of Anesthesiology physical status III, IV)  
Children, especially those below 10 years

**Table 33-2** Common Nonoperating Room Anesthesia Procedures

	Procedure
Radiologic imaging	Computed tomography Magnetic resonance imaging Positron emission tomography
Interventional radiology <sup>a</sup>	Vascular imaging, stenting, and embolization procedures Biopsy and/or drainage of lesions, tumors, cysts Radiofrequency ablation Transjugular intrahepatic portosystemic shunt
Interventional neuroradiology <sup>a</sup>	Occlusive (“closing”) procedures <ul style="list-style-type: none"> <li>• Embolization of cerebral aneurysm</li> <li>• Embolization of arteriovenous malformations</li> <li>• Embolization of vascular tumors</li> </ul> “Opening” procedures in acute thromboembolic stroke, cerebral atherosclerosis, or cerebral vasospasm <ul style="list-style-type: none"> <li>• Angioplasty</li> <li>• Stenting</li> <li>• Thrombolysis</li> </ul>
Radiotherapy	Radiation therapy Intraoperative radiotherapy
Interventional cardiology <sup>a</sup>	
Cardiac catheterization laboratory	Diagnostic cardiac catheterization Percutaneous coronary interventions Percutaneous ventricular assist devices Percutaneous closure of septal defects Alcohol septal ablation Structural heart procedures <ul style="list-style-type: none"> <li>• Transcatheter aortic valve replacement</li> <li>• Mitral valve repair for mitral regurgitation (“MitraClip”)</li> <li>• Left atrial appendage occlusion</li> </ul>
Electrophysiology laboratory (EPL)	Cardiac implantable electronic devices Electrophysiology studies with ablation Laser lead extraction
Other cardiac procedures	Cardioversion Diagnostic transesophageal echocardiography
Gastroenterology <sup>a</sup>	Upper gastroenterology endoscopy Esophageal dilatation or stenting Percutaneous endoscopic gastrostomy tube placement Endoscopic retrograde cholangiopancreatography Colonoscopy Liver biopsy
Psychiatry	Electroconvulsive therapy

<sup>a</sup>Diagnostic and therapeutic procedures.

**Table 33-3** American Society of Anesthesiology Standards for Nonoperating Room Anesthetizing Locations<sup>1</sup>

1. Oxygen-reliable source—ideally piped and full backup E-cylinder
2. Suction—adequate and reliable
3. Scavenging system if inhalational agents are administered
4. Anesthetic equipment
  - Backup self-inflating bag capable of delivering at least 90% oxygen by positive-pressure ventilation
  - Adequate anesthetic drugs, supplies, and equipment for intended anesthesia care
  - Adequate monitoring equipment to allow adherence to the ASA standards for basic monitoring<sup>6</sup>
  - Anesthesia machine with equivalent function to those in the operating rooms and maintained to the same standards
5. Electrical outlets
  - Sufficient for anesthesia machine and monitors
  - Isolated electrical power or ground fault circuit interrupters if “wet location”
6. Adequate illumination of patient, anesthesia machine, and monitoring equipment; battery-operated backup light source
7. Sufficient space for:
  - Personnel and equipment
  - Easy and expeditious access to patient, anesthesia machine, and monitoring equipment
8. Resuscitation equipment immediately available
  - Defibrillator/emergency drugs/cardiopulmonary resuscitation equipment
9. Adequately trained staff to support the anesthesiologist and a reliable means of two-way communication
10. All building and safety codes and facility standards should be observed
11. Postanesthesia care facilities<sup>7</sup>
  - Adequately trained staff to provide postanesthesia care
  - Appropriate equipment to allow safe transport to main postanesthesia care unit

## **6 Anesthesia Equipment and Monitors**

Anesthesia machines and monitors may or may not be provided in NOR locations. Small, portable anesthesia machines and monitors are available if a site does not offer a permanent anesthesia work station. Anesthesia machines and monitors that remain in a NOR location need to undergo routine maintenance. Infrequent use may result in degradation of equipment and the use of preprocedural checks, preferably with a standardized checklist, cannot be overemphasized before embarking on NORA. If more advanced monitors (e.g., an arterial line, central venous pressure, or intracranial pressure [ICP] monitoring) are required, these devices should be readily available. A preprepared cart containing essential equipment that is checked and restocked after each case is recommended.

## **Patient Safety in Nonoperating Room Anesthesia**

Patient safety is of utmost importance in all types of anesthesia, not least NORA.

### **Adverse Events**

Significant adverse events occur infrequently in NOR locations, although the large multicenter studies needed to determine their true incidence are lacking. A recent study of the NACOR database<sup>3</sup> indicated that contrary to previous reports,<sup>8</sup> NORA procedures appear to have a lower incidence of both minor and major complications and mortality than OR procedures. However, the continuing need for vigilance and attention to detail remains high in NORA. The ASA closed claims database has identified NORA as an area of liability for the anesthesiologist.<sup>8</sup> The gastroenterology suite, cardiac laboratory, and the emergency department are sites where adverse events are likely to occur and the elderly, medically complex patients have been determined to be more at risk by both the closed claims and the NACOR analyses.<sup>3,9</sup> Respiratory depression secondary to oversedation was the most common type of adverse event in the closed claims study.<sup>8,9</sup> Capnography provides an early monitor of impending respiratory depression during sedation and is recommended.<sup>6,10,11</sup> Adverse events associated with NORA have been divided into minor and major and appear to be more frequent in patients undergoing radiology procedures and in cardiology locations (Table 33-4).<sup>3</sup>

### **Preprocedural Checklists**

The use of checklists and pre- and postprocedural team briefings has been broadly embraced in operating room practice and emerging evidence points toward improved patient outcomes when checklists are employed.<sup>12,13</sup> Similar systems should be adopted in NOR sites and recently a checklist has been proposed for use in interventional radiology suites.<sup>14</sup>

**Table 33-4** Complications of Nonoperating Room Anesthesia<sup>3</sup>

<b>Minor Complications (in order of frequency)</b>
Postoperative nausea and vomiting
Inadequate postoperative pain control
Hemodynamic instability
Minor neurologic complications such as postdural puncture headache (cardiology and radiologic locations)
Minor respiratory complications (cardiology and radiologic locations)
Complications related to central/intravenous lines (cardiology locations)
Need for opioid reversal (cardiology and radiologic locations)
<b>Major Complications</b>
Unintended patient awareness (gastroenterologic locations)
Anaphylaxis (radiology procedures and cardiology locations)
Need for upgrade of care
Serious hemodynamic instability
Respiratory complications
Need for resuscitation
Central and peripheral nervous system injury (radiology procedures and cardiology locations)
Vascular access-related complications (radiology procedures and cardiology locations)
Wrong patient/wrong site (radiology procedures and cardiology locations)
Fall or burn (radiology procedures and cardiology locations)

## **Standards of Care for Nonoperating Room Anesthesia**

### **7 Patient Transfer**

Sick, unstable patients may be transferred back and forth between the intensive care unit, the operating rooms, and NOR locations for imaging, therapeutic, or diagnostic procedures. During transport the patient should be accompanied by skilled personnel to evaluate, monitor, and support the patient's medical condition. A specialized transport team may contribute to reducing the number of critical incidents that occur during the transport of ventilated and critically ill patients.<sup>15</sup> Patients are often mechanically ventilated and receiving a number of drug infusions for both sedation and hemodynamic support. Portable ventilators are useful for transport; these are often oxygen powered, and adequate supplies of oxygen must be available for the transfer. A manual self-inflating bag is essential in the event of ventilator failure. Infusion pumps and portable monitors should have adequate battery power for transit. The transport team should carry spare anesthetic and emergency drugs, equipment for intubation or reintubation, portable suction, and if the patient's condition requires, a portable defibrillator. It is vital to notify the destination area that the patient is in transit, so that appropriate preparations to receive the patient can be made in advance. It is also useful to send personnel ahead to secure the elevators to prevent delays during transfer.

## Sedation and Anesthesia

### *Definition of Sedation and Anesthesia*

Many NOR procedures are performed under sedation and MAC for which the ASA developed guidelines.<sup>16</sup> A consistent definition of these terms is essential for clear communications between the various stakeholders involved in provision of NORA. On January 14, 2011, the Centers for Medicare and Medicaid Services (CMS) issued a revision to Interpretive Guideline (IG) for Hospitals No. 482.52 concerning anesthesia services. This revised guideline places the responsibility and oversight for all anesthesia services under the direction of one suitably qualified individual, the “director of anesthesia services.”<sup>17</sup> IG 482.52 defines “anesthesia,” to mean general anesthesia, regional anesthesia, deep sedation/analgesia, or MAC. “Analgesia/sedation” is defined as local/topical anesthesia, minimal sedation, and moderate sedation/analgesia (“conscious sedation”).

### *The Continuum of Anesthesia*

Anesthesia exists along a continuum and the transition from minimal sedation to general anesthesia is not clear-cut (Table 33-5).<sup>16-19</sup> As sedation deepens, it is important to recognize the progressive blunting and loss of airway reflexes and patency, together with depression of spontaneous ventilation and cardiovascular function. The individual responsiveness of patients to different sedative agents varies, as do the levels of stimulation during the course of a procedure. Consequently, during the course of an NOR procedure under sedation, the patient may drift to a deeper level than the one intended, including transitioning into general anesthesia with loss of airway reflexes and possibly airway obstruction. In any circumstances where a particular level of sedation is being provided, services must be immediately available to rescue a patient from a deeper than intended level of sedation or general anesthesia.<sup>18</sup>

## Environmental Considerations for Nonoperating Room Anesthesia

8

### *X-rays and Fluoroscopy*

X-rays are produced when electrons are accelerated through a high voltage in a vacuum tube and collide with a metal target. In medical x-ray tubes, the target is usually tungsten or a more crack-resistant alloy of rhenium (5%) and tungsten (95%). X-ray production is determined by, and directly proportional

to, the tube current and the voltage. Fluoroscopy is a technique used to obtain real-time moving images of the internal structures. The patient is positioned between the x-ray source and a fluorescent screen. By coupling the fluoroscope to an x-ray image intensifier and a video camera, the images can be recorded and played on a monitor. Fluoroscopy is widely and increasingly used in NOR locations including interventional radiology, cardiac catheterization, and electrophysiologic procedures and in the gastroenterology suite. Large, C-shaped, mobile fluoroscopy devices (C-arms) are used to provide images in multiple dimensions. The C-arm moves back and forth around the patient during the procedure, taking up large amounts of space, limiting access to the patient, and serving as a means of dislodging intravenous lines and endotracheal tubes (Fig. 33-2).

**Table 33-5** Definition of General Anesthesia and Levels of Sedation/Analgesia<sup>18</sup>

	Minimal Sedation (Anxiolysis)	Moderate Sedation/Analgesia (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful <sup>a</sup> response to verbal or tactile stimulation	Purposeful <sup>a</sup> response after repeated or painful stimulation	Unarousable, even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

<sup>a</sup>Reflex withdrawal from a painful stimulus is *not* considered a purposeful response.

**Figure 33-2** A radiology suite showing a C-arm and the high density of equipment that may separate the anesthesiologist from the patient.

## Hazards of Ionizing Radiation

The effects of ionizing radiation on biologic tissues are classified as deterministic (dose related causing cell death and tissue damage) and stochastic (the development of cancer from direct DNA ionization or the creation of hydroxyl radicals from x-ray interactions with water molecules). Patient exposure to radiation during imaging and treatment varies depending on the type of procedure as well as patient- and operator-related factors.<sup>20</sup> For example, the radiation a patient receives from a simple chest x-ray is 0.02 millisieverts (mSv), and between 20 and 40 mSv for pulmonary angiography.<sup>21</sup> Exposure from fluoroscopy is 100 and 1,000 greater than from simple x-rays. Standard procedures exist to minimize patient exposure to radiation and efforts to reduce occupational exposure for staff including anesthesiologists working in radiology suites are an important consideration. A number of terms are used to define exposure to radiation<sup>22</sup>; these are summarized in [Table 33-6](#).

**Table 33-6** Common Terms Used in Radiation Exposure<sup>22</sup>

Term	Units	Definition	Notes
Exposure	Roentgen (R)—defined as $2.58 \times 10^{-4}$ coulombs (C)/kg (SI units).	Quantity of x-radiation or gamma radiation required to produce an amount of ionization (electric charge) in air at standard temperature and pressure	Ionization measurements are often made in exposure rate, i.e., amount of exposure per unit time, e.g., fluoroscopy is measured in R/min
Absorbed dose	Rad (radiation absorbed dose) or Gray (Gy, the SI unit)	Amount of ionizing radiation absorbed by the body	Depends on exposure to x-ray beam and the tissue type A Gray represents 100 times more radiation than a Rad
Dose equivalent	Sievert (Sv) or roentgen equivalent in man (rem)	Absorbed dose multiplied by a radiation quality factor specific for the type of radiation	Measures the “harmfulness” of any radiation-absorbed dose
Effective dose	Sievert (Sv)	Dose equivalent to the entire body caused by irradiating only a localized area. Calculated by multiplying the dose equivalent by a weighting factor specific for the irradiated organ	Takes into account the differing radiosensitivity of different organs Used to estimate cancer risk for patients (stochastic effects) and to calculate equivalent whole body exposure in staff wearing personal dosimeters for comparison with annual personnel dose limits

Staff, including the anesthesiologists, must be aware of the hazards of occupational exposure to ionizing radiation and take appropriate measures to protect themselves.<sup>23</sup> Exposure to ionizing radiation may come from direct exposure and scatter. Patients are subjected to direct exposure where the beam enters the skin, whereas staff members working in fluoroscopy suites are more at risk from scattered radiation. As a general rule the exposure to staff is 1/1,000th the entrance skin exposure at 1 m from the fluoroscopy

tube. A recent study of radiation exposure to operating room personnel during fluoroscopic-guided endovascular repair of thoracoabdominal aortic aneurysms using fenestrated endografts (FEVAR) identified that anesthesiologists were likely to receive 15 times the dose of radiation compared to the scrub nurses even though both types of practitioners were at the same distance (7 feet) from the C-arm.<sup>24</sup> This finding was attributed to anesthesiologists being less likely to use the protective shielding during their patient care activities. Another recent study demonstrated that anesthesiologists working in the neurointerventional suite were at equal risk of developing cataracts as neuroradiologists, and that the radiation may even be directed away from the neuroradiologists and toward the anesthesiologist.<sup>25</sup> These studies highlight the need for anesthesiologists to be aware of the risks and the means to protect themselves from radiation, especially in areas where fluoroscopy is used.

Staff exposure to radiation can be minimized by a number of precautions<sup>22,23</sup>:

1. *Limiting the time of exposure to radiation.*
2. *Increasing the distance from the source of radiation. (Dose rates increase or decrease according to the inverse square of the distance from the source.)*
3. *Using protective shielding (lead-lined garments and fixed and/or movable shields).*

Lead aprons, thyroid shields, and leaded eyeglasses are recommended despite being bulky and contributing to staff fatigue. Anesthesiology staff should consider using movable or fixed lead-lined glass shields so that they can gain easy access to their patients while protecting themselves from radiation.

4. *Measuring occupational exposure to radiation.*

The dose limits for occupational exposure to radiation established by the International Commission on Radiological Protection (ICRP) have been adopted in most countries.<sup>26</sup> In the United States, the National Council on Radiation Protection and Measurements (NCRP) recommends an occupational limit of 50 mSv in any 1 year and a lifetime limit of 10 mSv multiplied by the individual's age in years.<sup>23,27</sup> Health-care workers including anesthesiologists should be issued individual dosimeter badges to monitor their cumulative exposure to radiation. These data should be regularly reviewed by the facility's radiation safety section or medical physics department.

## ***Intravenous Contrast Agents***

Intravenous contrast agents are commonly used in radiologic and MRI to enhance vascular imaging. Radiologic contrast media are iodinated

compounds classified according to their osmolarity (high, low, or iso-osmolar), their ionicity (ionic or nonionic), and the number of benzene rings (monomer or dimer). Nonionic contrast agents cause less discomfort on injection and have a lower incidence of adverse reactions.<sup>28</sup> MRI contrast agents are also divided into ionic and nonionic compounds. They are chelated metal complexes containing gadolinium, iron, or manganese.

Adverse reactions to contrast agents may be divided into renal adverse reactions and hypersensitivity reactions.<sup>29</sup>

## Renal Adverse Reaction

Contrast agents are eliminated via the kidneys, and contrast-induced nephropathy (CIN) associated with their use is estimated to account for nearly 10% of hospital-acquired acute renal failure.<sup>30</sup> CIN is defined as an increase in serum creatinine of 0.5 mg/dL or a 25% increase from the baseline within 48 to 72 hours after iodinated contrast medium administration. Chronic kidney disease is the most important predictor of CIN, increasing the risk by 20 times<sup>30</sup>; other risk factors for CIN include history of renal disease, prior renal surgery, proteinuria, diabetes mellitus, hypertension, gout, and use of nephrotoxic drugs. Preventative measures to avoid CIN include adequate hydration, maintaining a good urine output, and using sodium bicarbonate infusions to improve elimination of the contrast agent. Nephrotoxic medications such as nonsteroidal anti-inflammatory drugs, aminoglycosides, and diuretics should be avoided for 24 to 48 hours before and after the use of intravenous contrast agents. The efficacy of N-acetylcysteine and other agents such as fenoldopam, dopamine, calcium-channel blockers, atrial natriuretic peptide, and L-arginine in mitigating CIN has not been proven.<sup>31</sup>

## Hypersensitivity Reactions

Hypersensitivity reactions to contrast media are divided into immediate (<1 hour) and nonimmediate (>1 hour) reactions.<sup>28,29</sup> Mild immediate reactions occur in about 0.5% to 3% and severe reactions occur in 0.01% to 0.04%. Fatal hypersensitivity reactions may occur in about 1 per 100,000 contrast administrations. The frequency of nonimmediate reactions is much more variable (0.5% to 23%) related partly to difficulty in determining whether symptoms relate to contrast agents or not. The clinical manifestations of various hypersensitivity reactions to contrast media are outlined in [Table 33-7](#).<sup>32</sup> Although widely used, the effectiveness of corticosteroids and antihistamines in preventing hypersensitivity reactions to contrast agents in unselected patients is doubtful.<sup>33</sup> Treatment of severe hypersensitivity reactions includes discontinuing the causative agent and supportive therapy, oxygen, intubating the trachea, cardiovascular support with fluids,

vasopressors, and inotropes, and if required, bronchodilators.<sup>29</sup> Reactions to gadolinium-based contrast agents used for MRI are less frequent than to iodinated contrast agents. Hypersensitivity to gadolinium-containing agents occurs in 5.9 per 10,000 injections and the rate is higher (13 per 10,000) in patients undergoing abdominal MRI examinations. Severe reactions occur 1:10,000 to 1:40,000 and the mortality rate is 1 in a million injections.<sup>34</sup> Gadolinium-containing compounds have been associated with nephrogenic systemic fibrosis (NSF), a disease manifesting fibrosis of the skin and internal organs with some similarities to scleroderma in patients with renal insufficiency.<sup>29,35</sup>

## Specific Nonoperating Room Procedures

### *Angiography*

Angiography causes minimal discomfort and may be performed under local anesthesia with or without light sedation. Patients are required to remain completely motionless during these procedures, which may be lengthy, particularly spinal angiography. Neurologic disorders such as recent subarachnoid hemorrhage, stroke, and depressed level of consciousness or raised ICP may necessitate anesthesia with intubation for airway protection. Angiography is often performed via the femoral artery; the femoral vein may also be accessed when imaging arteriovenous malformations (AVMs) or dural venous abnormalities. Liberal use of local anesthetic at the puncture site precludes the need for intravenous analgesia. The injection of contrast media into the cerebral arteries may cause discomfort, burning, or pruritus around the face and eyes. Hypotension and bradycardia may also occur and discomfort from a full bladder as a result of fluid and IV contrast administration is a consideration in nonanesthetized patients. During angiography and other interventional radiologic procedures, the patient is placed on a moving gantry and the radiologist positions the patient to track catheters as they pass from the groin into the vessels of interest. It is vital to have extensions on all anesthesia breathing circuits, infusion lines, and monitors to prevent these implements from being accidentally dislodged as the radiologist swings the x-ray table back and forth. Care should be taken with positioning of radiopaque pieces of equipment. The electrocardiogram electrodes and metallic coils in the cuffs of endotracheal tubes may cause interesting and annoying artifacts if they lie over the area being imaged.

**Table 33-7** Clinical Manifestations of Immediate and Nonimmediate Hypersensitivity Reactions to Radiocontrast Agents<sup>a,32</sup>

<b><i>Immediate Reactions</i></b>
<i>Pruritus</i>
<i>Urticaria</i>
Angioedema/ facial edema
Abdominal pain, nausea, diarrhea
Rhinitis (sneezing, rhinorrhea)
Hoarseness, cough
Dyspnea (bronchospasm, laryngeal edema)
Respiratory arrest
Hypotension, cardiovascular shock
Cardiac arrest
<b><i>Nonimmediate Reactions</i></b>
<i>Pruritus</i>
<i>Exanthema (mostly macular or maculopapular drug eruption)</i>
Urticaria, angioedema
Erythema multiforme minor
Fixed drug eruption
Stevens–Johnson syndrome
Toxic epidermal necrolysis
Graft-versus-host reaction
Drug-related eosinophilia with systemic symptoms (DRESS)
Symmetrical drug-related intertriginous and flexural exanthema (SDRIFE)
Vasculitis

<sup>a</sup>Most frequent are in italics.

## Interventional Neuroradiology

A variety of neurosurgical conditions especially neurovascular diseases are effectively managed by interventional neuroradiology.<sup>36</sup> These procedures may be subdivided as “occlusive” and “opening” procedures (Table 33-2).

Cerebral aneurysms and AVMs are particularly amenable to occlusive endovascular treatments.<sup>37</sup> A commonly employed technique is to insert detachable platinum coils into the abnormal vessel(s). Other occlusive agents include cyanoacrylates, “Onyx liquid embolic system” (Micro therapeutics Inc., USA), a biocompatible liquid embolic agent, and polyvinyl alcohol particles. These particles may also be used to produce temporary occlusion of blood vessels for preoperative embolization of vascular tumors, particularly meningiomas. In 2009, a large multicenter study, the International Subarachnoid Aneurysm Trial (ISAT) reported better outcomes in patients with ruptured anterior and posterior circulation aneurysms undergoing interventional neuroradiology compared to surgical clipping.<sup>38</sup> The benefits of coiling appear to be prolonged with the most recent follow-up of ISAT reporting the probability of disability-free survival to be significantly greater in the endovascular group compared to the neurosurgical group at 10 years.<sup>39</sup> The World Federation of Neurosurgical Societies’ (WFNS’s) poor grade for cerebral aneurysms in elderly patients did not clearly establish the superiority

of one treatment or the other.<sup>40,41</sup> The management of an unruptured intracranial aneurysm depends on many factors including aneurysm size, shape, location, and patient comorbidity. In 2015, the American Heart Association and American Stroke Association jointly published guidelines for management of unruptured intracranial aneurysms.<sup>42</sup>

“Opening” procedures include the management of acute thromboembolic stroke and postsubarachnoid hemorrhage vasospasm. In the case of acute ischemic stroke, early (within 6 hours of symptoms) intervention to recanalize the occluded vessel by superselective intra-arterial thrombolytic therapy has been shown to improve outcome.<sup>43,44</sup> Specialized centers have developed various “stroke code protocols”<sup>45</sup> to manage these patients with the NOR anesthesiologist forming a key member of the team.

## **Procedural and Anesthetic Technique Considerations in Interventional Neuroradiology**

For most interventional neuroradiologic procedures, arterial access is gained using a 6 or 7 French gauge sheath via the femoral or, rarely, the carotid or axillary artery. The umbilical vessels are an alternative route in neonates. Anticoagulation is required during and up to 24 hours after interventional radiologic procedures to prevent thromboembolism. Heparin, between 3,000 and 5,000 IU (50 to 70 IU/kg), followed by an infusion is used to keep the activated clotting time (ACT) between two and three times the patient’s baseline.<sup>43</sup> At the end of the procedure or in case of hemorrhage heparin may be reversed with protamine. General anesthesia and conscious sedation are both suitable techniques for interventional neuroradiology depending on the complexity of the procedure, the need for blood pressure manipulation, and the need for intraprocedural assessment of neurologic function.<sup>36,43</sup> The anesthetic management of patients undergoing endovascular treatment for acute ischemic stroke received much attention recently.<sup>46,47</sup>

Cases performed under general anesthesia and associated with hypotension have been related to poorer neurologic outcome compared to cases performed under local anesthesia and no hypotension. General anesthesia for interventional neuroradiology is usually conducted with endotracheal intubation and intermittent positive-pressure ventilation, although the laryngeal mask airway (LMA) is a suitable alternative in selected cases.<sup>48</sup> Sedation techniques vary; propofol infusions are widely used, as are combinations of a benzodiazepine (usually midazolam) and opioid (usually fentanyl). The anesthesiologist may facilitate the procedure by manipulating systemic blood pressure and controlling end-tidal carbon dioxide tension. Controlled hypotension is often requested to facilitate embolization of AVMs and moderate hypertension may help reduce cerebral ischemia by maintaining

cerebral perfusion. Certain procedures require patients to be awake for part of the procedure. The Wada test (injection of a small dose of a barbiturate or other anesthetic drug directly into one) is used to determine the dominant side for cognitive functions such as speech and memory. This procedure may be used prior to surgery for non-life-threatening conditions such as epilepsy. Permanent neurologic deficits follow embolization of AVMs in approximately 10% of cases.<sup>49</sup> The superselective anesthesia functional examination (SAFE), an extension of the Wada test, may be performed prior to permanent embolization by injecting anesthetic into the vessels to identify angiographically occult vessels that supply normal brain tissue.<sup>50</sup> The worldwide unavailability of amobarbital has led to the use of other agents in these tests including propofol<sup>50,51</sup> and etomidate.

Major complications of interventional neuroradiology are hemorrhagic, such as aneurysm rupture, intracranial vessel injury, or dissection; occlusive, such as displacement or fragmentation of embolic materials or vasospasm; or non-CNS complications, such as contrast hypersensitivity, anaphylaxis, CIN, and hemorrhage at the peripheral vessel puncture site causing groin or retroperitoneal hematoma.<sup>36,43</sup>

## **Computed Tomography**

Computed tomography (CT) scanners obtain a cross-sectional image in a few seconds, and spiral scanners can image a slice of the body in less than 1 second, minimizing problems with motion artifacts. The procedure is painless and most adults do not require sedation or anesthesia. There is an absolute requirement for the patient to remain motionless while the study is being performed and children or adults with psychologic or neurologic disorders preventing immobility may require sedation or anesthesia (Table 33-1). Contrast agents for CT imaging may be administered orally and the anesthesiologist needs to be aware of the possibility of a full stomach. CT scanning may be employed to facilitate invasive procedures such as abscess localization and drainage, ablation of bony metastases, and radiofrequency ablation (RFA) of malignancies. Patients with acute thoracic, abdominal, and cerebral trauma often require urgent imaging to facilitate diagnosis. These patients may develop hemorrhagic shock, raised ICP, depression of consciousness, and cardiac arrest in the CT scanner and must be adequately resuscitated and stabilized before transportation to the radiology department.

## **Radiofrequency Ablation**

Percutaneous RFA is carried out in the radiology suite for treatment of primary and metastatic tumors in the liver, lung, adrenal gland, breast,

thyroid, prostate, kidney, and spleen. A high-frequency alternating current is used to generate a localized heat source directly into the tumor causing coagulative necrosis and tumor cell death while avoiding injury to the surrounding tissues. The majority of these procedures are tolerated without sedation. If an anesthesiologist does become involved in the care of these patients, careful evaluation is required; patients may be in the later stages of their disease, have often failed surgical treatment, and may have undergone extensive radiation therapy and/or chemotherapy. Recently, high-frequency jet ventilation (HFJV) has been evaluated in patients undergoing anesthesia for RFA of liver tumors.<sup>52</sup> Positioning of the probe is critical and excursions of the diaphragm in ventilated or spontaneously ventilating patients may cause excessive movement; HFJV minimizes liver motion during these procedures. A variety of anesthesia techniques have been described for percutaneous RFA of hepatic tumors including general anesthesia, sedation, thoracic epidural, and thoracic paravertebral block.<sup>53</sup>

### *Transjugular Intrahepatic Portosystemic Shunt*

The transjugular intrahepatic portosystemic shunt (TIPS) is a connection between the hepatic portal and systemic circulations created via a percutaneous catheter inserted in the internal jugular vein and directed into the liver. The TIPS functions to decompress the portal circulation in patients with portal hypertension. Beneficial effects include reduction in bleeding from varices and control of refractory cirrhotic ascites. The TIPS is often performed in patients who have failed to respond to medical therapy and may be used as a bridge to transplant in patients with poor liver function. The procedure causes minimal stimulation, lasts between 2 and 3 hours, and may be performed under sedation or general anesthesia.<sup>54</sup> Patients presenting for a TIPS procedure, in general, have significant hepatic dysfunction, and require careful preoperative assessment and intraoperative management. The considerations are outlined in [Table 33-8](#) (see also [Chapter 46](#) The Liver: Surgery and Anesthesia).

**Table 33-8** Considerations in Patients Presenting for the Transjugular Intrahepatic Portosystemic Shunt Procedure

Airway—risk of aspiration	Recent gastrointestinal bleeding Raised intragastric pressure due to ascites Decreased level of consciousness due to hepatic encephalopathy
CNS	Hepatic encephalopathy Altered mental status Variable response to anesthetic agents
Respiratory system	Decreased functional residual capacity due to ascites Pleural effusion Intrapulmonary shunts Pneumonia
Cardiovascular system	Associated alcoholic cardiomyopathy Altered volume status Acute hemorrhage from esophageal varices Intraperitoneal hemorrhage
Hematologic system	Coagulopathy Thrombocytopenia
Fluid balance	Ascites Risk of hepatorenal syndrome
Endocrine system	Tendency to hypoglycemia
Pharmacokinetics	Increased volume of distribution Decreased protein binding, drug metabolism, and elimination

## Magnetic Resonance Imaging

### Physical Principles

The physical principles of MRI are well described in detail elsewhere.<sup>55</sup> Briefly, when atoms with an odd number of protons in their nuclei, notably hydrogen, are subjected to a powerful static magnetic field, they align themselves with the magnetic field. If they are then intermittently exposed to a radiofrequency wave, the nuclei change their alignment. As the radiofrequency pulses are discontinued, the protons return to their original alignment (“relax”) within the magnetic field and, as they do, they release energy. The release of energy over time (the relaxation time) is specific for given tissues and is used to generate the MRI signal. Magnetic field strengths are expressed in Gauss (G) and Tesla (T) (1 T = 10,000 G). The earth’s magnetic field is approximately 0.3 to 0.7 G. MRI scanners used for clinical purposes generate a field of 1.5 to 3 T, and machines generating magnetic fields from 4 to 9.4 T are used in research.

### Hazards of MRI

MRI is devoid of the risks related to ionizing radiation; however, peripheral nerve stimulation (PNS) has been reported in biologic tissues exposed to radiofrequencies greater than 60 Hz. PNS results in sensory phenomena ranging from mild tingling to intolerable pain. MRI workers may experience transient vertigo-related symptoms and a metallic taste in the mouth when working in high ( $>3$  T) magnetic fields.<sup>56</sup> Ferromagnetic implantable medical devices may move in the magnetic field with disastrous consequences. This issue is a particular concern in patients with cardiac pacemakers, which may also malfunction, and cerebral aneurysm clips.<sup>57</sup> Before entering the vicinity of the magnet, patients and staff need to complete a rigorous checklist to ensure that they have no ferrometallic objects in their bodies. The magnetic field takes several days to establish and is constantly present, decreasing in strength with distance from the center of the magnet. Ferromagnetic equipment such as IV poles, gas cylinders, laryngoscopes, and pens become potentially lethal projectiles if brought too close.

Considerable noise is generated by the rapidly alternating currents of the MRI scanner; this may exceed the occupational exposure limits, defined as a weekly average exposure of 99 dB and peak exposure of 140 dB.<sup>58</sup> Patients and staff should wear ear protection and staff should minimize time spent in the scanner. Cables and wires wound in loops may cause induction-heating effects and thermal injury may also occur in skin with large tattoos, especially those with ferromagnetic inks. Patient monitors, ventilator equipment, and electrical infusion pumps may all malfunction when they come too close to the magnetic field. The electrocardiogram is sensitive to the changing magnetic signals, and it is nearly impossible to eliminate all artifacts. The electrodes should be placed close together and toward the center of the magnetic field and the leads insulated from the patient's skin to avoid causing thermal injury. MRI-compatible devices have been developed; however, in the absence of MRI-compatible monitors, tube extensions can be used to keep standard infusion pumps and monitors at a distance.<sup>55</sup> An MRI sequence takes upward of 30 minutes and many patients find it difficult to stay still for long periods. It may become very warm within the coil of the magnet, often reaching 80°F, adding to patient discomfort and is of particular concern in children whose temperatures should be monitored. Once a scan sequence is initiated, no one may enter or leave the scan room. In the case of an emergency, the MRI technicians should be notified, the scan sequence stopped, and the patient rapidly removed. Resuscitation attempts should take place outside the scanner because equipment such as laryngoscopes, oxygen cylinders, and cardiac defibrillators cannot be taken close to the magnet.

## Anesthetic Technique

Claustrophobia is a real concern for up to 15% of all adult patients undergoing MRI necessitating sedation or even general anesthesia for them to complete the imaging studies.<sup>59</sup> Sedation may be provided by the oral route with benzodiazepines, as intravenous sedation or MAC. Interventions including the design of the MRI scanner, cognitive-behavioral strategies, prone positioning, and fragrance administration have also been reported to reduce anxiety during MRI scan.<sup>60</sup> Anesthesiologists may become involved with more complex patients such as those with obesity, obstructive sleep apnea, raised ICP, movement disorders, developmental delay, and when there is a potential for a difficult airway.

### ***Pediatric Sedation and Anesthesia for MRI and CT Scans***

In children, a combination of incomprehension, separation anxiety, and fear can result in noncooperation and intolerance of relatively brief periods of immobility. Most children younger than 5 years and some as old as 11 years, particularly those with developmental delay, require sedation or general anesthesia for successful acquisition of MRI or CT images.<sup>61</sup> There is ongoing debate about the optimal care and techniques for these cases.<sup>62,63</sup> The benefits of a “sedation-only” approach include ease of medication administration (oral, rectal, or sometimes intravenous), lower cost (a sedation-trained nurse rather than an anesthesiologist), and more rapid waking and discharge home. Disadvantages include a higher failure rate than general anesthesia, airway complications arising from oversedation, unpredictable onset of enteral sedatives causing schedule delays, and inadequate analgesia during painful procedures. The choice of sedation or general anesthesia for a particular child is multifactorial and has been obfuscated in the past by the use of imprecise terms to describe the different clinical states.<sup>64</sup> As with all NORA, the standards of care for pediatric patients undergoing sedation and/or general anesthesia for MRI and CT imaging are the same as those in the operating room; a useful acronym “SOAPME” (Suction, Oxygen, Airway equipment, appropriate Pharmaceuticals, Monitoring, and special Equipment) has been coined before embarking upon any pediatric sedation or anesthetic.<sup>65</sup>

### **Sedative Agents**

Older sedation practices in pediatric patients included the use of oral chloral hydrate, “lytic cocktails,” barbiturates, and the “feed, wrap, and scan” technique in otherwise healthy neonates avoiding sedation or anesthesia altogether. These techniques, however, are being superseded by the use of short-acting agents including propofol, remifentanyl, and dexmedetomidine<sup>4</sup> which provide more reliable pharmacologic profiles and have preferable track

records for adverse events.<sup>66</sup>

## **Radiation Therapy**

External beam radiation is a common treatment for children with malignancies, making use of either highly tissue-targeted or total body irradiating (TBI) doses of x-rays. Proton beam therapy is a newer modality of this therapy, which has less potential for collateral injury to adjacent or beam-traversed tissues, a factor of utmost importance in pediatric patients at risk of long-term complications of radiation exposure.<sup>67,68</sup> Radiosensitive malignancies occurring in children are shown in [Table 33-9](#). Tumors commonly involve vital structures such as the airway, thorax, mediastinum, heart, and central nervous system (CNS). Thorough preoperative assessment is essential, including assessment for raised ICP in children with CNS tumors. Many children receive concurrent cytotoxic or immunosuppressive chemotherapy and are at increased risk of sepsis, thrombocytopenia, and anemia. The challenges of anesthesia for children undergoing radiation therapy have recently been reviewed.<sup>68-70</sup> Patients are typically scheduled for a series of daily treatments, which can last upward of 45 minutes, over a 6-week period. Radiation doses in the range of 180 to 250 centigray (cGy) are employed, so interfaced systems of closed-circuit television and telemetric microphones are used with standard monitoring to prevent staff being exposed to high levels of radiation. In the event of a problem, shutdown of the radiation beam and immediate access to the patient (within 20 to 30 seconds) is crucial. Children older than 6 or 7 years can sometimes tolerate repeated treatment sessions without sedation or anesthesia using behavioral techniques,<sup>70</sup> although most require general anesthesia or deep sedation techniques with propofol.<sup>71,72</sup> Absence of movement is crucial to ensure treatment beam accuracy and immobilization devices, especially those applied to the face and head, are unpleasant for the child and may cause airway concerns for the anesthesiologist. Most children will have indwelling central venous access, avoiding the need for repeated intravenous puncture or inhalational induction. Radiation treatments are also used in adults who have a greater capacity than children to remain still without sedation or general anesthesia.

**Table 33-9** Common Radiosensitive Tumors in Children

Primary CNS tumor—neuroblastoma, medulloblastoma  
Acute leukemia—CNS leukemia  
Radiosensitive ocular tumors—retinoblastoma  
Intra-abdominal tumors—Wilms tumor  
Rhabdomyosarcoma  
Other tumors—Langerhans cell histiocytosis

## **Positron Emission Tomography**

Positron emission tomography (PET) scanning is a newer imaging modality using radiolabeled isotopes to measure tissue glucose uptake thereby estimating tumor extent. Anesthesia concerns are those for CT; studies typically take longer to complete which may affect choice of technique/agent. Patients are typically exposed to greater ionizing radiation from both isotope and CT sources.<sup>55</sup>

## **Gastroenterology**

Procedures commonly performed in the gastrointestinal (GI) endoscopy suite are described in [Table 33-2](#). Procedures may be performed under general anesthesia or sedation.<sup>73</sup> The American Gastroenterological Association reports that 98% of patients for upper and lower endoscopies receive sedation.<sup>74</sup> Of these, over one-third are performed in ambulatory surgery centers and only 29% of these procedures involve anesthesia care providers.<sup>74,75</sup> Controversy surrounds the administration of sedation for GI procedures both in the United States<sup>74</sup> and world-wide.<sup>76</sup> A wide variety of sedation techniques are practiced and gastroenterologists are increasingly advocating for the use of propofol sedation by nonanesthesiologists, citing the safety and efficacy of these techniques (nonanesthesiologist administered propofol “NAAP” or nurse-administered propofol sedation “NAPS”).<sup>77,78</sup> However, the use of propofol by those without expert airway skills remains controversial in the anesthesiology community.<sup>79</sup> It should, however, be noted that in recently published guidelines, gastroenterologists do universally agree that patients in ASA classes III or IV, for complex procedures, or with histories of adverse or inadequate responses to sedation require the involvement of an anesthesiologist.<sup>76,80</sup>

## **Upper Gastrointestinal Endoscopy**

Upper GI endoscopy is performed for diagnostic procedures, such as biopsy, and for therapeutic procedures, such as retrieval of foreign bodies, treatment of esophageal varices with sclerotherapy or band ligation, dilation of

esophageal strictures, and placement of a percutaneous endoscopic gastrostomy. Patients may have a number of comorbidities, or a risk of gastroesophageal reflux, hepatic dysfunction, coagulopathy, and ascites. Sedation techniques or general anesthesia may be used after careful patient assessment and discussion with the endoscopist. Under general anesthesia, tracheal intubation is the gold standard to protect the airway and facilitate passage of the endoscope; however, a-LMA may serve as an alternative device for airway management.<sup>81</sup> Local anesthetic is sprayed into the oropharynx to facilitate passage of the endoscope, which can abolish the gag reflex, increasing the risk of aspiration. A bite block is inserted to prevent the patient from biting down on the endoscope and damaging both the teeth and the endoscope. Procedures are performed in the prone or semiprone position with the patient's head rotated to the side, making the airway less accessible. Care and attention should also be paid to pressure areas, particularly the eyes, lips, and teeth, and extreme rotation of the neck should be avoided. Most procedures are brief, lasting 10 to 30 minutes, and are generally painless.

### **Endoscopic Retrograde Cholangiopancreatography**

Endoscopic retrograde cholangiopancreatography (ERCP) is important in the diagnosis and treatment of both biliary and pancreatic diseases. During the procedure, the biliary and pancreatic duct systems are identified, instrumented, and therapeutic maneuvers such as the passage of stents or removal of stones carried out. The complication rate during ERCP is reported as between 5% and 10% with a mortality of 0.1% to 1%. Complications include acute pancreatitis, hemorrhage, and perforation.<sup>82,83</sup> Patients usually experience discomfort during ERCP and general anesthesia or deep sedation techniques are recommended for the procedure, which usually lasts between 20 and 80 minutes. The airway and patient positioning considerations are similar to those for GI endoscopy. Sphincter of Oddi manometry may be performed in which case drugs that affect sphincter pressure such as atropine, glycopyrrolate, glucagon, and various opioids should be avoided. Patients presenting for ERCP may have significant comorbidities including acute cholangitis with septicemia, jaundice with liver dysfunction and coagulopathy, bleeding from esophageal varices resulting in hypovolemia, or biliary stricture following major hepatobiliary surgery, including liver transplantation. Transient bacteremia may occur during endoscopy, and antibiotic prophylaxis is recommended for patients with cardiac valvular abnormalities. Gastroenterologists frequently use antispasmodics such as glucagon and intravenous hyoscyamine to reduce duodenal motility and improve operating conditions during endoscopy<sup>84</sup>; sinus tachycardia may occur.

## ***Cardiology and Interventional Cardiology***

The number of interventional cardiology and electrophysiology (EP) procedures has dramatically increased in most institutions over the last decade, with approximately 400,000 pacemakers and implantable cardiac defibrillators (ICDs) being placed each year in the United States.<sup>85</sup> As volumes and patient complexity increase anesthesiologists are playing a much more significant role in the EP and cardiac catheterization laboratories. Hybrid operating rooms with fluoroscopy capability are becoming more common in the design plans for new ORs and these are usually designed with the anesthesiologist in mind. Cardiac catheterization laboratories and EP laboratories are often simply modified to accommodate anesthesia providers. This retrofit can make for frequent territorial and ergonomic constraints.

### **Percutaneous Intervention**

For patients with evidence of myocardial ischemia, cardiac catheterization and coronary angiography is an essential step in the diagnosis of coronary artery disease. Often this step is followed by coronary angioplasty with stenting for intracoronary luminal obstructions that are more than 70%.<sup>86</sup> The procedures are usually done with mild sedation administered by the catheterization laboratory team: blood pressure, EKG, and pulse oximetry are monitored and the patient breathes spontaneously with oxygen administered by nasal prongs or a facemask. However, the care of an anesthesiologist may be required for patients who are hemodynamically unstable or in cardiogenic shock either before or during the procedure. Early recognition of at-risk patients allows for coordination between the anesthesiologist and cardiologists to avoid hypoxia and hypercarbia. Certain percutaneous interventions (PCIs) have a higher level of complexity and can involve patients with significant comorbidities. Coronary atherectomy for chronic total occlusion can be time consuming and technically difficult due to complex anatomy and general anesthesia is usually required. The anesthesiologist should prepare for potential hemodynamic instability with routine anesthetic monitors, possible arterial blood pressure monitoring, and good peripheral or central IV access. Cardiologists are often working through the femoral veins and in an emergency situation it is possible to link sterile intravenous tubing to the access sites for administration of inotropes and vasopressors.

### **Percutaneous Ventricular Assist Devices**

Patients in cardiogenic shock or having high-risk PCI or EP procedures may benefit from the hemodynamic support provided by percutaneous ventricular assist devices. The TandemHeart (Cardiac Assist, Inc., Pittsburg,

Pennsylvania) is a left atrial to femoral bypass system that offers flow rates up to 4.0 L/min through an external centrifugal pump. It is designed for short duration support (14 to 162 hours for cardiogenic shock and 1 to 24 hours for high-risk PCIs).<sup>87</sup> The Impella Recover 2.5 and 5.0 (Abiomed Inc., Danvers, MA, USA) are similar devices but allow for easier implantation as there is no requirement for a transseptal puncture and the device is smaller. A microaxial pump supports either 2.5 or 5.0 L/min.<sup>88</sup> Patients who are unable to keep still or lie flat will require general anesthesia; the rest can be managed with light sedation using agents such as dexmedetomidine or propofol. Transesophageal echocardiography (TEE) guidance may also be required to guide cannula positioning.

### **Percutaneous Closure of Septal Defects**

A number of different devices have been introduced for the closure of patent foramen ovals (PFOs) and atrial septal defects (ASDs). These devices are placed by the cardiologist under the guidance of fluoroscopy and ultrasound. The introduction of intracardiac echocardiography (ICE) has lessened the need for general anesthesia to facilitate TEE guidance<sup>89</sup>; however, general anesthesia is still useful to ensure patient comfort and safety while the devices are deployed. Special attention should be paid to avoiding air in any intravenous tubing as left to right shunts can be reversed with the drop in systemic vascular resistance that accompanies many anesthetic agents.

### **Alcohol Septal Ablation**

Alcohol septal ablation offers an alternative to open heart myomectomy for patients with hypertrophic cardiomyopathy with equivalent mortality outcomes.<sup>90</sup> Specific septal perforator vessels are identified using coronary angiography and injection of approximately 3 mL of absolute ethanol into these vessels causes a controlled infarction of the hypertrophic septum.<sup>91</sup> This infarction can be visualized in real time on live echocardiography. Although the majority of the procedure requires only minimal sedation the alcohol injection can be very painful. A controlled myocardial infarction feels very much like an uncontrolled one so deep sedation will be necessary for the injection portion of the procedure.

### **Structural Heart Procedures**

#### *Transcatheter Aortic Valve Replacement*

Calcific aortic stenosis affects almost 5% of adults over the age of 65.<sup>92</sup> Once symptoms of syncope and heart failure begin, 50% of patients will die within 3 years; however, surgical aortic valve replacement (SAVR) in elderly patients

with multiple comorbidities can carry a mortality rate of up to 20%.<sup>93</sup> Transcatheter aortic valve replacements (TAVRs) use a sophisticated catheter delivery system to deploy a folded replacement valve through a sheath in the common femoral artery, subclavian artery, or via a minithoracotomy directly into the aorta or left ventricular apex.<sup>92</sup> Rapid ventricular pacing is used to minimize left ventricular ejection so that the new valve can be deployed into the correct position. Initially TAVR was only offered to extremely high-risk surgical patients; however, ongoing studies show potential benefit to intermediate surgical risk patients.<sup>93</sup>

The CoreValve ReValving System (Medtronic, Inc., Minneapolis, MN) is self-expanding and is made of bioprosthetic porcine pericardial tissue sutured into a malleable metal stent that is rigid at body temperature.<sup>92</sup> The compressed CoreValve is slowly deployed as its delivery system is pulled back and allows for some repositioning before the valve is fully released. The Edwards SAPIEN XT transcatheter heart valve (Edwards Lifesciences, Irvine, CA) is a bovine pericardial tissue valve in a cobalt chromium alloy stent, which has a smaller diameter delivery system. This valve expands with a balloon within the native valve with the goal of displacing the native leaflets.<sup>93</sup>

Research and development in structural heart procedures is ongoing and new and improved TAVR devices will be available for clinical use soon. Initial experience with TAVR procedures required general anesthesia and TEE for all patients; however, many institutions are using sedation with transthoracic echo (TTE) standby.<sup>94</sup> These patients are at high risk for cardiac death during the procedure and experience frequent hemodynamic instability during the rapid ventricular pacing that is required for balloon valvuloplasty and for valve deployment.<sup>94,95</sup> Cardiopulmonary bypass standby is present for many patients. Given the physiologic sequelae of aortic stenosis, all patients undergoing TAVR procedures should have preinduction arterial line blood pressure monitoring. Central access in the neck or groin is essential for inotrope and vasopressor administration and large bore IV access is necessary for fluid resuscitation if blood loss is significant. The large cannulae that are exchanged in and out of the groin during the procedure can result in a surprising drop in hematocrit which should be checked frequently during the procedure. One-lung ventilation may be helpful for both the transapical approach and when directly cannulating the ascending aorta, which can be accomplished with either a double lumen tube or a bronchial blocker. The goal for most of these procedures is to extubate the patient in the procedure room or shortly thereafter. Many of the patients are elderly and at high risk for delirium; thus, benzodiazepines and long-acting opioids should be avoided if possible.

## MitraClip

Mitral regurgitation (MR) is the most common valvular disorder in the aging population in the United States.<sup>96</sup> Cardiac surgical mitral valve repair should be offered to all surgical candidates with symptomatic MR.<sup>97</sup> In North America, the MitraClip (Evalve, San Francisco, California) is intended to treat patients with moderately severe to severe symptomatic degenerative MR who are considered too high risk for open heart surgery.<sup>96</sup> In Europe, these guidelines expand to also include those with severe symptomatic functional MR.<sup>98</sup> The MitraClip delivers a clip device percutaneously that mimics the Alfieri edge-to-edge repair to create a double orifice mitral valve (Figs. 33-3 and 33-4).<sup>99</sup>

Recent evaluations have shown that the MitraClip is effective in reducing MR and improving LV remodeling. As well, mortality associated with the MitraClip is less than with surgery using the predicted outcomes surgical risk predictors.<sup>96</sup> Patients undergoing the MitraClip procedure receive a general anesthetic with invasive monitors and TEE.

**Figure 33-3** Three dimensional en face view of mitral valve. *Blue arrow* points to A3 portion of anterior mitral leaflet. *Red arrow* points between P1 (left) and P2 prolapsing segments of the posterior leaflet with flail chordae visible. (Courtesy of Dr G.B. Mackensen MD, PhD, FASE.)

**Figure 33-4** Three dimensional en face view of mitral valve after two MitraClips deployed. *Purple arrow* shows where the two clips have been placed between A2 and P2 segments of the mitral valve. (Courtesy of Dr G.B. Mackensen MD, PhD, FASE.)

### *Left Atrial Appendage Occlusion*

The left atrial appendage (LAA) is a source of clot formation in patients with atrial fibrillation and patients require lifelong anticoagulation to prevent this source of embolism. If the LAA can be removed, then anticoagulation is no longer necessary. Traditionally LAA closures have been performed through median sternotomy; however, the Watchman (Boston Scientific, Minneapolis, MN) is a novel device that can be deployed directly into the LAA via a transfemoral catheter.<sup>100</sup> Presently the Watchman is offered to patients with nonvalvular atrial fibrillation and at least one risk factor (age >75 years, hypertension, diabetes, or prior stroke/transient ischemic attack).<sup>101</sup> An additional indication for this device is patients who have a major contraindication to long-term anticoagulation. The device has been shown to reduce hemorrhagic stroke and cardiovascular death when compared to warfarin although there is an increased incidence of ischemic stroke as a periprocedural event.<sup>102</sup> The procedure requires meticulous evaluation of the LAA by TEE to ensure proper device is selected. Arterial catheters should be used to measure arterial blood pressure for most of these procedures.

### **Electrophysiology**

Like many catheterization laboratory procedures, sedation for EP procedures can sometimes be managed by cardiologists; however, both patient and procedure complexity often necessitate general anesthesia to facilitate a safe and comfortable experience for the patient. EP studies can be divided into cardiac implantable electronic devices (CIEDs) and EP studies with ablation.<sup>103</sup>

## *Cardiac Implantable Electronic Devices*

CIEDs include pacemakers for symptomatic bradycardia and for chronic resynchronization therapy (CRT) and implantable cardioverter defibrillators (ICDs). These devices are usually implanted in the left pectoral area with one to three transvenous leads inserted into the axillary, subclavian, or cephalic veins.<sup>104</sup> Pacemakers can generally be placed under light sedation with local anesthetic to the skin for the pacemaker pocket; if significant patient comorbidities exist it may be necessary to administer general anesthesia for this procedure. ICDs decrease the risk of sudden cardiac death by both primary and secondary prevention of ventricular tachycardia and ventricular fibrillation.<sup>105</sup> Primary prevention ICDs are indicated for those with an EF less than 35%, with NYHA class II–III symptoms who are on optimal heart failure medical therapy.<sup>106</sup> Secondary prevention ICDs are for patients who have had a documented ventricular fibrillation cardiac arrest or an episode of sustained ventricular tachycardia.<sup>107</sup> The implantation of the device is similar to the process for placing a pacemaker; however, the defibrillation threshold testing requires much deeper sedation. General anesthesia may be necessary for threshold testing in patients with left ventricular dysfunction.<sup>85</sup> CRT pacemakers are indicated for those with cardiomyopathy, an EF less than 35%, a left bundle branch block (LBBB), QRS duration less than 120 milliseconds, and NYHA class II–IV symptoms.<sup>108</sup> A lead is placed transvenously into the coronary sinus which allows for simultaneous pacing of the left and right ventricles: this reduces mortality and improves quality of life.<sup>109</sup> Many patients in heart failure are unable to lie flat for the duration of the procedure and placing a lead into the coronary sinus in someone with ventricular dilatation and valvular regurgitation can be challenging with sedation alone.<sup>85</sup>

## *EP Studies with Ablations*

EP studies can be performed for risk stratification or to evaluate specific symptoms that suggest an arrhythmia<sup>105</sup>; however, it is uncommon to not pair these with concurrent ablation procedures, especially if the ablation is to treat tachyarrhythmias ([Table 33-10](#)).

**Table 33-10** Arrhythmia Classification

<b><i>Bradyarrhythmias</i></b>
Sick sinus syndrome
Atrioventricular block
First-degree heart block
Second-degree heart block (Mobitz type I and II)
Third-degree heart block
<b><i>Tachyarrhythmias</i></b>
<i>Regular rhythm, normal QRS</i>
Sinus tachycardia
Atrioventricular nodal reentrant tachycardia
Atrioventricular reciprocating tachycardia—orthodromic
Junctional tachycardia
Atrial flutter
<i>Irregular rhythm, narrow QRS</i>
Atrial fibrillation
Multifocal atrial tachycardia
Frequent premature atrial contractions
<i>Regular rhythm, wide QRS</i>
Monomorphic ventricular tachycardia
Atrioventricular reciprocating tachycardia, antidromic
Regular supraventricular tachycardias with bundle branch block
<i>Irregular rhythm, wide QRS</i>
Polymorphic ventricular tachycardia
Ventricular fibrillation
Frequent premature ventricular contractions
Irregular supraventricular tachycardias with bundle branch block

The most common ablation procedures performed currently are for narrow complex tachycardias such as atrial fibrillation or atrial flutter and for wide complex tachycardias like polymorphic ventricular tachycardia. Patients with atrial fibrillation should be effectively anticoagulated or have a TEE assessment preablation to rule out an LAA thrombus. Ablation catheters are inserted via the femoral veins into the right heart to try to induce arrhythmias. Complex mapping techniques localize the source of the arrhythmia and an energy source is applied to ablate this source. Ablations can be performed with either radiofrequency or cryotherapy with the former being much more stimulating for the patient.<sup>110</sup> Saline irrigation is used to cool the energy delivery system and therefore can result in significant volume administration during long procedures.<sup>111</sup> The phrenic nerve lies close to the right upper pulmonary veins and is at risk during ablation. Avoidance of neuromuscular blockade will alert the electrophysiologist to phrenic irritation when this area is being ablated.<sup>109</sup> Although drugs that affect the sympathetic and parasympathetic systems can influence the sinus and atrioventricular nodes, there is little evidence to support the notion that general anesthesia affects inducibility of specific arrhythmias.<sup>85,112</sup> The duration of ablation procedures can be lengthy (4 to 8 hours) and mapping requires minute catheter adjustments that are sensitive to patient movement. The ablation

process can also be painful and general anesthesia may be required. Invasive arterial blood pressure monitoring is helpful in these patients, especially for those with reduced ejection fractions in whom hemodynamically unstable arrhythmias might be induced.

### *Laser Lead Extractions*

As pacemakers and ICDs become more widespread, so does the need for lead extractions. Device infections, lead endocarditis, thrombosis or venous stenosis, chronic pain due to leads/device, and nonfunctional leads are all reasons for lead removal.<sup>113</sup> Leads become well adhered to the subclavian vein and/or the endocardium which makes this particular procedure very anxiety provoking for all involved. Vascular injury causing significant blood loss and cardiac tamponade is rare but the involved clinicians should be prepared for it. General anesthesia with large bore intravenous access and invasive blood pressure monitoring is essential; TEE is usually advisable for prompt evaluation of hemodynamic changes. As expected, centers with higher lead extraction volume have a lower probability of complications and death.<sup>114</sup>

### **Cardioversions and Diagnostic TEEs**

Cardioversion and TEE procedures are brief procedures but are exquisitely stimulating. Elective electrical cardioversions are ideally performed with a bolus of propofol on fully monitored patients under the supervision of an anesthesiologist. Atrial fibrillation is the most common reason for an elective cardioversion, so it is necessary to rule out the presence of an LAA clot if the patient is not on therapeutic anticoagulation to avoid embolic complications.<sup>115</sup> TEE is the gold standard for evaluating the LAA.<sup>116</sup> Topical anesthesia in the pharynx with 4% lidocaine can facilitate TEE probe insertion and an infusion of low-dose propofol sedation provides patient comfort with spontaneous ventilation. Standard monitors should be applied, and although end-tidal CO<sub>2</sub> monitoring is not completely necessary, it can be very helpful. Many of the patients presenting for cardioversion and elective TEE have compromised cardiac function; thus, resuscitation drugs should be readily available.

The anesthesiologist may also be involved in elective TEEs for specific indications under the American Society of Echocardiography (ASE) guidelines including evaluation of suspected aortic dissection, determining suitability for valve repair, diagnosis of endocarditis, evaluation of persistent fever with an intracardiac device, and evaluation for LAA thrombus.<sup>117</sup> Anesthesiologists caring for these patients should ensure that there are no contraindications to TEE related to known esophageal pathology (strictures, varices, malignancy,

recent ulcer or hemorrhage, Zenker diverticulum) or those with a history of unevaluated dysphagia.<sup>117</sup> Although topical anesthesia and sedation are usually sufficient, uncooperative patients and those with a potentially difficult airway should be prophylactically intubated and maintained on TIVA. In these situations, the anesthesiologist can help facilitate passage of the TEE probe using a laryngoscope.

**Table 33-11** Anesthetic Consideration for Electroconvulsive Therapy

Anesthetic Requirements	Comments
Amnesia	With induction agent of choice
Airway management	Usually with bag-mask ventilation, although the laryngeal mask has been used with success <sup>122</sup>
Moderate hypocapnia	Improves the quality and duration of seizures <sup>123</sup>
Protection of the teeth and tongue during the seizure	Using a soft bite block
Prevention of seizure-related injuries (fractures and dislocations)	Small doses of muscle relaxant, e.g., succinic choline (0.75–1.5 mg/kg) are most commonly used unless there are contraindications
Control of hemodynamic responses	Labetalol; esmolol; and the calcium channel antagonists nifedipine, diltiazem, and nicardipine all attenuate the hemodynamic responses to ECT. Dexmedetomidine (1 µg/kg administered over 10 minutes just before induction of anesthesia) has been shown to be effective in controlling blood pressure without affecting seizure duration. <sup>124</sup>
Control or prevention of the parasympathetic effects of ECT (salivation, transient bradycardia, and asystole)	Can be prevented with glycopyrrolate or atropine
Analgesia to relieve postseizure myalgia	Ketorolac 15–30 mg is effective in younger patients Acetaminophen or aspirin may be used in older patients or where NSAIDs are contraindicated

## Electroconvulsive Therapy

 Electroconvulsive therapy (ECT) has had an important role in the management of depression, mania, and affective disorders since the 1930s.<sup>118</sup> Typically it is performed three times a week for 6 to 12 treatments, followed by weekly or monthly maintenance therapy to prevent relapses.<sup>119</sup>

### Physiologic Response to Electroconvulsive Therapy

The physiologic response to ECT includes generalized motor seizures and an acute cardiovascular response. The seizure usually lasts several minutes and minimum seizure duration of 25 seconds is recommended to ensure adequate antidepressant efficacy.<sup>120</sup> The cardiovascular response includes transient bradycardia and occasional asystole giving way to more prominent hypertension and tachycardia. Increased cerebral blood flow, raised ICP and cardiac dysrhythmias, myocardial ischemia, infarction, or neurologic vascular events may be precipitated. Short-term memory loss is also common

following ECT. Other sequelae include myalgias, bone fractures, joint dislocations, headache, emergence agitation, status epilepticus, and sudden death.

## Anesthetic Considerations for ECT

Scalp electrodes are placed to monitor the electroencephalogram and a blood pressure cuff is applied to an extremity and inflated before muscle relaxant is administered to monitor the seizure. Patients presenting for ECT are often elderly, with a number of coexisting conditions.<sup>121</sup> Patients may be taking antidepressant medications which include tricyclic antidepressants, monoamine oxidase inhibitors, and selective serotonin-reuptake inhibitors. Of these drugs, the monoamine oxidase inhibitors have the most significant interactions with anesthetic agents. The anesthetic requirements for ECT are described in [Table 33-11](#).

Most of the intravenous induction agents have been used for ECT,<sup>121</sup> despite their anticonvulsant effects. Methohexital (1 to 1.5 mg/kg), historically considered the “gold standard,” appears to have less anticonvulsant activity than the other agents. Etomidate (0.15 to 0.3 mg/kg) is generally associated with longer seizure duration and is the preferred agent of some psychiatrists, despite a slightly longer recovery and associated myoclonus. Propofol is more effective at attenuating the acute hemodynamic responses than etomidate and in small doses (0.75 mg/kg) seizure duration is usually acceptable.<sup>125</sup> Short-acting opioids, such as remifentanyl, can be used to decrease the dose of induction agent and prolong seizure duration without reducing the depth of anesthesia.<sup>126</sup> Recently ketamine, either alone or in combination, has been attributed intrinsic antidepressant effects when used as an anesthetic agent for ECT, although its effects are far from certain.<sup>127</sup>

## Summary

The number and complexity of NOR procedures is steadily increasing. This increase has resulted in an expansion of anesthesia services in areas remote from the operating room that may not be familiar to anesthesia providers. In preparing to administer anesthesia or sedation in a NOR site, a simple three-step approach can be followed. This approach involves giving careful consideration to the evaluation and the needs of the *patient*, the particular challenges posed by the *procedure*, and the hazards and limitations of the *environment*. In all cases, the standards of anesthesia care and monitoring should be no different than those provided in the conventional operating room.

# 34 Anesthesia for the Older Patient

ITAY BENTOV • G. ALEC ROOKE

## Demographics and Economics of Aging

### The Process of Aging

Functional Reserve and the Concept of Frailty

Physiologic Age

### The Physiology of Organ Aging

Changes in Body Composition, and Liver and Kidney Aging

Central Nervous System Aging

Drug Pharmacology and Aging

Cardiovascular Aging

Pulmonary Aging

Thermoregulation and Aging

### Conduct of Anesthesia

The Preoperative Visit

Intraoperative Management

Postoperative Care

Perioperative Complications

### The Future

## KEY POINTS

- 1 The aging of America presents a medical and economic challenge to the entire health-care system as older patients present for surgery in ever-increasing numbers.
- 2 The aging process affects connective tissue and cellular function, including the mitochondria, and inevitably leads to decreased function and, ultimately, frailty.
- 3 The rate at which diminished function and frailty develop is highly variable and lends credence to the concept of physiologic age.
- 4 Decreased organ reserve and increased sensitivity to anesthetic agents result from generalized body composition changes such as connective tissue stiffening and decreased muscle mass, plus impaired autonomic reflexes, and increased sensitivity to drugs.
- 5 Preoperative preparation will more often involve evaluation of how best to enhance recovery of function after surgery, and discussions

surrounding informed consent, living wills, and ethical treatment of the older patient.

- 6 Intraoperative management must take into account the increased sensitivity to drugs in the elderly patient, as well as an increased likelihood of hemodynamic, pulmonary, and thermoregulatory instability.
- 7 Analgesia is an important component of postoperative care, but is made more difficult by the increased likelihood of adverse consequences from the analgesic regimen.
- 8 Perioperative complications, most notably pulmonary, cardiac, and central nervous system complications such as delirium or cognitive decline, occur more commonly in the elderly patient because of an interaction between comorbid disease and the decreased physiologic reserve of aging.

*Age is not a particularly interesting subject. Anyone can get old. All you have to do is live long enough.*

—Don Marquis

This quote suggests that aging is dull. To many medical practitioners, it is far worse than “dull.” It is high risk due to the complexity of care, and discouraging in its monetary reimbursement. To those concerned with the federal budget and personal expenses, medical care for the aged threatens to bankrupt the nation. Nevertheless, the impact of aging on the practice of medicine is far-reaching and profound, and therefore cannot be ignored. Just as children are not “little adults,” the older patient is truly different from the younger adult counterpart. All caregivers, including anesthesiologists, should be knowledgeable of at least some aspects of aging in order to provide intelligent deviation from their standard practice. Basic information is more available than ever before, much of it electronically from the American Society of Anesthesiologists ([www.asahq.org](http://www.asahq.org)), the Society for the Advancement of Geriatric Anesthesia ([www.sagahq.org](http://www.sagahq.org)), and the American Geriatrics Society ([www.americangeriatrics.org](http://www.americangeriatrics.org)). In reality, caring for an older patient is rarely dull, if for no other reason than their diverse and fascinating lives. Anyone with a passing interest in physiology should enjoy the application of aging physiology to anesthetic management. Yes, their care is often time-consuming, stressful, and requires extra effort, but more often than not it provides the anesthesia caregiver the opportunity to truly practice medicine and make a positive impact on a vulnerable patient’s life. Furthermore, the older patient is likely to be a prime candidate for the benefits provided by the perioperative surgical home (PSH).

## Demographics and Economics of Aging

*I advise you to go on living solely to enrage those who are paying your annuities. It is the only pleasure I have left.*

—Voltaire

When Social Security was initiated in 1935, only 6.1% of the US population was older than 65 years.<sup>1</sup> By 2010 that percentage had grown to 13.0% and represented 40 million people.<sup>2</sup> By 2040 it is expected to be nearly 20% of the US population and represent 71 million people.<sup>3</sup> The percentage of the US population older than 85 is expected to more than double from 2010 to 2040 (from 1.8% to an estimated 4.5%).<sup>3</sup> The growth of the US population and its older subgroups is shown in [Figure 34-1](#). The impact of these statistics is enormous with respect to medical care. In 2010, patients over 65 represented 13% of the population but accounted for 45% of the 167 million total US inpatient days, a rate per capita more than five times greater than for those under 65.<sup>4</sup> On the examination of the 2006 inpatient and ambulatory procedure data, there were an estimated 73 million surgical and nonsurgical procedures performed in the United States after exclusion of procedures that were unlikely to have involved anesthesia services.<sup>5,6</sup> Of these, 28% were on patients older than 65 years. Thus it appears that people over age 65 have surgery 2.7 times more often than people under age 65.

**Figure 34-1** The actual and estimated US population from 1940 to 2040 is shown broken down by age range. *Yellow bar* = age above 65; *purple bar* = age 65 to 74; *green bar* = age 75 or above for years 1940 to 1970, and age 75 to 84 from 1980 on; *red bar* = age 85 or above. (From <http://www2.census.gov/library/publications/2011/compendia/statab/131ed/tables/pop.pc> Accessed December 3, 2015.)

Federal spending for Medicare in 2015 was \$546 billion or 14.8% of the

**1** federal budget. This amount is approximately twice what was spent in 2000 after adjusting for inflation, and represents an approximate 50% increase per enrollee.<sup>7</sup> As impressive as Medicare expenditures may be, federal spending grossly underestimates the total cost of all health-care spending for people over age 65. It is estimated that people over age 65 account for nearly half of the nation's health-care costs, which totaled \$3.1 trillion in 2014, or approximately 17.8% of the gross national product.<sup>8,9</sup> In consequence, there is considerable pressure to contain health-care costs in this country, including physician reimbursement, by both private insurance companies and the federal government. Unfortunately, federal reimbursement to anesthesiologists is especially poor. In 2004, Medicare reimbursed anesthesia care at approximately 33% of what commercial insurance companies paid.<sup>7</sup> This percentage is in sharp contrast to all other specialties, for which Medicare reimbursement is approximately 83% of commercial rates.<sup>10</sup> The average conversion factor has improved considerably in the last few years. Nevertheless, the 2015 national average value of \$22.61 has barely matched inflation since the nadir of \$16.60 in 2002.<sup>11</sup> Although Medicare will reimburse at the 50% level for up to four concurrent medically directed procedures, academic programs had been at a disadvantage since faculty are not permitted to staff more than two procedures simultaneously if residents were involved. Fortunately, as of 2010, Medicare now reimburses academic institutions at 100% for two concurrent cases.

## The Process of Aging

*You can't help getting older, but you don't have to get old.*

—George Burns

Aging involves a gradual, cumulative process of damage and deterioration. The question could be posed: Why is such a process allowed in nature? Classical evolutionary teleologic explanations would suggest that aging confers an advantage to the survival of the species. In the end of the nineteenth century, August Weismann theorized (and later abandoned his theory) that older members of a species need to remove themselves to sustain the turnover that is essential for evolution. Newer theories arose in the second part of the twentieth century, such as mutation accumulation, which suggests that the random, detrimental mutations that do not cause mortality early in life will ultimately accumulate and lead to deterioration later in life. Another proposal was antagonistic pleiotropy, meaning that a single gene has more than one phenotype (effect or trait). The phenotypes may prove beneficial in early life but detrimental in old age. Lastly, the disposable soma theory suggested that the organism must allocate energy to bodily functions

and resources that are focused upon early survival, growth, and reproduction while compromising repair functions that would prevent deterioration with age. The existence of mechanisms that promote death (e.g., apoptosis, cellular senescence, and telomerase shortening) are used by some to support the classical evolutionary theories, and by others to criticize them.

A new, hierarchical approach to aging groups the mechanisms of aging into three tiers. The first tier is primary mechanisms, all of which are clearly negative. Examples of the first tier mechanisms include: DNA damage and mitochondrial DNA mutations, and telomere loss. Telomeres are stretches 2 of DNA at the ends of chromosomes, analogous to plastic tips on shoelaces. Without them the chromosome would unravel and stick to each other, which could scramble the DNA. Each time a cell divides, the telomeres get shorter, and when they become too short, the cell can no longer divide.

Another first tier mechanism is epigenetic drift: nongenetic DNA changes that influence gene expression. The most studied epigenetic phenomenon is the addition of methyl groups (methylation) of DNA. Most of the genome undergoes gradual demethylation while other, specific regions undergo hypermethylation, leading to disrupted transcription. Lastly, the production, folding, and degradation of proteins within the cell regulate their functionality. These pathways or homeostasis of proteins are referred to as proteostasis. Defective proteostasis has been implicated in several diseases like diabetes and Alzheimer's, as well as the aging process.

The second tier includes antagonistic mechanisms that are primarily beneficial and protect the younger individual from damage or nutrient shortage. After prolonged use, however, these mechanisms themselves produce damage. Mechanisms in the second tier include senescence, a state in which the cell is alive and metabolically active but is not capable of dividing. Oxygen is important to providing large amounts of energy; however, reactive oxygen species such as peroxides and superoxides cause damage to DNA and proteins. Another second tier mechanism is disrupted nutrient-sensing; for example, the mammalian target of rapamycin (mTOR) is a protein that senses cellular nutrient, oxygen, and energy levels. Activation of mTOR supports cell growth, proliferation, and survival. However, activation of mTOR is not without a price. Reduction in mTOR activity (e.g., due to a restrictive diet) has been found to increase life span in several animal models.<sup>12</sup> The last mechanism in the second tier is mitochondrial dysfunction; age is correlated not only with the accumulation of mitochondrial DNA mutations but also with a decline in respiratory chain function which may contribute to inefficient use of energy in the cell and reduced exercise capacity.

The third tier consists of integrative mechanisms which operate when the accumulated damage caused by the primary and antagonistic hallmarks cannot be compensated by tissue homeostatic mechanisms: stem cell numbers

decline with age, suggesting that there has been a failure to replace damaged cells. Another mechanism is altered intercellular communication. Examples of intercellular communication are neurohormonal signaling processes such as renin–angiotensin, adrenergic, or insulin-IGF1 signaling pathways. Deregulated neurohormonal signaling in the aged is implicated in development of diseases such as hypertension, heart failure, diabetes, and malignancies.

The newly coined term “geroscience” refers to an interdisciplinary field which aims to understand the relationship between aging and age-related diseases.<sup>13</sup> A fundamental concept of geroscience is that numerous human diseases arise, at least in part, from aging itself. Aging is the major risk factor for diseases like Alzheimer’s, Parkinson’s, and numerous malignancies. Studying aging mechanisms across a wide variety of pathologies raises an important question: are aging and disease different processes or are they, at least to some degree, inseparable? Elucidating each one of these processes could provide not just insight but potential solutions for the other.

Most of the gains in average human life span have been as the result of reducing those factors that cause premature death: predation, accidents, and disease. The inability to thwart aging entirely implies that the human life span is limited, and that if everyone died only of “old age,” the age at death would end up being a bell-shaped curve centered at a certain value, probably around age 85.<sup>14</sup> Nevertheless, it is possible that the bell-shaped curve could be shifting to a higher value, but how far it can be shifted is unclear. The focus of research has transitioned from just extending the number of years lived (life span) to extending the period during which one is generally healthy and free from serious comorbidities (healthspan). Several interventions (smoking cessation, weight loss, and exercise) have been shown to improve both life span and healthspan.<sup>15,16</sup>

## **Functional Reserve and the Concept of Frailty**

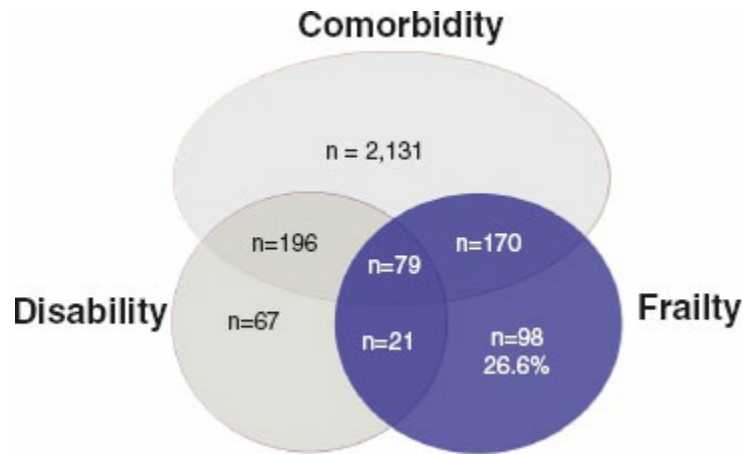

*Old age is no place for sissies.*

—*Bette Davis*

Functional reserve represents the degree to which organ function can increase above the level necessary for basal activity. For healthy individuals, reserve peaks at approximately age 30, gradually declines over the next several decades, and then experiences more rapid decline beginning around the eighth decade. Assessment of reserve is something anesthesiologists perform all the time. For example, the ability to achieve a minimum of four metabolic equivalents appears to confer enough cardiovascular reserve to tolerate the stress of most surgical procedures.<sup>17</sup> As age advances, there emerges an

extreme form of decreased reserve and limited resistance to stressors. This biologic syndrome is often referred to as frailty. Frailty is a result of cumulative declines across multiple physiologic systems, and causing vulnerability to adverse outcomes. Frailty, disability, and comorbidity overlap but are not synonymous (Fig. 34-2). Although the diagnosis of frailty is often intuitive, there are two classical ways to define it. The first method is the frailty phenotype which is defined as a clinical syndrome in which three or more of the following criteria are present: unintentional weight loss (10 lb in past year), self-reported exhaustion, weakness (grip strength), slow walking speed, and low physical activity.<sup>18</sup> The second definition of frailty is the frailty index which considers frailty in relation to deficit accumulation. A list of symptoms, signs, diseases, and disabilities are surveyed and scored in a binomial fashion (yes/no), and the fraction of the positive deficits from the total number surveyed is calculated (e.g., 10 positive out of 40 surveyed equals a frailty index of 0.25).<sup>19</sup> Although the frailty phenotype and the frailty index do not necessarily identify the same patients,<sup>20</sup> both predict mortality and institutionalization in community dwelling elderly. Numerous studies that used a range of assessment tools to determine frailty status have shown that frail patients undergoing surgical procedures had a higher likelihood than nonfrail patients of experiencing mortality, morbidity, complications, increased hospital length of stay, and discharge to an institution.<sup>21</sup> A population-based retrospective cohort study that examined over 200,000 community dwelling adults older than 65 years undergoing elective, major, noncardiac surgery from 2002 to 2012 found that while preoperative frailty appears to impact some surgical procedures more than others, overall it is associated with an increased risk of 1-year mortality that was particularly notable in the early postoperative period.<sup>22</sup> It is tempting to hypothesize that once frailty is identified, could a preoperative habilitation program potentially reverse frailty and improve surgical outcomes? In the general nonsurgical population, trials of exercise (resistance training, aerobic training, balance, and flexibility), nutritional supplements, and pharmaceutical agents show limited success at reversing frailty and improving outcomes.<sup>23</sup> For patients scheduled for elective surgery, it seems that interventions provided before surgery (prehabilitation) were superior to similar interventions provided after surgery (rehabilitation).<sup>24</sup> A meta-analysis of eight RCT studies that examined preoperative conditioning to improve physiologic function and clinical outcomes suggested that a major obstacle is the low adherence to the prehabilitation programs.<sup>25</sup> A trial is currently underway that will compare preoperative, interdisciplinary exercise and health promotion intervention in a population of frail patients undergoing elective cardiac surgery to determine if the intervention improves 3- and 12-month clinical outcomes (The PREHAB trial).<sup>26</sup>

**Figure 34-2** Overlap of frailty with disability and comorbidity. 2,762 community dwelling adults (age >65) who had comorbidity (defined as two or more out of the following nine diseases: myocardial infarction, angina, congestive heart failure, claudication, arthritis, cancer, diabetes, hypertension, COPD) and/or disability (defined by inability to perform one or more activities of daily living [ADL] tasks) and/or frailty. Of 368 frail subjects, 98 (26.6%) were not identified by assessment of disability or comorbidity. (Reproduced with permission from Fried LP, Tangen CM, Walston J, et al. Frailty in older adults: evidence for a phenotype. *J Gerontol A Biol Sci Med Sci.* 2001;56:M146–M157.)

## Physiologic Age

*If you didn't know how old you were, how old would you be?*

—James Hubert 'Eubie' Blake

The aging process is highly variable from one individual to the next. The older we get, the more different we become. Ideally, an index of physiologic age would be available that would quantify functional reserve. One interesting approach to this objective that is available to the lay public is to quantify many of the known modifiable and nonmodifiable factors that influence life expectancy.<sup>7</sup> By plugging one's individual data into the program, a measure of how old you are relative to your chronologic age is provided, plus tips on how you can improve your health status and “lower” your age. Such an approach may be useful for promoting a healthy lifestyle, but does not address the ultimate goal of being able to quantify the reserve of each organ system, including the brain, and predict the risk of common perioperative complications.

## The Physiology of Organ Aging

*If I'd known I was going to live this long, I'd have taken better care of myself.*

—James Hubert 'Eubie' Blake, age 100

Defining what constitutes “normal aging” is difficult. Is it what happens under

the best of circumstances, or what happens to the “average” person? Comparisons of young and elderly subjects may not strictly reflect aging, as the elderly subjects may have experienced a much different diet, lifestyle, and environmental exposure than what the young group will have experienced by the time they become old. Following a group of healthy subjects over a long period is more likely to define the effects of aging, but not all available data come from such longitudinal studies. Studies that examine only the very old may actually underestimate the typical effects of aging because individuals generally do not achieve old age unless there is something intrinsically robust about them. Lastly, the reader is reminded to keep two principles in mind. The effect of aging varies considerably from one patient to another, and, disease will interact with aging to further diminish functional organ reserve.

### **Changes in Body Composition, and Liver and Kidney Aging**

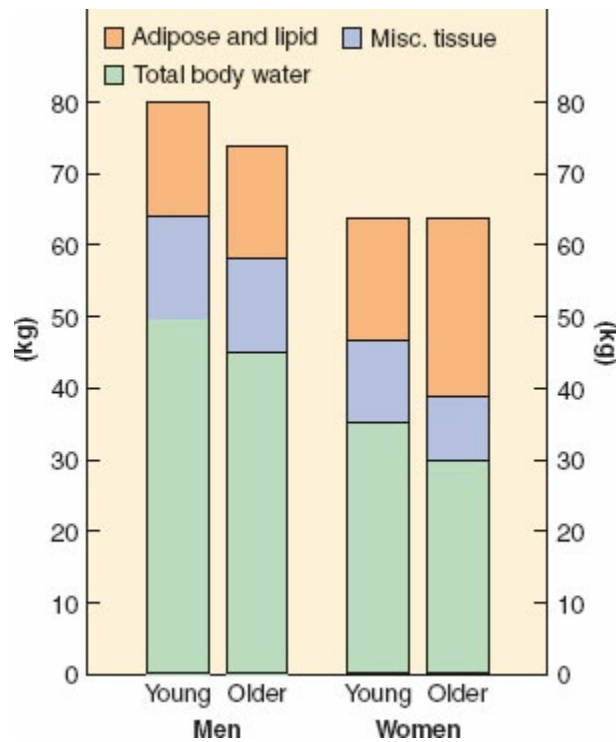

*I have everything I had twenty years ago, only it's all a little bit lower.*

—Gypsy Rose Lee

Changes in body composition are primarily characterized by a gradual loss of skeletal muscle and an increase in body fat, although the latter is more prominent in women (Fig. 34-3). Basal metabolism declines with age, with most of the decline accounted for by the change in body composition.<sup>27</sup> There is a reduction in total body water that reflects the reduction in cellular water that is associated with a loss of muscle and an increase in adipose tissue.<sup>28</sup> Aging causes a small decrease in plasma albumin levels; however, there is a small increase in  $\alpha_1$ -acid glycoprotein.<sup>29</sup> However, the effect of these changes on drug protein binding and drug delivery appear to be minimal.

Liver mass decreases with age, and accounts for most, but not all, of the 20% to 40% decrease in liver blood flow.<sup>30</sup> There is also a modest reduction in phase I drug metabolism and bile secretion with age. Other than the effect of aging on drug metabolism, liver reserve should be more than adequate even in the very old in the absence of disease.

Renal cortical mass also decreases by 20% to 25% with age, but the most prominent effect of aging is the loss of up to half of the glomeruli by age 80.<sup>31</sup> The decrease in the glomerular filtration rate of approximately 1 mL/min/yr after age 40 typically reduces renal excretion of drugs to a level where drug dosage adjustment becomes a progressively important consideration beginning at approximately age 60. Nevertheless, the degree of decline in glomerular filtration rate is highly variable and is likely to be much less than predicted in many individuals, especially those who avoid excessive dietary protein.<sup>32</sup>

**Figure 34-3** Age-related changes in body composition are gender-specific. In women, total body mass remains constant because increases in body fat (*upper shaded segment*) offset bone loss (*middle segment*) and intracellular dehydration (*lower shaded segment*). In men, body mass declines despite maintenance of body lipid and skeletal tissue elements because accelerating loss of skeletal muscle and other components of lean tissue mass produces marked contraction of intracellular water (*lower shaded segment*).

The aged kidney does not eliminate or retain sodium when necessary as effectively as that of a young adult.<sup>32</sup> Part of the failure to conserve sodium when appropriate may be because of reduced aldosterone secretion. Similarly, the aged kidney does not retain or eliminate free water as rapidly as young kidneys when challenged by water deprivation or free water excess. Lastly, the sensation of thirst declines with age. In short, fluid and electrolyte homeostasis is more vulnerable in the older patient, particularly when an older patient suffers acute injury or disease and eating and drinking becomes more of a chore.

For the most part, functional endocrine decline does not interact with anesthetic management to any significant degree. However, aging is associated with decreased insulin secretion in response to a glucose load, and also increased insulin resistance, particularly in skeletal muscle.<sup>33</sup> Thus, even healthy elderly patients may require perioperative insulin therapy more often than young adults. Aging also results in decreases in testosterone, estrogen, and growth hormone production.<sup>34</sup> The use of hormonal therapy to reduce sarcopenia, frailty in general, and cognitive decline and dementia is controversial, and does not have any current relevance to anesthetic management.

## Central Nervous System Aging

*By the time you're eighty years old you've learned everything. You only have to remember it.*

—George Burns

Brain mass begins to decrease slowly beginning at approximately age 50 and declines more rapidly later, such that an 80-year-old brain has typically lost 10% of its weight.<sup>35</sup> Neurotransmitter functions suffer more significantly, including dopamine, serotonin,  $\gamma$ -aminobutyric acid, and especially the acetylcholine system.<sup>36</sup> The latter is especially important because of its connection to Alzheimer disease. Response times increase, and learning is more difficult, but vocabulary, “wisdom,” and past knowledge are better preserved.<sup>35</sup> Nevertheless, of those individuals aged 85 and older, nearly half have significant cognitive impairment. In addition, some degree of atherosclerosis appears to be inevitable. Fortunately, and contrary to prior belief, the aged brain does make new neurons and is capable of forming new dendritic connections.<sup>37</sup>

The major effect of brain aging on anesthetic management is the increased sensitivity to many anesthetic agents. Perhaps the best-known example is the approximately 6% decrease in minimum alveolar concentration (MAC) per decade.<sup>38</sup> However, many intravenous agents also demonstrate an enhanced response in the older brain. These effects of aging are relatively simple to deal with in the clinical arena. More difficult to manage is the potential interaction of anesthesia, the stress of surgery, and a brain with minimal reserve. Age is a major risk factor for postoperative delirium and/or cognitive decline (see “Perioperative Complications”).

## Drug Pharmacology and Aging

*I don't do alcohol anymore. I get the same effect just standing up fast.*

—Unknown

Drugs typically have a more pronounced effect in an older patient. The cause can be either pharmacodynamic, in which case the target organ (often the brain) is more sensitive to a given drug tissue level, or pharmacokinetic, in which case a given dose of drug commonly produces higher blood levels in older patients.

Most intravenous anesthetic drugs are highly lipid soluble and so begin to enter tissue even before fully mixed in the blood. The rate of transfer depends on the rate of delivery (concentration times blood flow per gram of tissue), the concentration gradient of the drug between the blood and the tissue

(obviously a high gradient initially), the ease with which the drug crosses the blood and tissue membranes, and the solubility of the drug in the tissue. Thus, the vessel-rich group (brain, heart, kidney, muscle) will acquire drug much more rapidly than the vessel-poor group (fat, bone). Protein binding may affect transfer, with drugs that are highly protein-bound having a lower free concentration and a slower rate of transfer.

Given the preceding, there are many ways for a drug bolus to have a more pronounced initial effect on older patients. During the drug redistribution phase the blood concentration typically is higher in older patients, partly because of a mildly contracted blood volume and partly because the reduction in muscle mass limits the rate and amount of drug removal by muscle. By keeping drug blood levels higher for a longer time, more drug will be driven into the other organs of the vessel-rich group such as the brain (often the target organ) or heart. A prime example of this phenomenon is sodium pentothal, and to a lesser degree, propofol.<sup>39</sup>

Despite the fact that drugs typically have a greater effect on older patients, there is a general impression that bolus drugs take longer to achieve that greater effect. It is not entirely clear why this is so. Slower circulation is sometimes hypothesized, but total blood flow to any organ does not appear to decrease beyond that expected from the decrease in organ mass. Another possibility is a slower rate of transfer into the target organ. Drug effects are the result of tissue, not plasma concentrations. Brain-plasma equilibration is not instantaneous, and for at least some drugs (e.g., remifentanyl), the equilibration half-life is prolonged in older brains.<sup>40</sup> Why crossing the blood-brain barrier should take longer with age is not understood.

Ultimately, though, the drug will distribute throughout the body based on tissue mass and solubility. Because most intravenous drugs used in anesthesia are highly lipid-soluble, most of the drug will end up in fat. How completely the drug is dispersed out of the blood and into the tissue is reflected by  $V_{d_{ss}}$ , the drug's volume of distribution at steady state. This variable is expressed as the liters of plasma that would be necessary to dilute the amount of drug administered down to the concentration observed in the plasma. As such, drugs that are very fat-soluble can have a value for  $V_{d_{ss}}$  that is several times greater than total body water. After the initial redistribution into vessel-rich group tissue, the drug will slowly diffuse back into the plasma as it continues to be absorbed into fat. In so doing, the target organ (e.g., brain) drug level will fall because the target organ is always in the vessel-rich group. Once a single therapeutic dose of a drug has fully distributed throughout the body, the blood and target organ drug levels are typically too low to have a meaningful clinical effect. However, very large doses, repeated doses, or infusions will eventually deliver enough drug to yield residual drug levels that produce therapeutic effects. At this point, the only way to decrease blood

and target organ levels and eliminate the drug's effects is through metabolism. The elimination or metabolic half-life of a drug in the blood equals the volume of distribution at steady state ( $V_{d_{ss}}$ ) divided by the clearance, where clearance represents the amount of blood from which drug is eliminated per minute.

The most prominent and consistent pharmacokinetic effect of aging is a decrease in drug metabolism, typically due to both a decrease in clearance and an increase in  $V_{d_{ss}}$  (Fig. 34-4).

**Figure 34-4** The effect of age on the volume of distribution at steady state ( $V_{d_{ss}}$ ) for pentothal in women. (Reproduced with permission from Jung D, Mayersohn M, Perrier D, et al. Thiopental disposition as a function of age in female patients undergoing surgery. *Anesthesiology*. 1982;56:263.)

**Figure 34-5** The effect of age on the elimination half-life of diazepam. The half-life in hours is equal to approximately the patient's age in years. (Reproduced with permission from Klotz U, Avant GR, Hoyumpa A, et al. The effects of age and liver disease on the disposition and elimination of diazepam in adult men. *J Clin Invest*. 1975;55:347.)

The increase in  $V_{d_{ss}}$  with age is likely due to the increase in body fat. Clearance decreases with age for any drug metabolized by the liver or kidney. When drug metabolism is via the liver, decreased liver mass and blood flow

will decrease clearance for both high and low extraction drugs. In addition, elderly patients are often on a host of chronic medications, a setup for drug interactions as well as for inhibition of drug metabolism. Drugs with primarily renal elimination will experience decreased metabolism because of reductions in glomerular filtration rate with aging. The net effect on drug metabolism is typically a doubling of the elimination half-life between old and young adults. However, with some drugs, the effect on half-life can be dramatic. In the case of diazepam, the half-life in hours is roughly equal to the patient's age (Fig. 34-5).<sup>41</sup> For a 72-year-old person, it would therefore require 3 days to metabolize half of a dose of diazepam. Such pharmacokinetics clearly illustrate why there is no place in modern medicine for the chronic use of diazepam and other drugs with similar half-lives when the desired effect is supposed to be transient (e.g., as a sleeping aid).

When dealing with infusions—or for that matter a series of bolus injections—the time it takes to decrease the blood and target organ drug levels to below the therapeutic threshold will depend on many factors. This is where the concept of the context-sensitive half-time proves useful; that is, the time necessary for a 50% (or any desired percent) decrease in plasma concentration following termination of an infusion. At one extreme, if the residual level produced by the cumulative drug administration is still very low, and only a modest decrease in blood level is necessary to reverse the drug effect, then the rapid redistribution of the most recently administered drug will lead to a rapid decrease in the blood level and termination of effect. At the other extreme, if there has been significant accumulation of drug in the body, and/or the maintenance blood level was high, then a long time may be required to decrease the drug levels enough to terminate the drug effect. As a general rule, the time to decrease the effect site drug concentration is increased most dramatically by aging when a large percentage decrease in plasma level is necessary to dip below the therapeutic threshold.<sup>42</sup>

Review of the literature can yield a confusing picture when trying to sort out what pharmacologic variable is responsible for a given clinical effect. Fortunately, one does not need to know such details in order to use anesthetic drugs in an intelligent fashion with older patients. Table 34-1 summarizes some of this information for many of the common anesthetic drugs.<sup>42–45</sup> The effect of aging on sedative–hypnotic agents variably involves both pharmacodynamic and pharmacokinetic changes. For the opioids, the older brain appears to be more sensitive than that of young adults, whereas the pharmacokinetics of opioids are largely unaffected by age.

Despite the loss of muscle and motor neurons with age, muscle relaxants do not appear to be more potent in the older patient when steady-state blood levels for a given level of paralysis are compared.<sup>45</sup> Muscle relaxants often have a decreased initial volume of distribution, but this pharmacokinetic

change does not seem to translate into smaller doses. The most commonly used relaxants, vecuronium and rocuronium, have modestly slowed metabolism with aging, so an increased duration of effect should be expected, especially with repetitive dosing. As such, the older patient is at greater risk for residual neuromuscular blockade (see section on Intraoperative Management).

## Cardiovascular Aging

*A man is as old as his arteries.*

—Thomas Sydenham

Virtually all components of the cardiovascular system are affected by aging. The major changes include (1) decreased response to  $\beta$ -receptor stimulation; (2) stiffening of the myocardium, arteries, and veins; (3)  changes in the autonomic nervous system with increased sympathetic activity and decreased parasympathetic activity; (4) conduction system changes; and (5) defective ischemic preconditioning. Although atherosclerosis appears to affect everyone by virtue of the fact that the mechanisms of aging contribute to the development of atherosclerosis, it is not clear that it inevitably leads to functional impairment or disease.

With age, there is increased sympathetic activity at rest and there is typically an exaggerated response to stimuli that increase sympathetic activity.<sup>46</sup> Although there is decreased responsiveness of  $\alpha$ -receptors with age, the swings in sympathetic activation during surgery can still produce significant changes in vascular resistance during anesthesia. These changes in vascular resistance contribute to the lability in blood pressure in the aged, as well as to a decrease in blood pressure when anesthesia removes the sympathetic tone.<sup>47,48</sup>

The efficacy of baroreflex control of blood pressure decreases with age.<sup>49</sup> The mechanism is primarily a decrease in the heart rate response and not a decrease in the baroreflex control of vascular tone. The decreased heart rate response to changes in blood pressure is in part due to lesser vagal tone at rest but the major mechanism is a decrease in the cardiac response to  $\beta$ -receptor stimulation.<sup>48</sup> The mechanism does not appear to be a downregulation of  $\beta$ -receptors on the heart, but a defect in the intracellular coupling. Both heart rate and contractility increase less in response to endogenous release or exogenous administration of catecholamines. The increase in heart rate with exercise is therefore also diminished, as is maximal heart rate (often quoted as 220 minus age), and the decrement contributes to the decreased exertional capacity with age, even in trained individuals. The decrease in resting vagal tone may limit the increase in heart rate after

administration of atropine or glycopyrrolate.

Conductance artery (aorta to arterioles) stiffening typically leads to systolic hypertension via two mechanisms.<sup>50,51</sup> First, approximately half of the stroke volume remains in the thoracic aorta after ejection. Pressure must increase more to stretch out a stiffened aorta to accommodate that volume. Secondly, generalized arterial stiffening causes the pressure wave to transmit more rapidly. In everyone, the pressure wave reflects off the arterial walls and branch points and returns to the thoracic aorta. The reflected waves return more rapidly in an older person because of the stiffer vessels. In young people, the reflected waves do not return to the heart until after ejection is complete. These waves are responsible for the modest bump in pressure in the aortic root just after the aortic notch. But in older people, the reflected waves return to the heart by late ejection and increase the pressure against which the left ventricle must pump to complete the stroke volume. At the end of ejection the ventricular contraction weakens, so ideal coupling would have the ventricle pushing against an ever-decreasing pressure. Since in the older person the ventricle must now pump against a higher pressure, this increased stress to the muscle stimulates hypertrophy.

**Table 34-1** Effect of Age on Drug Dosing

Drug	Bolus Administration	Multiple Boluses or Infusion	Comments <sup>a</sup>
Propofol	20–60% reduction, dose on lean body mass, 1 mg/kg in very old	50% reduction, infusions beyond 50 min progressively increase the time required to decrease the blood level by 50% (but effect site levels may decrease faster in elderly)	↑ brain sensitivity (by some reports), decreased $V_{cen}$ , slowed redistribution
Dexmedetomidine	Consider reduction	Consider reduction	Higher incidence of bradycardia and hypotension
Thiopental	20% reduction	20% reduction	= brain sensitivity, decreased $V_{cen}$ , slowed redistribution
Etomidate	25–50% reduction	—	= brain sensitivity
Midazolam	Compared to age 20, modest reduction at age 60, 75% reduction at age 90	Similar to bolus (metabolic $t_{1/2}$ longer, but not meaningful unless very large doses are used)	↑↑ brain sensitivity
Morphine	Probably 50% reduction. Peak morphine effect is 90 min (though half of peak effect at 5 min)	Long effect site equilibration time translates into very slow reduction in effect on termination of infusion (4 hrs for 50% reduction)	Metabolite morphine-6-glucuronide build-up requires prolonged morphine use, but its renal excretion will make it very long acting
Fentanyl	50% reduction	50% reduction	↑ brain sensitivity, minimal changes in pharmacokinetics; delayed absorption from fentanyl patch
Alfentanil, sufentanil	50% reduction	50% reduction	Probably ↑ brain sensitivity, minimal changes in pharmacokinetics
Remifentanyl	50% reduction	50% reduction	Slower blood–brain equilibration, suggesting slower onset and offset, modest decreased $V_{cen}$
Hydromorphone	No studies on aging exist, but assume increased potency in elderly	Assume 50% reduction	Compared with morphine, no active metabolite, faster onset
Methadone	No studies on aging exist, but assume increased potency in elderly	Assume 50% reduction	—
Meperidine	Use only for postoperative shivering	Do not use	Toxic metabolite normeperidine, whose renal excretion decreases with age
Vecuronium	Slower onset (= 33%)	Slower recovery times	Slightly greater liver metabolism than renal, age nearly doubles metabolic $t_{1/2}$
Mivacurium	Equally fast onset in young and old	Modest dose reduction for infusion, longer recovery time on repeated bolus	Elimination by plasma cholinesterase, modest prolongation of metabolic $t_{1/2}$ by age
Cisatracurium	Slower onset (= 33%)	No significant changes with age	Mostly Hoffmann elimination, modest prolongation of metabolic $t_{1/2}$ by age
Rocuronium	Minimally slower onset	—	Liver metabolism slightly greater than renal, modest increase in metabolic $t_{1/2}$ by age
Pancuronium	—	—	Primarily renal elimination, aging doubles metabolic $t_{1/2}$
Pipecuronium	Slower onset (= 50%), elderly may be <i>less</i> sensitive	—	Primarily renal elimination, no apparent change in metabolic $t_{1/2}$
Succinylcholine	Slower onset (= 40%)	—	—
Edrophonium	Similar dosing and onset	—	↑ $V_{cen}$ , primarily renal elimination, modest increase in metabolic $t_{1/2}$ by age
Neostigmine	Despite pharmacokinetic changes, some studies indicate need for increased dose with age	—	↑ $V_{cen}$ , hepatic elimination, modest increase in metabolic $t_{1/2}$ by age

<sup>a</sup> $V_{cen}$ , central volume of distribution or initial volume of distribution. Although  $V_{cen}$  does not have an anatomic correlate, a smaller  $V_{cen}$  will increase initial plasma levels and enhance transfer of the drug in the target organ (e.g., brain, muscle).

Hypertrophy in and of itself stiffens the ventricle, but even worse, hypertrophy slows diastolic relaxation that, in turn, impairs ventricular filling

in early diastole. The left ventricle now becomes more dependent on the atrial kick and requires an increase in left atrial pressure in order to preserve diastolic filling. The increase in atrial pressure is present at rest, but can be quite dynamic with acute increases during stress such as tachycardia. This phenomenon, termed diastolic dysfunction, increases in severity with age. The majority of cases of congestive heart failure in very old persons are due to diastolic dysfunction and occur in the absence of clinically significant systolic dysfunction.<sup>48,52</sup>

Adequate ventricular filling becomes more critical with age. The decreased response to  $\beta$ -receptor stimulation requires the ventricles to depend more on an adequate end-diastolic volume to generate enough contractile strength via the length–tension (Frank–Starling) relationship. The diastolic dysfunction requires an increase in central and pulmonary venous pressure to maintain that end-diastolic volume. The range in acceptable filling pressures ends up becoming narrower with age because too low a pressure results in inadequate filling. Since the normal pressure is already elevated, any further increase is that much closer to a pressure that results in fluid extravasation and adverse consequences such as pulmonary edema.

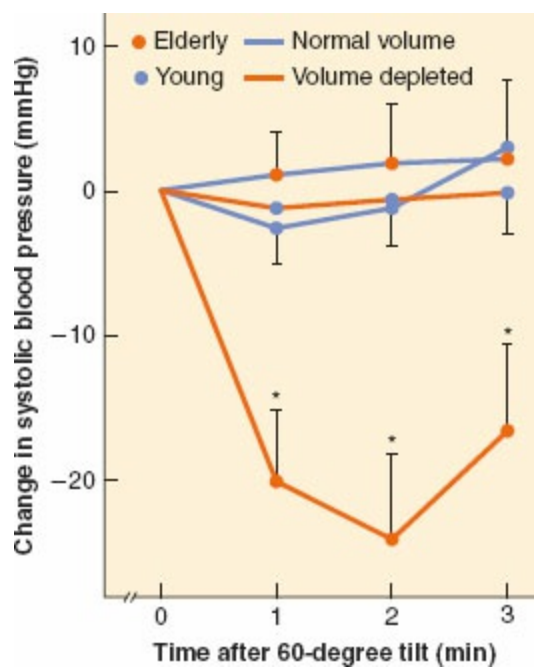

Unfortunately, aging also decreases the ability to maintain filling pressures in the acceptable range. In everyone, the veins serve as a reservoir for blood and serve to buffer changes in blood volume in order to maintain ventricular filling at an appropriate level. However, veins stiffen with age.<sup>53</sup> Venous stiffening impairs this buffering capacity and creates a situation where modest changes in venous blood volume may produce more dramatic changes in venous pressures and cardiac filling. In short, the system has become  inherently more unstable as illustrated by the development of postural hypotension in elderly persons but not in young adults with mild hypovolemia (Fig. 34-6).<sup>54</sup>

Rhythm disturbances may develop with age. Fibrosis of the conduction system may lead to conduction blocks, and loss of sinoatrial node cells may make the older patient more prone to sick sinus syndrome. The prevalence of atrial fibrillation climbs exponentially with age, perhaps in part because of atrial enlargement.

Aging appears to diminish or even eliminate any protective effect of ischemic preconditioning, a phenomenon whereby a brief period of myocardial ischemia will lessen the adverse effects of a subsequent, more prolonged ischemic event. “Warm-up angina” is the ability to achieve a higher level of exertion after first exercising to the point of angina. Starting around age 65 the increment in the level of exertion progressively diminishes with age.<sup>48</sup> In younger adults, death or heart failure is a less frequent complication of a myocardial infarction if the patient had been experiencing angina within 2 weeks of the myocardial infarction. This protective effect of angina is not

present in older adults.<sup>48</sup>

This section began with a quote from Thomas Sydenham. Evidence is mounting that the quote is truly prophetic: arterial stiffening may indeed be a marker of physiologic age. One of the manifestations of arterial stiffening is a widened pulse pressure. Once the difference between systolic and diastolic pressure reaches 80 mmHg or more, there is a clear association with all-cause mortality; cardiovascular mortality; and a variety of morbidities including stroke, coronary disease, and renal failure.<sup>50,55</sup> Increased pulse pressure is also associated with increased morbidity and mortality after coronary artery bypass grafting.<sup>50</sup>

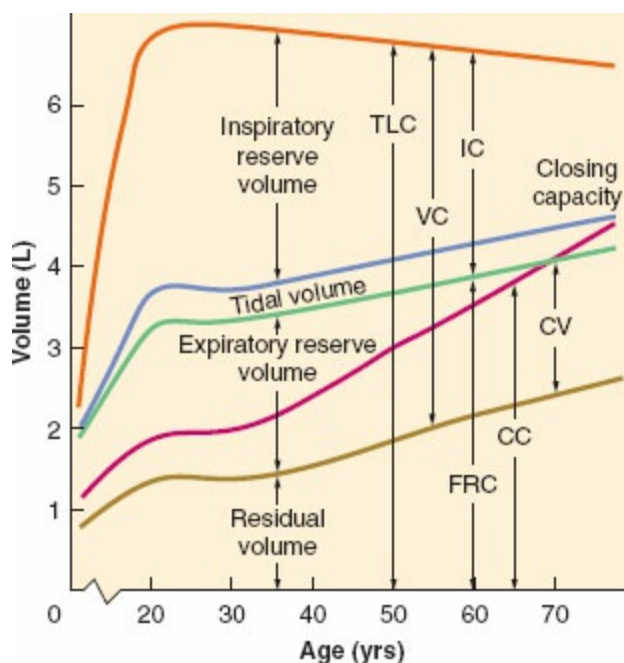

**Figure 34-6** Young and elderly adults are subjected to a passive tilt test in their euvoletic state and after an approximate 2 kg of water and 100 mEq of sodium loss. With tilt, blood pools in the legs. Although young subjects tolerate tilt under both circumstances, the combination of hypovolemia and tilt exceeds the compensatory mechanisms of the older subjects. (Reproduced with permission from Shannon RP, Wei JY, Rosa RM, et al. The effect of age and sodium depletion on cardiovascular response to orthostasis. *Hypertension*. 1986;8:438.)

## Pulmonary Aging

The most prominent effects of aging on the pulmonary system are increased stiffness of the chest wall and a decreased stiffness of the lung parenchyma.<sup>56,57</sup> With aging, the thorax becomes more barrel-shaped which leads to flattening of the diaphragm. Less diaphragmatic curvature provides a mechanical disadvantage for the generation of negative pressure in the intrapleural space. The stiffened chest wall and flattened diaphragm increase the work of breathing. Combined with an age-related loss of muscle mass, it

is easy to understand how the older patient will be more prone to fatigue when challenged by an increase in minute ventilation, and thus more likely to experience respiratory failure.

The decrease in lung tissue stiffness is due to a loss of elastin with age. Unlike elsewhere in the body, the elastin is not replaced with collagen and so older lungs become easier to inflate. There are several adverse effects of this increase in compliance. Small airways do not have enough inherent stiffness and so depend on tethering by the surrounding tissue to remain open. The degree of outward pull by the tissue depends on the stiffness of the tissue and the degree of stretch of the tissue. As the tissue loses its springiness, greater lung inflation is needed to produce the same amount of outward pull on the airways. The need for greater lung inflation to prevent small airway collapse is reflected by the increase in closing capacity with age (Fig. 34-7). Closing capacity typically exceeds functional residual capacity in the mid-60s, and will eventually exceed the tidal volume at some later age. Decreased lung tissue stiffness also increases ventilation—perfusion mismatch as each piece of lung tissue is less tethered to its neighbor, making ventilation less uniform. These changes, plus a modest reduction in alveolar surface area with age, contribute to a modest decline in resting PaO<sub>2</sub> with age.<sup>58</sup>

**Figure 34-7** Effect of aging on lung volumes. With age, inspiratory capacity (IC) is compromised because of the combined effect of modest decreases in total lung capacity (TLC) and modest increase in functional residual capacity (FRC). Vital capacity (VC) decreases because of the decrease in IC and the increase in residual volume. However, the most dramatic change with aging is the increase in closing volume (CV) and closing capacity (CC) such that in very old persons, closing capacity exceeds functional residual capacity. (Adapted from Smith TC. Respiratory system: aging, adversity, and anesthesia. In: McLeskey CH, ed. *Geriatric Anesthesiology*. Baltimore,

Less-effective small airway tethering also leads to greater limitations during forced exhalation. At all ages, forced exhalation produces positive pressures in the intrapleural space that tends to compress intrathoracic airways. Only the airway connective tissue and lung tissue tethering oppose that compression. With less lung tissue tethering, airways compress at a larger lung volume in older subjects and produce a limitation in air flow during exhalation over a much larger percentage of the exhalation (e.g., the last 45% in a 70-year-old person) than in a younger subject (e.g., 20% in a 30-year-old person).<sup>59</sup>

Changes within the nervous system further influence the respiratory system. Aging leads to an approximate 50% decrease in the ventilatory response to hypercapnia, and an even greater decrease in the response to hypoxia, especially at night.<sup>60</sup> Generalized loss of muscle tone with age applies to the hypopharyngeal and genioglossal muscles and predisposes elderly persons to upper airway obstruction. A high percentage, perhaps even 75%, of people over age 65 have sleep-disordered breathing, a phenomenon that may or may not be the same as sleep apnea, but certainly places the elderly people at increased risk of hypoxia postoperatively.<sup>61</sup> Aging also results in less-effective coughing and impaired swallowing. Aspiration is a significant cause of community-acquired pneumonia and may well play a role in the development of postoperative pneumonia.<sup>62</sup>

### *Thermoregulation and Aging*

In the past two decades there has been heightened awareness of the adverse consequences of perioperative hypothermia as well as improved methods to prevent hypothermia. Even outside the operating room, elderly individuals are prone to hypothermia when stressed by modestly cold environments that would not affect younger individuals. The initial response to a cold environment is vasoconstriction, and if that response is insufficient and the subject becomes colder, then shivering is the second response. Both mechanisms are triggered by decreases in core and/or skin temperature. The two temperatures interact such that a decrease in skin temperature of 1° is equivalent to a decrease in core temperature of approximately 0.2°.<sup>63</sup> Although there is great variability among the elderly over the degree to which vasoconstriction and shivering are impaired, one should anticipate that elderly patients will have not only impaired vasoconstriction but also decreased heat production due to a lower metabolism.<sup>64</sup>

At all ages, both inhalational and some intravenous agents (e.g., propofol and alfentanil but not midazolam) alter the regulatory thresholds such that

body temperature must fall by as much as 4°C (7°F) before initiation of vasoconstriction or shivering. Aging further impairs the thresholds, by approximately 1°C (2°F), not only during general anesthesia but during spinal anesthesia as well.<sup>63</sup>

Given the impaired temperature regulation and decreased heat production of the elderly, it is not surprising that hypothermia occurs more frequently in older patients.<sup>65</sup> The risks of hypothermia include myocardial ischemia, surgical wound infection, coagulopathy with increased blood loss, and impaired drug metabolism.<sup>63</sup> Shivering places a significant metabolic stress on a patient and may not be well tolerated by a patient with borderline cardiac or pulmonary reserve. The prevention and treatment of hypothermia in an elderly patient does not appear to be any different than for younger adults.

## Conduct of Anesthesia

*We've put more effort into helping folks reach old age than into helping them enjoy it.*

—Frank A. Clark

### The Preoperative Visit

The preoperative visit can be extremely important in the care of the elderly patient. Although the goals of the visit are no different than for any other patient, there are issues more common among the elderly population that should be raised. For example, will the patient's living situation provide the support necessary for a successful recovery? An aged spouse may not be physically capable of helping the patient dress, bath, or perform some other activity of daily living (ADL) that the surgery temporarily prevents the patient from performing. Furthermore, elderly patients may require a long time to return to their preoperative level of function, assuming full recovery is even possible. For example, after major abdominal surgery, most older patients require at least 3 months for ADLs and independent ADLs to return to baseline.<sup>66</sup> Persistent disability at 6 months varies with the task. Although there is only a 9% incidence of persistent ADL deficits, there is a 19% incidence of deficit in independent ADLs, and a 52% incidence of diminished grip strength.

Older patients often recognize that the end of their lives is no longer the theoretical consideration of youth, so they are more likely to have living **5** wills, health-care proxies, and health-care directives in place at the time of surgery. Yet they often have surgery near the end of life. A retrospective cohort survey of elderly Medicare beneficiaries found that almost a third undergo surgery in their last year of life and that over 18% undergo surgery

in the last month of their lives.<sup>67</sup> The older patient's expectations from surgery may be much different than that of their younger counterparts, and medical practitioners must be careful not to judge a patient's decision-making based on the practitioner's values or expectations. The prospect of functional impairment may be more worrisome to the older patient than even death. Such personal values are particularly important when questions of competence arise and the physician could be tempted to question competence if the patient's decision does not coincide with the opinion of the physician.<sup>68</sup> A discussion of risks and benefits needs to include the probable degree of functional recovery and the speed with which that recovery is likely to occur. If health-care directives prohibit various life-sustaining or resuscitative procedures, the patient/proxy and anesthesiologist must come to a mutual understanding of what will or will not be performed if an untoward event occurs in the perioperative period.

Polypharmacy and drug interactions are a huge problem for the elderly. As much as 30% of ambulatory older adults require medical care for adverse drug events, and upward of 30% of hospitalizations in the elderly are related to drug effects.<sup>69</sup> In fact, one of the major goals of geriatric consult services to surgical patients is to pare down those medications whenever possible. The anesthesiologist can help by alerting the primary care team to this issue and suggest a geriatric consult. In the very old, dehydration, elder abuse, and malnutrition are all more common than generally appreciated. In the case of malnutrition, the deficit may be limited to isolated deficiencies such as vitamin D or B<sub>12</sub>, or it may be more global and include inadequate caloric intake from poor oral hygiene or the "anorexia of aging," in which neuroendocrine changes lead to early satiety and diminished sense of taste.<sup>70</sup> Nutritional status is an underappreciated risk factor for surgery. In fact, the Veterans Affairs National Surgical Quality Improvement Program found albumin to be as sensitive an index for mortality or morbidity as any other single indicator, including the American Society of Anesthesiologists status.<sup>71</sup>

Clearly there are many issues surrounding surgery in the elderly that are rarely present with younger patients. Integration of the patient's medical status, the impact of surgery, and the patient's goals require a comprehensive approach that encompasses both preoperative optimization and potentially prolonged postoperative recovery. For these reasons the aged are an important opportunity for the potential advances offered by the PSH.<sup>72</sup> The ASA supported initiative of PSH is a patient-centered, physician-led, interdisciplinary, and team-based care model, that strives to achieve better health, better health care, and reduced expenditures by implementing multidisciplinary interventions as soon as need for surgery or procedure is identified.<sup>73</sup> In the preoperative period coordination of care, cost-effective testing and consultation and development of discharge and transition plans

are started immediately leading to identification of patients who need specialized care and interventions to optimize preoperative status and improve the likelihood of maintained, if not improved, functional status after surgery.

## *Intraoperative Management*

There are no magic bullets for the induction of general anesthesia in older patients. The effects of a bolus induction dose on a single patient are highly variable, so admittedly there is a certain amount of guesswork. In general, smaller doses are needed in comparison with young adults, and the efficacy of using a lesser amount becomes more apparent if more time is allowed for the drug to achieve its peak target organ (brain) effect. A given blood level of propofol causes a greater decrease in brain activity in an older patient, but the decrease in blood pressure is even more dramatic in comparison to the decrease observed in young adults.<sup>74</sup> Many strategies can be used to minimize the decrease in blood pressure, but most attempt to reduce the amount of propofol with the use of adjuncts such as opioids, or combining small doses of propofol with etomidate. Some advocate induction with a propofol infusion of 400 µg/kg/min until the bispectral index (BIS) reaches 60 to lessen the risk of overdose.<sup>43</sup> Etomidate has been observed to produce less hypotension than propofol in older patients.<sup>75</sup> Care must be taken, though, not to underdose at induction. It can be argued that an excessive hypertensive response to intubation may be more harmful than a brief period of hypotension. One must expect that significant changes in blood pressure, up or down, will occur, and the sooner the practitioner recognizes those changes, the quicker the aberration can be treated. Cycling the blood pressure cuff every minute should alert the practitioner to these changes sooner than would less frequent cycling. Although swings in blood pressure may not be desirable, there is little evidence that even major, but brief, changes in blood pressure lead to adverse outcomes.

Whether general or neuraxial anesthesia is used, the maintenance phase of anesthesia will commonly result in a significant decrease in systemic blood pressure, more so than typically occurs in younger patients.<sup>76</sup> Although decreases in both systemic vascular resistance and cardiac output likely occur, the decrease in vascular resistance is probably the largest contributor, although this observation has really been confirmed only during spinal anesthesia.<sup>47</sup> Figure 34-8 demonstrates this large decrease in vascular resistance and further shows that venous pooling is responsible for a decrease in preload that in turn decreases cardiac output. However, the afterload reduction from the decrease in blood pressure presumably allowed the ejection fraction to increase, thereby ameliorating the effect the decrease in

6

end-diastolic volume had on stroke volume. Because vascular resistance contributes significantly to the decrease in blood pressure during anesthesia, it has been argued that the use of  $\alpha$ -agonists is an appropriate therapy and may be more effective than volume alone.<sup>48</sup>  $\alpha$ -Agonists also tend to promote venoconstriction, thereby shifting blood back to the central circulation and reducing the decrease in ventricular preload by venous pooling, and presumably reducing the need for at least some volume administration. Although no one would advocate vasoconstriction as a treatment for hypovolemia (except as a stopgap measure), the ventricle can only get so big; therefore, it is impossible for volume administration alone to raise cardiac output enough to compensate for a large decrease in vascular resistance. Furthermore, when sympathetic nervous system activity returns postoperatively, blood will shift from the periphery to the central circulation. Excess peripheral volume now becomes excess central volume and could push an elderly heart into diastolic heart failure. In short, volume administration to an older patient may be problematic, with a very fine line between too much and too little, and what was “just right” in a deeply anesthetized state may become “too much” later on.

**Figure 34-8** The response to total sympathectomy from spinal anesthesia as illustrated in older men with cardiac disease. Over 70% of the decrease in mean arterial blood pressure (MAP) was due to a decrease in systemic vascular resistance (SVR). Cardiac filling (EDV, end-diastolic volume) was markedly diminished, but its effect on stroke volume (SV) and cardiac output (CO) was ameliorated by an increase in ejection fraction (EF). Although heart rate (HR) increased in some subjects and decreased in others, the overall effect was no change. (Reproduced with permission from Rooke GA, Freund PR, Jacobson AF. Hemodynamic response and change in organ blood volume during spinal anesthesia in elderly men with cardiac disease. *Anesth Analg.* 1997;85:99. Copyright © 1997 International Anesthesia Research Society.)

The choice between an endotracheal tube and a laryngeal mask airway

involves many considerations, including body habitus, apparent frailty, surgical positioning, risk of regurgitation, and duration of surgery (see [Chapter 29](#)). An endotracheal tube will likely have more adverse effects than a laryngeal mask on mucociliary clearance and possibly on swallowing. The advantage of an endotracheal tube is in the ability to guarantee control of ventilation and thereby greater ability to prevent hypercarbia and intraoperative atelectasis.

If positive-pressure ventilation is utilized, one important goal is to have the lung volume exceed closing capacity during the respiratory cycle in order to prevent atelectasis. Two approaches have been advocated: high tidal volumes versus modest tidal volumes (generally accompanied by positive end-expiratory pressure [PEEP]). Initial studies found that the low tidal volume strategy tended to be associated with lower levels of inflammatory markers.<sup>77</sup> More recently, studies have appeared that document a decreased incidence of perioperative pulmonary complications with the use of modest tidal volumes, a conclusion best summarized in a meta-analysis.<sup>78</sup> Consequently, the modest tidal volume strategy plus PEEP as needed appears to be the preferred approach.

Another aspect of anesthetic management that is likely deleterious to the aging pulmonary system is the presence of residual neuromuscular blockade. Initially observed with pancuronium, intermediate acting neuromuscular blocking agents have also been implicated and the phenomenon is associated with adverse respiratory events such as hypoxia and airway obstruction.<sup>79</sup> Further complicating this picture is the observation that the use of neostigmine reversal may actually worsen residual blockade.<sup>80,81</sup> The adverse effect of neostigmine may be ameliorated by the use of neuromuscular transmission monitoring, presumably by permitting selection of an appropriate dose of neostigmine,<sup>82</sup> but even this observation is controversial.<sup>81</sup> Nevertheless, at least one study has shown that older patients (average age 75) are at almost double the risk of residual neuromuscular blockage and adverse respiratory events in comparison to middle-aged adults.<sup>83</sup> This observation argues for very careful use of nondepolarizing muscle relaxants in older patients.

## **Postoperative Care**

The goals of emergence and the immediate postoperative period are no different for an elderly than a young patient; they are just more difficult to achieve. Analgesia is a major goal, and it should be stated up front that there is no evidence that pain is any less severe or any less detrimental in an older patient than in young patients. Less drug may be required (or not), but given that the standard approach to analgesia is to titrate to the desired effect, the

outcome should be good pain relief for patients of any age. However, there are impediments to achieving adequate analgesia in an older patient.<sup>84</sup> Elderly patients sometimes underreport their pain level and may be more tolerant of their acute pain, perhaps partly because of the existence of chronic pain in their life. Older patients have more difficulty with visual analog scoring systems than verbal or numeric systems. If the patient is cognitively impaired, communication of pain is further impaired; indeed, demented patients often experience severe pain after hip surgery, but even mild cognitive impairment can lead to problems with pain assessment or with use of a patient-controlled analgesia machine.

Failure to achieve adequate levels of analgesia is associated with numerous adverse outcomes, including sleep deprivation, respiratory impairment, ileus, suboptimal mobilization, insulin resistance, 7 tachycardia, and hypertension. The apparent paradox of adequate analgesia is that opioids are the mainstay of postoperative analgesia, and opioids are capable of producing many of those same adverse outcomes. Therefore, as with all medical care of elderly patients, good judgment, caution, and frequent monitoring of analgesia and adverse effects are essential. Adjunctive medications such as nonsteroidal anti-inflammatory drugs have been shown to reduce opioid requirements and some of the opioid adverse effects, but often carry their own risks such as renal damage or gastrointestinal toxicity.<sup>84</sup> Epidural analgesia is well known to provide analgesia that is superior to intravenous therapy, a finding that has been specifically replicated in the elderly.<sup>85,86</sup> Although improved cardiopulmonary outcomes were equivocal, more rapid return of bowel function, earlier mobilization, and nutritional status were better with epidural analgesia.

Although many aspects of postoperative care are more likely to be the purview of the surgeon or the internist, there are some things that the anesthesiologist could and probably should be watchful for when performing a postoperative visit on an older patient. If a patient had a surgery with major fluid requirements, it is important to look for signs of fluid overload, including rales, dyspnea, tachypnea, and orthopnea, particularly around postoperative day 2 when third space fluid tends to mobilize. A timely administration of a diuretic may prevent the development of overt pulmonary edema and the accompanying escalation of therapy and risk. Feel the pulse: atrial fibrillation is often intermittent and the more often someone looks for it, the more likely it will be detected. Delirium often goes undetected in older patients, in part because it may come and go. Take the time to chat with the patient for a few minutes. It should not be difficult to become suspicious if the patient demonstrates waxing and waning alertness, is inattentive or distractible, displays rambling or incoherent speech, is disoriented, or has perceptual disturbances. It has been demonstrated that overall recovery and

avoidance of complications, including delirium, pneumonia, uncontrolled pain, infection, and length of stay, can be enhanced by comprehensive evaluation and management of risk factors.<sup>87,88</sup> Anesthesiologists should be prepared to support such programs as much as possible.

## *Perioperative Complications*

*My diseases are an asthma and a dropsy and, what is less curable, seventy-five.*

—Samuel Johnson

The older patient is at increased risk for complications in the perioperative period, in part from comorbid disease and in part from the reduction in organ system reserve due to the aging process. Whether the aging process can be thought of as mere decreased reserve or subclinical disease is a matter of semantics. The result is the same: the elderly are at increased risk for almost every possible perioperative complication including cardiovascular, pulmonary, renal, central nervous system, wound infection, and death.<sup>89–91</sup>

There is increasing evidence that anesthetic management may influence long-term outcomes. The elderly are particularly sensitive to the effect of anesthetics and thus may be more susceptible to the detrimental effects of anesthesia. Although specific sensitivity to anesthesia is difficult to define, several lines of evidence suggest that it can be attained by clinically available modalities. For example, an intraoperative state of “triple low” (low concentrations of volatile anesthetics that is accompanied by low blood pressure and a deep hypnotic level as defined by a BIS monitor) is associated with longer hospital stay and increased 1-month mortality.<sup>92</sup> Although association does not imply causation and the “triple low” state may merely be a marker of low physiologic reserve, it is possible that identification of sensitivity may lead to improved outcomes. Additional studies show an association between intraoperative hypotension and other 1-month adverse outcomes including cardiac events, kidney dysfunction, and possibly stroke.<sup>93–96</sup> Age above 68 was an independent risk factor in one of these studies.<sup>94</sup> Another study that looked at 1-year mortality found no relation to intraoperative hypotension in the younger adult population, but found that the elderly subjects had a higher 1-year mortality that corresponded to the duration of the intraoperative hypotension.<sup>97</sup> Again, whether the hypotension is causal or just a marker is not clear, but these studies do suggest that permitting prolonged hypotension may not be a good idea.

Anesthesiologists who care for the elderly frequently face a worrisome query: does the choice of anesthetic technique (regional vs. general) or depth of anesthesia, affect outcome? With an estimated annual incidence of more than 1.5 million cases worldwide, operative fixation of hip fractures is the

classical case in question. Hip fractures carry an ominous inhospital and 30-day mortality (roughly 5% to 10%) with high rates of cardiovascular and pulmonary complications and substantial postoperative disability. Any potential improvement for this vulnerable group has far reaching social and economic implications. Initially a meta-analysis of 141 clinical trials prompted the use of regional anesthesia as it found a reduction in postoperative mortality compared to general anesthesia.<sup>98</sup> However, some of the quoted studies were small, some had methodologic flaws and some were conducted over three decades ago. Although a large retrospective observational study from Taiwan found more adverse outcomes in patients who had general anesthesia when compared to neuraxial anesthesia,<sup>99</sup> recent observational studies examining large cohorts in United States and England did not find mortality rate differences between general and regional anesthesia.<sup>100–102</sup> A large, prospective multicenter clinical trial (REGAIN—REgional versus General Anesthesia for promoting INdependence after hip fracture) is scheduled to enroll 1,600 patients with the goal of comparing outcomes of those treated with spinal versus general anesthesia and would potentially provide insight into this important question.

Because the mechanisms of aging contribute not only to normal aging but also to the development and severity of disease, one might expect that age and disease would interact in their contribution to perioperative risk. **8** Confirmation of such a hypothesis is provided by a prospective survey of nearly 200,000 anesthetics in France.<sup>103</sup> Both age and the number of chronic diseases are associated with an increased rate of complications, but what is particularly interesting is an apparent interaction of these two factors. **Figure 34-9** demonstrates that, for any given age group, the number of complications increases with the number of comorbid diseases. To be young and sick likely represents a special case as suggested by the point representing the no more than 34-year-old group with three or more comorbid diseases. Ignoring that outlier, connecting the dots of equal number of comorbid disease reveals a modest increase in risk with age for patients with zero comorbid disease, but examination of points for one, two, or three or more diseases reveals an effect of age that becomes increasingly larger. In other words, age appears to interact with comorbid disease to increase risk.

Complications of the cardiovascular and pulmonary systems are associated with the greatest perioperative mortality. The best database is provided by the Veterans Affairs National Surgical Quality Improvement Project, and much of the database involves examination of patients older than 80 (**Table 34-2**).<sup>90</sup> Although the perioperative complications of myocardial infarction or cardiac arrest carry higher associated mortality rates than pneumonia, prolonged intubation, or reintubation, the higher incidences of the pulmonary complications suggest that greater mortality results from pulmonary

complications than from cardiac complications. That pulmonary complications are so significant underscores the need for a better understanding of the mechanism of postoperative pneumonia, particularly the likely contribution of silent aspiration.<sup>104</sup>

**Figure 34-9** The interaction between age and comorbid disease. For each age bracket, as comorbid disease increases, so does the rate of complications. The effect of age on the complication rate is best visualized by examining points of equal comorbid disease. At zero disease, only a modest increase in complications is observed with increasing age. At ever-increasing degrees of comorbid disease, however, the increase in complications with age becomes more and more pronounced. With kind permission from Springer Science+Business Media.)

**Table 34-2** Effect of Age on Selected Perioperative Complications and Associated Mortality<sup>a</sup>

Complication	Complication Rate		Mortality Rate from the Complication	
	Age <80	Age ≥80	Age <80	Age ≥80
Myocardial infarction	0.4	1.0	37.1	48.0
Cardiac arrest	0.9	2.1	80.0	88.2
Pneumonia	2.3	5.6	19.8	29.2
>48 hrs on ventilator	2.1	3.5	30.1	38.5
Required reintubation	1.6	2.8	32.3	44.0
Cerebrovascular accident	0.3	0.7	26.1	39.3
Coma >24 hrs	0.2	0.3	65.9	80.9
Prolonged ileus	1.2	1.7	9.2	16.0

<sup>a</sup>All differences between patients less than 80 versus 80 and older are significant at  $p < 0.001$ , except for coma mortality ( $p = 0.004$ ). Modified from Hamel MB, Henderson WG, Khuri SF, et al. Surgical outcomes for patients aged 80 and older: morbidity and mortality from major noncardiac surgery. *J Am Geriatr Soc.* 2005;53:424.

Central nervous system complications are also a major source of morbidity and mortality. The most burdensome problems appear to be stroke, postoperative delirium, and postoperative cognitive decline. All have the potential to cause debilitating morbidity and an adverse impact on the patient's quality of life, their families, and the cost of medical care. Postoperative cognitive dysfunction (POCD) is a highly controversial topic in geriatric anesthesia, primarily because of the concern that general anesthesia may play an etiologic role.

In a nonsurgical elderly population, there is an annual stroke incidence of approximately 1%. The incidence of perioperative stroke in the older general surgical population is approximately 0.5% (Table 34-2).<sup>90,105-107</sup> Risk factors include age, atrial fibrillation (odds ratio 2.0), history of a prior stroke or TIA (odds ratio at least 1.6), recent myocardial infarction, COPD or current smoking, acute renal dysfunction or chronic dialysis, the type of surgery, and a variety of comorbid diseases including diabetes and renal or cardiovascular disease.<sup>105-109</sup> A particularly interesting risk factor, at least for cardiac surgery patients, is an elevated arterial pulse pressure.<sup>110</sup> This finding supports the concept that age-related changes can influence perioperative risk just as it appears to influence morbidity in the general population. The PeriOperative ISchemic Evaluation study (POISE) raised the issue of perioperative  $\beta$ -blockade increasing the risk of stroke, but when chronic, less intense  $\beta$ -blockade is used that risk is not present.<sup>111,112</sup> Strokes typically occur well after surgery, on average 7 days later, although upward of half occur within 24 hours.<sup>105,107</sup> Most perioperative strokes are ischemic and presumably from thromboembolism originating in the heart or arteries. The contribution of hypotension to focal stroke is questionable, although the POISE study could be cited as evidence that hypotension increases stroke risk.<sup>107</sup> Mortality after a perioperative stroke is approximately twice that of a stroke in the general population, and overall mortality from perioperative stroke is at least 20%.<sup>105,109</sup>

Postoperative delirium is an acute confusional state manifested by an acute onset (hours to days) and vacillating levels of attention and cognitive skill.<sup>113-115</sup> Disorientation, perceptual disturbances (from situational misinterpretation to overt hallucinations), disorganized thinking, and problems with memory may be manifested. Emergence delirium alone does not qualify as postoperative delirium, but may be a risk factor.<sup>116</sup> Although most often short-lived (24 hours), delirium can be persistent and extend beyond hospital discharge.<sup>113</sup>

Delirium is most often diagnosed using Confusion Assessment Method, at least in research studies.<sup>113,117</sup> The mini-mental status examination can also be helpful, but its utility is higher for the identification of patients with pre-existing dementia. The risk of postoperative delirium after major surgery in

older patients is approximately 10%; however, the risk varies with the surgical procedure.<sup>114</sup> Highest risk is emergent hip surgery, with an incidence of some 35%. The etiology of delirium is multifactorial. Risk factors include age, baseline low cognitive function (including dementia), depression, overall frailty, and general debility including dehydration or visual/auditory impairment.<sup>113,115,118,119</sup> The more risk factors present, the fewer perioperative stressors are required to push the patient over the edge to delirium.<sup>114</sup> Those additional stressors can include virtually any drug with central nervous system effects, including narcotics (especially meperidine), benzodiazepines (especially lorazepam), and drugs that possess anticholinergic properties (except perhaps glycopyrrolate). Other factors that likely contribute to delirium include sleep deprivation, being in an unfamiliar environment, and perioperative blood loss. The role of absolute intraoperative hypotension in the development of postoperative delirium is controversial, yet delirium is associated with fluctuations in blood pressure.<sup>120</sup>

The effect of anesthetic depth in general anesthesia on particularly neurologic outcomes is highly controversial. It is the routine practice of many anesthesiologists to provide adequate anesthetic depth to not only ensure there is no recall but also control increases in blood pressure. Perhaps it is the latter goal that accounts for what appears to be a tendency to provide higher levels of volatile anesthesia to the elderly when anesthetic dosing is adjusted for age.<sup>121</sup> A new body of evidence from different types of anesthetic techniques for hip, major noncardiac and cardiac surgery suggests that using a BIS-guided strategy to reduce anesthetic exposure and depth reduces the risk of postoperative delirium.<sup>122-124</sup> Similar findings demonstrated that using processed EEG, cumulative time of burst suppression was correlated with the risk of postoperative delirium.<sup>125</sup> Furthermore, in a study that employed BIS-guided sedation with propofol in patients having hip fracture repair under spinal anesthesia, it was found that in the sicker patients (Charlson comorbidity index >4), light sedation was associated with lower 1-year mortality than deep sedation.<sup>126</sup> An international trial (BALANCED) looking at general anesthesia with inhaled anesthetics titrated to BIS, planning to recruit 6,500 patients, will potentially answer the question of whether anesthetic depth is associated with poor outcomes in the aged.

Narcotic administration represents a fine line between too much and too little, as inadequate pain control is also associated with delirium.<sup>127</sup> Analgesia with meperidine should be avoided, except perhaps in small doses for shivering, as it is clearly a risk factor for delirium, but there appears to be no superior choice among fentanyl, hydromorphone, and morphine.<sup>128</sup> Nevertheless, multimodal analgesia to reduce opiate use is considered a rational approach. Disappointingly, the selection of epidural analgesia over IV opioid analgesia does not appear to reduce the incidence of delirium.<sup>128</sup>

Similarly, the use of regional instead of general anesthesia does not seem to reduce delirium, but this result may be due to the use of inappropriate drugs and/or heavy sedation in conjunction with the regional technique. Controlled sedation along with regional anesthesia does appear to reduce the incidence of delirium.<sup>114,124</sup> This is an important concept, as patients with diminished cognitive function have lower drug requirements for the same level of sedation.<sup>113,129</sup> Dexmedetomidine may be a better choice than benzodiazepines for ICU sedation.<sup>113,130</sup>

Delirium often goes undiagnosed in the elderly patient as it is typically hypoactive. The patient does not demonstrate behavior that draws attention. This characteristic is unfortunate because delirium is associated with an increased duration of hospitalization and its attendant costs, poorer long-term functional recovery, and increased mortality.<sup>113,114,131</sup> Outcomes are worst when the delirium is persistent. Once detected, management focuses on reversible risk factors such as current medications, pain management, and a better sleep environment. Special care programs designed to limit the reversible risk factors appear to reduce the incidence of delirium by up to 50%.<sup>88,132</sup> In the event the delirium is agitated, haloperidol in doses no greater than 1.5 mg can be helpful.<sup>113</sup> Prophylactic haloperidol in hip surgery reduced the severity and duration of delirium but not its incidence,<sup>133</sup> whereas in critically ill elderly patients after noncardiac surgery, haloperidol (0.5 mg intravenous bolus injection followed by continuous infusion at a rate of 0.1 mg/hr for 12 hours administered at ICU admission) reduced the incidence of delirium.<sup>134</sup> The use of a subanesthetic dose of intraoperative ketamine to decrease the incidence of postoperative delirium is currently being examined in the PODCAST (Prevention of Delirium and Complications Associated with Surgical Treatments) study.<sup>135</sup> To summarize, effective approaches for prevention and treatment of postoperative delirium include targeting reversible risk factors with preemptive assessment and multifactorial interventions, limiting use of sedatives (especially benzodiazepines), avoiding drugs with atropinic properties (except glycopyrrolate), judicious treatment of postoperative pain, and, perhaps, careful use of antipsychotics.<sup>136</sup> The National Institute for Health and Clinical Excellence in United Kingdom (NICE) and the American Geriatric Society recently published guidelines on how to recognize, prevent, and treat delirium.<sup>137,138</sup>

POCD is characterized by a long-term decrease in mental abilities after surgery. Other than the rare patient who suffers obvious impairment, POCD is inherently more difficult to diagnose than delirium because it usually requires sophisticated neuropsychologic testing, including baseline tests prior to surgery. Selection of tests, their timing, and what deficits are required to qualify as cognitive decline have proven problematic in the literature.<sup>115</sup> The

question is whether anesthesia contributes to POCD, and if so, to what degree?

Animal studies provide the most evidence for anesthetic CNS toxicity. Many studies of animals (typically rodents) exposed to volatile anesthesia demonstrate impaired memory and diminished learning ability that persists for at least months after exposure.<sup>139</sup> Volatile anesthesia increases brain production of  $\beta$ -amyloid and abnormal  $\tau$  protein (leads to neurofibrillary tangles), both of which are associated with Alzheimer disease, and also cell apoptosis.<sup>139,140</sup> However, other studies found that memory impairment and CNS chemical change only occurred in animals that had surgery plus anesthesia. Anesthesia without surgery was no different than control animals.<sup>139</sup> Curiously, the anesthetics in these latter studies were fentanyl, droperidol, and chloral hydrate, thereby raising the possibility that not all anesthesia agents yield similar results. In addition to the potential neurodegenerative mechanism described above, cognitive decline could also result from a neuroinflammatory stress response to surgery and/or anesthesia.<sup>141</sup>

A seminal study not only examined surgical patients before and after surgery but included control subjects who were tested over time as well, but did not have surgery. At 3 months, a 10% incidence of POCD was observed in the patients who had surgery, in comparison to a 3% incidence who did not.<sup>142</sup> Risk factors for POCD at 3 months after surgery include age, lower levels of education, prior history of stroke even in the absence of residual deficit, and POCD at hospital discharge.<sup>143</sup> Increased mortality at 1 year is associated with patients who demonstrate cognitive decline at both hospital discharge and at 3 months postoperatively.<sup>143</sup> A study that examined the association between exposure to surgery and anesthesia and cognitive function in 8,503 pairs of middle aged and elderly twins identified 87 monozygotic and 124 dizygotic same-sexed twin pairs in whom one had major surgery and the other did not. A statistically significant but clinically negligible difference was found. For example, when participants were asked to provide as many names of animals as possible in 1 minute, the mean number of animals named was 23.5 in those that were exposed to surgery versus 24.2 in those that were not.<sup>144</sup>

Regarding the first few days after surgery, a few observations have been made that are neither surprising nor particularly worrisome. First of all, there is a similar degree of cognitive deficit in all age groups, not just the elderly.<sup>145</sup> Secondly, greater cognitive impairment can be observed with general anesthesia than with regional anesthesia.<sup>146</sup> Lastly, for the first few days the choice of general anesthesia makes a difference with propofol < desflurane < sevoflurane in degree of cognitive decline.<sup>147,148</sup> By 3 months, however, the presence of POCD is almost exclusively a problem in older

patients.<sup>145</sup> Furthermore, no differences can be detected between general and regional anesthetic options.<sup>146–148</sup> By 1 year, even the best controlled studies suggest little or no demonstrable cognitive decline.<sup>115,149</sup> A longitudinal analysis of an Alzheimer disease database of patients who started with none to mild dementia showed the same overall rate of cognitive decline whether or not they had surgery or suffered a major illness.<sup>150</sup> Using before and after neuropsychologic testing, the incidence of POCD was compared for patients who underwent coronary angiography, total hip arthroplasty, or coronary artery bypass grafting.<sup>151</sup> At 1 week postoperatively, POCD was documented in 43% of the bypass graft patients and 17% for the hip replacement patients (angiography patients not tested at 1 week). At 3 months postprocedure, the incidence of POCD was 16% for both surgical groups and 21% for the angiography group (differences not significant). These two studies suggest there is no overall long-term adverse cognitive impact on patients, and that it is not the anesthetic which is to blame for whatever changes do occur. Effective treatment strategies for POCD are still absent and therefore the best treatment seems to be prevention. Small limited trials have assessed different strategies to reduce the incidence of POCD in animal models<sup>152</sup> and in humans,<sup>122,153–155</sup> but guidelines or recommendations that are supported by rigorous science are unavailable.

Delirium and POCD are often inappropriately perceived as a single entity along a time continuum. There may be an association between delirium and POCD, but if there is, the relationship has not been fully elucidated. Predictors of postoperative delirium such as hypoxemia<sup>156</sup> were not found to be risk factors for POCD.<sup>142</sup> Furthermore, postoperative delirium has not been found to be a risk factor for cognitive dysfunction at 3 months.<sup>118</sup>

So what do we tell our patients about stroke, delirium, and POCD? This is not an easy question to answer, especially for cognitive decline. However, patients are usually satisfied to know the facts and are willing to accept the unknown, including the fact that there does not seem to be any clear evidence that basic anesthetic techniques differ in their impact on outcome. Furthermore, at least for POCD, some believe that the accumulated evidence does not support the concept of long-term POCD as a clinical problem and that patients can be reassured that surgery and anesthesia are unlikely to be implicated in causing persistent cognitive decline or dementia.<sup>157</sup>

Nevertheless, there are a few specific points about the conduct of anesthesia that can be made. Besides the obvious caveats (“avoid hypotension and hypoxia”), the basic approach to an anesthetic for an elderly patient can be described as cautious. Since stroke is likely a thromboembolic phenomenon, there may be little that can be done beyond standard, good anesthetic care. However, it is not clear that antiplatelet therapy needs to be discontinued for surgery as much as currently occurs. The efficacy of statins

has also not been adequately assessed. As previously discussed, drug choices and dosage have a potentially major impact on delirium. Pain control with multimodal therapy to reduce opioid consumption is probably a good thing, but poor pain control may be as bad as too much opioid. Finally, it is not clear what the relationship is between anesthesia and cognitive decline, if there is one at all. Given that unsatisfactory statement, it seems reasonable to choose the anesthetic technique based on the other factors germane to the patient and surgery.

## The Future

*I will never be an old man. To me, old age is always 15 years older than I am.*

—Francis Bacon

Improvements in surgical and anesthetic techniques that reduce the overall stress to the patient are permitting more surgeries to be performed on older and sicker patients than ever before. Nevertheless, the older patient will continue to experience the majority of perioperative adverse outcomes. Much remains to be accomplished in the quest to find ways to decrease the incidence and severity of those adverse outcomes.<sup>104</sup> The most pressing issues are arguably the prevention of postoperative delirium, cognitive decline, pneumonia, respiratory failure, and cardiovascular complications. Improved pain-control techniques that also diminish side effects, especially to the brain and bowels, would be welcome. However, other realms of care are just in their infancy, most notably whether preoperative improvement in the functional status of frail patients is helpful. For example, can short courses of better nutrition, exercise regimens, or even dietary supplements reduce complications, speed recovery, or improve functional recovery? When caring for the elderly, especially the frail elderly, the overriding goal should be to produce as little stress to the patient as possible during both surgery and the subsequent hospitalization and recovery. Complete care will be multidisciplinary out of necessity. No single specialty possesses the total perspective, and the anesthesiologist's expertise is an important component of that care.

## KEY POINTS

- 1 A growing body of evidence suggests that spinal and epidural anesthesia are associated with less morbidity and mortality than general anesthesia. This association is strongest in patients undergoing major hip or knee surgery.
- 2 The epidural space is not a homogeneous, continuous cylinder surrounding the subarachnoid space. Instead, discrete pockets of epidural fat lie in the posterior and lateral epidural space. Epidural veins pass through the anterior and lateral space. Blood in an epidural needle or catheter suggests that you are not in the midline.
- 3 Develop a mental model of spinal anatomy that will allow you to systematically locate the spinal or epidural space.
- 4 The hemodynamic effects of spinal and epidural anesthesia are proportional to the extent of local anesthetic block.
- 5 Patient variables (age, height, weight, etc.) minimally effect the spread of intrathecal and epidural medications.
- 6 Unrecognized *intrathecal (subarachnoid)* injection of local anesthetics is a common cause of morbidity during epidural block. Early signs of unintended intrathecal local anesthetic injection can be subtle and easily missed. Commonly used intrathecal test doses can produce excessive levels of sensory and motor block.
- 7 *Intravenous* injection of local anesthetics can produce seizures and cardiac arrest. Test doses and incremental injection are key safety steps to prevent this complication.
- 8 Patients receiving antithrombotic or thrombolytic medications are at increased risk of developing spinal or epidural hematoma. Refer to the American Society of Regional Anesthesia and Pain Medicine Regional Guidelines for Antithrombotic and Thrombolytic Therapy for current information.

## Introduction

Subarachnoid spinal and epidural anesthesia are key techniques that every anesthesiologist should master. Subarachnoid or intrathecal anesthesia is commonly referred to as spinal anesthesia. Some use the term peridural instead of epidural. Caudal block refers to injection into the caudal epidural space via the sacral hiatus. Neuraxial includes both subarachnoid and epidural injection.

Subarachnoid injection of a small dose of local anesthetic can rapidly produce dense surgical anesthesia. Subarachnoid injection is almost always done in the lumbar region, below the termination of the spinal cord.

Subarachnoid anesthesia can provide excellent operating conditions for lower abdominal, pelvic, and lower extremity surgery. Most subarachnoid anesthetics are single injections and have a finite duration. Single injection subarachnoid anesthesia will last 2 to 3 hours at most. It is not a good choice for prolonged or unpredictable surgeries.

Continuous subarachnoid anesthesia with a catheter can provide extended duration block. However, continuous subarachnoid anesthesia requires a large-gauge dural puncture. Such needles can produce an unacceptably high incidence of headache, especially in younger patients (see “Complications”). Micro subarachnoid catheters, which could be inserted through a 25-gauge needle were associated with permanent neurologic injury and are no longer available. In addition, subarachnoid catheters can be mistaken for epidural catheters. Dangerous levels of block can occur if a larger epidural dose of medication is accidentally injected into a continuous subarachnoid catheter. Still, continuous subarachnoid anesthesia allows careful titration of medication, which may provide better hemodynamic stability in fragile patients. In addition, subarachnoid catheters can be redosed as needed during prolonged surgeries.

Epidural anesthesia requires larger doses of local anesthetic and takes more time to establish. However, when a catheter is in the epidural space, local anesthetic can be injected repeatedly and anesthesia can be prolonged to match the duration of the surgery. Epidural injection can safely be performed in the lumbar, thoracic, and even cervical regions. Lumbar epidural anesthesia and subarachnoid anesthesia can be used for many of the same procedures. Thoracic epidural anesthesia is a useful adjunct to general anesthesia for upper abdominal and thoracic surgeries. Cervical epidural injection is rarely used for surgery; however, it is commonly used to treat pain associated with cervical disc disease. See Chronic Pain chapter for further discussion of cervical epidural injection.

The caudal canal is the lower extension of the epidural space. Caudal anesthesia and analgesia are uncommon in adults but can be useful for pediatric surgeries.

Epidural injection of medications also can provide analgesia. Dilute mixtures of local anesthetic and opioid can provide postoperative analgesia with minimal motor block. Epidural analgesia is a key element of many enhanced recovery protocols. The flexibility of continuous epidural block makes it an excellent choice for labor pain relief. Dilute local anesthetic and opioid solutions can provide labor *analgesia* with minimal maternal motor block and negligible effects on the progress and outcome of labor. Should surgical delivery be required, the epidural catheter can be dosed with more concentrated local anesthetics to provide operative *anesthesia* (see OB anesthesia chapter).

In some settings, the anesthesiologist may combine subarachnoid and epidural injections. This approach offers the rapid onset of dense anesthesia produced by subarachnoid injection of local anesthetic and the flexibility of an epidural catheter.

## Indications and Contraindications

There are no absolute indications for subarachnoid or epidural anesthesia. Their use is determined by a combination of patient, surgeon, and anesthesiologist preferences. Contraindications to neuraxial anesthesia include patient refusal, coagulopathy, hemodynamic instability, and infection at the site of injection.

## Neuraxial Anesthesia and Outcome

Many investigators have compared patient outcomes associated with neuraxial and general anesthesia. Small randomized controlled trials examining major morbidity and mortality after high-risk and vascular surgeries yielded conflicting results.<sup>1,2</sup> By 2012, 40 studies including over 3,000 patients were available for meta-analysis.<sup>3</sup> Subarachnoid and epidural anesthesia were associated with a lower risk of death within 30 days of **1** surgery (risk ratio [RR] 0.71). Neuraxial anesthesia also reduced the risk of postoperative pneumonia (RR 0.45), but not the risk of myocardial infarction (RR 1.17). Interestingly, adding neuraxial anesthesia to general anesthesia did not reduce the risk of death or myocardial infarction compared to general anesthesia alone. However, the combination of neuraxial and general anesthesia was associated with a reduced risk of postoperative pneumonia (RR 0.69).

Large, multi-institutional databases allow robust comparisons of neuraxial and general anesthesia. In more than 18,000 patients undergoing hip fracture surgery, neuraxial anesthesia was associated with a decreased risk of in-hospital death and pulmonary complications.<sup>4</sup> However, the same authors reported a follow-up study of more than 50,000 patients and did not find any decreased mortality after neuraxial anesthesia.<sup>5</sup> In contrast, neuraxial anesthesia was associated with lower 30-day mortality and fewer prolonged hospital stays in nearly 400,000 patients undergoing hip or knee replacement.<sup>6</sup>

Neuraxial anesthesia also may improve outcomes in some subgroups of patients. A small retrospective review from a single institution found fewer postoperative pulmonary complications and arrhythmias as well as shorter intensive care unit stays among patients receiving regional instead of general anesthesia for lower extremity amputation.<sup>7</sup> A review of more than 5,000

patients with chronic obstructive pulmonary disease (COPD) found that regional anesthesia (subarachnoid, epidural, or peripheral nerve block) was associated with fewer adverse respiratory events (postoperative pneumonia, prolonged ventilator dependence, and unplanned postoperative intubation) than general anesthesia.<sup>8</sup> There were fewer wound infections, blood transfusions, pneumonias, and total infections associated with neuraxial versus general anesthesia among more than 14,000 patients undergoing total knee arthroplasty.<sup>9</sup> Hospital length of stay was also shorter in the neuraxial anesthesia patients.<sup>10</sup> In contrast, a different review of more than 7,000 hip fracture patients found no anesthesia-related differences in mortality but an *increased* risk of superficial wound infection and urinary tract infection among patients receiving subarachnoid anesthesia.<sup>11</sup>

Some investigators have reported a lower risk of thromboembolism in patients receiving neuraxial anesthesia.<sup>12</sup> However, not all studies have confirmed this benefit.<sup>6</sup> There are insufficient data to determine if regional anesthesia improves outcomes for patients undergoing major vascular surgery.<sup>13</sup> One retrospective study of 822 patients found that regional anesthesia does *not* improve graft patency after lower extremity revascularization.<sup>14</sup>

An intriguing advantage of epidural anesthesia and analgesia might be improved survival after cancer surgery. Regional anesthesia and analgesia avoid the immunosuppression associated with general anesthesia and postoperative opioid analgesia. In a recent meta-analysis, epidural anesthesia and analgesia was associated with longer survival but no difference in cancer recurrence after surgery.<sup>15</sup>

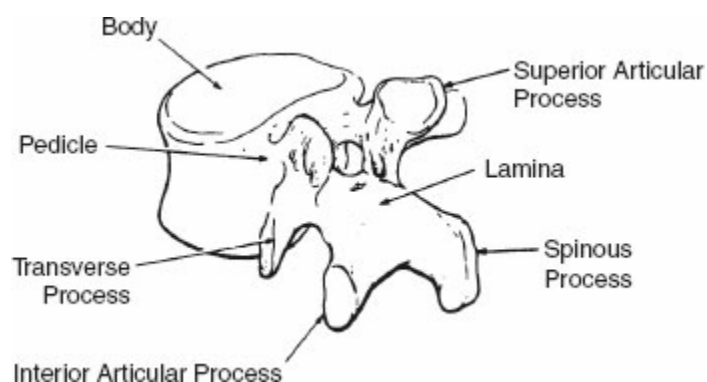

## Anatomy

Subarachnoid and epidural anesthesia are exercises in applied anatomy. The anesthesiologist must have a thorough grasp of the relationships between surface landmarks and deeper structures. Text and two-dimensional images are a useful, but imperfect, way to learn vertebral anatomy. Careful examination of skeletal models can help. Recently, investigators have used high-resolution magnetic resonance images to construct interactive virtual three-dimensional models of bony, ligamentous, and nervous structures of the spine (<http://hdl.handle.net/2445/44844>).<sup>16</sup>

## Vertebrae

The spine is comprised of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal. All vertebrae have the same structural components but with varying shapes and sizes at different levels. The

vertebrae surround and protect the vertebral canal, which contains the spinal cord, cerebrospinal fluid (CSF), meninges, spinal nerves, and epidural space. Each vertebra has a body anteriorly, two pedicles that project posteriorly from the body, and laminae that connect the two pedicles (Fig. 35-1). The transverse processes arise laterally from the junction of the pedicle and lamina, and the spinous process projects posteriorly from the union of the bilateral laminae. The paraspinal muscles and ligaments attach to these bony projections.

**Figure 35-1** The vertebral body. (From Norris MC, ed. *Obstetric Anesthesia*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 1999:286.)

The pedicles form the superior and inferior vertebral notches, through which the spinal nerves exit the vertebral canal. The lamina and pedicles meet at the superior and inferior articular processes, which form the joints that connect the adjacent vertebrae. The first and second cervical vertebrae, also referred to as the atlas and dens, have a unique appearance in that C1 lacks a vertebral body or spinous process and C2 has a large articulating process (dens).

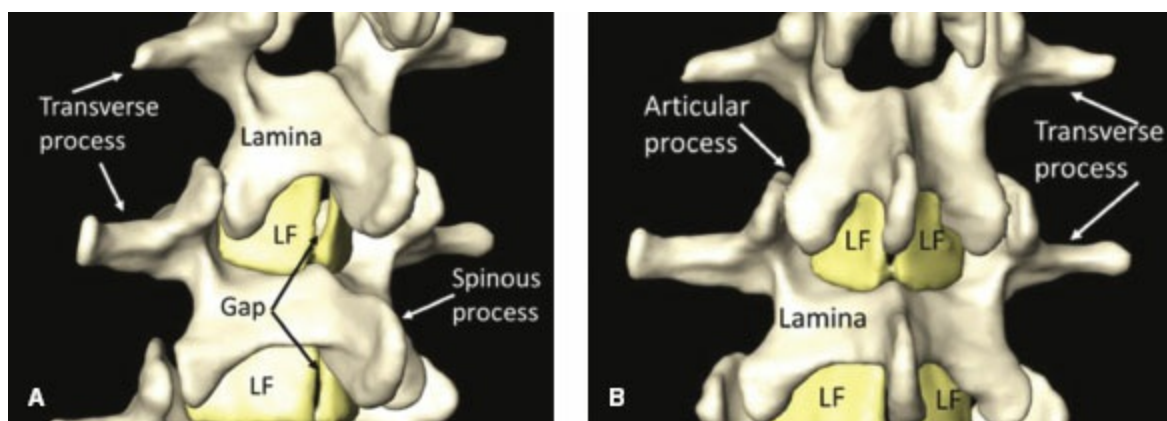

Five fused vertebrae form the sacrum. In 0.9% to 6.4% of the population, sacralization (fusion of the L5 and S1 vertebrae) occurs.<sup>17</sup> Up to 60% of those with this variation have only unilateral fusion, known as hemisacralization.<sup>17</sup> The fifth sacral vertebra does not fuse posteriorly, forming the sacral hiatus, which provides access to the most caudal point of the epidural space. The sacral hiatus is usually open in children but its patency varies in adults. The four coccygeal vertebrae fuse to form the coccyx, which represents a vestigial tail and serves as an anchor for the attachment of tendons, ligaments, and muscles.

In surgical and obstetric patients, neuraxial block is usually accomplished without the aid of imaging. Attaining the desired level for neuraxial block and avoiding complications requires familiarity with surface landmarks. Commonly identified landmarks include the C7 spinous process (vertebra prominens), the twelfth rib, and the iliac crests. Many anesthesiologists use the line between the iliac crests (Tuffier line) to identify the L4–L5 interspace. However, this landmark commonly misleads even experienced

anesthesiologists.<sup>18</sup> When possible, locating the L5–S1 interspace and counting up is a more reliable way to identify a specific lumbar interspace. In obese patient, a midline skin crease and the gluteal cleft can help local the midline.

## Ligaments

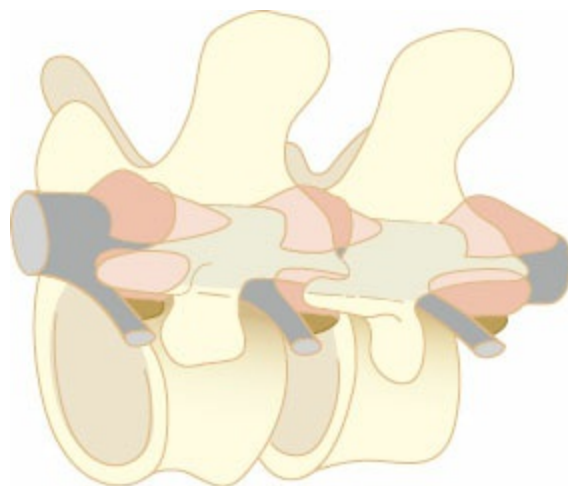

Several ligaments serve to stabilize the vertebral column. The anterior and posterior longitudinal ligaments link the ventral surfaces of the vertebral bodies. Dorsally, the supraspinous and interspinous ligaments, as well as the dense ligamentum flavum, connect the vertebrae. The supraspinous ligament covers the tips of the spinous processes between C7 and the sacrum; from C7 to the external occipital protuberance it continues as the ligamentum nuchae. The supraspinous ligament thins in the lower lumbar region, allowing greater flexion of the spine. The interspinous ligament runs between spinous processes. It may contain slit-like, fat-filled cavities that can create a false loss of resistance during attempts to identify the epidural space. The interspinous ligament merges with both supraspinous ligament and ligamentum flavum. The ligamentum flavum (yellow ligament) is a pair of dense trapezoid-shaped structures made mostly of elastin. The two ligaments fuse in the midline at an 80- to 90-degree angle. This fusion is often incomplete. Lumbar midline gaps occur in approximately 10% of patients (Fig. 35-2).<sup>19</sup> When attempting to locate the epidural space, try to appreciate the “snap” of the supraspinous ligament, the “mushy” interspinous ligament, and the “gritty” ligamentum flavum.

**Figure 35-2** Three-dimensional reconstruction of human lumbar ligamentum flavum (LF). **A:** Posterior-lateral view. **B:** Posterior view. Note the gap (arrow) between the two halves of the ligamentum flavum. (Adapted from Reina MA, Lirk P, Puigdemívol-Sánchez A, et al. Human lumbar ligamentum flavum anatomy for epidural anesthesia: reviewing a 3D MR-based interactive model and postmortem samples. *Anesth Analg.* 2016;122:903–907. ©2016 International Anesthesia Research Society.)

## Epidural Space

The epidural space lies within the vertebral canal but outside the dural sac. It extends from the foramen magnum to the sacral hiatus. The epidural space is bound anteriorly by the posterior longitudinal ligament and posteriorly by the lamina and ligamentum flavum. Laterally the epidural space extends to the pedicles where it communicates with the paravertebral space via the intervertebral foramina.<sup>20</sup> The epidural space is often absent because the dural intermittently abuts the bony and ligamentous structures of the spine. The remainder of the space consists of discontinuous, fat-filled pockets that open readily upon injection of air or liquid.<sup>20</sup> The cervical level contains no epidural fat. In the lumbar region, fat in the anterior and posterior aspects of the epidural space forms multiple, metameric, discrete collections (Fig. 35-3).<sup>20,21</sup> This fat may play an important role in the kinetics of epidural medications.<sup>22</sup>

**Figure 35-3** The compartments of the epidural space (grey) are discontinuous. Areas in between are a potential space where the dural mater normally abuts the sides of the vertebral canal. (Adapted from Hogan Q. Lumbar epidural anatomy: a new look by cryomicrotome section. *Anesthesiology*. 1991;75:767–775.)

Epidural veins are located mostly in the anterior epidural space. The intervertebral foramina allow transmission of intra-abdominal pressure into the epidural space. Conditions that increase intra-abdominal pressure (i.e., pregnancy) can cause engorgement of epidural veins, leading to more frequent venous cannulation and possibly enhancing the spread of injected medications.

## Meninges

The meninges surround and protect the spinal cord, cerebral spinal fluid (CSF), and nerve roots until they exit the foramina. The dura, arachnoid, and pia mater form three structurally distinct meningeal layers (Fig. 35-4).

**Figure 35-4** The spinal meninges of a dog, showing the pia mater (PM) in apposition to the spinal cord, the subarachnoid space (SS), the arachnoid mater (AM) with trabeculae stretching from the arachnoid mater to the pia mater, and the dura mater (DM). The separation between the arachnoid mater and the dural mater is the subdural space, which was created here as an artifact of preparation. (Adapted from Peters A, Palay SL, Webster H, eds. *The Fine Structure of the Nervous System: The Neurons and Supporting Cells*. Philadelphia, PA: WB Saunders; 1976.)

## Dura

The dura mater (hard mother) is the thickest, outermost meningeal layer. It is 270 to 280  $\mu\text{m}$  thick and consists mostly of collagen fibers arranged in about 80 layers of very fine lamellae (Fig. 35-5). The external (epidural surface) contains bands of collagen fibers running in different directions. The dura also contains thick elastic fibers and fine granular material. The inner (subarachnoid) surface includes fine fibers that fuse with the arachnoid mater.<sup>23</sup> A potential subdural space exists between the dura and arachnoid mater. Drugs, needles, or catheters intended for the epidural or subarachnoid spaces rarely may end up there (Fig. 35-6).

**Figure 35-5** Scanning electron microscopic image of a radial longitudinal section of human dura mater. Total thickness is a composite of all concentric layers. (Adapted from Reina MA, Dittmann M, Lopez Garcia A, et al. New perspectives in the microscopic structure of human dura mater in the dorsolumbar region. *Reg Anesth.* 1997;22:161–168.)

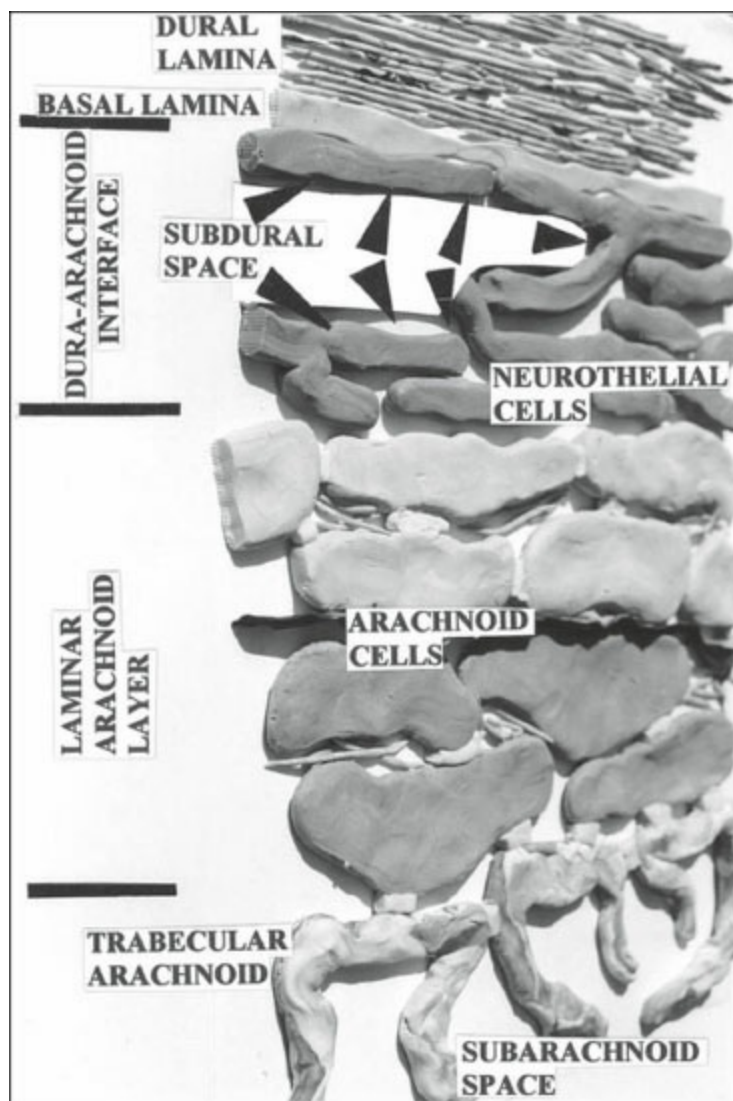

**Figure 35-6** Human spinal dural sac. **A:** Enhanced view ( $\times 20$ ) of an epidural catheter inside a subdural space. **B:** Detail ( $\times 60$ ) of **A**. Sample was obtained from a cadaver under scanning electron microscopy. (Adapted from Reina MA, Collier CB, Prats-Galino A, et al. Unintentional subdural placement of epidural catheters during attempted epidural anesthesia: an anatomic study of spinal subdural compartment. *Reg Anesth Pain Med.* 2011;36:537–541.)

The dura is a continuation of the spinal meninges, extending from the foramen magnum to approximately S2, where it fuses with the filum terminale. It extends laterally with individual nerve roots and fuses with the epineurium near the intervertebral foramina.

## Arachnoid

The arachnoid mater (spider mother) lies within the dura. It has two portions. A compact lamellar layer of flattened epithelial-like cells that are tightly connected to one another covers the inner surface of the dura. Then, a trabecular web-like portion extends to the pia mater (Fig. 35-7).<sup>24</sup> Because of this cellular architecture, the arachnoid, not the dura, hinders drug movement through meninges. The low permeability of the arachnoid mater keeps the CSF in the subarachnoid, not the subdural space.<sup>25</sup> Specialized intercellular junctions within the internal portion of the arachnoid mater explain its selective permeability.<sup>26</sup>

**Figure 35-7** Dura–arachnoid interface model. From the top: the dural lamina (dura mater’s most internal portion) is followed by the dura–arachnoid interface; the interface is filled with neurothelial cells, and forms the subdural space. Below are the laminar and trabecular portions of the arachnoid mater. (Adapted from Reina MA, De Leon Casasola O, Lopez A, et al. The origin of the spinal subdural space: ultrastructure findings. *Anesth Analg.* 2002;94:991–995.)

The spinal nerve roots traverse the dura and arachnoid membranes as they exit the vertebral foramina. Here, the arachnoid mater herniates through the dura and forms arachnoid granulations. These granulations provide an exit for material leaving the central nervous system.

## Pia

The innermost layer of the spinal meninges is the pia mater (soft mother). The pia consists of flat overlapping cells that coat the spinal cord and nerve roots. The pial cells contain numerous fenestrations along the lumbar spinal cord and nerve roots (Fig. 35-8). Any role these fenestrations might play in the action of subarachnoid or epidural medications is speculative.<sup>27</sup>

## Cerebrospinal Fluid

CSF is an aqueous solution consisting of 99% water. Multiple minor components include protein, glucose, electrolytes, and neurotransmitters. In adult humans, the volume of CSF is 100 to 160 mL. For many years, we thought that CSF was primarily produced in the choroid plexus and then flowed from the ventricles to the subarachnoid space, where it was absorbed by arachnoid granulations. This hypothesis is incomplete and probably incorrect. The choroid plexus is not the sole site of CSF production and the arachnoid granulations are not its primary absorption sites. CSF and interstitial fluid (IF) are closely related. They are both mainly produced and absorbed in the parenchymal capillaries of the brain and spinal cord. The lymphatic system also absorbs a considerable amount of CSF and IF.<sup>28</sup> CSF movement is not unidirectional flow. Instead, transmitted cardiac oscillations produce local mixing, whereas other drugs spread slowly by diffusion. Solutes are reabsorbed across capillary membranes into the bloodstream.<sup>29</sup>

**Figure 35-8** Fenestrations in the pial cellular layer at the level of the spinal cord. Numerous fenestrations appear in this scanning electron micrograph. (Adapted from Reina MA, De Leon Casasola O, Villanueva MC, et al. Ultrastructural findings in human

spinal pia mater in relation to subarachnoid anesthesia. *Anesth Analg.* 2004;98:1479–1485.)

## Spinal Cord

In the first trimester fetus, the spinal cord extends to the end of the sacrum. The vertebral column grows faster than the spinal cord and at birth the cord usually ends at the level of the third lumbar vertebra. In adults, the cord most often ends at around L1. However, there is considerable interindividual variation. The cord ends at T12 in some but may extend to L3 in up to 10% of adults.

There are 31 pairs of spinal nerves, each with an anterior motor root and a posterior sensory root. These nerve roots arise from individual spinal cord segments. Each posterior sensory root innervates a specific dermatome (Fig. 35-9). The sympathetic nervous system arises from the intermediolateral grey matter of the T1 to L2 spinal cord segments. This grey matter contains the cell bodies of the preganglionic sympathetic neurons, which travel with the corresponding spinal nerve through the intervertebral foramen. They then diverge and join the sympathetic chain ganglia.

 The spinal nerves and their corresponding dermatomes are named for the foramina through which they exit the vertebral column. In the cervical region, spinal nerves are named after the lower vertebrae (i.e., C5 exits between C4 and C5). Elsewhere, the roots are named by the upper vertebrae (L2 emerges between L2 and L3). Since the vertebral column is longer than the spinal cord, the thoracic, lumbar, and sacral nerve roots traverse progressively greater distances from their originating spinal cord segment to their exiting foramina. The lumbar and sacral spinal nerves that extend beyond the tip of the cord are called the cauda equina. These nerve roots, covered only by pia mater, may be more susceptible to chemical injury than more proximal roots.

In one study examining magnetic resonance images of seven adults, the dural sac volume from S1 to T12 was 43 mL. The average CSF volume was 34 mL. The remaining 9 to 10 mL consisted of conus medullaris and nerve roots. The percentage of nerve volume to dural sac volume increased from 7% to 14% at L5, to 25% at L4, to 30% to 43% at T12. Not only do upper lumbar punctures risk contact with the conus medullaris, but the cauda equina also is vulnerable to contact with lower punctures.<sup>30</sup>

## Ultrasound Anatomy of the Spine

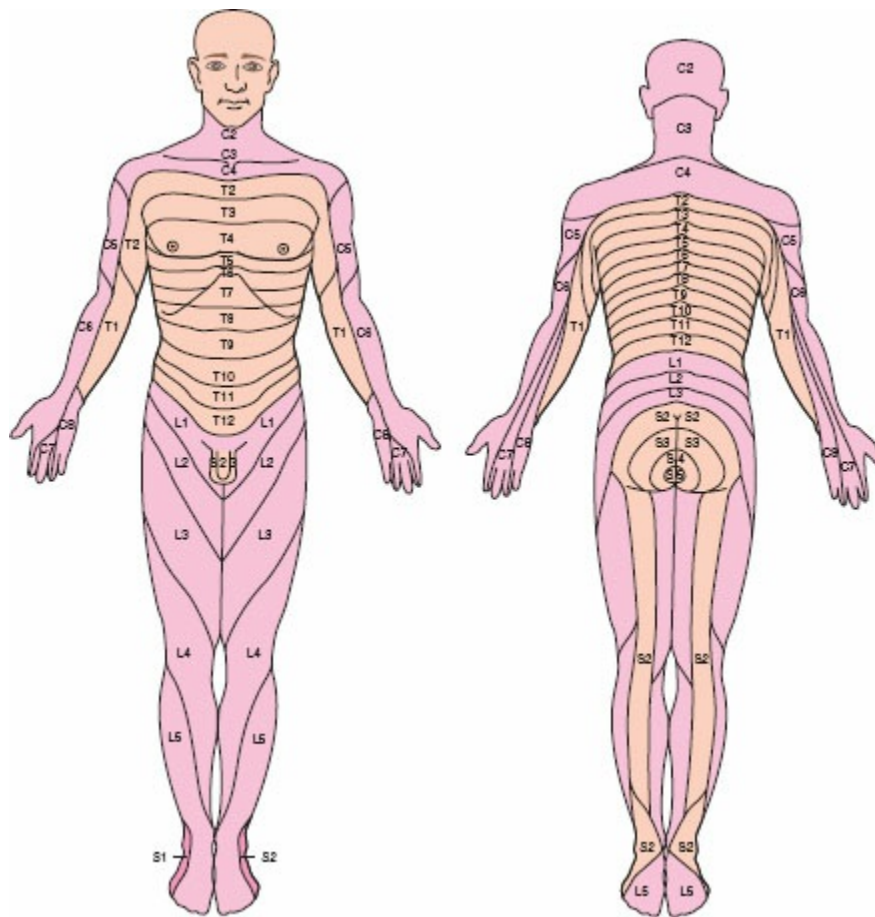

There has been increasing interest in using ultrasound to complement clinical examination when performing neuraxial blocks. Ultrasound examination of

the lumbar spine can establish the depth of the epidural space, identify the intervertebral level, and locate the midline and interspinous/interlaminar spaces. This information can help guide subsequent needle insertion. Systematic reviews suggest that ultrasound increases the success and reduces the technical difficulty of lumbar neuraxial blocks. Ultrasound may reduce the risk of traumatic procedures, and may contribute to the safety of lumbar neuraxial blocks.<sup>31</sup>

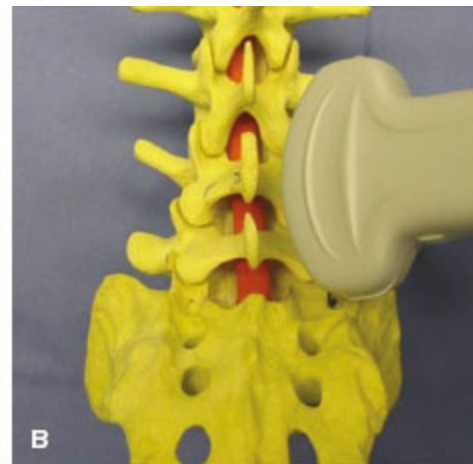

Although real-time, ultrasound-guided approaches have been described,<sup>32</sup> most experts use ultrasound before attempted neuraxial block to locate landmarks. Once mastered, a preprocedure ultrasound examination can quickly identify the exact lumbar interspace, the midline, the skin puncture point, the angle of needle insertion, and the depth of the epidural space.<sup>33</sup>

The basic ultrasound examination of the lumbar spine consists of two scans: a paramedian longitudinal scan and a transverse or axial scan. The paramedian longitudinal approach can identify specific interspace levels by scanning through interlaminar windows. Place the transducer longitudinally along the spine, parallel to it, 2 to 3 cm lateral to the midline, and directed toward the center of the spinal canal. Multiple vertebral levels can be seen in one scanned image. The structures seen in this view include sacrum, lamina, ligamentum flavum, and dorsal dura mater (Fig. 35-10).<sup>33</sup> The ligamentum flavum and dorsal dura mater appear as a single bright line in the interlaminar window. A deeper bright reflection emanates from the ventral dura/posterior longitudinal ligament/vertebral body complex. Once the desired puncture level is identified in the paramedian longitudinal plane, turn the transducer perpendicular to the axis of the spine to view the entire interspace. The structures that can be seen in the axial plane include the ligamentum flavum and dorsal dura mater, the ventral dura/posterior longitudinal ligament/vertebral body complex, the articular processes, and the transverse processes (Fig. 35-11).<sup>33</sup>

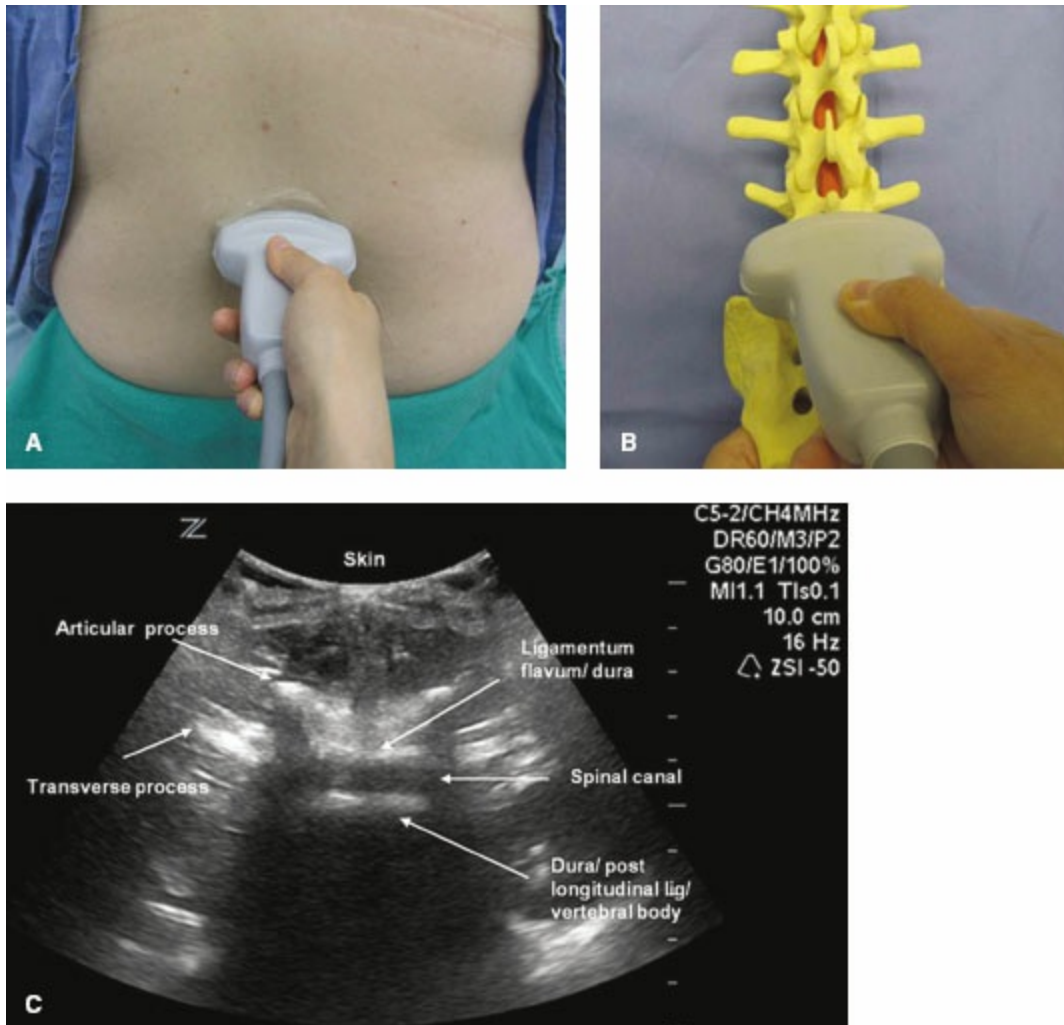

After acquiring the best image of interspace structure and ligamentum flavum/dura, center the target interspace on the screen of the ultrasound machine. Then, holding the probe steady, mark the skin at the midline of both the vertical and horizontal edges of the probe. Remove the probe and connect the marks to make a cross. With a transverse probe, this cross will identify a midline puncture site (Fig. 35-12). With a longitudinal probe, the cross identifies a paramedian insertion site. By freezing the image on the ultrasound machine, one can also measure the depth of the ligamentum flavum/dura and estimate the best angle for needle insertion.<sup>33</sup>

**Figure 35-9** Human sensory dermatomes.

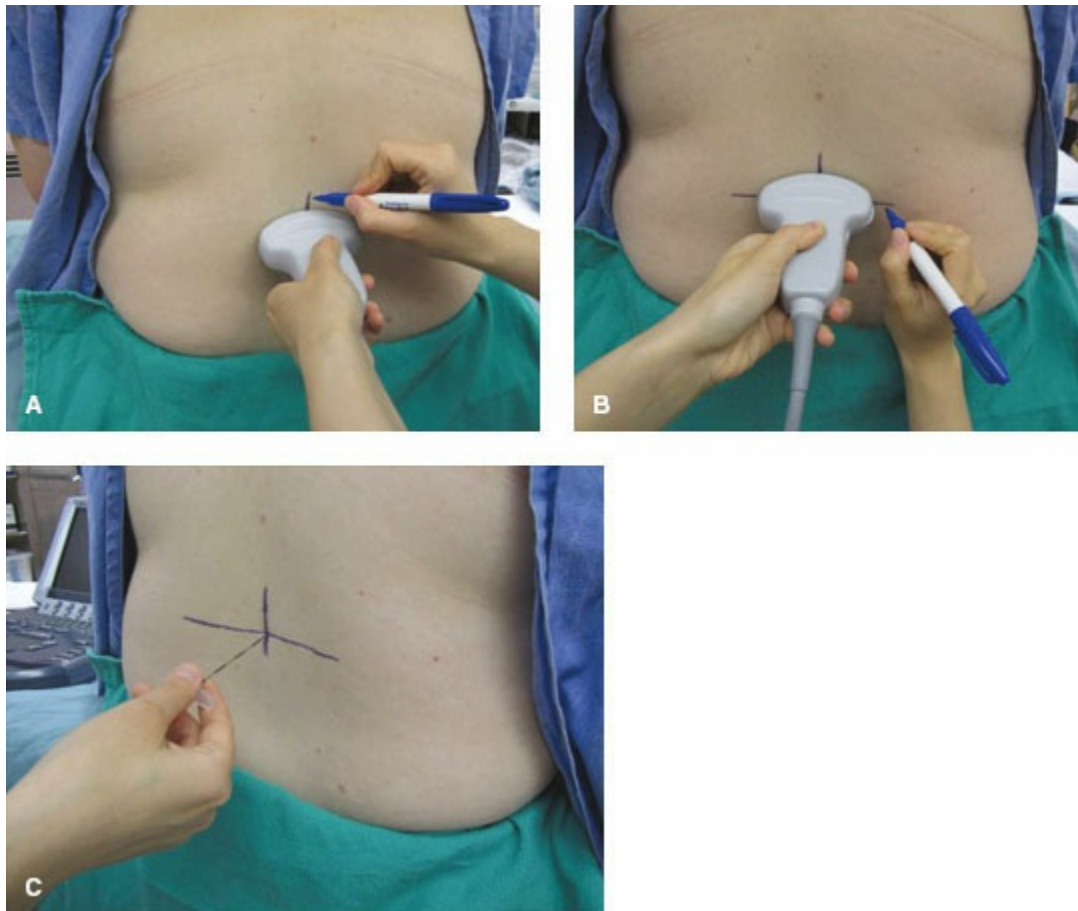

**Figure 35-10** **A:** Scanning in the paramedian longitudinal plane. **B:** Probe oriented parallel to the axis of spine model. **C:** Ultrasound image with a typical saw-tooth sign: hyperechoic flat band on the right represents sacrum, saw-teeth indicate lamina, and the two parallel bands between saw-teeth correspond to the interspace containing the ligamentum flavum–dorsal dura unit (*upper*) and the ventral dura posterior longitudinal ligament–vertebral body complex (*lower*). (Adapted from Balki M. Locating the epidural space in obstetric patients—ultrasound a useful tool: continuing professional development. *Can J Anesth.* 2010;57:1111–1126.)

**Figure 35-11** **A:** Scanning in the transverse plane. **B:** Probe oriented perpendicular to the axis of spine model. **C:** Typical sonogram of a lumbar interspace: midline hyperechoic structures represent the ligamentum flavum–dorsal dura unit (*upper*) and the ventral dura posterior longitudinal ligament–vertebral body complex (*lower*); bilateral symmetrical hyperechoic structures indicate articular and transverse processes with their acoustic shadows. (Adapted from Balki M. Locating the epidural space in obstetric patients—ultrasound a useful tool: continuing professional development. *Can J Anesth.* 2010;57:1111–1126.)

## Technique

### Patient Preparation

#### Equipment

Before inducing subarachnoid or epidural anesthesia, assemble all of the equipment you might need. This list includes both the supplies needed to perform the block and the emergency equipment required to treat rare, but potentially catastrophic complications. Always monitor at least blood pressure and pulse oximetry. Subarachnoid anesthesia is usually induced in an operating room or nearby procedure room. The needed supplies and equipment should be readily available. Epidural anesthesia can be induced in a labor room or in the preoperative holding area. A dedicated cart can hold the needed supplies ([Table 35-1](#)).

#### Positioning

Most patients will either sit or lie on one side during induction of neuraxial anesthesia. Inserting a spinal needle with the patient in the prone jackknife position has been described, but is rarely used in contemporary practice. Still, a recent report describes a real-time ultrasound-guided approach to the L5–S1 interspace in prone patients.<sup>32</sup> The choice between sitting and lateral position depends on the provider, the patient, and the procedure. Many providers prefer the sitting position.<sup>34</sup> Thin patients (BMI <25) report being more comfortable in the lateral position. Obese patients (BMI >30) may prefer sitting.<sup>35</sup> Some clinical situations dictate the lateral position (i.e., hip fractures, labor analgesia in rapidly progressing patients, and certain emergency cesarean sections). You should be comfortable inserting spinal and epidural needles with patients in either position so you can choose the most suitable approach for each patient and procedure.

When sitting, place the patient squarely on the operating table with back and buttocks at the near edge. Have the patient relax his shoulders and curl to flex the lumbar spine (Fig. 35-13). Tilting the operating table may help flex the patient's hips and lumbar spine, further opening the lumbar interspaces (Fig. 35-14).<sup>36</sup> Having obese patients, and those with poorly palpable landmarks, sitting can make it easier to identify the subarachnoid or epidural space. When positioned properly, a line from the C7 vertebral prominence to the gluteal cleft identifies the midline.

**Table 35-1** Suggested Contents for an Epidural Cart

<b><i>Epidural Supplies</i></b>
Epidural trays
Sterile gloves
Sterile prep sticks
Extra epidural needles/catheters
Extra loss of resistance syringes
Sterile dressings
Tape
<b><i>Emergency Equipment</i></b>
Self-inflating bag–valve mask
Oral airways
Working laryngoscope and blade
Endotracheal tubes/supraglottic airways
20% lipid emulsion

**Figure 35-13** Sitting position for neuraxial block. Position the patient squarely on the bed or operating table with the buttocks at the edge near the operator. The patient's legs can be supported by the table, a stool, or (in Labor and Delivery) flexed on the bed. An assistant should provide support. Instruct the patient to relax their shoulders and flex their lumbar spine. ("Arch your back like a rainbow.")

**Figure 35-14** Tilting the operating table can encourage the patient to flex her hips and lumbar spine.

**Figure 35-15** Lateral position for neuraxial block. The patient's hips and shoulders are even with the edge of the bed. The head and neck are supported to remain even with the spine.

When using the lateral position, bring the patient's back to the edge of the table. Position the hips and shoulders perpendicular to the bed (Fig. 35-15). Place a pillow under the patient's head. An assistant can help the patient bend her knees and hips and flex her lumbar spine. The site of surgery and baricity of the local anesthetic will determine the choice of side. With hyperbaric drug, position the operative side down. With isobaric/hypobaric drug, put the operative side up. When inducing subarachnoid anesthesia for cesarean section using either hyperbaric or isobaric drug, place the patient on her *right* side, then turn supine, and provide *left* uterine displacement.<sup>37</sup>

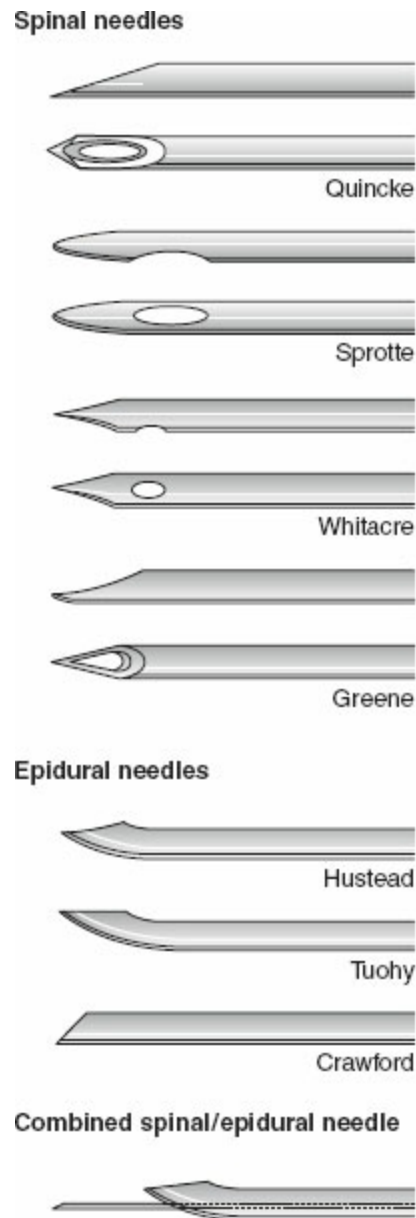

In either position, keep in mind patient comfort. Use blankets and pillows to make sure the patient is warm, comfortable, and appropriately covered. Light sedation with midazolam or fentanyl may sometimes be appropriate. Patients with painful fractures may need deeper sedation to allow appropriate positioning. Here, use small doses of ketamine or propofol. Although skilled pediatric anesthesiologists have a good record of safely inducing neuraxial anesthesia after induction of general anesthesia in children,<sup>38</sup> this approach does not seem prudent in adults.<sup>39,40</sup>

## Skin Preparation

Pay close attention to aseptic technique. The American Society of Anesthesiologists (ASA) recommends removing jewelry (e.g., rings and watches), hand washing, sterile gloves, caps, and masks.<sup>41</sup> Use individual antiseptic packets to cleanse the skin. (Previously opened, multiple-use bottles of povidone-iodine can be contaminated).<sup>42</sup> Both chlorhexidine with alcohol and povidone-iodine with alcohol provide effective skin decontamination.<sup>43</sup>

## Needles

Spinal and epidural needles are categorized by the design of their tips (Fig. 35-16). Spinal needles may have a beveled, cutting tip or a pencil-point, noncutting tip. Pencil-point needles produce fewer postdural puncture headaches (PDPHs) than cutting tip needles. Most anesthesiologists use thin ( $\leq 24$ -gauge) needles to limit the risk of headache. A shorter introducer needle helps puncture the skin and guide the flimsier spinal needle toward the subarachnoid space.

**Figure 35-16** Some spinal and epidural needles. Needles are distinguished by their tip designs.

Epidural needles are usually larger than spinal needles (Fig. 35-16). This larger diameter improves the tactile feel as the needle advances through the ligamentum flavum and into the epidural space. In addition, an 18-gauge needle will allow passage of a 20-gauge catheter. Epidural needles usually

have a curved tip to help guide the catheter in the epidural space. Curved tip epidural needles, as well as the straight-tipped Crawford needle, also can be used for caudal block.

Combined subarachnoid epidural block can be performed sequentially with regular needles or as a needle-through-needle technique. The needle-through-needle technique can be done most simply with an extra long spinal needle and a regular epidural needle (Fig. 35-17). Here, the spinal needle should protrude at least 1.5 cm beyond the tip of the epidural needle. Specialized needle-through-needle, or needle-beside-needle combinations are also available (Fig. 35-16).

### Approach

Lumbar neuraxial block can be performed with either a midline or paramedian approach (Fig. 35-18). The thoracic spinous processes slope steeply and the thoracic spine does not flex as much as the lumbar spine. As a result, the thoracic epidural space is more easily entered using the paramedian approach.

**Figure 35-17** Combined spinal epidural using standard needles. **A:** An 18-gauge, 90-mm Tuohy needle and 27-gauge, 127-mm Whitacre needle side by side. **B:** Whitacre needle inserted through Tuohy needle.

### Technique

**3** Identifying the subarachnoid or epidural space is an exercise in applied

anatomy. Understand the relationship between surface landmarks (i.e., the spinous process) and the target (the subarachnoid or epidural space). Sometimes, the needle will strike bone. Recognize which part of the vertebrae (spinous process, lamina) and where (midline, right, or left) the needle is touching and make an informed choice to redirect the needle toward the target (Fig. 35-19).

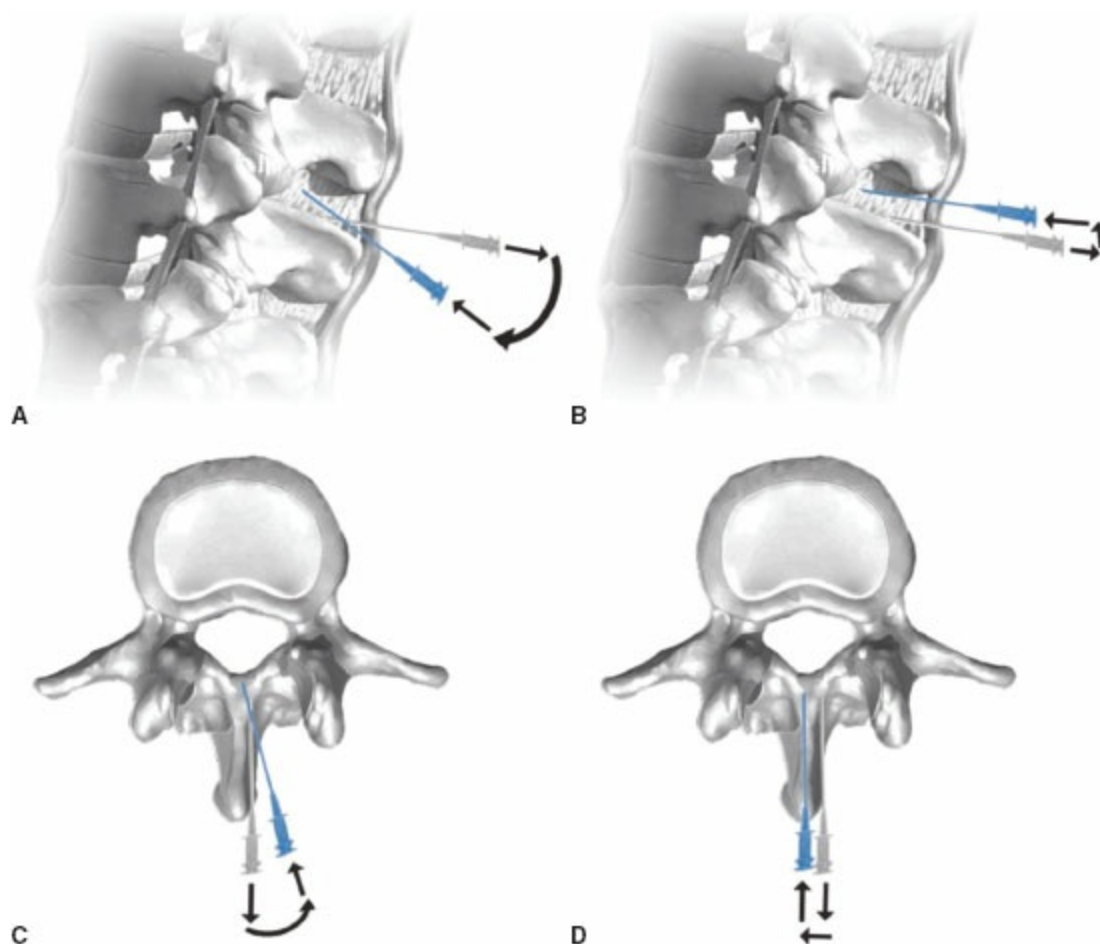

**2** The midline approach is the most straightforward. After positioning the patient, identify the midline by palpating the spinous processes. In obese patients, estimate the midline by imagining a line between the C7 prominence and the intergluteal cleft. Insert the needle in the middle to upper part of the desired interspace. In patients with poor landmarks, insert the needle in the presumed midline and explore. If the needle strikes bone, assess your location (spinous process: intermediate or shallow depth; lamina: deeper) and adjust your approach accordingly.

**Figure 35-18** Vertebral anatomy of the lumbar midline and paramedian approaches. The midline approach requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach adds the oblique plane. The paramedian approach requires less lumbar flexion. The paramedian needle insertion site is 1 cm lateral and slightly below the cephalad edge of the more caudal spinous process. The needle is inserted 10 to 15 degrees off both sagittal and horizontal planes (*inset*). (Adapted from Chestnut DH, Wong CA, Tsen LC, et al., eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 5th Ed. Philadelphia, PA: WB Saunders; 2014:239.)

The paramedian approach requires some applied geometry. The insertion site is approximately 1 cm lateral to the superior edge of the inferior spinous process (Fig. 35-18). Angle the needle slightly cephalad and slightly medial, aiming for the midline at the estimated depth of the epidural or subarachnoid space. A bony obstruction at the estimated depth of the subarachnoid or

epidural space is usually lamina. Most often, the needle strikes the upper edge of the lateral, lower lamina. Gradually walk the needle cephalad until you enter the epidural or subarachnoid space. When attempting thoracic epidural needle placement, many experts intentionally contact the lamina of the vertebral body below the target interspace. This contact provides an estimation of the depth of the epidural space. The epidural needle can then be walked up the lamina and into the desired epidural space (Fig. 35-20).

**Figure 35-19** Troubleshooting contact with bones. The *gray* needle is the initial approach; the *blue* needle is the adjusted approach. **A:** If the needle is midline, redirect slightly more cephalad. **B:** Or, lift the needle after withdrawing into the subcutaneous tissues. **C:** If the needle is off midline and contacting lamina, redirect as in **A**. **D:** Or, withdraw the needle into the subcutaneous tissue and shift as in **B**. (Adapted from Chestnut DH, Wong CA, Tsen LC, et al. eds. *Chestnut's Obstetric Anesthesia: Principles and Practice*. 5th Ed. Philadelphia: WB Saunders; 2014:239.)

## Subarachnoid Spinal Anesthesia

After positioning the patient, preparing the skin, and applying a sterile drape, infiltrate the skin with a small amount of local anesthetic. A single pass with a finder needle may help identify the interspace. Injecting too much local anesthetic can obscure landmarks and make things more difficult. Using either

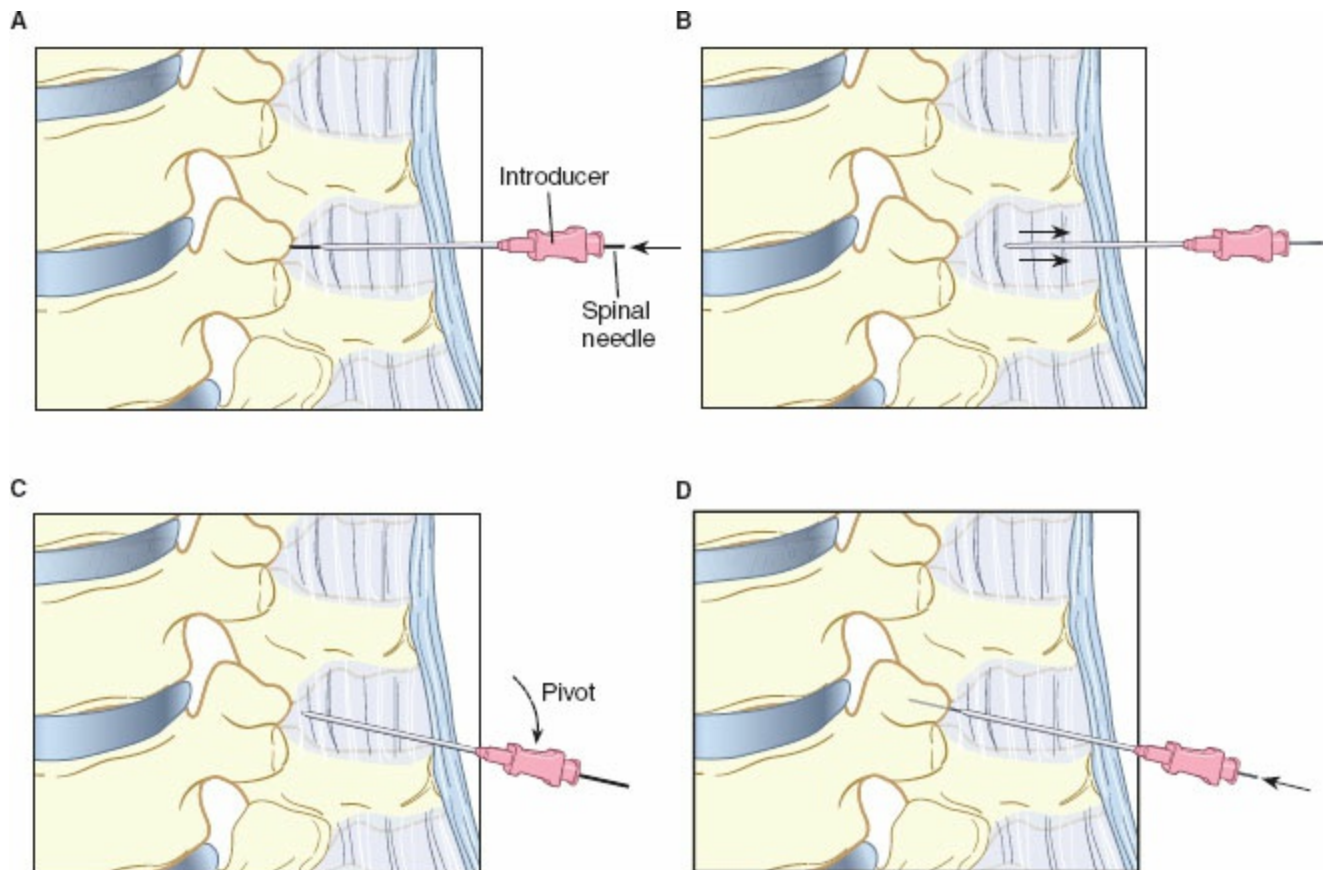

a midline or paramedian approach, insert the introducer needle. Note that the introducer needle has a beveled tip. In the occasional thin or small patient, the introducer needle may accidentally enter the subarachnoid space. To limit the risk of PDPH in this situation, always insert the introducer needle as you would a cutting tip spinal needle with the bevel oriented parallel to the longitudinal axis of the back. Next, pass the spinal needle through the shaft of the introducer needle and advance toward the subarachnoid space. Hold the hub of the spinal needle with your fingertips and appreciate the “clicks” and “pops” as the needle traverses the ligamentum flavum and the dura. Remove the stylet from the spinal needle after each pop. Look for CSF. If the patient is sitting, CSF should appear promptly. If the patient is lying on her side (or prone), or if the spinal needle tip is angled downward, CSF may appear more slowly. If the spinal needle contacts bone, withdraw it into the shaft of the introducer needle and *pivot* the introducer slightly and reinsert the spinal needle (Fig. 35-21). If a midline introducer needle is inserted in the center of an interspace and the spinal needle contacts bone, it is most likely lamina of the lower vertebra (Fig. 35-19). By slowly redirecting the needle cephalad, you should be able to “walk” off the lamina and into the subarachnoid space. The spinal needle should advance a little deeper with each redirection. If you still do not enter the subarachnoid space, remove the spinal needle, palpate the back, and reassess the insertion site of your introducer needle.

**Figure 35-20** Thoracic epidural insertion: use the lamina as a depth marker and “walk” the needle into the epidural space.

Patients will occasionally report a transient paresthesia during spinal

needle insertion. These paresthesias may be from needle to nerve root contact within the subarachnoid space<sup>44</sup> or they may emanate from the dura. Should a transient paresthesia occur, stop advancing the spinal needle, and withdraw the stylet. If you see CSF, inject the medication into the subarachnoid space. Do not inject if the paresthesia persists or recurs. Instead, remove and reposition the spinal needle.

**Figure 35-21** Using an introducer needle. If the spinal needle contacts bone (A), withdraw it into the shaft of the introducer needle (B). Otherwise, the spinal needle will merely bend, not change direction. After withdrawing the spinal needle, pivot the introducer (C) and reinsert the spinal needle (D).

Once clear CSF appears in the hub of the spinal needle, fix the needle in position with your nondominant hand and attach the syringe containing the medication. Aspirate gently. If using a hyperbaric solution, you will see birefringence (Schlieren lines), which indicates the mixing of solutions of differing baricities. Some experts recommend rotating the spinal needle 360 degrees to confirm free flow of CSF in four quadrants. This step is unnecessary.

Drug emerges directly from the tip of cutting point needles, so needle bevel orientation has no effect on the subsequent level of subarachnoid block. Pencil-point needles have side holes, which produce directional flow of injected drug. Side-hole orientation, especially caudal versus cephalad, influences the distribution of both hyperbaric and isobaric local

anesthetics.<sup>45,46</sup> In most cases, orient the side-hole toward the head to ensure adequate sensory block and to minimize the risks of local anesthetic pooling around the cauda equina (see toxicity, below).

## Continuous Subarachnoid Spinal Anesthesia

After identifying the subarachnoid space with a large-gauge needle, insert an appropriate sized catheter 2 to 3 cm into the subarachnoid space. The catheter will advance more easily and be more likely to lie cephalad to the insertion site if the bevel or orifice of the needle is directed toward the patient's head. Caudally directed catheters may cause pooling and maldistribution of local anesthetic, which has been associated with permanent neurologic injury (see Complications).

## Epidural Anesthesia

The epidural space can be identified with either the hanging drop or loss of resistance technique. With the hanging drop technique, place a drop of saline at the hub of the epidural needle. As the needle enters the epidural space, the drop of liquid will be pulled into the needle. This technique relies on negative pressure within the epidural space. It is more reliable for thoracic than lumbar needle insertion.

Most anesthesiologists use a loss of resistance technique to identify the epidural space. When the tip of the epidural needle lies within the ligamentum flavum, there is resistance to injection. As the tip of the needle enters the epidural space, this resistance disappears. Common variations of the loss of resistance technique use air or saline in the loss of resistance syringe and intermittent or continuous pressure to advance the epidural needle.

### *Air versus Saline*

Anesthesia providers often have a preference for air or saline in the loss of resistance syringe. Air has the advantage of simplicity. In addition, using air makes it easier to recognize an accidental or intentional dural puncture or an intrathecal catheter. However, intracranial air, injected  after an accidental dural puncture, will produce an instant headache.<sup>47</sup> In addition, large amounts of epidural air, especially in smaller patients, may interfere with the distribution of local anesthetic. Possible advantages of saline include fewer dural punctures, fewer PDPHs, easier insertion of the epidural catheter, fewer paresthesias, fewer intravascular catheters, better analgesia, and fewer unblocked segments after epidural local anesthetic injection. *But*, a recent meta-analysis found no advantages of saline versus

air.<sup>48</sup> Clinical outcomes are similar when anesthesiologists use the technique of their choice.<sup>49</sup>

**Figure 35-22** Hand positions for intermittently advancing a needle toward the epidural space using a winged needle. Grasping the wings with your index fingers and thumb, place your long fingers alongside the shaft at the site of insertion. Your thumb and index fingers advance the needle while the middle fingers control the needle's forward movement.

### *Intermittent versus Continuous*

The epidural needle can be advanced intermittently or continuously. In the United States, the intermittent, or “stop go,” technique is probably more common. Grasp the epidural needle firmly with both hands (Fig. 35-22) and advance it millimeter by millimeter. The intraspinal ligament will present little resistance, whereas the ligamentum flavum will feel firm and gritty. In between each advance, firmly tap the plunger of the loss of resistance syringe. If using saline in the syringe, include a bubble of air that can be compressed with each tap. When the needle is in the ligamentum flavum, the plunger will recoil. Once the tip of the needle enters the epidural space, the plunger will collapse.

Continuous pressure techniques have been described by Bromage<sup>50</sup> and

Doughty.<sup>51</sup> For the Bromage technique, make a fist with your nondominant hand and place your carpal–metacarpal joints on the patient’s back. Firmly grasp the shaft of the epidural needle between your thumb and forefinger. Advance the needle slowly by rolling your fist into the patient’s back. Meanwhile, use your dominant hand to apply continuous pressure to the plunger of the loss of resistance syringe, which can contain either air or saline. Stop advancing the needle when the plunger collapses (Fig. 35-23).

**Figure 35-23** The Bromage technique for identifying the epidural space. (From Norris MC, ed. *Obstetric Anesthesia*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 1999:302.)

In the Doughty technique, the roles of the hands are reversed. Now, *brace* the epidural needle with your nondominant hand to control its advance. Grasp the barrel of the loss of resistance syringe with your dominant hand so the metacarpal head of your index finger is positioned on the end of the plunger (Fig. 35-24). Slowly advance the needle by balancing the driving pressure from your dominant hand with resistance from your bracing hand. Use the metacarpal head of the dominant index finger to exert pressure on the end of the plunger; you will perceive the loss of resistance immediately upon entering the epidural space.<sup>51</sup>

More common today are various “son-of-Doughty” techniques. Here, the driving pressure is applied directly to the plunger of a saline-filled loss of resistance syringe (Fig. 35-25).<sup>52</sup> When the tip of the needle enters the epidural space, the plunger collapses and the needle stops advancing.

As with the choice between air and saline, any technique done well is better than the best technique done poorly.

## The Epidural Catheter

After identifying the epidural space, you can inject local anesthetic through either the needle or a catheter. Injecting through the needle will provide slightly faster onset but risks complications if drug is accidentally injected intrathecally or intravenously. Inserting a catheter into the epidural space encourages more careful injection of the initial dose of medication and allows the provision of epidural anesthesia or analgesia for as long as needed. Most epidural catheters are made of nylon or polyamide. Some are wire reinforced. Catheters can have a single orifice at the tip or multiple orifices along the distal end. Multiorifice catheters allow wider distribution of injected medication and, in laboring women, are associated with more extensive block and better analgesia. Nylon and polyamide catheters can be flimsy and kink at the hub of the epidural needle. Many come with “threading assist devices” that seat in the hub of the epidural needle and ease catheter insertion. Try to insert about 5 cm of catheter into the epidural space. Inserting less increases the chances that the catheter will become dislodged. Inserting more makes it more likely that the catheter will enter a blood vessel.<sup>53</sup> Although the orientation of the epidural needle bevel will determine the initial direction of the epidural catheter, it does not reliably aim the catheter in a cephalad or caudad direction. Most epidural catheters curl on themselves at the level of insertion. If you meet resistance while inserting the catheter, *do not* withdraw and try to reinsert. Some epidural needles have a sharp inner bevel that can shear the tip of a catheter. Instead, remove both needle and catheter together and reidentify the epidural space.

**Figure 35-24** The Doughty technique: the nondominant (*left*) hand braces the needle against the patient's back. The dominant (*right*) hand advances the needle by grasping the hub while applying pressure to the plunger with the metacarpal head of the index finger. The right hand will feel the loss of resistance as soon as it occurs.

Once the epidural catheter is inserted, it is time to remove the needle. Hold the epidural catheter about 1 cm from the hub of the needle. Gently withdraw the needle, sliding it along the catheter until the hub meets your fingertips. Move your fingers back another centimeter and repeat the process. When the tip of the needle comes out of the skin, grasp the catheter between the needle and the skin and slide the needle off the catheter.

## **Combined Subarachnoid Spinal Epidural**

### *Technique*

The needle-through-needle technique is the most common method of combined subarachnoid spinal epidural (CSE) block. Because the conus medullaris sometimes extends to L2 or even L3, it is safest to perform CSE block at the L3–L4 or L4–L5 interspaces (see Complications, below). First, identify the epidural space with your usual technique. Using air in the loss of resistance syringe will assure that any liquid flowing through the spinal needle is indeed CSF. After identifying the epidural space, insert a long, small-gauge spinal needle. You should feel some resistance as the tip of the spinal needle passes the tip of the epidural needle. Then you will feel a subtle pop as the spinal needle pierces the dura. Stabilize the spinal needle by pinching the hubs of both needles between your thumb and finger ([Fig. 35-26](#)). Withdraw the stylet from the spinal needle and look for CSF. Carefully inject the subarachnoid medication, withdraw the spinal needle, and insert the epidural catheter.

**Figure 35-25** Hand positions for (A) the original Doughty technique and (B), (C), and (D) various “son-of-Doughty” techniques. (A, B, and D from Russell R, Porter J, Scrutton M. In: Reynolds F, ed. *Pain Relief in Labour*. London: BMJ Publishing, 1997, with permission; C from Reynolds F. Hand positions and the ‘son-of-Doughty’ technique. *Anaesthesia*. 2005;60:717–718. ©2016 Association of Anaesthetists of Great Britain & Ireland.)

**Figure 35-26** Hand position for stabilizing CSE needles. The thumb and index finger pinch the hubs of both spinal and epidural needles to fix the position of the spinal needle.

## *Troubleshooting*

The most common problem encountered with the needle-through-needle technique is failure to see CSF in the hub of the spinal needle (Fig. 35-27). Most often, the spinal needle has not entered the subarachnoid space. The epidural needle may not be in the epidural space or it may be directed laterally. Sometimes the needle does not extend far enough to penetrate the dura. This problem is more likely to occur if the patient is in the lateral position instead of sitting. Sometimes, rotating the spinal needle 360 degrees will be enough to enter the subarachnoid space. Otherwise, consider proceeding with an epidural technique or reidentifying the epidural space.

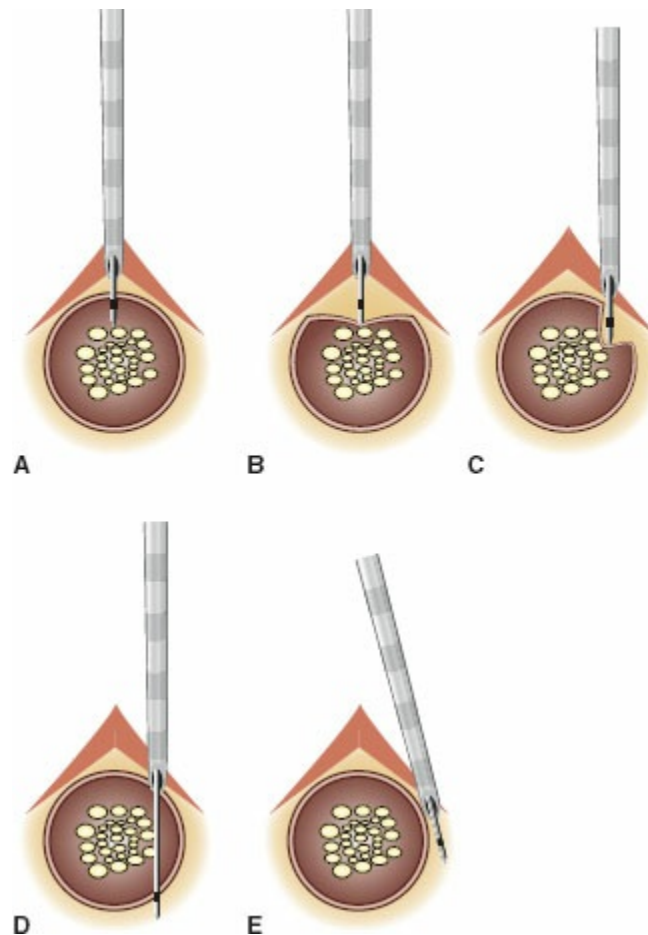

## *Drug Dosing*

The CSE technique can alter the behavior of both intrathecal and epidural medications. Because the epidural catheter can be used to supplement the subarachnoid block, it is possible to use smaller doses of subarachnoid medication. Less intrathecal local anesthetic may limit the hemodynamic effects of subarachnoid anesthesia. Epidural injection of local anesthetic or saline can raise the level of sensory block even after the level of subarachnoid anesthesia has stabilized (Fig. 35-28). The presence of a small-gauge dural hole also may enhance the spread of subsequent epidural medications. This effect may be responsible for the improved labor epidural analgesia reported after previous 25-gauge needle dural puncture.<sup>54</sup>

## *Choice of Technique*

Subarachnoid anesthesia, with its rapid onset of dense sensory block is often the best choice for surgeries of known duration (usually <2 hours). Epidural anesthesia is slower in onset, which may be helpful when caring for hemodynamically fragile patients. In addition, the epidural catheter can be used for postoperative analgesia. Thoracic epidural analgesia is an important part of many enhanced recovery after surgery (ERAS) protocols for patients undergoing major intra-abdominal and intrathoracic procedures. CSE anesthesia can offer the benefits of both techniques for lower abdominal and lower extremity surgeries. The intrathecal component can provide rapid anesthesia, whereas the epidural catheter can be used later. In addition, the epidural catheter can be dosed during surgery to enhance or prolong the subarachnoid anesthetic. The CSE technique also is a good alternative to subarachnoid anesthesia in morbidly obese patients. It can be easier to find the subarachnoid space after identifying the epidural space with a 17- or 18-gauge needle than when using just a short introducer needle and a small-gauge spinal needle.<sup>55</sup> Again, the epidural catheter can be used to prolong the

anesthetic for longer operations.

**Figure 35-27** Different positions of epidural and spinal needles with the needle-through-needle CSE technique. **A:** The ideal position; a midline epidural needle guides the spinal needle into the subarachnoid space. **B:** Spinal needle too short; it indents but does not pierce the dura. **C:** Spinal needle too short and too lateral. **D:** Spinal needle too long; it has passed through the subarachnoid space. **E:** Spinal needle too lateral; the epidural needle is in the epidural space but it guides the spinal needle away from the dural sac. (Adapted from Norris MC, ed. *Obstetric Anesthesia*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:307.)

**Figure 35-28** Spread of sensory block with CSE. Nonpregnant patients received 10 mg 0.5% bupivacaine intrathecally. After the maximum level of sensory block had been

achieved, patients received nothing (○), 10 mL epidural saline (△), or 10 mL epidural bupivacaine (▽). (Adapted from Norris MC, ed. *Obstetric Anesthesia* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:309.)

## Efficiency and Neuraxial Anesthesia

Despite the advantages of subarachnoid and epidural anesthesia, surgeons often discourage their use because they fear being delayed. There are many ways to relieve these concerns and use neuraxial anesthesia efficiently. Epidural catheters can be sited before the patient enters the operating room. Some operating suites have designated procedure rooms or block rooms for this purpose. In other settings, epidural catheters can be placed in the preoperative holding area. Subarachnoid anesthesia kits can be opened in advance. Drugs can be drawn up into appropriately labeled sterile syringes. The kit can then be rewrapped and set aside, ready to use as soon as the patient enters the OR. Lastly, performing subarachnoid and epidural blocks regularly will improve skills and build confidence, both yours and your surgeon's.

## Pharmacology

### Subarachnoid Anesthesia

#### Spread and Duration

Density and dose are the two most important factors that determine the spread and duration of subarachnoid anesthesia. Density is the ratio of the mass of a substance to its volume. Baricity is the ratio of two densities; here, the density of CSF and that of the injected local anesthetic. Currently used local anesthetics are made *hyperbaric* by mixing with dextrose. Plain local anesthetic solutions are isobaric or slightly *hypobaric*. [Table 35-2](#) offers suggestions for dose and baricity when performing subarachnoid anesthesia for various surgeries.

**Figure 35-29** In the supine position, hyperbaric local anesthetics injected at the apex of the lumbar lordosis (*circle*) flow with gravity and pool in the sacrum and thoracic kyphosis. Thoracic pooling may be why hyperbaric solutions typically produce mid-

thoracic levels of sensory block. (From Barash PG, Cullen BF, Stoelting RK, et al., eds. *Clinical Anesthesia*. 7th ed. Philadelphia, PA: Wolters Kluwer; 2015;917.)

Hyperbaric local anesthetics are denser than CSF and will flow with gravity to the dependent areas of the spine, usually the upper thoracic region in supine patients (Fig. 35-29). Positioning patients upright or lateral can limit the initial spread of hyperbaric local anesthetic. But, when the patient returns to the supine position, even after 20 to 30 minutes, the sensory level reaches the usual mid-thoracic dermatomes.

Bulk displacement determines the initial spread of isobaric drug. Subsequently, movement of CSF by either transmission of cardiac pulsations<sup>56</sup> or gross patient movements (i.e., turning from lateral to supine position<sup>57</sup>) will determine the ultimate spread of block.

In nonpregnant patients, hyperbaric local anesthetics produce more consistent levels of sensory block than isobaric drug (Fig. 35-30).<sup>58</sup> Isobaric drugs produce longer blocks.<sup>59</sup> When used for subarachnoid anesthesia for cesarean section, there is little difference between equal doses of isobaric or hyperbaric bupivacaine.<sup>60</sup>

## Patient Variables

Height, weight, body mass index, and vertebral column length have no clinically significant effect on the spread of subarachnoid anesthesia. 5 Increasing age is associated with slower onset and longer duration but no change in extent of subarachnoid block.<sup>61</sup> Both female gender and pregnancy increase motor block produced by intrathecal isobaric bupivacaine.<sup>62</sup> One small study reported that CSF volume correlated with the spread of subarachnoid anesthesia.<sup>63</sup> Pregnant patients will develop higher levels of sensory block than nonpregnant patients when given the same dose of intrathecal local anesthetic. This enhanced sensitivity disappears shortly after delivery.<sup>64</sup> In nonpregnant adults, increasing abdominal girth correlates with increasing extent of sensory block after intrathecal injection of isobaric bupivacaine.<sup>65</sup> Increases in intra-abdominal and consequently epidural space pressure associated with both pregnancy and obesity may enhance sensory spread by decreasing lumbar CSF volume.

## Local Anesthetic Dose

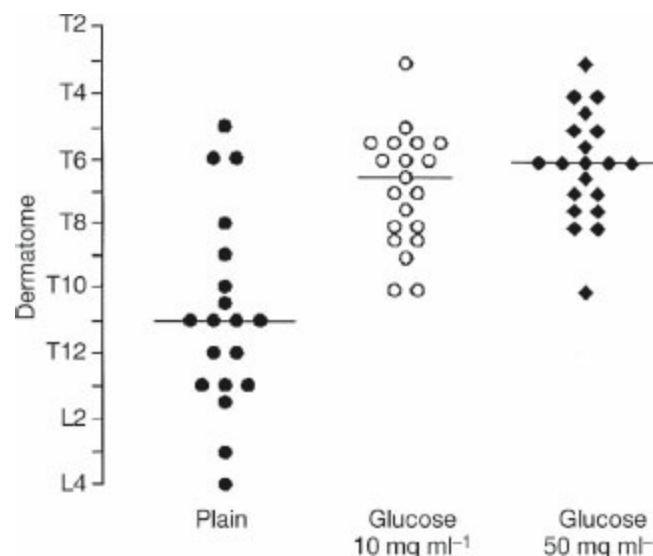

Within commonly used ranges (i.e., 7.5 to 12 mg hyperbaric bupivacaine), increasing the dose of local anesthetic does not significantly increase the level of block.<sup>61</sup> At some point (i.e., 15 mg hyperbaric bupivacaine) a higher sensory level will develop.<sup>66</sup> Larger doses of both hyperbaric and isobaric local anesthetics do produce denser and longer lasting anesthesia.

**Table 35-2** Some Common Surgical Procedures That Can Be Done with Subarachnoid Spinal Anesthesia

Procedure	Level	Local Anesthetic	Comments
<b>Obstetrics</b>			
Cesarean section	≥ T6	12–15 mg hyperbaric bupivacaine <sup>a</sup>	Lower doses may produce less hypotension but should be used as part of a combined subarachnoid epidural technique. Adding a lipophilic opioid may improve intraoperative analgesia.
Postpartum tubal ligation (mini laparotomy)	≥ T8	10–12 mg hyperbaric bupivacaine	
Cervical cerclage	≥ T10	5–7.5 mg hyperbaric bupivacaine	Faster discharge with smaller doses
<b>Orthopedics</b>			
Hip fracture or replacement	≥ T12	15–20 mg isobaric <sup>b</sup> bupivacaine	Sitting or lateral position with the operative side up
Knee replacement	≥ T12	12–15 mg hyperbaric bupivacaine	Higher level if tourniquet used
Knee arthroscopy	≥ T12	5–7.5 mg either isobaric or hyperbaric bupivacaine	Faster discharge with smaller dose. Lipophilic opioid may help with tourniquet pain. Some use 40 mg preservative-free 2-chloroprocaine for outpatient procedures.
Ankle surgery	≥ T12	At least 7.5 mg hyperbaric bupivacaine	Dose depends on expected duration of procedure. Combined subarachnoid epidural can add postoperative analgesia.
<b>Urology</b>			
Cystoscopy	≥ T10	2.5–5.0 mg isobaric or hyperbaric bupivacaine	Faster discharge with smaller dose
Trans urethral resection of bladder tumor or prostate	≥ T10	At least 7.5 mg isobaric or hyperbaric bupivacaine	Adjust dose according to expected duration of surgery.
Penile prosthesis	≥ T10	12–15 mg hyperbaric bupivacaine	
<b>General Surgery</b>			
Inguinal hernia repair/open appendectomy	≥ T8	12–15 mg hyperbaric bupivacaine	
Perianal/perirectal	Sacral	5–7.5 mg hyperbaric bupivacaine (lithotomy position)	Smaller doses of isobaric bupivacaine (2.5–5 mg) can be used if the patient will be prone.

<sup>a</sup>In the United States: 0.75% bupivacaine with 8.25% dextrose.

<sup>b</sup>Preservative-free 0.5% bupivacaine.

**Figure 35-30** Range of sensory block after intrathecal injection of two different solutions of 0.5% tetracaine. Solutions containing dextrose, which are hyperbaric, produce more consistent levels of block than plain (isobaric) solutions. (From Whiteside JB, Burke D, Wildsmith JA. Spinal anesthesia with ropivacaine 5 g.mL<sup>-1</sup> in glucose 10 mg.mL<sup>-1</sup> or 50 mg.mL<sup>-1</sup>. *Br J Anaesth.* 2001;86:241–244.)

## Adjuvants

Many drugs have been studied for their ability to prolong or improve subarachnoid anesthesia. Vasoconstrictors, such as epinephrine or phenylephrine may prolong the intrathecal block by inhibiting absorption of intrathecal local anesthetics or by acting directly on spinal cord  $\alpha$ -receptors. Vasoconstrictors prolong the duration of intrathecal tetracaine. They have no clinically significant effects on the duration of intrathecal lidocaine or bupivacaine.

The  $\alpha_2$ -agonists clonidine and dexmedetomidine prolong the duration of subarachnoid anesthesia and analgesia. Associated bradycardia may require atropine.<sup>67</sup> Larger doses of intrathecal clonidine also can cause hypotension and sedation.<sup>68</sup>

Lipid soluble opioids (fentanyl or sufentanil) can enhance intraoperative anesthesia and provide a few hours of postoperative analgesia. Small doses of fentanyl (5 to 10  $\mu$ g) are as effective as larger doses and may produce less itching. Intrathecal morphine can provide prolonged (12 to 24 hours) postoperative analgesia but side effects, including itching and nausea and vomiting, are common and challenging to treat. Rarely, intrathecal morphine can produce delayed respiratory depression.

## Epidural Anesthesia

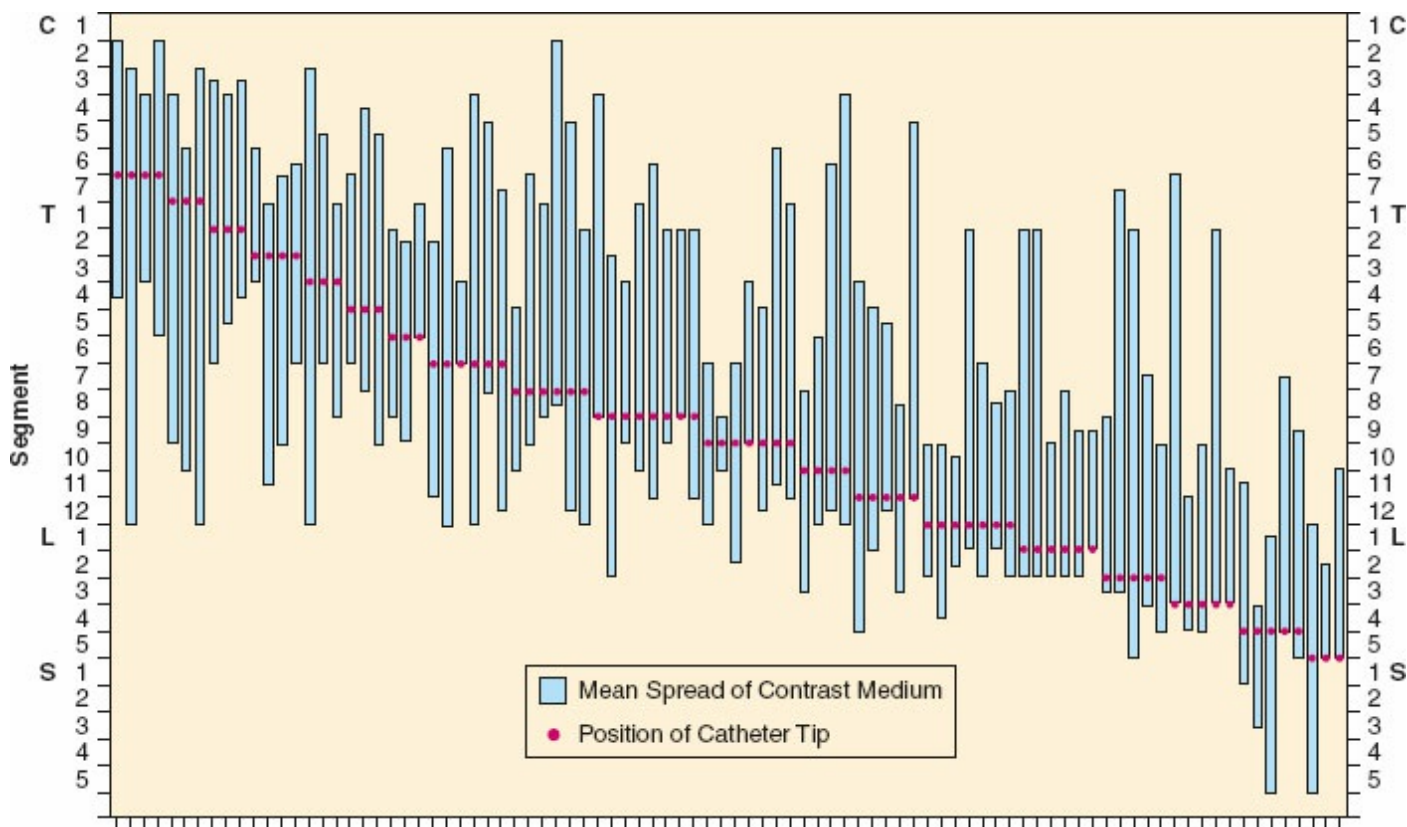

Lumbar epidural anesthesia can be used interchangeably with subarachnoid anesthesia in most cases. One exception is procedures involving the S1 dermatome (i.e., ankle surgery). S1 is the largest nerve root in the body and the onset of epidural block can be slow and incomplete. Thoracic epidural injection can provide segmental block, which can supplement general anesthesia for upper abdominal and intrathoracic surgeries (Table 35-3).

## Spread of Block

Patient variables, drug dose, and site of injection are the main determinants of the spread of epidural block.<sup>69</sup> A given dose of local anesthetic will spread farther in older compared to younger patients. As a result, the risk of hypotension associated with epidural local anesthetics may be greater in older patients. Height, weight, and BMI have no clinically significant effects on the extent of epidural block. Pregnant patients will develop more extensive block after a fixed dose of local anesthetic than nonpregnant patients.<sup>70</sup>

The extent of epidural block is proportional to the dose of local anesthetic injected. Mass of drug, not the volume injected, mostly determines the extent of sensory block. However, the relationship is not linear. A smaller dose produces a relatively greater spread (dermatomes/dose) than a larger dose.<sup>69</sup>

Site of injection has a major impact on the spread of epidural block. Small doses of local anesthetic (5 to 10 mL) will produce a band of block around the injection site. Lumbar injection spreads more cephalad than caudad, whereas upper thoracic drug blocks more dermatomes below than above the injection site (Fig. 35-31).<sup>71</sup>

**Figure 35-31** Mean radiographic spread after epidural injection of 5 mL iotrolan, 240 mg I/mL, in 90 patients. C, cervical segment; L, lumbar segment; S, sacral segment; T, thoracic segment. Cervical injection spreads more caudally, whereas lumbar injection spreads more cranially. (Adapted from Yokoyama M, Hanazaki M, Fujii H, et al. Correlation between the distribution of contrast medium and the extent of blockade during epidural anesthesia. *Anesthesiology*. 2004;100:1504–1510.)

**Table 35-3** Recommendations for Epidural Anesthesia

Type of Surgery	Insertion Site	Typical Spread of Block
Thoracic	T2–T6	T2–T6 (5–10 mL local anesthetic)
Abdominal	T6–L1	T1–L4 (10–20 mL local anesthetic)
Lower extremity Pelvic Peripheral vascular Obstetric	Lumbar L2–L5	T8–S5 (20 mL local anesthetic)  C8–T8 (upper level of sensory block)

Modified from Visser WA, Lee RA, Gielen MJM. Factors affecting the distribution of neural blockade by local anesthetics in epidural anesthesia and a comparison of lumbar versus thoracic epidural anesthesia. *Anesth Analg*. 2008;107:708–721.

## Onset and Duration

Onset and duration of epidural anesthesia depend largely on the choice of anesthetic (Table 35-4). Some sign of sensory block should be detectable at the dermatomal level of injection within 5 to 10 minutes. The full extent of block usually develops within 20 to 30 minutes. Differences in onset time between local anesthetics are small and rarely clinically significant.<sup>72</sup> 2-Chloroprocaine has the shortest duration followed by lidocaine and mepivacaine. The more potent drugs, bupivacaine and ropivacaine have the slowest onset but the longest durations. Lidocaine produces relatively more motor block than sensory block. Postoperative patients may have pain before the motor block has completely regressed. Sensory block usually outlasts motor block with mepivacaine, ropivacaine, and bupivacaine.

**Table 35-4** Local Anesthetics Used for Surgical Epidural Block

Drug	Duration		Prolongation by Epinephrine (%)
	Two-dermatome Regression (min)	Complete Resolution (min)	
2-Chloroprocaine 3%	45–60	100–160	40–60
Lidocaine 2%	60–100	160–200 <sup>a</sup>	40–80 <sup>b</sup>
Mepivacaine 2%	60–100	160–200	40–80
Ropivacaine 0.5%–1.0%	90–180	240–420	No
Bupivacaine 0.5–0.75% <sup>c</sup>	120–240	300–460	No

<sup>a</sup>Motor block can outlast sensory block.

<sup>b</sup>Epinephrine also improves quality of sensory block.

<sup>c</sup>Use only 0.5% bupivacaine in obstetric patients.

Surgery often outlasts the duration of the initial epidural injection. Injecting half the initial dose once the block has regressed by two dermatomes should maintain an adequate level of block. Another way to maintain surgical anesthesia is to inject a fixed dose of drug at regular

intervals. For lumbar epidural catheters, inject 5 mL 0.5% ropivacaine or bupivacaine every 60 minutes. Use the same approach with thoracic epidural catheters, but inject a smaller dose (2.5 mL).

## **Adjuvants**

Adjuvants can speed the onset, improve the quality, and prolong the duration of epidural block.<sup>69</sup>

### *Sodium Bicarbonate*

Sodium bicarbonate raises the pH of commercially prepared local anesthetics, increasing the amount of nonionized, active, drug. Adding sodium bicarbonate speeds the onset and increases the density of epidural local anesthetic block. These effects are most pronounced with lidocaine. Bupivacaine readily precipitates in the presence of sodium bicarbonate.

### *Epinephrine and $\alpha_2$ -Agonists*

Epinephrine-induced vasoconstriction decreases systemic absorption of local anesthetics. In addition, stimulation of spinal cord  $\alpha_2$ -receptors produces analgesia. Adding  $\alpha_2$ -agonists (epinephrine, clonidine, or dexmedetomidine) to local anesthetic speeds the onset and improves the quality of epidural anesthesia. Clinically, adding epinephrine, 5  $\mu\text{g}/\text{mL}$  to lidocaine markedly improves the quality of epidural anesthesia for cesarean section. Patients who receive lidocaine with epinephrine are about half as likely to experience intraoperative pain or need conversion to general anesthesia compared with women who receive plain lidocaine.<sup>73</sup> Epidural clonidine or dexmedetomidine intensify and prolong the effects of epidural local anesthetics.<sup>74</sup> These drugs also provide postoperative analgesia.<sup>75</sup> Sedation is common.

### *Opioids*

Epidural opioids also speed the onset and improve the quality of block produced by local anesthetics. Fentanyl, sufentanil, and morphine are the most commonly used opioids. These drugs also can provide postoperative analgesia. Itching, nausea, and vomiting are common side effects, especially with epidural morphine.<sup>76</sup>

## **Test Doses**

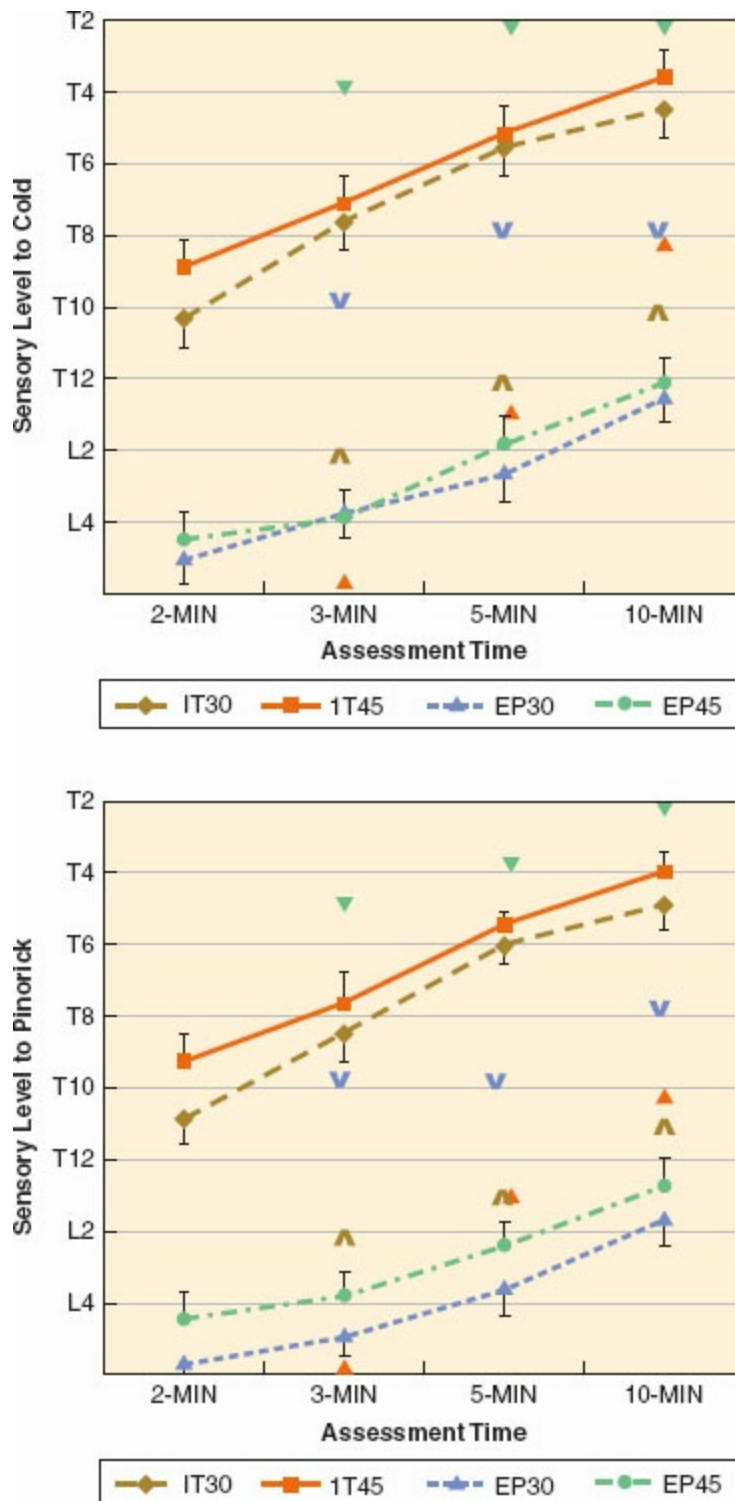

Currently, most clinicians use a blind technique to identify the epidural space and insert a catheter. Intended epidural catheters may be subarachnoid, subdural, intravascular, or elsewhere. Misplaced injection of drugs intended for the epidural space can have serious adverse consequences. To minimize

these risks, all epidural catheters should be tested *throughout* their use. The purpose of these tests is twofold: to prove that the catheter is not in an unintended place (i.e., intrathecal or intravenous) *and* to prove that the catheter is indeed in the epidural space.

The most common cause of significant anesthetic-related morbidity and mortality in laboring women is unrecognized *intrathecal* injection of local anesthetics.<sup>77,78</sup> When inducing epidural anesthesia or analgesia, first 6 inject a small dose of local anesthetic (i.e., 30 to 45 mg lidocaine or 5 to 10 mg bupivacaine) through the catheter and look for signs of subarachnoid anesthesia. Within 2 to 3 minutes of intrathecal local anesthetic injection, patients will note warmth and tingling in their legs or feet. Sensory block to cold and pinprick can be detected.<sup>79</sup> In parturients, intrathecal lidocaine will also produce motor block by 3 minutes. In laboring women, rapid onset of analgesia should also alert to intrathecal injection. Pay close attention to the intrathecal test dose. Positive findings can be subtle and easily overlooked on a busy labor and delivery floor.

Be aware of two limitations of lidocaine as an intrathecal test dose in pregnant women. First, some women will report warmth in their legs and motor weakness after *epidural* injection of 30 to 45 mg lidocaine. As a result, a positive intrathecal test dose should be evaluated carefully to avoid removing an appropriately placed epidural catheter. Second, these small doses of lidocaine can produce extensive sensory and sympathetic block (Fig. 35-32). Dangerously high subarachnoid anesthesia can occur.<sup>80</sup> In a recent report, unplanned intrathecal injection of 45 mg lidocaine produced clinically significant complications in 60% of patients (Table 35-5).<sup>81</sup>

Intravascular local anesthetic injection can produce seizures and even cardiac arrest. The most widely used intravenous test dose is lidocaine 7 with epinephrine. Intravenous injection of epinephrine 15  $\mu$ g will increase heart rate by at least 10 beats per minute and systolic blood pressure by at least 15 mmHg.<sup>82</sup> Unfortunately, sedation, general anesthesia,  $\beta$ -blockade, advancing age, and pre-existing neuraxial block can blunt this response. In laboring women, pain-induced tachycardia can be confused with a positive epinephrine response. In one study, the epinephrine test dose produced more false positive than true positive responses.<sup>83</sup>

**Figure 35-32** Spread of sensory block after intrathecal (IT) or epidural (EP) injection of 30 or 45 mg lidocaine. Both intrathecal doses produced significantly higher block than both epidural doses ( $P < 0.01$  for each). IT30 = intrathecal injection of 30 mg lidocaine; IT45 = intrathecal injection of 45 mg lidocaine; EP30 = epidural injection of 30 mg lidocaine; EP45 = epidural injection of 45 mg lidocaine. The maximum and minimum outliers for each dose are added to demonstrate the overlap in sensory levels between epidural and intrathecal dosing. Maximum epidural outliers are represented by the *blue open triangle* for 30-mg dose, and *green solid triangle* for 45-mg dose. Minimum intrathecal outliers are represented by *black open triangle* for the 30-mg dose, and *red solid triangle* for the 45-mg dose. (Adapted from Pratt S, Hess P, Vasudevan A. A prospective randomized trial of lidocaine 30 mg versus 45 mg for epidural test dose for

intrathecal injection in the obstetric population. *Anesth Analg.* 2013;116:125–132.)

**Table 35-5** Complications of Unintended Intrathecal Injection of 45 mg of Lidocaine in Parturients

Number of Patients (%)	Complication
8 (32%)	Hypotension prompting vasopressors (only)
3 (12%)	Cesarean delivery for nonreassuring fetal status (also received vasopressors)
4 (16%)	High spinal (shortness breath, sensory level above T4, vasopressors)
10 (40%)	No complication

Data from Bolden N, Gebre E. Accidental dural puncture management: 10-year experience at an academic tertiary care center. *Reg Anesth Pain Med.* 2016;41:169–174.

In pregnant women, observation and aspiration will detect almost all intravascular catheters. It is tempting to withdraw an intravascular catheter until blood can no longer be aspirated. Unfortunately, these catheters are often still in a blood vessel.<sup>83</sup>

Rarely, a catheter may be subdural (inside the dura mater but outside of the arachnoid mater) (Fig. 35-6).<sup>84</sup> Subdural catheters can present with varying degrees of sensory, motor, and sympathetic block. The subdural space may extend as far as the floor of the third ventricle. Unrecognized subdural injection may be the cause of excessive epidural block. (The epidural space ends at the base of the skull and the cervical epidural space is very narrow. Lumbar *epidural* injection of local anesthetics should not produce cervical or higher levels of sensory block.)

The best test of an epidural catheter is to obtain a level and density of block that are consistent with the local anesthetic injected. Thus, a laboring woman should develop bilateral sensory change and effective analgesia 20 to 30 minutes after receiving 10 to 15 mL of dilute local anesthetic or dilute local anesthetic opioid solution. A surgical patient should notice warmth and numbness 5 to 10 minutes after receiving 2-chloroprocaine or lidocaine and 15 to 30 minutes after bupivacaine or ropivacaine. However, even a properly sited epidural catheter can migrate into a blood vessel or penetrate the dura.

Because no test dose is foolproof and even working epidural catheters can migrate, inject *all* drugs in increments small enough that they will not cause harm if misplaced (i.e., every dose is a “test” dose). Incremental injection may not detect intravascular catheters, but it should prevent systemic toxicity. If an epidural catheter does not behave as expected, do not inject more drug. Instead, remove and replace it.

## Physiology

## Central Nervous System

### Site of Action

The exact site of action of subarachnoid and epidural anesthesia remains unknown. Local anesthetic can be detected throughout the spinal nerve rootlets and spinal cord after intrathecal injection. Local anesthetic injected into the epidural space diffuses through the dura and arachnoid and also can be identified in the nerve rootlets and spinal cord.

Intrathecal local anesthetics reduce, but do not routinely eliminate, somatosensory evoked potentials (SSEPs). Cortical evoked potentials from direct spinal cord stimulation diminish but persist. These results suggest that some block of spinal cord conduction occurs but that subarachnoid anesthesia occurs mostly within the spinal nerve roots.<sup>85</sup>

In monkeys, epidural local anesthetics alter evoked potentials in the nerve roots, dorsal root entry zone, and the long tracts of the spinal cord white matter.<sup>86</sup> In humans, epidural local anesthetics decrease SSEPs in areas of sensory block but not in dermatomes above or below,<sup>87</sup> suggesting a peripheral, but not spinal cord site of action.

Although intrathecal and epidural local anesthetics do not reach the brain, extensive neuraxial anesthesia does produce sedation. Neuraxial block also potentiates the effects of sedatives and decreases the minimum alveolar concentration of potent inhaled agents.<sup>88,89</sup>

### Differential Nerve Block

Neuraxial local anesthetics have different potencies on motor, sensory, and sympathetic nerves. This differential block is largely related to the size of different nerves. Large motor nerves (and larger lumbar and sacral nerve roots) are most resistant to local anesthetic block. Sensory nerves have intermediate sensitivity. Preganglionic sympathetic fibers are the smallest and most sensitive to local anesthetics. These differences occur with both subarachnoid and epidural anesthesia. Analgesia (loss of sensation of sharpness to pinprick) extends two or more segments more cephalad than anesthesia (loss of sensation to touch).<sup>90</sup> Sympathetic block (as measured by increase skin temperature) may extend as many as six spinal segments higher than the upper limit of sensory block.<sup>91</sup>

## Cardiovascular System

### Subarachnoid

Intrathecal injection of local anesthetics produces extensive sympathetic block. Earlier investigators argued that venodilation and the subsequent fall

in venous return led to lower cardiac output and hypotension. Intravenous fluids should help prevent or treat hypotension by this mechanism. Unfortunately, multiple studies have shown that increasing intravascular volume with infusions of crystalloid or colloid have little effect on the incidence of subarachnoid anesthesia-related hypotension. Recent studies monitoring cardiac output have clearly and consistently shown that cardiac output **increases** after induction of subarachnoid anesthesia and that a fall in systemic vascular resistance leads to lower blood pressures (Fig. 35-33).<sup>92,93</sup> The degree of hypotension varies widely among patients. Risk factors include pregnancy, hypovolemia, advanced age, obesity, concurrent general anesthesia, and sensory level above T6.<sup>94</sup>

Heart rate may increase, decrease, or remain unchanged. Thoracic levels of anesthesia can produce cardiac sympathetic block (T1–T4). The resultant vagal predominance can decrease heart rate. A decrease in cardiac filling pressures may also stimulate vagally mediated bradycardia via the Bezold–Jarisch reflex. This bradycardia is usually benign, but can occasionally be profound. Cardiac arrest has been reported.<sup>95</sup> A review of 14 closed anesthesia malpractice claims from the 1970s found that prompt treatment with ephedrine, atropine, and chest compressions, but delayed administration of epinephrine produced uniformly poor neurologic outcomes after subarachnoid anesthesia-associated cardiac arrest.<sup>96</sup> Unrecognized hypoxemia may have contributed to the earlier adverse outcomes. Recent cases with pulse oximetry monitoring report better outcomes.<sup>95,97</sup>

## **Epidural**

Hypotension and bradycardia can also occur during epidural anesthesia. The major risk factors for hypotension are the extent and onset of sensory block: Faster onset and more extensive block increase the frequency of hypotension.<sup>98</sup> Bradycardia (heart rate  $\leq$  45 beats per minute) is more common in males. Genetics also may alter the risk of hypotension after epidural anesthesia. One study, using phenylephrine requirement as a marker, found that  $\beta_2$ -adrenoreceptor gene variants altered vasopressor requirements during thoracic epidural anesthesia. These authors also reported that women required more vasopressors than men.<sup>99</sup>

## **Prevention and Treatment**

### *Volume*

Intravenous fluids have long been used to prevent or treat hypotension associated with neuraxial anesthesia. However, even large volumes of crystalloid (2 L) do not reliably prevent maternal hypotension at cesarean

section.<sup>100</sup> Colloid infusion is more effective, but hypotension is still common.<sup>101</sup> Fluids infused after the induction of epidural anesthesia increase both blood pressure and plasma volume. However, they are no more effective than vasopressors and, when given in excess, cause complications of their own.<sup>102</sup> In parturients, rapid infusion of 750 mL crystalloid slightly increased cardiac output and decreased systemic vascular resistance. It also significantly increased markers of endothelial glycocalyx destruction.<sup>103</sup> (The endothelial glycocalyx is an intricate meshwork of proteoglycans and glycoproteins that line the vascular endothelium. An intact glycocalyx prevents extravasation of intravascular fluid by maintaining an oncotic gradient.)

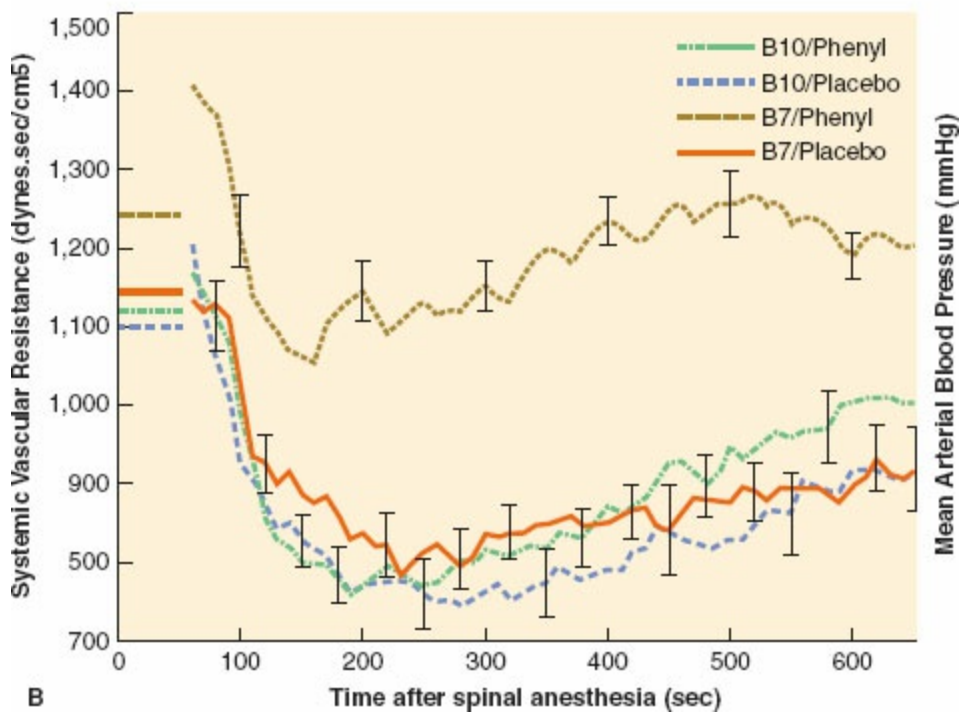

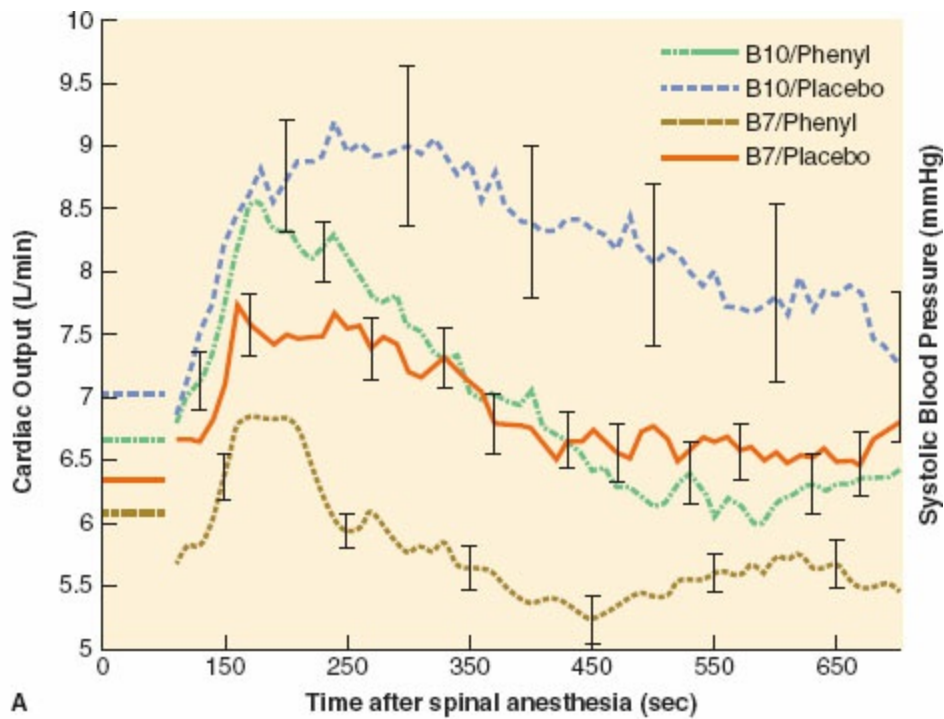

### *Vasopressors*

Ephedrine and phenylephrine are the most commonly used vasopressors for hypotension associated with neuraxial anesthesia. In parturients during cesarean section, ephedrine raises blood pressure primarily by increasing stroke volume and cardiac output. Phenylephrine increases systemic vascular resistance and decreases cardiac output (Fig. 35-34).<sup>104</sup> However, since cardiac output increases with induction of subarachnoid anesthesia, it usually remains above baseline even after phenylephrine.<sup>104</sup> Changes in heart rate parallel the changes in cardiac output. Ephedrine usually increases heart rate, whereas phenylephrine causes a reflex slowing.<sup>104</sup>

Norepinephrine also can be used to prevent or treat maternal hypotension associated with subarachnoid anesthesia. Unlike phenylephrine, norepinephrine maintains heart rate and cardiac output.<sup>105</sup> The clinical implications of these findings remain to be seen. Vasopressin may be a treatment of last resort in severe hypovolemic hypotension or for patients taking medications that impair the renin–angiotensin system.

The Bezold–Jarisch reflex is an alternate explanation for the bradycardia that often accompanies hypotension after neuraxial anesthesia. This reflex is mediated by 5HT-3 serotonin receptors located in the vagus nerve and in ventricular myocardium. Activation of these receptors in response to systemic hypotension increases efferent vagal signaling, producing bradycardia, reduced cardiac output, and worsened hypotension.<sup>106</sup> Several groups have studied the effects of HT-3 receptor antagonists like ondansetron on the hemodynamic effects of neuraxial anesthesia. Meta-analysis of these results suggests that ondansetron may halve the risk of subarachnoid anesthesia-induced hypotension.<sup>107</sup> Ondansetron also limited the risk of bradycardia, nausea, and vomiting. Unfortunately, the small number of patients studied to date and the high likelihood publication bias limits the strength of these conclusions.<sup>108</sup>

**Figure 35-33** Mean differences in cardiac output (**A**) and systemic vascular resistance (**B**) in term parturients after intrathecal injection of 7 (B7) or 10 (B10) mg isobaric bupivacaine. Placebo patients received a normal saline intravenous infusion after injection. Phenyl patients received an intravenous infusion of phenylephrine after injection. (Adapted from Langesaeter E, Rosseland LA, Shubhaug A. Continuous invasive blood pressure and cardiac output monitoring during cesarean delivery. *Anesthesiology*. 2008;109:856–863.)

## Respiratory System

Subarachnoid and epidural anesthesia have little effect on pulmonary function. Although patients often note chest tightness and dyspnea with

thoracic levels of sensory block, respiratory function is usually unchanged. One study reported decreased forced vital capacity (FVC) and one second forced expiratory volume (FEV(1)) only in patients over 60 years old with subarachnoid block above T6.<sup>109</sup> Cervical levels neuraxial block can impair diaphragmatic function and produce significant respiratory compromise.

### ***Gastrointestinal System***

Neuraxial anesthesia-induced sympathetic block leads to unopposed vagal stimulation of the gastrointestinal system. Secretions increase, sphincters relax and the bowel constricts. Many patients experience nausea and vomiting. Risk factors for nausea and vomiting include: female gender, opioid premedication and high level of block.<sup>94</sup> At cesarean section, nausea and vomiting are strongly associated with maternal hypotension.

**Figure 35-34 A:** Percentage changes from prevasopressor values in cardiac output (CO), heart rate (HR), and mean arterial pressure (MAP) after the administration of phenylephrine or ephedrine. **B:** Percentage changes from prevasopressor values, in stroke volume (SV), and systemic vascular resistance (SVR) after the administration of phenylephrine or ephedrine. (Adapted from Dyer RA, Reed AR, van Dyk D, et al. Hemodynamic effects of ephedrine, phenylephrine, and the coadministration of phenylephrine with oxytocin during spinal anesthesia for elective cesarean delivery. *Anesthesiology*. 2009;111:753–765.)

## Temperature Homeostasis

Hypothermia occurs routinely. Neuraxial anesthesia inhibits central thermoregulatory control. More importantly, block of peripheral sympathetic and motor nerves prevents vasoconstriction and shivering. As with general anesthesia, body temperature initially falls because heat redistributes from the core to the periphery. Heat loss continues through convection, radiation, and evaporation. Eventually, shivering may arise in the upper extremities, but this response does little to maintain body temperature.<sup>110</sup> Forced air warming, fluid warming, or both may limit the fall in maternal temperature after induction of subarachnoid anesthesia for cesarean section.<sup>111</sup>

## Complications

### Backache

Back pain is common after pregnancy. A poorly controlled, retrospective study published in 1990 suggested that labor epidural analgesia was associated with an increased risk of long-term backache.<sup>112</sup> Multiple subsequent studies have failed to confirm this association.<sup>113</sup> However, this concern may persist in some communities.<sup>114</sup> A recent case series reported that women who suffered an accidental dural puncture were more likely to report persistent backache at 6 weeks postpartum than women who had uncomplicated labor epidural analgesia (58% vs. 4%).<sup>115</sup>

### Headache

#### Risk Factors

Headache is one of the most common complications of both intentional and unintentional dural puncture. The risk of PDPH correlates with the needle tip design, size, and bevel orientation. Pencil-point needles produce fewer headaches than similar sized cutting-point needles. The smaller the needle, the lower the risk of PDPH. This relationship persists down to very fine (27-gauge) cutting tip needles.<sup>116</sup> Twenty-four-gauge and smaller pencil-point needles carry similar PDPH risks. When using a cutting tip needle (i.e., Quincke point spinal needle or Tuohy or Hustead epidural needle), orienting the bevel of the needle parallel to the longitudinal axis of the back decreases the PDPH risk by more than half.<sup>117,118</sup> The common explanation for this phenomenon is that dural fibers run parallel to the long axis of the spine and are separated, not sliced when entered by a parallel cutting needle bevel. However, the collagen fibers and lamellae of the dura are oriented randomly, making this reason unlikely. Bernards noted that the cells of lamellar layer of the arachnoid mater are oriented parallel to the long axis of the spine (Fig. 35-35). Parallel puncture of the arachnoid mater with a

beveled spinal needle results in a narrow slit-like hole. Perhaps minimizing damage to the arachnoid, not the dura mater, is the key to decreasing the frequency of PDPH.<sup>25</sup>

Other risk factors for PDPH include age; younger patients are *more* likely to develop PDPH and BMI; patients with a BMI above 30 kg/m<sup>2</sup> may be *less* likely to develop PDPH.<sup>119</sup> Females may be more susceptible to PDPH.<sup>120</sup> It is unknown if pregnant women are at greater risk than nonpregnant women. Patients with a history of PDPH or those with chronic headaches are more likely to develop a new PDPH.<sup>121</sup> Observational studies have reported a higher incidence of PDPH in women who deliver vaginally versus those who have a cesarean section.<sup>81,119</sup> The choice of air or saline for detecting loss of resistance while locating the epidural space does not influence the incidence of PDPH.<sup>48</sup>

**Figure 35-35** Transmission electron micrograph of the acellular dura mater (collagen bundles in the top one-third of the micrograph) and the cellular arachnoid mater (bottom two-thirds of the micrograph). *Arrows* indicate tight junctions, *SAS* indicates subarachnoid space, and *circled 3* identifies a mitochondrion. Note that the collagen bundles of the dura mater course in multiple planes (parallel, perpendicular, and oblique to the plane of section), whereas the arachnoid cells lie in a single plane oriented cephalocaudad. (Adapted from Bernardis CM. Sophistry in medicine: lessons from the epidural space. *Reg Anesth Pain Med.* 2005;30:56–66.)

## Diagnosis

Most PDPHs develop 24 to 72 hours after dural puncture. Patients usually complain of frontal and occipital pain that is made worse by standing and relieved by lying flat. Severe PDPH can also cause neck, shoulder, or back pain, which may not be relieved by lying down. Visual disturbances, vertigo, and cranial nerve palsies can occur.<sup>122,123</sup> Rarely, cortical vein thrombosis or subdural hematoma occur.<sup>124,125</sup> Death has been reported.<sup>126</sup> Differential

diagnosis includes tension, migraine, or cluster headache. In parturients, pre-eclampsia, magnesium therapy, or nifedipine can cause headaches. Rarely, intracranial masses, cortical vein thrombosis, or posterior reversible encephalopathy syndrome (PRES) may be the cause. Gadolinium-enhanced magnetic resonance imaging (MRI) may show diffuse meningeal enhancement from meningeal vessel dilation. Other MRI findings include cerebellar tonsillar descent with crowding of the posterior fossa, obliteration of the basilar cisterns, and enlargement of the pituitary gland. Unfortunately, these findings are nonspecific.<sup>121</sup> Still, MRI may be useful in the patient with atypical, severe, or intractable headache.

Most PDPHs resolve within 5 to 7 days or after therapeutic epidural blood patch. However, two recent case series report that, compared to matched controls, parturients who suffered an accidental dural puncture had an increased incidence of chronic headache at 6 weeks (35% vs. 2%) and 24 months (28% vs. 5%).<sup>115,127</sup>

The exact mechanism of PDPH is unknown. Loss of CSF through the iatrogenic dural tear seems to be the inciting factor. When the patient is upright, intracerebral CSF volume decreases. This change may cause the brain to sag toward the foramen magnum, stretching the pain-sensitive meningeal vascular covering. Alternatively, the diminished CSF volume may incite a compensatory increase in cerebral blood volume and produce a vascular headache.

## Prevention

Anesthesiologists have tried many interventions to prevent PDPH. The three most widely studied approaches are prophylactic epidural blood patch, intrathecal catheter placement, and epidural morphine injection. Despite multiple studies of varying quality, prophylactic epidural blood patch has not been shown to consistently reduce the incidence of PDPH or the need for therapeutic blood patch.<sup>128,129</sup> Intrathecal catheters do not consistently prevent PDPH but may lower the need for epidural blood patch.<sup>130–132</sup> Epidural morphine may decrease the frequency and severity of PDPH. However, itching, nausea, and vomiting are common with epidural morphine.<sup>133</sup> Two small case series have reported that intrathecal injection of 10 mL saline, either immediately after accidental dural puncture or just before removing an intrathecal catheter, is associated with a decreased need for epidural blood patch.<sup>81,134</sup>

## Treatment/Epidural Blood Patch

Once PDPH develops, most therapy is symptomatic. Bed rest will often relieve PDPH pain but does not shorten its duration.<sup>135</sup> Neither oral nor

intravenous hydration has any effect on PDPH.<sup>135</sup> Patients with PDPH should have access to adequate analgesics. Acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids can be effective. Caffeine may relieve the symptoms of PDPH but the data supporting its use are weak.

Epidural blood patch is the definitive therapy for PDPH. The efficacy of epidural blood patch has clearly been established in small, but well-conducted, randomized prospective trials.<sup>136</sup> Most authors report that a single epidural blood patch cures 75% to 90% of PDPHs.<sup>121,137</sup> A second blood patch is usually effective for patients with incomplete relief or recurrent symptoms. However, a recent study reported a significantly lower success rate.<sup>138</sup> Only 67% of women reported headache relief after a single epidural blood patch. Fewer than 20% reported permanent relief. PDPH often recurred 4 to 5 days after the original blood patch. Twenty one percent of the women received a second epidural blood patch.<sup>138</sup> Eleven percent of women in a series of 917 epidural blood patches collected from 30 hospitals in the United States received a second blood patch.<sup>77</sup>

Unresolved questions about epidural blood patch include the timing of the procedure in relation to the original dural puncture and the volume of blood that should be injected. Several retrospective chart reviews have suggested that epidural blood patch is more likely to provide headache relief if it is performed at least 72 hours after dural puncture compared with less than 24 hours after puncture.<sup>137,138</sup> However, these types of studies cannot control for headache severity. A more severe PDPH may have both a more rapid onset and be more difficult to cure with an epidural blood patch.

The initial reports of epidural blood patch used very small volumes (2 to 3 mL) of blood. Since then, the volume of blood injected has steadily increased. Most authors now recommend around 20 mL.<sup>138</sup> Patients often report back pain as blood is being injected into the epidural space. This pain usually recedes if the injection is halted. More blood can be injected after a moment or two. Stop trying to add more blood if the back pain returns immediately after resuming injection. Mild back pain is common after epidural blood patch. Serious complications are rare. However, epidural hematoma requiring surgical decompression has been reported.<sup>139</sup> Another patient with idiopathic intracranial hypertension developed acute vision loss after rapid epidural injection of 25 mL autologous blood.<sup>140</sup>

## Hearing Loss

Transient, low frequency hearing loss can occur after subarachnoid anesthesia.<sup>141</sup> This complication may be more common in the elderly.<sup>142</sup> Hearing loss is presumably due to the effects of decreased CSF pressure on inner ear function. The risk of hearing loss is lower with smaller-gauge versus

larger-gauge spinal needles.<sup>141</sup> Although hearing usually returns to normal in about 1 month, permanent loss has been reported.<sup>143</sup>

## High Block/Total Subarachnoid Spinal Block

Subarachnoid and epidural anesthesia have enviable safety records. However, high levels of sensory block can occur. If unrecognized or not managed properly, high levels of block can produce respiratory compromise and cardiac arrest.<sup>144</sup> The exact frequency of these events is unknown. High neuraxial block (otherwise undefined) complicated approximately 1 in 4,000 obstetric neuraxial anesthetics.<sup>77</sup> Suggested, but unproven, risk factors for high block included obesity, short stature, subarachnoid block after failed epidural, repeat epidural after unintended dural puncture, and spinal deformity. A disturbing cause of high block in laboring women is unrecognized intrathecal injection during attempted labor epidural analgesia.<sup>77,78,81</sup>

High neuraxial block can produce both cardiac and respiratory instability. Extensive sympathetic block can lead to hypotension and bradycardia. Extensive sympathetic block combined with moderate to deep sedation (and presumed hypoxemia) can lead to sudden cardiac arrest, even in otherwise healthy young patients. In a series of 14 such arrests, prompt treatment with ephedrine, atropine, and chest compressions, but delayed administration of epinephrine produced uniformly poor neurologic outcomes. More rapid treatment with epinephrine might help counter the subarachnoid anesthesia-induced sympathetic block and lead to better results.<sup>96</sup> High neuraxial block can also produce significant respiratory compromise. Although patients often note chest tightness and dyspnea with thoracic levels of sensory block, respiratory function is usually unchanged. As the block ascends into the cervical regions, handgrip will weaken. Lastly, blocks to C3–C5 will impair diaphragmatic function. These patients will only be able to whisper. They should be ventilated promptly and intubated if needed. When faced with a high level of sensory block after intrathecal injection of hyperbaric local anesthetic, you may be tempted to limit the rising block by placing the patient in reverse Trendelenburg position. Don't! This position may decrease the cephalad spread of sensory block but it will cause the patient's blood to pool in the legs, exacerbating the hypotensive effects of subarachnoid anesthesia. Reverse Trendelenburg position will also decrease blood flow to the brain, further hampering respiration. Instead, flex the patient's head at the neck. This may help prevent further cervical spread of the local anesthetic. Continue to monitor the patient's respiratory and cardiovascular status and intervene as needed.

## Systemic Toxicity

Systemic local anesthetic toxicity can follow absorption from the epidural space or unrecognized intravascular injection. Signs and symptoms range from tinnitus and metallic taste to seizures and cardiac arrest. Important safety steps to prevent local anesthetic toxicity include incremental injection, limiting the total dose of local anesthetic and using a test dose that contains a marker in intravascular injection.<sup>82</sup> Incremental injection of 3 to 5 mL of local anesthetic every 90 to 120 seconds is probably the most effective of these steps. Treatment of local anesthetic toxicity is discussed in [Chapter 22](#).

## Neurologic Injury

Neurologic injury is a rare, but potentially catastrophic complication of neuraxial block. Serious or permanent neurologic harm may occur after 1:20,000 to 35,000 neuraxial blocks.<sup>77,145</sup> Direct trauma, mass effect, and physiologic damage can cause neurologic injury.<sup>146</sup>

### Needle Trauma

Spinal and epidural needles can damage both the spinal cord and nerve roots ([Fig. 35-36](#)). Although the spinal cord typically ends at L1–L2 in adults, the exact termination varies and the cord extends farther caudad in children. In addition, anesthesiologists using palpation often misidentify the lumbar interspaces and end up inserting needles at a higher level than intended.<sup>18</sup> Permanent damage to the conus medullaris has been reported after attempted subarachnoid or CSE anesthesia at the presumed L2–L3 vertebral interspace.<sup>147</sup> In parturients, using the space just below, instead of above, the palpated intercrystal line can decrease the frequency of inserting the spinal or epidural needle at or above L2–L3.<sup>148</sup> Lateral deviation of the needle may injure the spinal nerve or the anterior or posterior primary ramus outside the foramen ([Fig. 35-36](#)).<sup>146</sup>

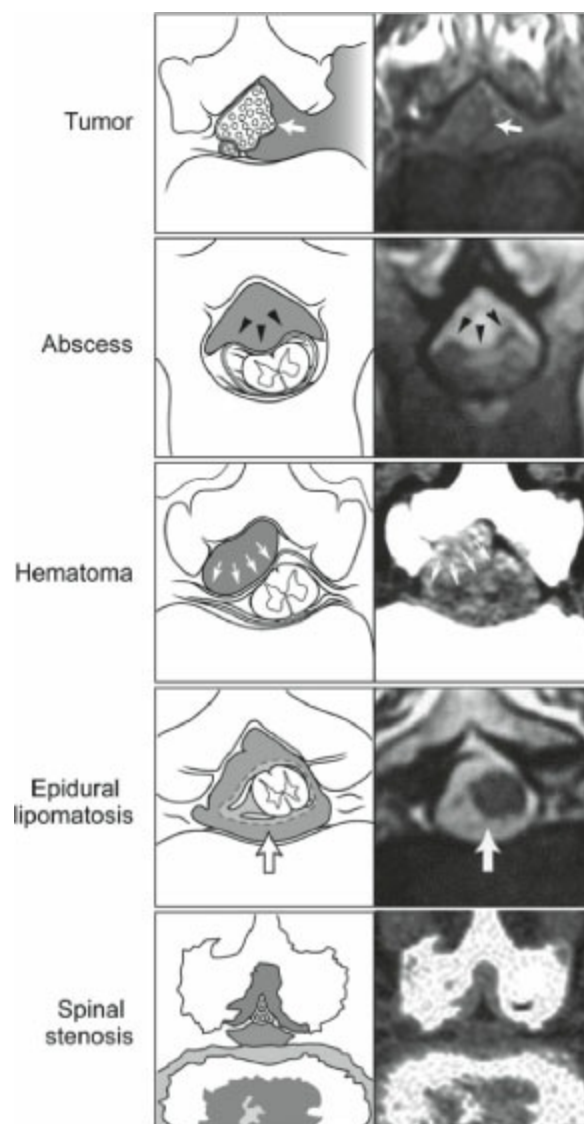

**Figure 35-36** Midline or paramedian approaches (needles A and B) may directly traumatize the spinal cord, whereas unintentional lateral deviation of the needle (C) may contact the spinal nerve or the anterior or posterior primary ramus outside the foramen. Intentional lateral approaches, for example, transforaminal approach (needle D), have the potential to come in close proximity to the spinal nerve or a spinal artery. Note that transforaminal approaches are typically at the cervical or lumbar levels, not the T6 level as illustrated. (Illustration by Gary J. Nelson. From Neal JM, Kopp SL, Pasternak JJ, et al. Anatomy and pathophysiology of spinal cord injury associated with regional anesthesia and pain medicine: 2015 update. *Reg Anesth Pain Med.* 2015;40:506–525.)

The risk of direct spinal cord injury is highest with cervical epidural injection. The cervical epidural space is narrow and the underlying spinal cord is vulnerable to needle trauma. Injury associated with cervical epidural injection was the most common damaging event in a recent review of pain medicine malpractice claims. Cervical epidural injections represent fewer than one-quarter of epidural injections but generate two-thirds of epidural injection related claims.<sup>149</sup>

## Mass Lesions

Mass lesions also can injure the spinal cord (Fig. 35-37). These lesions can compress the spinal cord and decrease perfusion pressure. Spinal cord ischemia or infarction can follow. Abscess and hematoma are the most widely studied compressive complications of neuraxial block. Significant hematoma may occur as often as 1:3,600 blocks or as rarely as 1:260,000.<sup>145</sup> Patients undergoing orthopedic procedures and those taking medications that interfere with coagulation are at greatest risk.<sup>144,145,150,151</sup> Hematoma is more common after epidural than subarachnoid block.<sup>152</sup> Hematoma also can occur after removing an epidural catheter. The American Society of Regional Anesthesia has a regularly updated guideline ([www.asra.com/advisory-guidelines](http://www.asra.com/advisory-guidelines)) that provides recommendations for the safe use of neuraxial block in patients taking antithrombotic or thrombolytic medications.

8

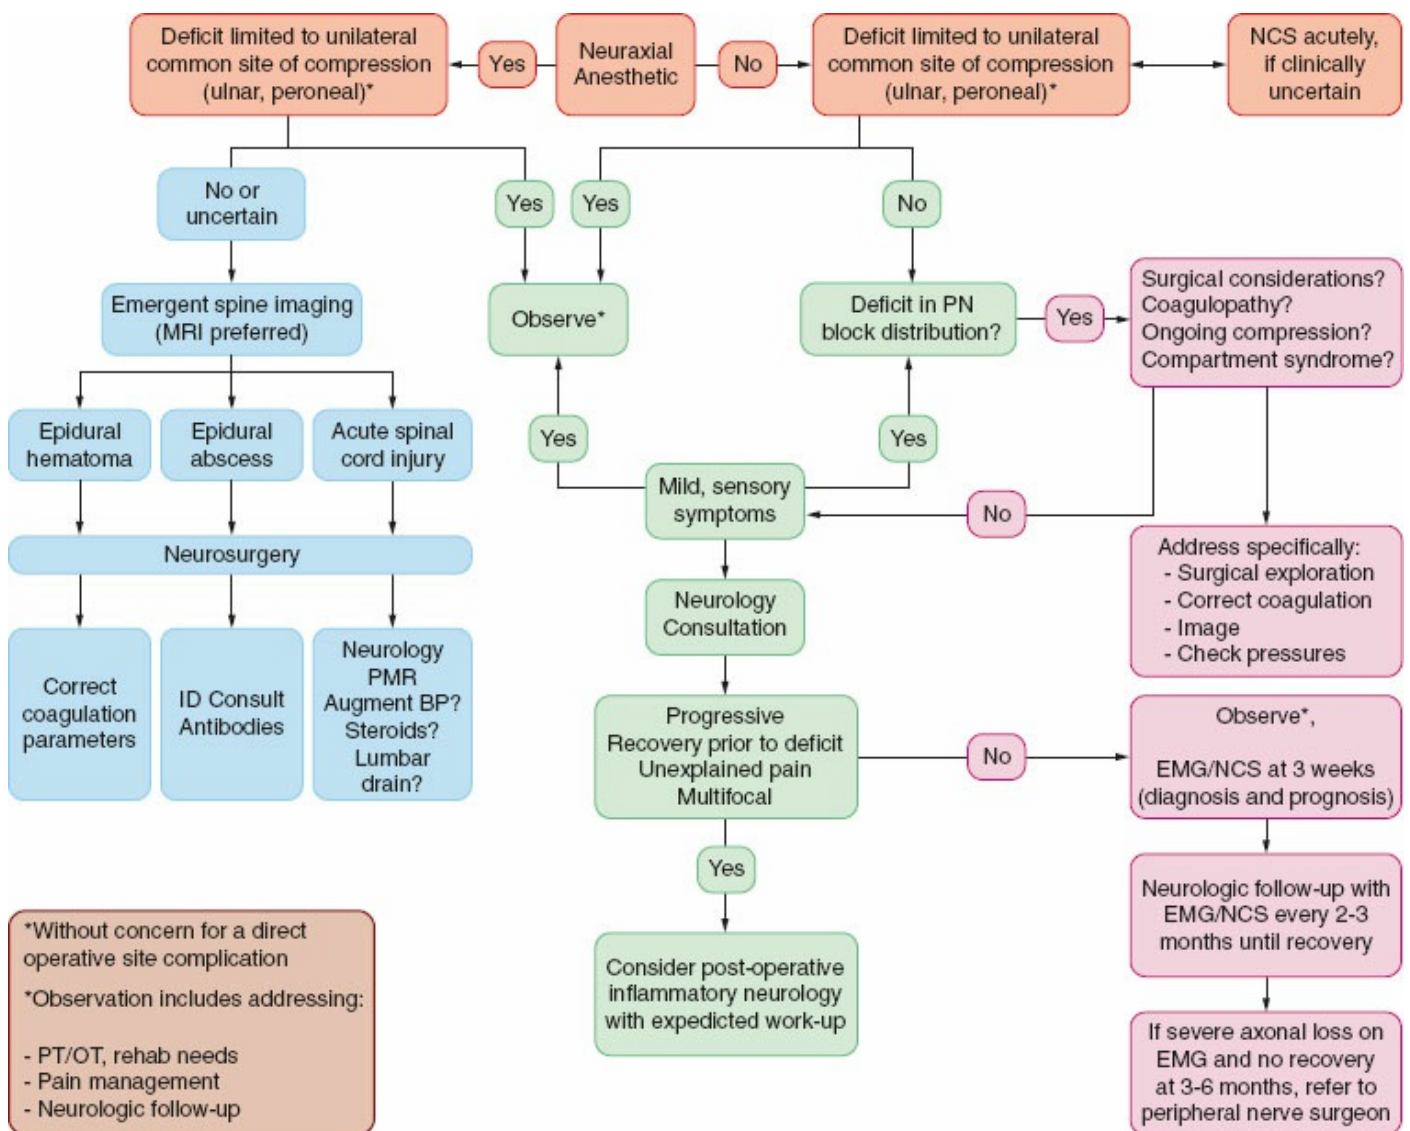

**Figure 35-37** Extradural mass lesions. Note how various conditions can reduce spinal canal cross-sectional area and either directly compress the spinal cord or the cauda equina (*arrows*) or increase epidural space or CSF pressures through their mass effect.

Epidural abscess is less common, complicating approximately 1:100,000

neuraxial blocks. Rarely, the combination of neuraxial local anesthetics and other mass lesions (tumors, lipomas, cysts, or granulomas) can produce compressive symptoms (Fig. 35-37).<sup>146</sup>

Patients with mass lesions may present with severe back pain. Other worrisome signs are persistent or recurrent sensory or motor block and bowel or bladder dysfunction. MRI provides more useful information about soft tissues and spinal canal pathology than computed tomography (CT). However, if MRI is not immediately available, CT can detect space-occupying lesions that may require immediate surgical intervention. Complete or partial neurologic recovery seems most likely if surgical decompression occurs within 8 to 12 hours of symptom onset.<sup>146</sup> However, complete recovery may occur even after a longer delay.<sup>151</sup> Figure 35-38 shows a systematic approach to the evaluation and treatment of a patient with suspected perioperative nerve injury.<sup>153</sup>

**Figure 35-38** Approach to perioperative nerve injury. BP, blood pressure; EMG, electromyography; NCS, nerve conduction studies; PMR, physical medicine rehabilitation specialty consultation; PN, peripheral nerve. (Adapted from Watson JC,

## **Hypoperfusion**

Other potential causes of spinal cord ischemia include direct needle trauma to the spinal cord vasculature, prolonged hypoperfusion related to systemic hypotension, and spinal stenosis. Direct needle trauma to spinal vessels is extremely rare. Spinal cord ischemia or infarction related to systemic hypotension also is unusual. However, there are cases of ischemic spinal cord injury attributed to a prolonged period of hypotension.<sup>146</sup> Risks may include spinal stenosis, anemia (reduced oxygen-carrying capacity), hypocapnia, raised intrathoracic pressure (e.g., during mechanical ventilation in lung-injured patients), extremes of patient position, chronic hypertension, unrecognized vascular abnormalities, and variation in the lower level autoregulation of cerebral blood flow. Current guidelines, based only on expert opinion, suggest keeping blood pressure within 20% to 30% of baseline.<sup>146</sup> However, rare, uniquely susceptible patients may suffer spinal cord ischemia during an otherwise routine subarachnoid anesthetic.<sup>154</sup>

## **Spinal Stenosis**

Pre-existing spinal stenosis also may increase the risk of neurologic injury after neuraxial block. Osteoporosis can cause degenerative spinal stenosis. Also, hypertrophy of the ligamentum flavum and bony elements of the spinal canal can reduce spinal canal cross-sectional area, limiting space for the spinal cord and nerve roots. Spinal stenosis, combined with degenerative narrowing of the intervertebral foramina, may lead to increased vertebral canal pressure and decreased spinal cord blood flow after neuraxial injection of local anesthetics. Currently, it is unclear if worsening neurologic symptoms after neuraxial block in patients with spinal stenosis represents an effect of the anesthetic or the progression of the underlying disease.<sup>152,155</sup>

## **Chemical Injury**

The cauda equina may be especially susceptible to chemical injury. These nerve roots travel long distances within the spinal canal and are not extensively myelinated.<sup>146</sup> Direct chemical injury can cause cauda equina syndrome, adhesive arachnoiditis and, possibly, transient neurologic symptoms after neuraxial anesthesia. In the 1980s, a series of cases implicated unrecognized intrathecal injection of 2-chloroprocaine as a cause of cauda equina syndrome or adhesive arachnoiditis. Most, but not all, laboratory studies attributed this complication to the sodium bisulfate preservative.

Today, some centers use preservative-free 2-chloroprocaine for subarachnoid anesthesia without reported complications.<sup>156</sup> Another possible cause of cauda equina syndrome is maldistribution of local anesthetics, most often hyperbaric lidocaine, especially when injected through a spinal catheter. Injecting hyperbaric local anesthetic through a caudally directed, side-holed, pencil-point needle also can cause sacral pooling of drug.<sup>45</sup>

Transient neurologic symptoms (persistent low back and leg pain) have been reported after subarachnoid anesthesia. The exact etiology of this complication is unclear. Some think it may represent subtle neurologic toxicity.<sup>146</sup> But, there is no firm evidence of neurologic pathology.<sup>157</sup> Transient neurologic symptoms are most commonly associated with intrathecal lidocaine and the lithotomy position. Most anesthesiologists have abandoned the use of lidocaine for subarachnoid anesthesia. Transient neurologic symptoms are much less common after other intrathecal local anesthetics.<sup>146,157</sup>

# 36 Peripheral Nerve Blockade

BAN C. H. TSUI • RICHARD W. ROSENQUIST

## Introduction

### General Principles and Equipment

- Preblock Stage
- Premedication and Sedation
- Block Performance Stage
- Other Related Equipment
- Postblock Stage
- Avoiding Complications

### Clinical Anatomy

- Head and Neck
- Spine
- Upper Extremity
- Trunk
- Lower Extremity

### Specific Techniques

- Head and Neck
- Upper Extremity
- Trunk Nerve Blocks
- Penile Block
- Lower Extremity
- Techniques
- Continuous Catheter Technique

### Acknowledgments

## KEY POINTS

- 1 Peripheral nerve blocks (PNBs) provide effective anesthesia and analgesia in a site-specific manner with the potential for long-lasting effects.
- 2 Safety and success of PNBs depends on accurate identification of target nerves and precise and adequate placement of local anesthetic.
- 3 Ultrasound imaging allows visualization of needle movement toward nerve structure(s) in real time, minimizing the risk of needle contact with critical structures and potentially reducing complications. Although

highly desirable as an aid to performing regional anesthesia, ultrasound technology requires considerable training and thorough knowledge of both the equipment and cross-sectional anatomy relevant to regional nerve blocks.

- 4 Peripheral nerve stimulators are useful tools to facilitate nerve blocks, but they do not eliminate the risk of nerve injury. In the adult patient, maintenance of responsiveness may allow reporting of nerve contact or pain during injection.
- 5 Nerve blocks associated with bony or vascular landmarks are more reliable and easier to perform than those dependent on surface landmarks alone.
- 6 Larger volumes of local anesthetic may increase the potential success of PNBs; however, total milligram dosage must be limited to avoid systemic toxicity. Higher concentrations of local anesthetics increase the degree of motor block. Ultrasound imaging, through increased accuracy of nerve localization and visualization of local anesthetic spread, may enable successful blocks to be performed with reduced volumes of local anesthetics, but this has yet to be proven.
- 7 Pediatric nerve block procedures are generally similar to those for adults but often require special considerations, the most important of which is that nerve blocks are routinely performed under general anesthesia or heavy sedation in children.

## Introduction

**1** Regional anesthesia enables site-specific, long-lasting, and effective anesthesia and analgesia. It is suitable for many surgical patients and can improve analgesia<sup>1</sup> and reduce morbidity, mortality, and the need for reoperation after major surgical procedures.<sup>2</sup> Peripheral nerve blocks (PNBs) can be used alone as the sole “surgical” anesthetic, as a supplement to provide analgesia and muscle relaxation together with general anesthesia, or as the initial step in providing prolonged postoperative analgesia, as with brachial plexus blocks or continuous peripheral nerve catheters. Compared to parenteral analgesics, single-injection or continuous PNB can provide superior analgesia and reduce the incidence of side effects.<sup>3–5</sup> Optimal pain relief and minimal side effects (e.g., nausea and vomiting) following surgery have a major impact on patient outcome, including patient satisfaction and earlier mobilization, as well as fulfilling the need for streamlined surgical services **2** with lower costs.<sup>6</sup> Nevertheless, the safety and success of PNB techniques are highly dependent on accurate delivery of the correct dose of local anesthetic. Even in experienced hands, there is an inherent failure rate associated with regional anesthesia<sup>7</sup> with the potential—albeit rare—for

systemic toxicity, infection, bleeding, permanent nerve injury, or other physical injury. In addition to the benefits of PNB, advances in knowledge (e.g., physiologic characteristics of solutions during electrical nerve stimulation [NS]) and technology (e.g., the introduction of anatomically based ultrasound [US] imaging) have encouraged many anesthesiologists and surgeons to use PNB on a more frequent basis.

Advancements in medical knowledge and techniques are being made constantly and, whereas new advancements provide an opportunity for improved patient care, they need to be studied and compared to currently accepted techniques to evaluate their safety and utility. In contrast, anatomic structures are static, and an understanding of basic anatomy cannot be replaced by excellent technical skills and knowledge of the technique when performing regional anesthesia. This chapter provides an in-depth discussion of regional anatomy, while providing an overview of two current techniques for nerve localization and block performance: NS and US imaging. Specific techniques are described in sections grouped by body location. Special considerations for nerve blocks in pediatric patients will be specifically addressed where appropriate.

## **General Principles and Equipment**

Regional anesthesia has long been regarded as an “art,” and, until recently, real success with these techniques was confined to a few gifted individuals. The introduction of NS, which relies on physiologic responses of neural structures to electrical impulses, was the first step toward transforming regional anesthesia into a “science.” There is considerable interindividual variation in physiologic response to NS. Furthermore, other factors, including injectates, physiologic solutions (e.g., blood), and disease, influence responses to NS. Despite these limitations, NS was one of the first objective methods available in regional anesthesia to guide needle placement in proximity to a target nerve with some reliability.

One of the most exciting recent advances in regional anesthesia technology has been the introduction of anatomically based US imaging. Since the beginning of regional anesthesia practice, this is the first time that the target nerve can be visualized. This is a quantum leap in technology for those in the field, and the realization of its potential benefits may encourage those anesthesiologists who had previously abandoned regional anesthesia techniques to resume or increase their use of them. Despite initial excitement over this advancement, US images are subject to individual interpretation depending on experience, training, and where that experience and training was obtained. Importantly, there is a substantial learning curve associated with US-guided regional anesthesia. It is therefore prudent in many situations

to combine NS and US imaging in order to try to achieve 100% block success. Used alone, US may allow good visualization of the needle and nerve as well as a reasonable estimate of the spread of the full dose of the local anesthetic, although the identity of the nerve may be unknown, especially for novice ultrasonographers.<sup>8</sup> By stimulating the nerve, its identity may be determined objectively by observing the motor response to NS or in some cases, the anatomic distribution of a paresthesia-like sensation in response to NS for a sensory nerve.

**Figure 36-1** Designated regional block room with labeled storage cart.

Patient monitoring and other factors related to optimizing patient care and prevention of complications are similar to those for general anesthesia, with some important differences. Safe and successful performance of PNB requires careful selection of patients and administration of an appropriate type and dose of local anesthetic in the correct location. In addition, the patient must be monitored during the procedure and prior to discharge, and ambulatory patients with home-going catheters should be monitored remotely with either telephone follow-up or home health-care team visits until the catheter has been removed and the block has resolved completely.

### **Preblock Stage**

#### **Setup**

Regional blocks can be performed in the operating room setting, although it is

preferable and desirable to administer them in a designated room or area outside the immediate operating room environment (Fig. 36-1) for adult patients. This is a consequence of what is commonly referred to as “soak time,” which is the time it takes for local anesthetics to cross the cell membrane, block action potentials, and produce either analgesia or surgical anesthesia. The designated area must contain the necessary equipment for safe monitoring and resuscitation but must also contain all of the supplies and equipment to perform common and sophisticated regional block techniques. Some important considerations for this “block room” are described here:

- All supplies located in this area must be readily identifiable and accessible to the anesthesiologist.
- The area should be of ample size to allow block performance, patient monitoring, and resuscitation.
- There should be equipment for monitoring, oxygen delivery, emergency airway management and suction, and the area should have sufficient lighting. In addition, cardiovascular resuscitation equipment (e.g., crash cart) should be readily available.
- A practically organized equipment storage cart (Fig. 36-1) is desirable and should contain all of the necessary equipment (including that required for emergency procedures), supplies, local anesthetics, needles, nerve stimulators, block trays, dressings, and resuscitation drugs. A US machine should also be present.
- It is ideal to have a prepared specialty tray that includes items for sterile skin preparation and draping, a marking pen and ruler for landmark identification, needles and syringes for skin infiltration, and specific block needles and catheters.
- A selection of sedatives, hypnotics, and intravenous anesthetics should be immediately available to prepare patients for regional anesthesia. These drugs should be titrated to maximize benefits and minimize adverse effects (high therapeutic index); short-acting drugs with a high safety margin are desirable.
- Emergency drugs should include atropine, epinephrine, phenylephrine, ephedrine, propofol, midazolam, succinylcholine, and Intralipid. In addition, guidelines for resuscitation in the event of local anesthetic toxicity should be laminated and kept with the Intralipid.

## Monitoring

When performing regional anesthesia, skilled personnel should be present at all times to monitor the patient. At a minimum, standard monitoring should include electrocardiogram (ECG), noninvasive blood pressure (NIBP), and pulse oximetry. In addition, the patient’s level of consciousness should be

gauged frequently with verbal contact since vasovagal episodes are common during many regional procedures. Although there are currently no practical or effective devices to detect rising blood levels of local anesthetic, the addition of pharmacologic markers, such as epinephrine, in appropriate concentrations to the local anesthetic can provide an indirect indication of increasing systemic local anesthetic dose. Close observation for systemic toxicity secondary to rapid intravenous injection (within 2 minutes) as well as delayed (~20 minutes) absorption is essential. The patient should be monitored for at least 30 minutes following a regional block.

- Standard ECG, blood pressure monitoring, and pulse oximetry are essential when performing regional anesthesia.
- Careful monitoring of the patient's heart rate (along with ECG measurement) is important to detect tachycardia seen with epinephrine when it is included in a test dose. It is also useful as an indicator of systemic toxicity with bupivacaine and other potent local anesthetics.
- Prior to performing blocks with significant sympathetic effects, a baseline blood pressure reading should be obtained. Once the regional anesthesia procedure is complete, monitors should remain attached. In conscious patients, end-tidal carbon dioxide monitoring is not required; however, there are special nasal prongs available for monitoring patients when this is considered necessary.
- At a minimum, stable vital signs following regional anesthesia must be present to fulfill discharge criteria from the recovery area. If the block has not begun to regress, appropriate protection for the anesthetized limb and complete instructions should be provided to the patient and their family before discharge. For inpatients, appropriate orders should be written to assure limb protection.
- Patients receiving perineural local anesthetic infusions should be visited regularly by a qualified physician or member of the Acute Pain Service postoperatively with ongoing documentation of their condition in the medical record.
- The same monitoring procedures apply to pediatric patients **3** undergoing regional anesthesia; however, due to their generally uncooperative nature and reduced ability to communicate pain clearly, nerve blocks in children are commonly performed under general anesthesia or deep sedation. As such, monitoring to reduce the risk of nerve damage (e.g., US, NS, and injection pressure) is especially important in pediatric practice. In addition, the use of muscle relaxants is contraindicated in anesthetized children receiving nerve blocks with NS guidance.

## **Premedication and Sedation**

The best preparation for a regional technique is careful patient selection and ensuring that the patient is adequately educated and informed about the anesthetic and surgical procedures. Supplemental medication is often helpful. Appropriate sedation and analgesia is an essential part of successful regional anesthesia in order to produce maximum benefit with minimal side effects. Effective sedation can be achieved with a variety of medications, including but not limited to propofol, midazolam, fentanyl, ketamine, remifentanyl, alfentanil, or a combination of these drugs. The medications should be titrated to reach an appropriate level of sedation for the individual patient, specific nerve block procedure, and length of surgery. Some examples are listed next.

## **Bolus**

- Midazolam 1 to 2 mg (titrated up to 0.07 mg/kg)
- Fentanyl 0.5 to 1 µg/kg
- Alfentanil 7 to 10 µg/kg
- Ketamine 0.1 to 0.5 mg/kg

In addition to the general comments about premedication discussed in earlier chapters, regional anesthesia techniques have special requirements. Sedation must be adjusted to the required level of patient cooperation. In the case of elicitation of a paresthesia (as during several blocks in the head and neck region) or electrical stimulation techniques, the level of sedation must be sufficient to allow the patient to identify and report nerve contact. Although a low dose of opioid (50 to 100 µg of fentanyl or equivalent) will help ease 4 the discomfort of nerve localization, patient responsiveness must be maintained. This does not preclude the use of an amnestic agent, and small doses of propofol or midazolam may provide excellent amnesia while maintaining levels of consciousness that still allow cooperation.

## **Documentation**

Creation of a preblock checklist is a key step in ensuring correct block performance in the correct location on the patient's body. The list should include documentation of relevant preoperative conditions, discussion of risks and benefits, and obtaining consent. In contrast to general and neuraxial anesthesia, no formal documentation guidelines exist for PNB, even though they are now considered routine and are associated with the same medicolegal implications as other forms of anesthesia. Documentation of PNB procedures is especially recommended in order to have a record of the procedure in case the information is required for quality assurance, research, or medicolegal reasons.

## Block Performance Stage

### Common Techniques: Nerve Stimulation

#### *Basics of Technique and Equipment*

Electrical stimulation of nerve structures was introduced to regional anesthesia in the late 1960s to 1970s.<sup>9,10</sup> A low-current electrical impulse applied to a peripheral nerve produces stimulation of motor fibers and theoretically indicates proximity to the nerve without actual needle contact or related patient discomfort. When NS techniques are used, actual contact with the nerve is unnecessary (in contrast to the paresthesia method). In theory, this implies that risk of nerve injury should be less when using NS methods, although this has not yet been proven. The concept of using NS to guide accurate placement was also applied to catheters, and stimulating catheters were introduced in an attempt to increase our ability to accurately advance catheters over greater distances.<sup>11,12</sup>

The main limitations with NS are related to the technique's inconsistent results<sup>13,14</sup> and the variance in electrical properties of different nerve stimulators.<sup>15</sup> In addition, many other variables affect the ability to stimulate nerves, including conductive area of the electrode (needle or stimulating catheter tip), electrical impedance of the tissues, electrode-to-nerve distance, current flow, and pulse duration.<sup>16</sup> Ultimately, NS relies on the physiologic responses of neural structures to the stimulating current, which is subject to considerable interindividual variation.

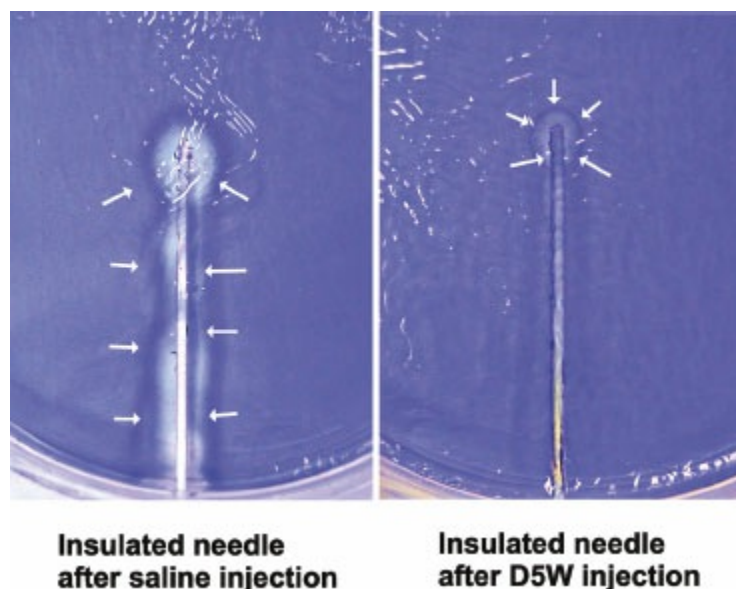

Today's nerve stimulators have features to improve ease-of-use and success, such as maintaining a constant current with adjustable frequency, pulse width, and current intensity (milliamperes [mA]). This enables a stable current output (an important safety feature) in the presence of varied resistances from the needle, tissues, and connectors. A clear digital display indicating the actual current delivery is important, as is regular calibration and testing. Some nerve stimulators are equipped with low (up to 6 mA) and high (up to 80 mA) current output ranges. The lower range is primarily for localizing peripheral nerves, whereas the higher range is mainly used for monitoring neuromuscular blockade. Recently, higher ranges have been used for transcutaneous NS techniques<sup>17</sup> (2 to 5 mA), including percutaneous electrode guidance<sup>18</sup> and surface nerve mapping,<sup>11,19</sup> and the epidural stimulation test (1 to 10 mA).<sup>20,21</sup> Most nerve stimulators deliver an electrical pulse width of 100 or 200 microseconds for stimulating motor nerves. Similar to current amplitude, the length of time over which the current is delivered (pulse width) is usually considered important, as shorter duration currents can selectively stimulate motor components of mixed nerves while sparing the discomfort caused by stimulation of sensory components. Some sophisticated

devices allow variable pulse widths from 50 microseconds to 1 millisecond in an attempt to provide such selective stimulation. The general rule is to use short-duration current of no longer than 100 microseconds for peripheral NS, although there is some evidence that duration does not impact patient discomfort<sup>22</sup> and that intensity (mA) of the stimulation is perhaps the most important variable.<sup>23</sup>

### *Practical Guidelines*

When using NS as the sole nerve-seeking device, the nerve stimulator should be set to deliver a current of 1 to 2 mA in order to gauge the approximate distance to the nerve during initial advancement of the needle. Depolarization of the nerve can also be improved by using the positive (red) pole of the stimulator as the ground (reference or surface electrode) electrode and the negative (black) lead as the connection to the needle itself (known as cathodal preference). The actual location of the ground electrode is of little importance with the use of constant-current nerve stimulators.<sup>23</sup> Generally, the needle is in proximity to the nerve when the threshold for motor response is between 0.3 and 0.5 mA; placing the needle to the point where a motor response only requires 0.1 to 0.2 mA may increase the chance of intraneural injection and should be avoided.<sup>24</sup> Once a low threshold response is obtained, 2 to 3 mL of local anesthetic is injected, and the operator watches for disappearance of the motor twitch, signaling to inject the remainder of the proposed dose in divided aliquots. This so-called “Raj test”<sup>25</sup> was originally thought to result from physical displacement of the targeted nerve by the injectate, but this response has also been attributed to a change in the electrical field at the needle–tissue interface. Electrically conducting solutions (e.g., local anesthetic or saline) reduce the current density at the needle tip, thereby increasing the current threshold for motor response, whereas solutions (e.g., dextrose 5% in water; D5W) increase the current density and maintain or augment the twitch response (Fig. 36-2).<sup>26</sup>

**Figure 36-2** Current density is localized to the needle tip when using nonconducting solutions (e.g., D5W), thereby maintaining the motor response to the threshold current level during nerve stimulation.

Following nerve localization with a stimulating needle, continuous analgesia can be delivered via stimulating catheter with continuous stimulation of the nerve. Similar current thresholds are applicable with the use of stimulating catheters. Use of an appropriate pulse width is critical for different applications during PNB and neuraxial block. Motor peripheral nerves can be stimulated with currents greater than 0.3 mA at a pulse width of 0.1 milliseconds. With a pulse width of 0.2 milliseconds, different threshold currents can be used to differentiate the epidural (1 to 15 mA) and intrathecal (<1 mA) spaces. Stimulation in the epidural space can also be performed with a pulse width of 1 millisecond and a threshold current of 6 mA. If it is desirable to dilate the perineural space, injection of D5W is preferable in order to maintain the motor response to stimulation.<sup>27</sup> The reader is referred to the section on Other Related Equipment for optimal features of stimulating catheters.

## Common Techniques: Ultrasound Imaging

### *Basics of Technique and Equipment*

US imaging has emerged as a valuable regional anesthesia tool, given 5 that the size, depth, and precise location of many nerves in their surrounding environment can be determined upon correct interpretation of the visual image. Visualization of the moving needle, once inserted at an appropriate angle and within the plane of the US probe, as well as the spread of local anesthetic, provides assistance to the anesthesiologist performing regional anesthesia. With US-guided PNB techniques, the operator can adjust needle or catheter placement under direct vision, which may lead to fewer

needle attempts and ultimately improved motor and sensory blocks. Furthermore, visibility of vital structures (e.g., blood vessels and pleura) is advantageous in order to avoid complications. Today, technologic advances have led to the development of US systems that can deliver high frequency ( $\geq 10$  MHz) sound waves, offering the high axial resolution required for visualization of nerves and the ability to distinguish them from surrounding anatomic structures (e.g., tendons, muscles). Compared to NS, the proposed benefits of US guidance for upper extremity blocks include improved block success<sup>28</sup> and completeness,<sup>29</sup> reduced block performance and onset times,<sup>28-31</sup> prolonged block duration,<sup>30</sup> and reduction in complications.<sup>32</sup> Although the cumulative evidence may appear convincing, many of the studies show conflicting results for certain parameters, and the large variability in trial methodologies and application of different outcome measures account for many of the discrepancies. Indeed, the various end points used in regional anesthesia research may bias outcomes when comparing multiple regional techniques. Marhofer et al.<sup>33,34</sup> have published an excellent review of the current status of US and its use in regional anesthesia. They emphasize that adequate training in US-guided techniques is essential and suggest that education and proper technique can help ensure safe blocks. In addition, current advantages of using US in regional anesthesia, including direct visualization of subcutaneous structures, identification of anatomic variation, ability to use less local anesthetic, and improvement in block quality and patient satisfaction, are discussed.

US is defined as any sound with a frequency above 20 kHz, although medical imaging generally requires between 3 and 15 MHz. Within the body, US scanners emit sound waves that produce an echo when they encounter a tissue interface. Therefore, US images reflect contours, including those of anatomic structures, based on differing acoustic impedances of tissue or fluids. Significant reflection of sound waves occurs at interfaces between substances of different acoustic impedance, resulting in good contour definition between different tissues. High US beam reflection from high impedance/dense structures (e.g., bone, connective tissue) results in a bright (hyperechoic) image, often with dorsal shadowing underneath; low impedance structures reflect beams to a smaller extent and appear gray (hypoechoic); minimal impedance structures/spaces (e.g., fluid in vessels) appear black (anechoic).

Higher frequencies offer the best spatial resolution at superficial locations (e.g., brachial plexus at supraclavicular fossa), whereas lower frequencies are often required for structure delineation at deep locations (e.g., sciatic nerve in the subgluteal region). Block location and depth of target nerve structures determine which transducer offers the best imaging and resolution. It is important to have familiarity with several functions of the US system,

including field and gain functions as well as Doppler Effect. Doppler Effect is useful for identifying blood vessels during nerve localization using US guidance since many nerves are situated in proximity to vascular structures.

### *Practical Guidelines*

Both the probe and skin of the patient should be prepared for maximum sterility and optimal imaging. Probe sterility is paramount if performing real-time, or dynamic, US guidance during block performance. This can be maintained by standard sleeve covers (Fig. 36-3A), but these can be expensive and cumbersome. For single-injection blocks, it is practical to use a sterile transparent dressing (e.g., Tegaderm; 3M Health Care, St Paul, MN) without the full cover of a sterile sleeve (Fig. 36-3B).<sup>35</sup> An issue when using standard long covers is the potential for air to track between the probe and the skin, which reduces image quality. The target area should be scanned using a generous amount of US gel (water soluble conductivity gel is optimal) prior to sterile preparation to identify the target structures. One of the most common reasons for poor visualization is lack of sufficient gel for skin-probe contact.

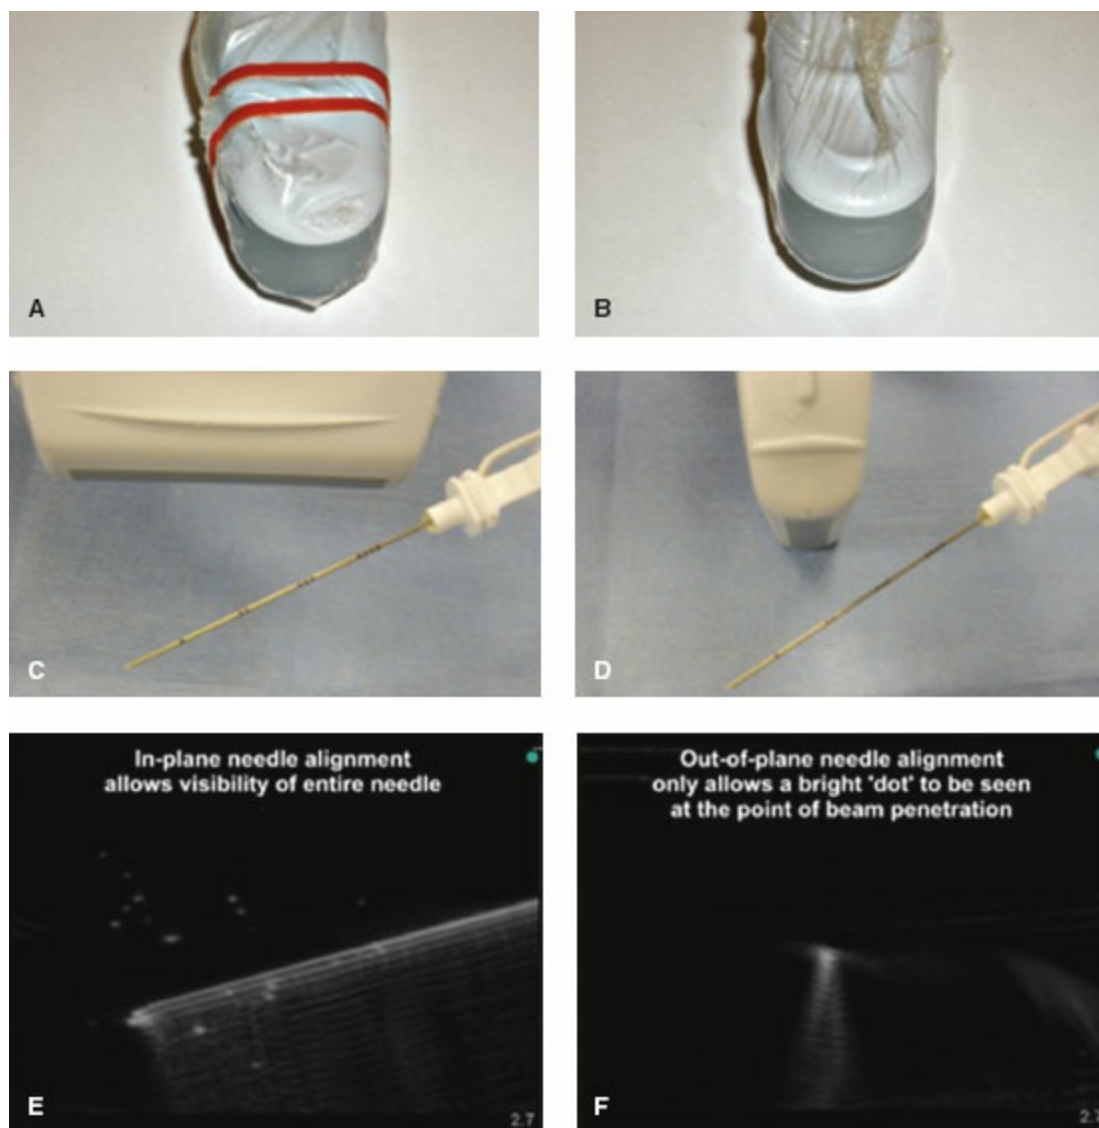

For nerve localization during US-guided PNB, it is helpful to first identify one or more reliable anatomic landmarks (bone or vessel) with a known relationship to the nerve structure. The operator can then localize the nerve at a location near the landmark, and proceed to follow, or “trace,” the nerve to the optimal block location (Table 36-1).<sup>36</sup> Generally, nerve structures are most visible when the angle of incidence is approximately 90 degrees to the US beam. Obtaining a transverse axis view of the nerve usually allows the best appreciation of the anatomic relationship of the nerve with its surrounding structures. To obtain the best possible view of the shaft and tip of the needle, it is imperative to align the needle shaft to the longitudinal axis (“in-plane” [IP]) of the US transducer (probe) (Fig. 36-3C). The nerve structure is often placed at the edge of the US screen to ensure adequate viewing distance for the needle shaft. An alternative approach uses a transverse or tangential (“out-of-plane” [OOP]) alignment, which only allows appreciation of the needle in cross-section (Fig. 36-3D). The nerve structure is often placed in the center of the screen to guarantee that aligning the needle puncture with the center of the probe will ensure close needle tip–nerve alignment. This approach can be beneficial in certain block locations (compact areas) and for inserting catheters (e.g., at the subgluteal area) but should never be used in areas where needle tip visibility in relation to vital structures is critical (e.g., supraclavicular fossa near the pleura).

After the needle is seen to be close to the nerve(s), a 1- to 2-mL test dose of D5W can be injected to visualize the spread. The solution will be seen as a hypoechoic expansion and will often illuminate the surrounding area,

enabling better visibility of the nerves and block needle. If NS is being used to confirm nerve identity, D5W should be used in order to maintain accurate motor responses.<sup>27</sup> This will be especially important during catheter introduction and advancement. If the test shows undesired injection near or within vessels or cavities, subsequent injection of local anesthetic should be postponed until better needle localization is achieved. If suboptimal spread of injectate is observed, the needle can be repositioned to allow another injection.

There can be a steep learning curve for US-guided nerve blocks, and techniques to improve needle and catheter visibility during advancement are important in order to improve training to use the technology. Two such approaches have been described experimentally:

The “walk-down” approach,<sup>37</sup> used during OOP needling, involves calculating the required depth of puncture (with measurement to the desired neural structure recorded using US prior to the block) and using trigonometry with the shaft angle and length to calculate a “reasonable” location to place the initial needle puncture site. The initial shallow puncture will be seen easily as a bright dot on the screen, and the needle tip can be followed as it is “walked down” to the final calculated depth. For example, if the final depth of penetration for the block is 2 cm, the needle will ultimately be at a 45-degree angle if the initial puncture site is 2 cm from the probe and the needle is incrementally angled to this level.

**Figure 36-3** Probe sterility using the full cover of a sterile sleeve (**A**) and a sterile transparent dressing (e.g., Tegaderm; 3M Health Care, St Paul, MN) (**B**). In-plane (**C**, **E**) and out-of-plane (**D**, **F**) needle alignment and needle visibility on ultrasound.

A method of needle–probe alignment using a laser attachment for the probe has also been reported; the laser line will project onto both the needle shaft and the midline of the probe, indicating an IP position.<sup>38</sup> Aligning the visible optical laser line with the longitudinal axis of the US probe will mimic the “invisible” beam from the US probe and allow improvements with IP needle alignment. With the laser-unit attachment, any misalignment of the needle to the US beam can be easily detected and adjusted in real-time. Recently, commercially available GPS guidance systems intended to guide the needle tip location have been developed, but the merit of these devices remains to be determined.

Most experts recommend the use of combined US and NS techniques. Using this approach, a typical setup will feature the nerve stimulator set at 0.3 to 0.5 mA, whereas the nerve is sought primarily using visualization under US guidance. The goal of nerve stimulator is to serve as an alert when the insulated needle tip is too close to nerve (i.e., contacting or inside the

nerve).

## ***Other Related Equipment***

### **Needles**

Needles used for regional techniques are often modified from standard injection needles. Although reports may speculate that needle design is a determinant of nerve or other tissue injury, there is insufficient evidence to fully substantiate this claim. For PNB, the “short bevel” (i.e., 30 to 45 degrees) or “B bevel” is often used to reduce the potential for injury to nerves.<sup>39</sup> Other modifications, such as the “pencil-point” needle, have been introduced in attempts to reduce nerve injury. Single-injection PNB techniques generally require 22- to 24-gauge insulated needles with short bevels. If superficial and field blocks are performed, smaller gauge (e.g., 25- to 26-gauge) sharp needles can be utilized. Continuous blocks require larger-bore needles to facilitate catheter introduction (e.g., 18-gauge needles for 20-gauge catheters) when using a catheter-through-needle technique. Blunt-tipped Tuohy needles are commonly used for continuous PNB with success.<sup>40</sup> Short-bevel and Tuohy needles offer more resistance and give a better “feel” when traversing different tissues. Desired needle length will depend on each specific block and individual patient characteristics. One must keep in mind that longer needles are more prone to bending upon insertion and may therefore benefit from the strength offered by a larger gauge. Clear markings throughout the entire length of the needle are important for measuring depth of penetration, particularly for correspondence to US measurements. A variety of echogenic needles are available for use with US; these needles possess special coatings, grooves, or “Cornerstone” reflectors that enhance echogenicity, allowing easier visualization when performing US-guided blocks.

**Table 36-1** Useful Anatomic Landmarks for Localizing Nerves during Common Ultrasound-guided Peripheral Nerve Blocks

Peripheral Nerve Block Location	Anatomic Landmark(s)	Approach for Ultrasound Imaging
<b>Interscalene</b>	Subclavian artery and scalene muscles	Locate the plexus trunks/divisions superolateral to the artery at the supraclavicular fossa, and trace proximally to where the roots/trunks lie between the scalenus anterior and medius muscles (Fig. 36-19).
<b>Supraclavicular</b>	Subclavian artery	Scan from lateral to medial on the superior aspect of the clavicle to locate the pulsatile artery; the plexus trunks/divisions lie lateral and often superior to the artery (Fig. 36-20). Color Doppler is useful.
<b>Infraclavicular</b>	Subclavian/axillary artery and vein	Place the artery at the center of the field and locate the brachial plexus cords surrounding the artery (Fig. 36-21).
<b>Axillary</b>	Axillary artery	The terminal nerves surround the artery (Fig. 36-22).
<b>Peripheral nerves</b>		
Radial nerve at anterior elbow	Humerus at spiral groove and deep brachial artery	To confirm the nerve's identity at the elbow, trace the nerve proximally and posteriorly toward the spiral groove of the humerus, just inferior to the deltoid muscle insertion. The nerve is located here adjacent to the deep brachial artery and can be followed back to the anterior elbow (Fig. 36-23).
Median nerve at forearm	Brachial artery	The large anechoic artery lies immediately lateral to the nerve (Fig. 36-25).
Ulnar nerve at forearm	Ulnar artery	Scan at the anteromedial surface of the forearm approximately at the junction of its distal third and proximal two-thirds, to capture the ulnar nerve as it approaches the ulnar artery on its medial aspect (Fig. 36-25).
<b>Lumbar plexus</b>	Transverse processes	The plexus lies between and just deep to the lateral aspect (tips) of the processes (Fig. 36-34).
<b>Femoral</b>	Femoral artery	The nerve lies lateral to the artery (vein most medial) (Fig. 36-35). Insert the needle above the branching of the deep femoral artery.
<b>Sciatic</b>		
Classical/Labat	Ischial bone and inferior gluteal or pudendal vessels	The nerve lies lateral to the thinnest aspect of the ischial bone. The inferior gluteal artery generally lies medial to and at the same depth as the nerve (Fig. 36-39).
Subgluteal	Greater trochanter and ischial tuberosity	The nerve lies between the two bone structures (Fig. 36-40).
Popliteal	Popliteal artery	Trace the tibial and common peroneal nerves from the popliteal crease to where they form the sciatic nerve. At the crease, the tibial nerve lies adjacent to the popliteal artery. Scanning proximally to the sciatic bifurcation, the artery becomes deeper and at a greater distance from the nerve (Fig. 36-41).
<b>Ankle</b>		
Tibial (posterior tibial)	Posterior tibial artery	The nerve lies posterior to the artery (Fig. 36-43).
Deep peroneal	Anterior tibial artery	The nerve lies lateral to the artery (Fig. 36-44).

### Practical Tips

Techniques and devices have been proposed to limit injection pressure since considerable variation exists among anesthesiologists with regard to the amount of pressure they apply during injections.<sup>41</sup> High-pressure injections into the nerve (especially intrafascicular) are associated with damage in animals.<sup>42,43</sup> Disposable, in-line injection pressure monitors are available, although their ability to prevent long-term injury is not well documented. Alternatively, a compressed air injection technique (CAIT) has been described to limit generation of excessive pressure during injection. With this method, air is drawn into the syringe and compressed by 50% during the entire injection to maintain pressures of approximately 760 mmHg (Boyle law: Pressure × volume = constant) (Fig. 36-4), which is well below the 1,300

mmHg threshold considered to be an associated risk factor for clinically significant nerve injury.<sup>44</sup>

## Catheters

Continuous-infusion catheter kits suitable for PNB are available that include a standard polyamide catheter, such as those previously used for epidural analgesia, combined with an insulated Tuohy needle with NS capability. Recently, catheters have been developed that are amenable to stimulation (an electrode is placed into the catheter tip), thereby enabling more accurate advancement of catheters over substantial distances to provide continuous analgesia. Some studies have suggested that it may be helpful to inject a solution to dilate the perineural compartment to facilitate advancement of the catheter. The reader is referred to the discussion of practical guidelines of NS in the section Common Techniques: Nerve Stimulation and Ultrasound Imaging for discussion of injection solutions for perineural dilation. The recent reintroduction of catheter-over-needle assemblies allows for the needle and catheter to be inserted as a single unit, avoiding the potential problems associated with threading the catheter through the needle. In theory, a catheter introduced over the needle is more stable in the skin and can be targeted to the desired location with good accuracy. These assemblies are discussed in more detail at the end of the chapter. There are a number of continuous-infusion devices now available for both inpatient and outpatient use, which allow delivery of dilute local anesthetic concentrations for as long as 72 hours after surgery. Standard precautions are required to maintain sterility of the catheter and the insertion site, but complications have been rare with these techniques and new devices.

**Figure 36-4** Compressed air injection technique (CAIT) used to avoid high injection pressure; 50% compression of air volume within the syringe corresponds to an injection

pressure of 760 mmHg.

## **Postblock Stage**

### **Block Assessment and Monitoring**

Following administration of a PNB, progression of the block should be monitored, and the patient's sensory and motor response in the blocked region should be assessed closely. Traditional block monitoring tools, which rely on application of cold stimuli (ice, alcohol swab) or touch (pinprick, pinch, monofilament), are generally subjective. More objective tools, such as infrared thermal imaging of the block area<sup>45,46</sup> and current perception threshold measurement<sup>47</sup> have also been studied. The latter has been shown to be a reliable method of monitoring block progression in a clinical setting.<sup>48</sup>

Sensory assessment relies primarily on collecting feedback directly from the patient using validated pain rating scales. The most popular of these are variations on the 0 to 10 scale, with 0 indicating "no pain" and 10 indicating "worst pain imaginable." Other pain scales consist of or incorporate cartoons representing a series of faces in progressing severity of pain; these scales are useful for children and individuals who cannot otherwise communicate their pain verbally. Pain rating scales for individuals with dementia or other cognitive impairments are also available and rely on the assessor's judgment of pain based on various physical and verbal cues.

Assessment of motor blockade is commonly performed by collecting a Bromage score<sup>49</sup> or equivalent score based on a graded scale where the lowest score indicates full range of movement and the highest score indicates complete blockade/no movement. As with sensory assessment, this method is subjective and relies on the assessor's ability to differentiate differing degrees of motor ability. A more objective tool is strength testing using a force transducer. The patient exerts force against a transducer to test the body part that has been blocked (e.g., shoulder abduction for axillary nerve assessment), and the force (or lack thereof) can be recorded over time to assess block onset or resolution.

### **Discharge Criteria**

Stable vital signs are a must in order to fulfill criteria for discharge from the recovery area. In some cases, acceptable evidence of regressing sensory and motor blocks should be present. However, if a long-lasting local anesthetic was used to perform the block or a continuous catheter with an infusion of local anesthetic is used, the block may not show evidence of regression at the time of discharge. Postoperative follow-up is important to confirm that neurologic function has returned to normal. If a deficit is suspected, early

neurologic assessment is critical to determine the appropriate course of management.

Patients should have well-controlled pain upon discharge. Incorporating a standard level of pain relief (e.g., on a verbal rating scale) prior to discharge home or to the ward is prudent. Specific common risks for certain blocks should be discussed with the patient prior to discharge. When discharging patients from postanesthesia care units while an extremity is still anesthetized (e.g., the block was performed to provide extended analgesia), it is absolutely necessary to provide in-depth instruction related to potential risks and their prevention (e.g., risk of burns to anesthetized areas will require avoidance of certain forms of cooking, and the potential for developing pressure neuropathies). A clear understanding of the information provided is important for both the patient and their caregivers. Written instructions including expected course, common side effects, and 24-hour contact information should be provided.

### **Avoiding Complications**

In general, regional anesthesia has an excellent safety record. Complication rates are as low as 8 per 10,000 for seizures<sup>2</sup> and lower than 0.1% to 1% for nerve injury.<sup>7,50</sup> Only rare cases of severe chronic pain syndromes following regional anesthesia have been reported.<sup>51</sup> Nevertheless, the incidence of some complications is often higher in PNB than other regional anesthesia/analgesia techniques, and the results can be devastating. Choosing a suitable patient and applying the right dose of local anesthetic in the correct location are the primary considerations. Careful attention to any unusual responses or reports of pain during block performance, as well as follow-up prior to and after discharge, is equally important, although often overlooked.

### **Patient Selection**

Patient selection is a critical element for the performance of safe and effective PNB. Not all patients are suitable candidates for PNB. In general, patients scheduled for extremity, thoracic, abdominal, or perineal surgery should be considered potential candidates for peripheral regional anesthetic techniques. Adamant refusal of regional anesthesia by a patient or, in the case of children, a parent/guardian, is an absolute contraindication to the procedure.

Other contraindications include local infection, systemic anticoagulation, and severe systemic coagulopathy. In most cases, schizophrenic patients should only receive regional techniques if general anesthesia is also performed. The presence of pre-existing neurologic disease is a controversial topic and, although limited data are available in the case of spinal anesthesia,

the safety with respect to PNB is unclear. One must be cognizant of the potential to compound existing neurologic deficits; therefore, clear documentation of the deficits prior to the procedure and a careful discussion of the potential risks and benefits are critical. For every clinical situation, the use of regional anesthesia must be evaluated carefully as a matter of risk versus benefit. It is imperative to follow applicable national and international guidelines, such as those set by the American Society of Anesthesiologists (ASA) for patient monitoring and those in place for anticoagulated patients, as provided by the American Society of Regional Anesthesia and Pain Medicine (ASRA).

## **Local Anesthetic Drug Selection, Toxicity, and Doses**

This section will provide an overview of drug selection and toxicity during PNB. For a more detailed discussion of the pharmacology and toxicity of local anesthetics, the reader is referred to [Chapter 21](#).

Rates of systemic and local toxicity and nerve injury with PNB are generally low, but the use of available methods to reduce inadvertent intravascular and intraneural injection is clearly warranted. It is important to note that lower concentrations of local anesthetic (e.g., 1% to 1.5% lidocaine, 0.125% to 0.5% bupivacaine) compared to those used for epidural anesthesia are appropriate for peripheral nerves. Neural toxicity of these anesthetics appears to be concentration-dependent.<sup>52</sup> The use of highly concentrated solutions may be useful to increase motor block, but it also increases the total milligram dose of local anesthetic. To limit total drug dose, lower concentrations are usually indicated when larger volumes are required to anesthetize poorly localized peripheral nerves or to block a series of nerves. Nevertheless, no clinical evidence exists to suggest that prolonged exposure (as with continuous PNB) of nerves to local anesthetic solutions of appropriate concentration predisposes to neurotoxic injury.<sup>53</sup>

Systemic toxicity is most often related to accidental intravascular injection and rarely to the administration of an excessive quantity of local anesthetic to an appropriate site. The risk of systemic toxic reactions is often related to the drug used. Ropivacaine (generally at 0.5%) is an example of a drug introduced into clinical practice in order to reduce central nervous system and cardiovascular toxicity through its physiochemical and stereoselective properties.<sup>54,55</sup> Nevertheless, there are examples of ropivacaine toxicity during PNB.<sup>56–59</sup> One potential strategy to achieve successful block while keeping local anesthetic volume and concentration low is US imaging, which allows more accurate needle positioning in proximity to the nerve and visualization of local anesthetic spread to ensure adequate exposure.<sup>60,61</sup> Of greatest importance is the ability to avoid intravascular injection. This risk

may be reduced when using US, especially if combined with color Doppler for vessel localization.

The degree of systemic drug absorption and duration of anesthesia can also vary depending on the site of injection (i.e., level of local vascularity) and addition of vasoconstrictors. The highest blood levels of local anesthetic occur after intercostal blocks, followed by caudal, epidural, brachial plexus, intravenous regional, and lower extremity blocks. Equivalent doses of local anesthetic may produce only 3 to 4 hours of anesthesia when placed in the epidural space but 12 to 14 hours in the arm and 24 to 36 hours when injected along the sciatic nerve. Many believe that the addition of epinephrine (1:200,000 to 1:400,000) is advantageous in prolonging the duration of block and in reducing systemic blood levels of local anesthetic, although this has more relevance to local anesthetics like lidocaine and less to ones like bupivacaine. Its use is not appropriate in the vicinity of “terminal” blood vessels, such as in the digits, penis, or ear or when using an intravenous regional technique. Using significant quantities of local anesthetic during PNB should not be performed unless oxygen, suction, monitoring, and appropriate resuscitation equipment is immediately available. However, even small doses of local anesthetic may produce significant side effects when injected into susceptible regions such as the neck. When performing PNB, a test dose of an epinephrine-containing solution and small incremental injections are recommended to reduce the risk of unrecognized intravascular injection. Toxicity can also occur from peripheral absorption of excessive doses of local anesthetic. Patients should be observed carefully for at least 30 minutes following injection since peak blood levels may occur at this time.

Animal studies<sup>62</sup> and case reports<sup>63,64</sup> have shown successful resuscitation from local anesthetic toxicity by intravenous administration of Intralipid 20% (not the 10% lipid of propofol), using one or more boluses (each of 1 to 2 mL/kg or 100 mL) followed by a 30-minute infusion (0.5 mL/kg/min). It is important to use this strategy as an acute resuscitation agent only after standard measures have proven ineffective.

## **Nerve Damage and Other Complications**

Peripheral nerve injury in humans may result from intraneural injection<sup>65,66</sup> or direct needle trauma,<sup>67</sup> although there are other causes, including those related to the surgical procedures (e.g., patient positioning, proximity of nerve to surgical site, and tourniquet application).<sup>68</sup> Needle-related trauma without injection may result in injury of lesser magnitude than that from injection injury.<sup>69</sup> In animal studies, nerve injury appears to occur when high injection pressures are applied intrafascicularly and particularly when highly concentrated local anesthetic solutions or their preservatives are used.<sup>42,43,70</sup>

One major sequela from intrafascicular injection is endoneurial ischemia.<sup>71</sup> Although in some cases these syndromes resolve uneventfully, full recovery of some peripheral injuries may never occur or may require several months, a result of slow regeneration of injured peripheral nerves.<sup>65</sup>

Other minor complications that have been reported following PNB include pain at the site of injection and local hematoma formation, but these are self-limiting side effects and are best dealt with by communication with the patient and reassurance by the anesthesiologist. A hematoma around a peripheral nerve is not of the same significance or risk as that occurring in the epidural or subarachnoid space. It is important to address concerns expressed by patients and to make every effort to relieve any pain or discomfort resulting from various interventions.

## Clinical Anatomy

Anatomical descriptions of major nerve structures, including plexuses and terminal/peripheral nerves are discussed in this section. The section is divided on the basis of regions of the body: head and neck, spine, upper extremity, trunk, and lower extremity.

### Head and Neck

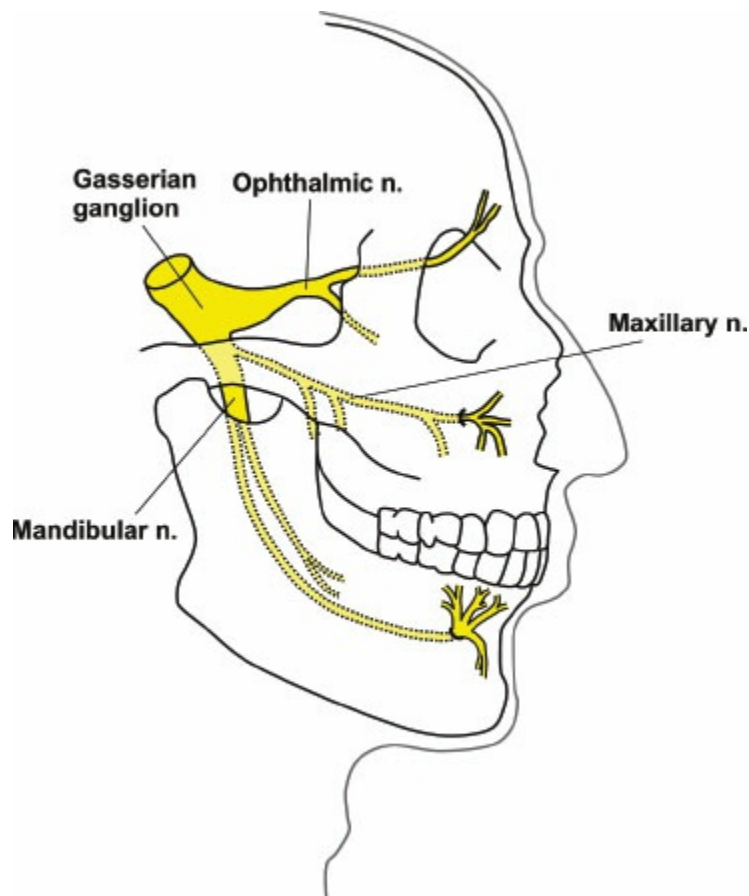

#### Trigeminal Nerve

Sensory and motor innervation of the face is provided by the branches of the fifth cranial (trigeminal) nerve. The roots of this nerve arise from the base of the pons and send sensory branches to the large semilunar (trigeminal or Gasserian) ganglion, which lies on the dorsal surface of the petrous bone. Its anterior margin gives rise to three main branches: The ophthalmic, maxillary, and mandibular nerves (Fig. 36-5). A smaller motor fiber nucleus lies behind the main trigeminal ganglion and sends motor branches to the terminal mandibular nerve. The three major branches of the trigeminal nerve each have a separate exit from the skull:

- The uppermost ophthalmic branch passes through the sphenoidal fissure into the orbit. The main terminal fibers of this sensory nerve, the *frontal nerve*, run to behind the center of the orbital cavity and bifurcate into the supratrochlear and supraorbital nerves. The *supratrochlear* branch traverses the orbit along the superior border and exits on the front of the face in the easily palpated supraorbital notch; the *supraorbital nerve* runs in a medial direction toward the trochlea.
- The *maxillary* nerve contains only sensory fibers. It exits the skull through the round foramen (foramen rotundum), passes beneath the

skull anteriorly, and enters the sphenopalatine fossa. At this point, it lies medial to the lateral pterygoid plate on each side. At the anterior end of this channel, it again moves superiorly to re-enter the skull in the infraorbital canal in the floor of the orbit. It branches to form the zygomatic nerve, which extends to the orbit, the short sphenopalatine (pterygopalatine) nerves, and the posterior dental branches. The anterior dental nerves arise from the main trunk as it passes through the infraorbital canal. The terminal infraorbital nerve penetrates through the inferior orbital fissure to the base of the orbit, to the infraorbital groove and canal (just below the eye and lateral to the nose), and reaches the facial surface of the maxilla. It then divides into the palpebral (lower eyelid), nasal (wing of the nose), and labial nerves (upper lip).

- The *mandibular* nerve is the third and largest branch of the trigeminal nerve and the only one to receive motor fibers. It exits the skull posterior to the maxillary nerve through the foramen ovale, forms a short thick trunk, and then divides into anterior and posterior trunks, which are mainly motor and sensory, respectively. The main branch (posterior trunk) continues as the inferior alveolar nerve medial to the ramus of the mandible and innervates the molar and premolar teeth. This nerve curves anteriorly to follow the mandible and exits as a terminal branch (mental nerve) through the mental foramen. The *mental* nerve provides sensation to the lower lip and chin. Other terminal nerves include the lingual nerve (floor of mouth and anterior two-thirds of tongue) and the auriculotemporal nerve (ear and temple).

**Figure 36-5** Major branches of the trigeminal nerve. The roots of the trigeminal nerve arise from the pons and form the large Gasserian (or semilunar) ganglion. The three major branches have separate exits from the skull. The main terminal fibers of the ophthalmic nerve—the frontal nerve—terminate as the supraorbital and supratrochlear nerves and exit their respective foramina. The maxillary and mandibular branches emerge from the skull medial to the lateral pterygoid plate. The maxillary nerve terminates as the infraorbital nerve (through the infraorbital foramen), and the mandibular nerve provides the inferior alveolar nerve (as well as motor branches), which exits at the mental foramen as the mental nerve.

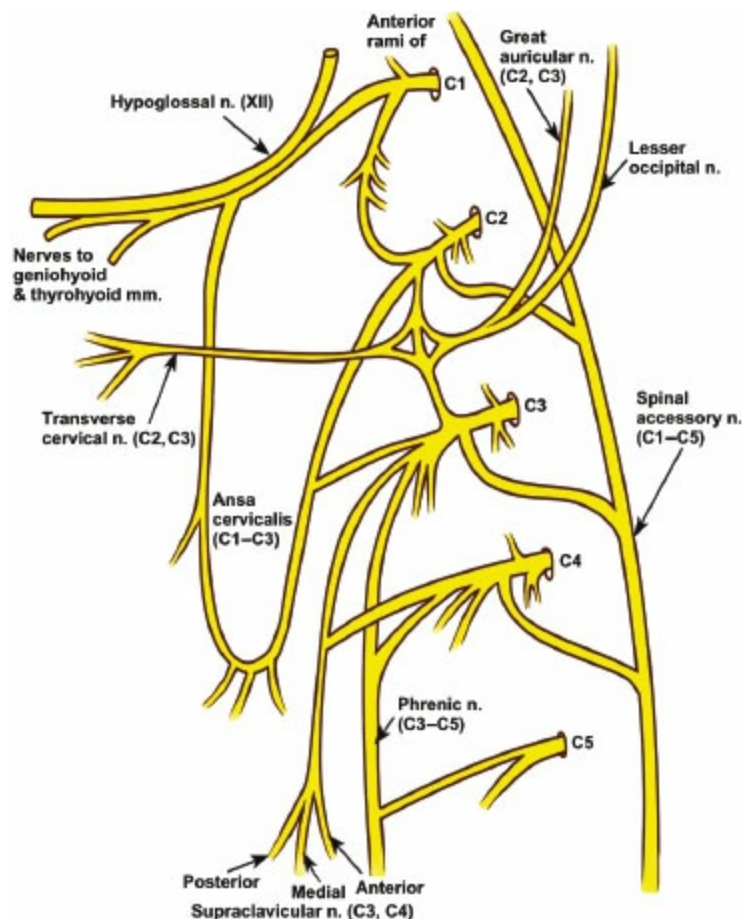

## Cervical Plexus

Sensory and motor fibers of the neck and posterior scalp arise from the anterior rami (branches) of the first four cervical (C1–C4) spinal nerves ([Fig. 36-6](#)). The cervical plexus is unique in that it divides early into cutaneous branches (penetrating the cervical fascia) and muscular branches (deeper branches that innervate the muscles and joints), which can be blocked separately (see Specific Techniques section). The dermatomes of the cervical nerves C2–C4 are illustrated in [Figure 36-7](#).

- Classic cervical plexus anesthesia along the tubercles of the vertebral body produces both motor and sensory blockade. The transverse processes of the cervical vertebrae form elongated troughs for the emergence of their nerve roots ([Fig. 36-8](#)). These troughs lie immediately lateral to a medial opening for the cephalad passage of

the vertebral artery. The trough at the terminal end of the transverse process divides into an anterior and a posterior tubercle, which can often be easily palpated.

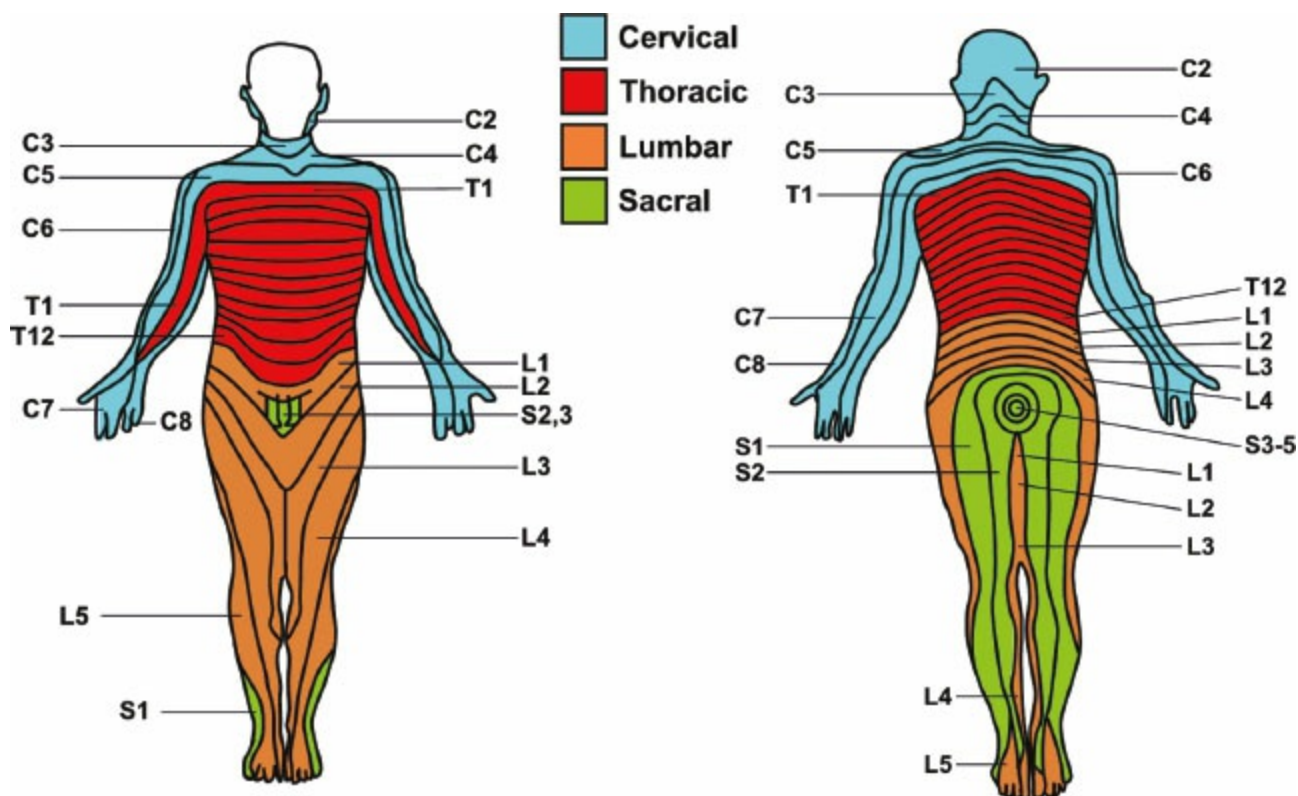

- These tubercles also serve as the attachments for the anterior and middle scalene muscles, which form a compartment for the cervical plexus as well as the brachial plexus immediately below. The compartment at this level is less developed than the one formed around the brachial plexus.
- The deep muscular branches curl anteriorly around the lateral border of the anterior scalene and then proceed caudally and medially. Many branches serve the deep anterior neck muscles, but other branches include the inferior descending cervical nerve, the trapezius branch of the plexus, and the phrenic nerve, which give anterior branches to the sternocleidomastoid muscle as they pass behind it.
- The sensory fibers emerge behind the anterior scalene muscle but separate from the motor branches and continue laterally to emerge superficially under the posterior border of the sternocleidomastoid muscle. The branches, including the lesser occipital nerve, great auricular nerve, transverse cervical nerve, and the supraclavicular nerves (anterior, medial, and posterior branches), innervate the anterior and posterior skin of the neck and shoulder.

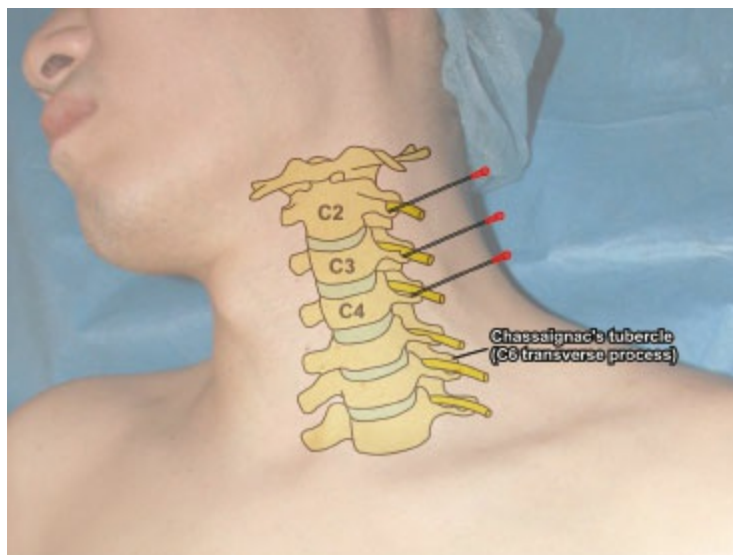

**Figure 36-6** Schematic diagram of the cervical plexus, which arises from the anterior

primary rami of C2–C4. The motor branches (including the phrenic nerve) curl anteriorly around the anterior scalene muscle and travel caudally and medially to supply the deep muscles of the neck. The sensory branches exit at the lateral border of the sternocleidomastoid muscle to supply the skin of the neck and the shoulder.

**Figure 36-7** The cervical, thoracic, lumbar, and sacral dermatomes of the body.

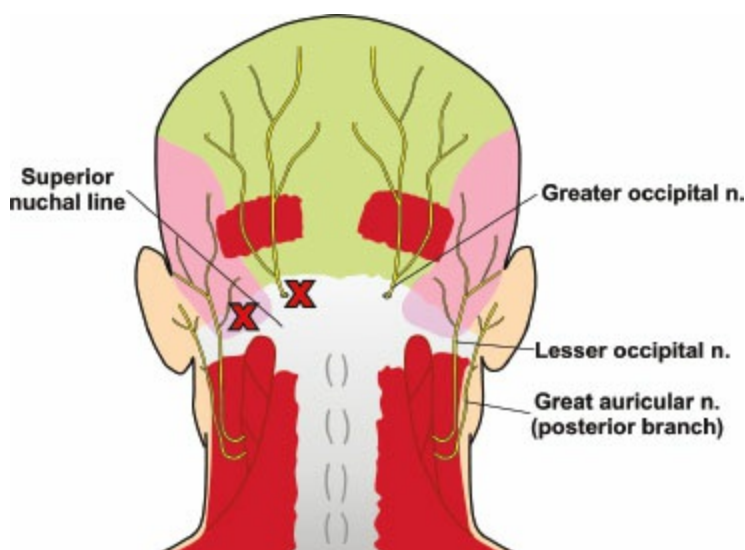

**Figure 36-8** Needle insertion points and angles for deep cervical plexus block. The nerve roots exit the vertebral column via troughs formed by the transverse processes. Using caudad and posterior angulation, the needle is inserted to contact the articular pillars of C2–C4.

## Occipital Nerve

The ophthalmic branch of the trigeminal nerve provides sensory innervation to the forehead and anterior scalp. The remainder of the scalp is innervated by fibers of the greater and lesser occipital nerves (Fig. 36-9).

- The *lesser occipital nerve* arises from the superficial (cutaneous) cervical plexus (Fig. 36-6), traverses cephalad from the posterior edge of the sternocleidomastoid muscle toward the top of the head, and divides into several branches. The *greater occipital nerve* arises from the posterior ramus of the second cervical spinal nerve (the cervical plexus arises from the anterior rami) and travels in a cranial direction to reach the skin in the area of the superior nuchal line while giving branches to supply the head and laterally toward the ear.
- These nerves can be blocked by superficial injection at the point on the posterior skull where they emerge from below the muscles of the neck.

**Figure 36-9** Greater and lesser occipital nerve anatomy, supply (green, greater occipital nerve; pink, lesser occipital nerve), and block needle insertion sites (X).

## Spine

Spinal/epidural anesthesia is not discussed in this chapter, but a basic description of the spinal nerves as well as vertebral structures is provided, given their relevance to the performance of other regional blocks.

### Spinal Nerves

The spinal nerves are part of the peripheral nervous system, along with the cranial and autonomic nerves and their ganglia. There are 31 pairs of spinal nerves—8 cervical (C1–C8), 12 thoracic (T1–T12), 5 lumbar (L1–L5), 5 sacral (S1–S5), and 1 coccygeal.

- The spinal nerves are formed by the union of the ventral (anterior) and dorsal (posterior) spinal roots and consist of both motor and sensory

fibers. In addition, all spinal nerves contain sympathetic fibers for supplying blood vessels, smooth muscle, and glands in the skin.

- The nerves give off sympathetic branches immediately after leaving the intervertebral foramen. Gray and white rami communicantes connect the spinal nerves to the sympathetic chain ganglia to allow preganglionic sympathetic fibers leaving the spinal cord (T1–L2/L3) to enter the chain and leave it again to be distributed with spinal nerves at all levels.
- Soon after exiting the intervertebral (spinal) foramina, each spinal nerve divides into a larger ventral and a smaller dorsal ramus (branches). The ventral rami course laterally and anteriorly to supply the muscles, subcutaneous tissues (superficial fascia) and skin of the neck, trunk, and the upper and lower extremities (see layout of dermatomes in [Fig. 36-7](#)). The dorsal rami course posteriorly and supply the paravertebral muscles, subcutaneous tissues, and skin of the back close to the midline.
- It is important to realize that the first cervical (C1) nerve leaves the spinal cord and courses above the atlas (C1 vertebra). Hence the cervical nerves are numbered corresponding to the vertebrae inferior to them. From this point on, all the spinal nerves are named corresponding to the vertebral level above. For example, the T3 and L4 spinal nerves exit below the T3 and L4 vertebrae, respectively.

## Paravertebral Space

The paravertebral space is a bilateral wedge-shaped area between the individual vertebrae, on both sides of and extending the entire length of the vertebral column. The spinal nerves pass through this space, giving off their sympathetic branch and a small dorsal sensory branch before exiting from the intervertebral foramina. In the thoracic region, its boundaries are as follows:

- Medially: The vertebral body, intervertebral disc and foramen, and spinous processes (angulation decreases from T1 to L4/L5).
- Anterolaterally: The parietal pleura.
- Posteriorly: The costotransverse process, approximately 2.5 cm from the tip of the spinous process, often in a slightly caudad orientation.

The intervertebral foramina at each level lie between the transverse processes and approximately 1 to 2 cm anterior to the plane formed by the transverse processes in their associated fasciae. At this point, the sympathetic ganglia lie close to the somatic nerves, and coincidental sympathetic blockade is usually attained.

## Orientation of the Vertebral Body Processes

There are variations in the anatomy of the vertebral column that should be considered when determining the desired location for needle insertion during trunk blocks.

- The spinous processes lie in the midline, with T7 at the distal tips of the scapulae and L4 at the level of the iliac crests.
- The transverse processes lie approximately 2.5 cm lateral to the spinous processes: at T1, the transverse process is directly lateral to its corresponding spinous process, but subsequent transverse processes are extended to increasingly cephalad locations (i.e., T7 transverse process is lateral to T6 spinous process).
- In the lumbar region, the spinous processes are straight, and the transverse processes lie opposite their own respective spinous process.

## Upper Extremity

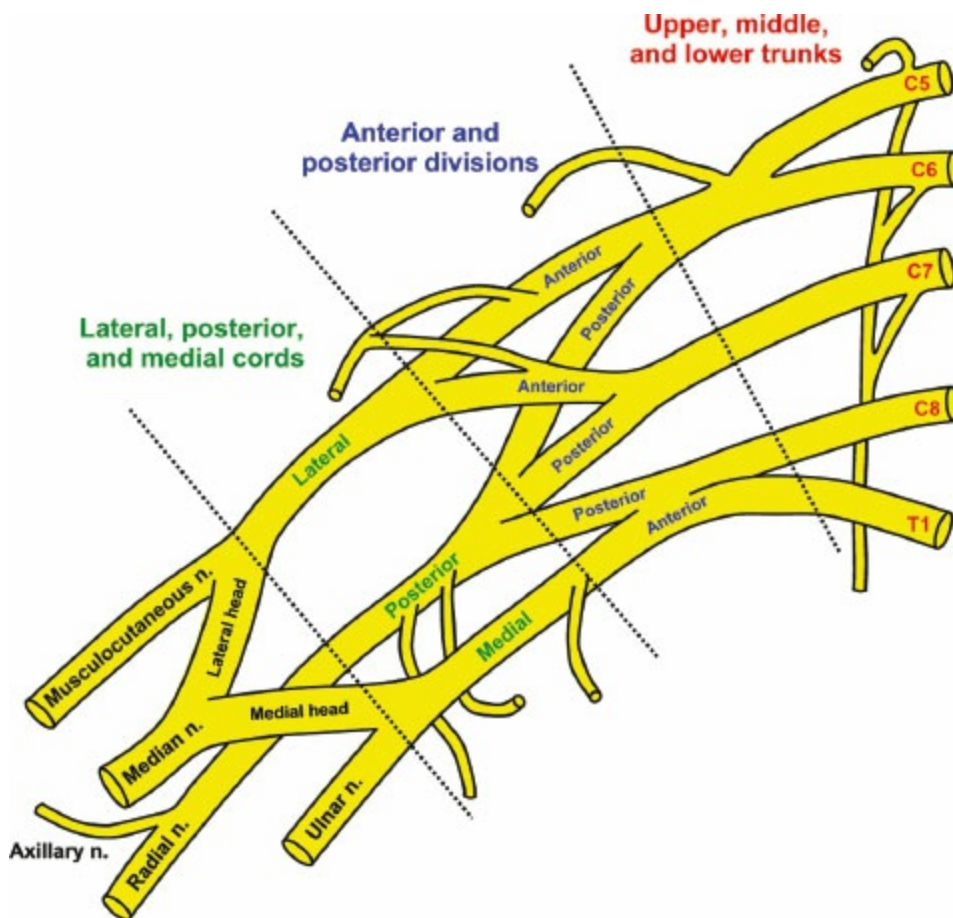

### Brachial Plexus

The brachial plexus (Fig. 36-10) arises from the anterior primary rami of C5–C8 and T1 spinal nerves. The plexus consists of five *roots*, three *trunks*, six *divisions* (two per trunk), three *cords*, and five major terminal nerves.

- The C5–T1 nerve roots emerge from their corresponding intervertebral foramina and then travel along the grooves between the anterior and posterior tubercles of the corresponding transverse process. They finally emerge between the scalenus anterior and medius muscles, above the second part of subclavian artery and posterior to vertebral artery.
- The C5 and C6 nerve roots unite to form the *upper (superior) trunk*, C7 continues as the *middle trunk*, and C8 and T1 converge into the *lower (inferior) trunk*.
- Fibrous sheaths (as part of the prevertebral fascia) surround the anterior and posterior parts of the plexus and continue to envelope the plexus between the scalene muscles more distally (called the *interscalene fascial sheath* proximally and the *axillary sheath* distally).
- The three trunks travel inferolaterally and cross the base of the posterior triangle of the neck (superficial) and the first rib (upper and middle trunks above the subclavian artery and lower trunk behind or below the artery). At the lateral border of first rib, each trunk bifurcates into *anterior* and *posterior* divisions.
- Approximately at the level where the nerves course under the pectoralis minor muscle, the divisions converge to form three *cords*: *Lateral cord*—anterior divisions of upper and middle trunks (C5–C7); *medial cord*—anterior division of lower trunk (C8, T1); *posterior cord*—

posterior divisions of all three trunks (C5–T1).

- The cords are grouped around the second part of the axillary artery (within 2.5 cm from its center).<sup>72</sup> There are three parts of the axillary artery named for their positions above (medial to), behind, and below (lateral to) the pectoralis minor muscle. Typically, with a US probe placed to view the transverse axis of the cords, the medial cord lies inferior, the lateral cord superior, and the posterior cord posterior to the first part of the axillary artery.
- Immediately beyond the pectoralis minor muscle, the three cords diverge into the terminal branches, including the median, ulnar, radial, axillary, and musculocutaneous nerves.
- The phrenic nerve normally descends anterior to the scalenus anterior muscle and crosses the muscle from lateral to medial as it descends and passes under the clavicle and through the superior thoracic aperture into the superior mediastinum, just medial to the external jugular vein. However, there is anatomic variation of the course of the phrenic nerve, and it is not always anterior to the scalenus anterior muscle.

**Figure 36-10** Schematic diagram of the brachial plexus. Not shown are the many branches, including the medial cutaneous nerves of the forearm and arm, which arise from the medial cord.

### *Terminal Nerves of the Brachial Plexus*

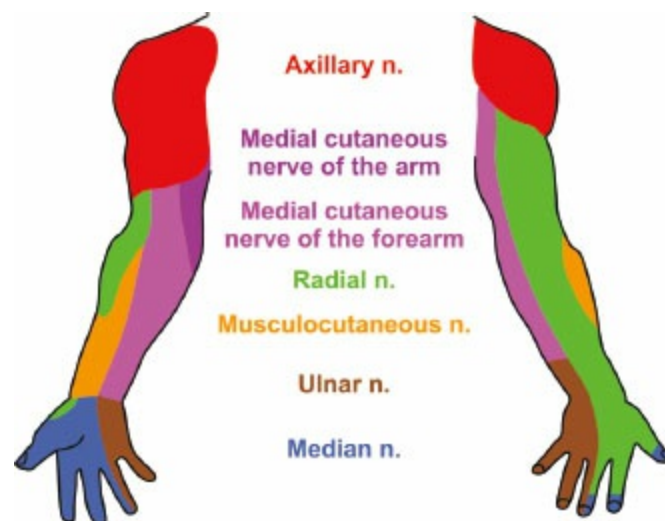

The anatomy of the peripheral nerves is outlined here, although the clinically related innervation patterns are included in the discussion of each block's technique. [Figure 36-11](#) illustrates the courses of these nerves within the upper extremity. [Figure 36-12](#) illustrates the cutaneous innervation of the terminal nerves of the upper extremity. The axillary nerve is an additional terminal nerve of the upper extremity, but the anatomy and blockade of this nerve will not be discussed here.

### **Radial Nerve (Originates from C5–C8 and T1 Roots, Upper and Middle Trunks, Posterior Divisions, and Posterior Cord)**

- This nerve originates deep (often posteromedial)<sup>73</sup> to the axillary artery, descends within the axilla (giving off branches to long head of the triceps brachii), passes between the medial and lateral heads of the triceps, and then descends obliquely across the posterior aspect of the humerus along the spiral (radial) groove at the level of the deltoid insertion.
- The nerve travels posterior and medial to the deep brachial artery of the arm and reaches the lateral margin of the humerus 5 to 7 cm above the elbow before crossing over the lateral epicondyle and entering the anterior compartment of the arm.
- In front of the elbow, the nerve divides and continues as the superficial radial (sensory) and the deep posterior interosseous (motor) nerves.

**Figure 36-11** Courses of the terminal nerves of the upper extremity. The anterior view shows branches from the lateral (musculocutaneous and median nerves) and medial (median and ulnar nerves) cords, whereas the posterior view shows branches from the posterior cord (axillary and radial nerves).

**Figure 36-12** Cutaneous innervation of the upper extremity.

**Median Nerve (Originates from C5–C8, T1, All Trunks, and Lateral and**

## **Medial Cords)**

- In the axilla, this nerve often lies anterolateral to the axillary artery.<sup>73,74</sup> The nerve descends along the medial aspect of the arm lateral to the brachial artery and crosses the artery, usually anteriorly, at the midpoint of the arm at the insertion of the coracobrachialis muscle.
- The nerve crosses the elbow lying medially on the brachialis muscle and just medial to the brachial artery and vein (all of these are medial to the biceps brachii tendon).
- Distal to the antecubital fossa, the nerve gives off the anterior interosseous nerve and cutaneous sensory branches.

## **Musculocutaneous Nerve (Originates from C5–C7 Roots, Upper and Middle Trunks, Anterior Divisions, and Lateral Cord)**

- This nerve leaves the fascial sheath of the plexus approximately at the level of the coracoid process; thus, the infraclavicular location for brachial plexus block is the most distal block for this nerve.
- Just distal (2 to 3 cm) to the pectoralis major muscle attachment, the nerve usually pierces the coracobrachialis muscle, after which it exits and comes to lie between the coracobrachialis muscle and the short and long heads of the biceps brachii muscle.
- Although it is difficult to observe using US, the nerve continues as the lateral cutaneous nerve of the forearm at the antecubital fossa and courses along the lateral aspect of the forearm providing subsequent anterior and posterior branches.

## **Ulnar Nerve (Originates from C7–C8, T1 Roots, Lower Trunk, Anterior Division, and Medial Cord)**

- Initially, the nerve often courses between the axillary artery and vein (it may lie anteromedial to the artery and vein) and then along the medial aspect of the brachial artery to the midpoint of the humerus before passing posteriorly and following the anterior surface of the medial head of the triceps.
- The nerve then passes behind the medial epicondyle of the humerus (in the condylar groove), divides between the humeral and ulnar heads of the flexor carpi ulnaris, and lies on the medial aspect of the elbow joint.
- During its descent through the forearm, the nerve courses anteriorly to approach the ulnar artery directly anterior to the ulna at the junction of the lower third and upper two-thirds of the forearm.
- At the wrist, it crosses superficial to the flexor retinaculum and divides into superficial and deep branches. The ulnar artery lies anterolateral

to the nerve at the wrist.

### *Anatomic Variation*

There are many variations in the anatomy of the brachial plexus<sup>75</sup> and in the course of the terminal nerves and vascular elements. Some of these variations may contribute to difficulty performing PNB since there may be unexpected NS responses (e.g., if two nerves are conjoined) or poor localization by NS or by US imaging (e.g., if the nerve follows a substantially different path). Some examples are described here:

- The plexus may include anterior rami from C4 to C8 (“prefixed”) or, less commonly, from C5 to T2 (“postfixed”).
- The existence and/or characteristics of the connective tissue sheath that invests the plexus at various regions are controversial. A continuous, tubular sheath has been shown unlikely, especially in the axillary region. A more convoluted and septated structure may be the cause of nonuniform distribution of local anesthetic in many cases, which supports the findings that multiple injection techniques may be superior.<sup>76</sup> US guidance can be valuable in this location to ensure circumferential spread of local anesthetic around the nerves.
- The interscalene groove may have variation in the relationship between the plexus roots and trunks and the muscles. For example, the C5 and/or C6 nerve roots may traverse either through or anterior to the anterior scalene muscle.<sup>77</sup>
- In many cadaver specimens, no inferior trunk exists.<sup>78</sup> A single cord or a pair of cords may develop. It has been observed that no discrete posterior cord forms in some cases, with the posterior divisions diverging to form terminal nerves.<sup>75</sup>
- The terminal nerves may lie in various relations to the axillary vessels. The use of combined NS- and US-guided technique to both confirm the nerve localization (NS) and obtain circumferential spread of local anesthetic around each of the nerves (US) may improve block success.<sup>8</sup> The musculocutaneous nerve may fuse to or have communications with the median nerve, which can result in the absence of the former from within the coracobrachialis muscle.<sup>79,80</sup> Communication between the median and ulnar nerves in the forearm are common, with the median nerve replacing the innervation to various muscles normally supplied by the ulnar nerve.<sup>81</sup>
- There may also be variations with respect to the vessels within the arm, with aberrant formations including double axillary veins, high origin of the radial artery, and double brachial arteries.<sup>82–84</sup>

## Trunk

### Intercostal Nerves and Articulations

#### *Intercostal Nerves*

- At the thoracic level, each anterior primary ramus enters a neurovascular bundle with its respective artery and vein and travels along the intercostal groove on the ventral caudad surface of each rib.
- The fasciae of the internal and external intercostal muscles provide the borders of the intercostal groove.
- As the intercostal nerves travel beyond the mid-axillary line, they give off a lateral sensory branch, whereas the main trunk continues on to the anterior abdominal wall to provide sensory and motor innervation for the trunk and abdomen down to the level of the pubis.
- The intercostal groove becomes less well defined anterior to the mid-axillary line, and the nerves begin to move away from their protected position. The lowermost intercostal nerve (subcostal; 12th) is less proximal to its accompanying rib and is not as easy to identify and anesthetize using a classic intercostal blockade technique.

#### *Costovertebral Articulations*

- The ribs articulate through two synovial joints with the vertebral column, each enclosed in fibrous capsules that are reinforced by ligaments:

*Costovertebral joint* is a synovial articulation of the head of the rib with the demi-facets on the adjacent thoracic vertebral bodies and the corresponding intervertebral disc of the upper vertebral joint (except for 1st, 10th, 11th, and 12th ribs, which articulate with a single vertebral facet).

*Costotransverse joint* is a synovial joint between the articular facets on the tubercles of the ribs and the transverse processes of the thoracic vertebrae (the 11th and 12th ribs lack this articulation since they do not possess tubercles). Penetration of the costotransverse ligament may occur during paravertebral block.

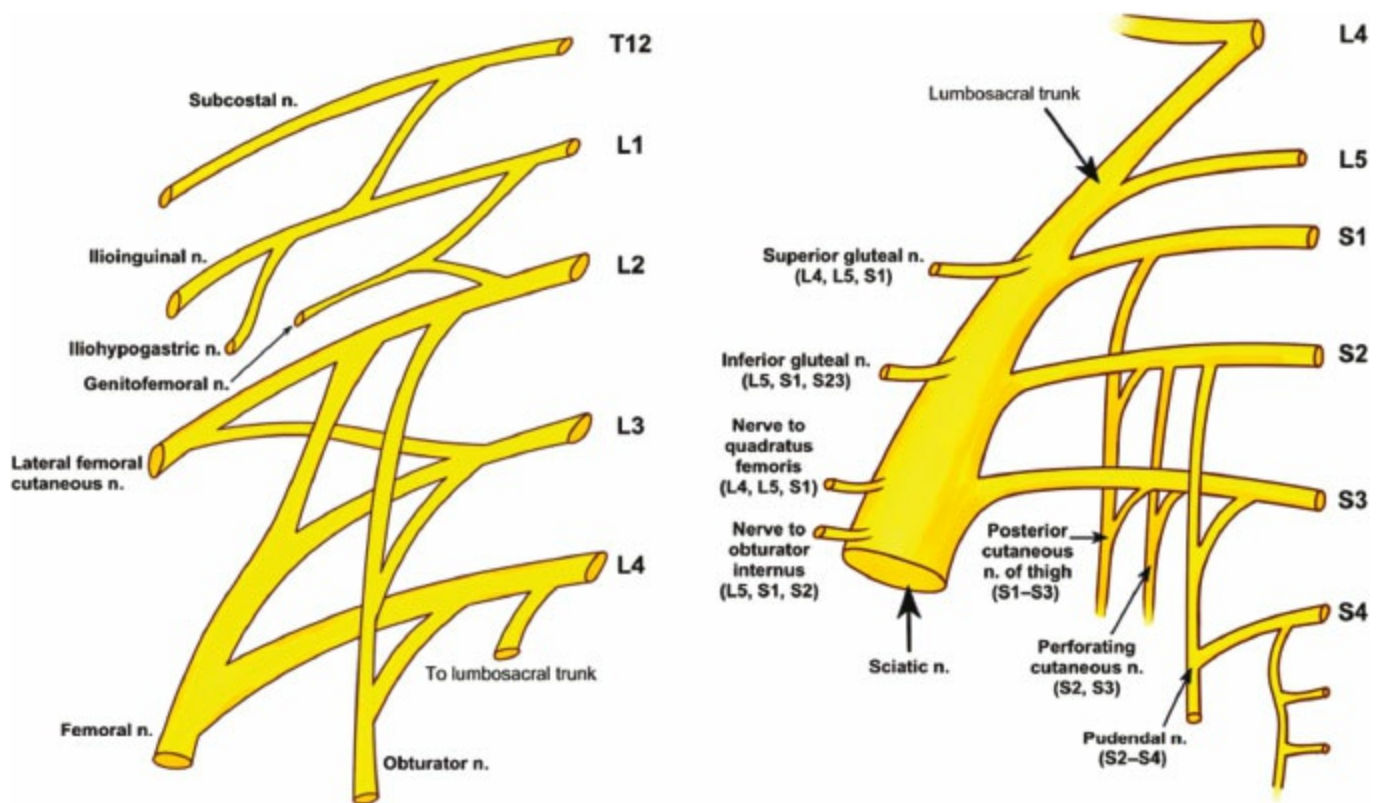

### Lumbar Spinal Nerves and Plexus

The spinal nerves at the lumbar level follow the same course as those of the thoracic level when leaving the intervertebral foramen, yet the anterior (ventral) rami form the lumbar plexus instead of continuing as intercostal nerves. The lumbar plexus ([Fig. 36-13](#)) is formed by the union of the anterior primary rami of L1–L3 and part of L4.

- The upper nerve roots emerge from their foramina into a compartment lined by the fasciae of muscles anterior and posterior to it. In this case,

the quadratus lumborum is posterior, whereas the posterior fascia of the psoas muscle provides the anterior border of the compartment before the nerves move into the body of the muscle.

- The lumbar plexus supplies the skin and muscles of the lower part of the anterior abdominal wall (including the external genitalia) and the skin and muscles of the anterior and medial compartments of the thigh. L1 bifurcates into an *upper* part (iliohypogastric and ilioinguinal nerves) and a *lower* part, which joins with a branch from L2 to form the genitofemoral nerve. L3, with portions of L2 and L4, divides into *anterior* and *posterior divisions*; the anterior division forms the obturator (L2–L4) and accessory obturator (L3, L4, when present) nerves, whereas the posterior division forms the lateral (femoral) cutaneous nerve of the thigh (L2–L3) and the femoral nerve (L2–L4).

**Figure 36-13** Schematic diagrams of the lumbar (left; L1–L4) and sacral (right; L4–S4) plexuses.

In anatomic relation to the psoas major muscle, the obturator (L2–L4) and accessory obturator nerves emerge from its medial border, the genitofemoral (L1, L2) pierces the muscle to lie on its anterior surface, and all others emerge from its lateral border.

Terminal nerves of the lumbar plexus are discussed in the Lower Extremity section.

## Inguinal Nerves

The iliohypogastric nerve penetrates the transverse abdominis muscle just above the iliac crest, supplies the muscle, and divides into anterior and lateral cutaneous branches:

- The anterior branch pierces and supplies the internal oblique muscle just 2 cm medial to the anterior superior iliac spine. It then courses deep to the external oblique muscle and superior to the inguinal canal and pierces the external oblique aponeurosis about 2 to 3 cm above the superficial inguinal ring, terminating subcutaneously in the skin of the suprapubic region.
- The lateral cutaneous branch supplies the anterolateral portion of the gluteal skin after piercing both the oblique muscles. The ilioinguinal nerve pierces and supplies the internal oblique muscle and then enters the inguinal canal, where it traverses outside the spermatic cord to emerge through the superficial (external) inguinal ring (the external oblique aponeurosis), providing cutaneous innervation to the skin of the scrotum (or labium majus) and adjacent thigh.

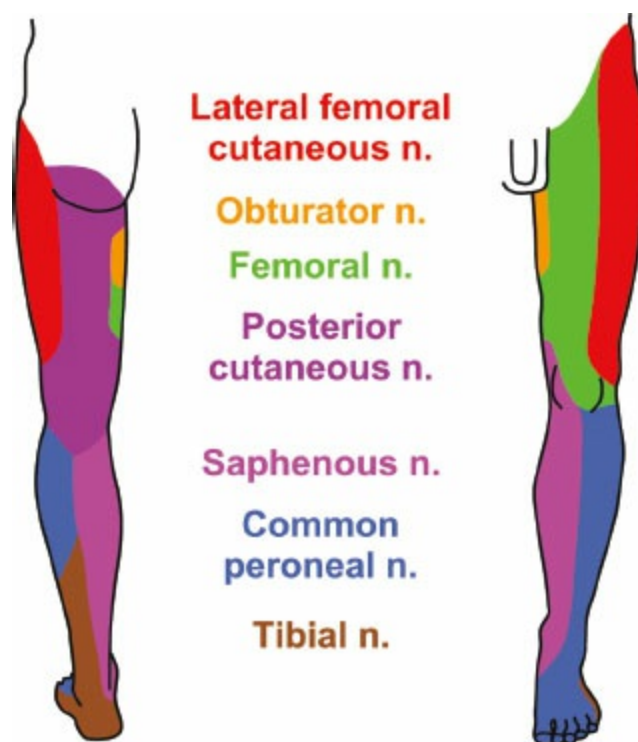

## Lower Extremity

Together, the lumbar and sacral plexuses ([Fig. 36-13](#)) supply the lower limb. The formation of the lumbar plexus is discussed in the section above. Important landmarks that contain the plexus during its course include the psoas compartment, bordered posteriorly by the quadratus lumborum muscle and anteriorly by the posterior fascia of the psoas muscle, and, more distally, the substance of the psoas major muscle. The anatomy of the terminal nerves is examined later, as are the formation and branches of the sacral plexus. Cutaneous innervation in the lower extremity is shown in [Figure 36-14](#). The lower extremity dermatomes are shown in [Figure 36-7](#).

### Sacral Plexus: Formation and Branches

At the medial border of the psoas major muscle, the lumbosacral trunk is formed by the union of a branch of L4 and the anterior ramus of L5. After exiting through the anterior sacral foramina, the anterior primary rami of S1–S4 join the lumbosacral trunk to form the sacral plexus ([Fig. 36-13](#)). The nerves of the plexus converge toward the greater sciatic foramen anterior to the piriformis muscle on the posterior pelvic wall. The main terminal nerves are the sciatic nerve (continuation of the plexus) and the pudendal nerves (“terminal branches”). Several other small branches are given off, including muscular branches (e.g., inferior and superior gluteal nerves and nerves to the quadratus femoris, piriformis, obturator internus, and external sphincter muscles), cutaneous branches (e.g., posterior cutaneous nerve of the thigh),

and visceral branches (pelvic splanchnic nerves). The gluteal vessels (superior and inferior) generally follow the course of the sacral nerves in the anterior plane and can be used to help identify the sciatic nerve at its proximal course. Additional vascular structures that may be identified under US imaging are the pudendal vessels, which pass from the greater to lesser sciatic foramen between the sciatic and pudendal nerves.

**Figure 36-14** Cutaneous innervation of the lower extremity by terminal nerves.

### Sciatic, Tibial, and Common Peroneal Nerves

The sciatic nerve—the largest nerve of the body—is usually the conjunction of two trunks initially enveloped in a common sheath: A lateral trunk (L4–S2), which eventually emerges as the common peroneal nerve and a medial trunk (L4–S3), which later becomes the tibial nerve. These combined nerves exit through the sciatic notch and pass anteriorly to the piriformis muscle to then lie between the ischial tuberosity and the greater trochanter of the femur. They curve caudally and descend in the posterior thigh adjacent to the femur. At a variable distance within the posterior thigh (often high in the popliteal fossa), the sciatic nerve bifurcates into the tibial and common peroneal nerves. The common peroneal nerve descends along the medial border of the biceps femoris muscle and then on the lateral border of the gastrocnemius muscle. At the fossa, it gives off the lateral sural nerve, which forms the lateral sural cutaneous nerve by joining the medial sural nerve supplied by the tibial nerve. It winds around neck of the fibula and terminates as the deep and superficial peroneal nerves. In the posterior thigh, the tibial nerve is covered medially by the semitendinosus and semimembranosus muscles and

laterally by the biceps femoris muscle. Beyond the knee joint, it is covered by both heads of the gastrocnemius muscle and then deep to the soleus muscle, before coming to an end on the tibialis posterior muscle and finally on the posterior surface of the tibial shaft medial to the medial malleolus. Within the fossa, it gives off muscular branches (gastrocnemius, soleus, popliteus, and plantaris muscles) as well as the medial sural nerve (to join its lateral counterpart from the common peroneal nerve). In the lower leg and foot, it gives off muscular, articular (ankle), and cutaneous branches and terminates as the medial and lateral plantar nerves. The nerve is often called the posterior tibial nerve in the lower leg.

## **Terminal Nerves of the Lumbar Plexus**

### *Genitofemoral Nerve (L1, L2)*

This nerve leaves the lumbar plexus at the lower border of the L3 vertebra. It pierces and then lies anterior to the psoas major muscle before descending subperitoneally and behind the ureter, where it divides into two branches (genital and femoral) at a variable distance above the inguinal ligament. The genital branch crosses the external iliac artery and traverses the inguinal canal. It supplies the cremaster muscle and skin over the scrotum and adjacent thigh (males) or the skin over anterior part of labium majus and mons pubis (females). The femoral branch descends lateral to the external iliac artery, passes under the inguinal ligament, enters the femoral sheath lateral to the femoral artery, and pierces the anterior layer of the femoral sheath and fascia lata. It innervates the skin immediately below the crease of the groin anterior to the upper part of the femoral triangle.

### *Lateral Cutaneous Nerve of Thigh (aka, Lateral Femoral Cutaneous Nerve) (L2, L3)*

This nerve passes obliquely from the lateral border of the psoas major muscle over the iliacus to enter the thigh below or through the inguinal ligament, variably medial to the anterior superior iliac spine ([Fig. 36-15](#)). On the right side of the body, the nerve passes posterolateral to the cecum, and on the left it traverses behind the lower part of the descending colon. The nerve lies on top of the sartorius muscle before dividing into anterior (supplies skin over the anterolateral aspect of the thigh) and posterior (supplies skin on the lateral aspect of thigh from the greater trochanter to the mid-thigh) branches. Occasionally, this nerve is a branch of the femoral nerve rather than its own nerve.

### *Femoral Nerve (L2–L4)*

The femoral nerve is the largest nerve of the lumbar plexus, supplying muscles and skin on the anterior aspect of the thigh. It descends through the psoas major muscle and emerges low at its lateral border, coursing inferiorly between the iliacus and psoas major muscles to enter the thigh under the inguinal ligament (Fig. 36-15). At the inguinal ligament (line running between anterior superior iliac spine and the medial pubic tubercle) and just distal to it (in the femoral triangle), the nerve lies slightly deeper (0.5 to 1 cm) and lateral (approximately 1.5 cm) to the femoral artery; the vein is medial to the artery (“VAN” is the mnemonic for the anatomic relationship, starting medially). At the femoral (inguinal) crease (a few centimeters caudad to the inguinal ligament), the nerve lies underneath the fascia iliaca (iliopectineal fascia), deep to the fascia lata. Beyond the femoral triangle, the nerve branches into anterior (quite proximally) and posterior divisions. The anterior division gives muscular branches to the pectineus and sartorius muscles and cutaneous branches (intermediate and medial cutaneous nerves of thigh) to the skin on the anterior aspect of the thigh. The posterior division sends muscular branches to the quadriceps femoris muscle and gives rise to the *saphenous nerve*, its largest cutaneous branch. The saphenous nerve follows the femoral artery, lying lateral to it within the adductor (Hunter’s, subsartorial) canal and then crossing it anteriorly to lie medial to the artery. Distal to the canal, the saphenous nerve leaves the artery to lie superficial at the medial aspect of the knee; the nerve then continues inferiorly (subcutaneously) with the long (great) saphenous vein along the medial aspect of the leg down to the tibial aspect of the ankle. The saphenous branch supplies the skin on the medial aspect of the leg below the knee and on the medial aspect of the foot; it provides articular branches to the hip, knee, and ankle joints.

**Figure 36-15** Illustration of the anterior pelvic area showing courses of major branches of the lumbar plexus. Needle insertion sites (•) for blocking the lateral femoral cutaneous, femoral, and obturator nerves are shown. ASIS, anterior superior iliac spine.

### *Obturator Nerve (L2–L4)*

The obturator nerve emerges from the medial border of the psoas major muscle at the pelvic brim to pass behind the common iliac vessels and lateral to the internal iliac vessels. It then courses inferiorly and anteriorly along the lateral wall of the pelvic cavity on the obturator internus muscle toward the obturator canal, through which it enters the upper part of the medial aspect of the thigh above and anterior to the obturator vessels. The nerve divides into its anterior and posterior branches near the obturator foramen (Fig. 36-15); the anterior branch passes into the thigh anterior to the obturator externus, descends in front of the adductor brevis, and behind the pectineus and adductor longus muscle, with its terminal cutaneous branches emerging as it courses alongside the femoral artery. It supplies the adductor longus, gracilis, adductor brevis (usually), and pectineus (often) muscles. Cutaneous branches supply the skin on the medial aspect of the thigh and perhaps to the medial knee. The nerve's posterior branch pierces the obturator externus muscle anteriorly and supplies it, then passes behind the adductor brevis muscle (sometimes supplies it) to descend on the anterior aspect of the adductor magnus muscle (medial to the anterior branch), which it supplies. There is no apparent cutaneous supply from this nerve. It then traverses the adductor canal with the femoral artery and vein to enter the popliteal fossa, where it terminates as an articular branch to the back of the knee joint capsule

(oblique popliteal ligament).

### *Accessory Obturator Nerve (L3, L4)*

This nerve is present in about 30% of individuals. It descends along the medial border of the psoas major muscle, crosses the superior pubic ramus behind the pectineus muscle, supplies the muscle, and gives articular branches to the hip joint.

## **Nerves at the Ankle**

By the time the femoral, tibial, and common peroneal nerves reach the ankle, there are five branches that cross this joint to provide innervation for the skin and muscles of the foot.

### *Deep Peroneal Nerve (L5, S1)*

This nerve lies anterior to the tibia and interosseus membrane and lateral to the anterior tibial artery and vein at the ankle. It travels deep to and between the tendons of the extensor hallucis longus and extensor digitorum longus muscles. Beyond the extensor retinaculum, it branches into medial and lateral terminal branches; the medial branch passes over the dorsum of the foot and supplies the first web space through two terminal digital branches, and the lateral branch traverses laterally and terminates as the second, third, and fourth dorsal interosseus nerves.

### *Tibial Nerve (aka, Posterior Tibial Nerve; S1–S3)*

On the posterior aspect of the knee joint, the tibial nerve joins the posterior tibial artery and then runs deep through to the lower third of the leg where it emerges at the medial border of the calcaneal tendon (Achilles tendon). Behind the medial malleolus it lies beneath several layers of fascia and is separated from the Achilles tendon only by the tendon of the flexor hallucis longus muscle. The nerve is posteromedial to the posterior tibial artery and vein, which are, in turn, posteromedial to the tendons of the flexor digitorum longus and tibialis posterior muscles. Just below the medial malleolus, the nerve divides into the lateral and medial plantar nerves. The nerve innervates the ankle joint through its articular branches and the skin over the medial malleolus, the inner aspect of the heel (including Achilles tendon), and the dorsum of the foot (through the medial and lateral plantar nerves) with its cutaneous branches.

### *Superficial Peroneal Nerve*

The superficial peroneal nerve lies lateral to the deep peroneal nerve in the

upper leg. In the anterolateral aspect of lower leg, it becomes superficial about 7 to 8 cm above the lateral malleolus and divides into medial and lateral dorsal cutaneous nerves to supply the dorsum of the foot.

### *Sural Nerve*

This nerve arises from tibial (medial sural nerve) and common peroneal (lateral sural nerve) nerves. It emerges to the superficial compartment at a similar but posterior level to the superficial peroneal nerve, 7 to 8 cm above the lateral malleolus. It then curves around the malleolus at some distance (1 to 1.5 cm) to enter and innervate the lateral aspect of the dorsal surface of the foot.

### *Saphenous Nerve*

The saphenous nerve is the superficial terminus of the femoral nerve and supplies the skin over the medial lower leg ([Fig. 36-14](#)). It leaves the femoral nerve proximally in the femoral triangle (Scarpa triangle), descends within the adductor canal, and courses beneath the sartorius muscle with the femoral artery (beginning lateral of the vessel at first and then crossing to the medial side superior to the artery just proximal of the lower end of the adductor magnus muscle). Further distally, the femoral artery departs away from the sartorius muscle, traveling deep to continue as the popliteal artery at the adductor hiatus. At this location, the saphenous nerve continues its course under the sartorius muscle, traveling adjacent to the saphenous branch of the descending genicular artery. It runs superficial at the medial surface of the lower leg and in front of the heel.

## **Specific Techniques**

The remainder of this chapter is devoted to the procedural details of specific blocks, arranged by regions of the body. In the sections for Upper Extremity, Trunk, and Lower Extremity, details for using NS and US imaging during the blocks are included. The nerve stimulator is set to deliver variable currents with a frequency of 2 Hz and pulse width of 0.1 millisecond unless stated otherwise. The volumes of local anesthetic included are those suggested for blocks during which NS was used for nerve localization; US guidance may reduce the required volume in some instances. The figures in these sections will focus predominantly on using combined US- and NS-guided technique, although procedures for blind techniques using NS are also described. The figures also include cadaveric sections obtained from the Visible Human Visualization Software which show anatomic arrangement of structures relevant to each of the blocks. It is important to note that the figures

illustrating techniques in humans are representative of the clinical scenario, but without any of the sterile preparation required so as to facilitate observation of proper probe and needle handling. The description of each technique is accompanied by practical tips and evidence-based recommendations. In addition, most of the suggestions related to volume of local anesthetic are based on conventional technique. More detailed descriptions of US- and NS-guided nerve block procedures can be found in Dr. Tsui's textbooks, *Atlas of Ultrasound- and Nerve Stimulation-Guided Regional Anesthesia*<sup>85</sup> and *Pediatric Atlas of Ultrasound- and Nerve Stimulation-Guided Regional Anesthesia*.<sup>86</sup>

## Head and Neck

Regional anesthesia for the head and neck is diverse, and many head and neck surgical procedures are amenable to some form of regional block. A regional technique may be the sole mode of anesthesia or may be incorporated into a balanced general anesthetic offering optimal postsurgical analgesia. Blocks can be used for ophthalmic, neurologic, ENT, plastic, and endocrine surgeries. Regional anesthesia techniques, such as trigeminal or occipital nerve block, may also be used for diagnostic and therapeutic purposes in acute and chronic pain syndromes. Block techniques range from local infiltration to field block to specific nerve blocks. Since intraoperative airway control can be challenging, the absence of definitive airway control is a frequent source of concern with regional techniques.

Regional anesthesia of the head and neck depends primarily on local infiltration and/or specific nerve blocks placed with reliable anatomic landmarks. Elicitation of paresthesia is the primary method for nerve localization, and neither NS nor US imaging have been performed or reported to any extent for these blocks. Therefore, the description of techniques in this section will deviate from other areas where there is greater reliance on nerve localization modalities using NS and US imaging.

### Trigeminal Nerve Blocks

For every procedure, prepare the needle insertion site and other applicable skin areas with an antiseptic solution, and use sterile equipment. All of the blocks described here use the extraoral route, although alternative intraoral routes may be suitable in many cases.

#### *Semilunar (Gasserian) Ganglion Block*

The most comprehensive blockade of the trigeminal nerve targets the central ganglion (Fig. 36-5). This block is usually performed by neurosurgeons under

fluoroscopic guidance for treatment of disabling trigeminal neuralgia. Few anesthesiologists perform this technically difficult block, and it will not be described in detail here.

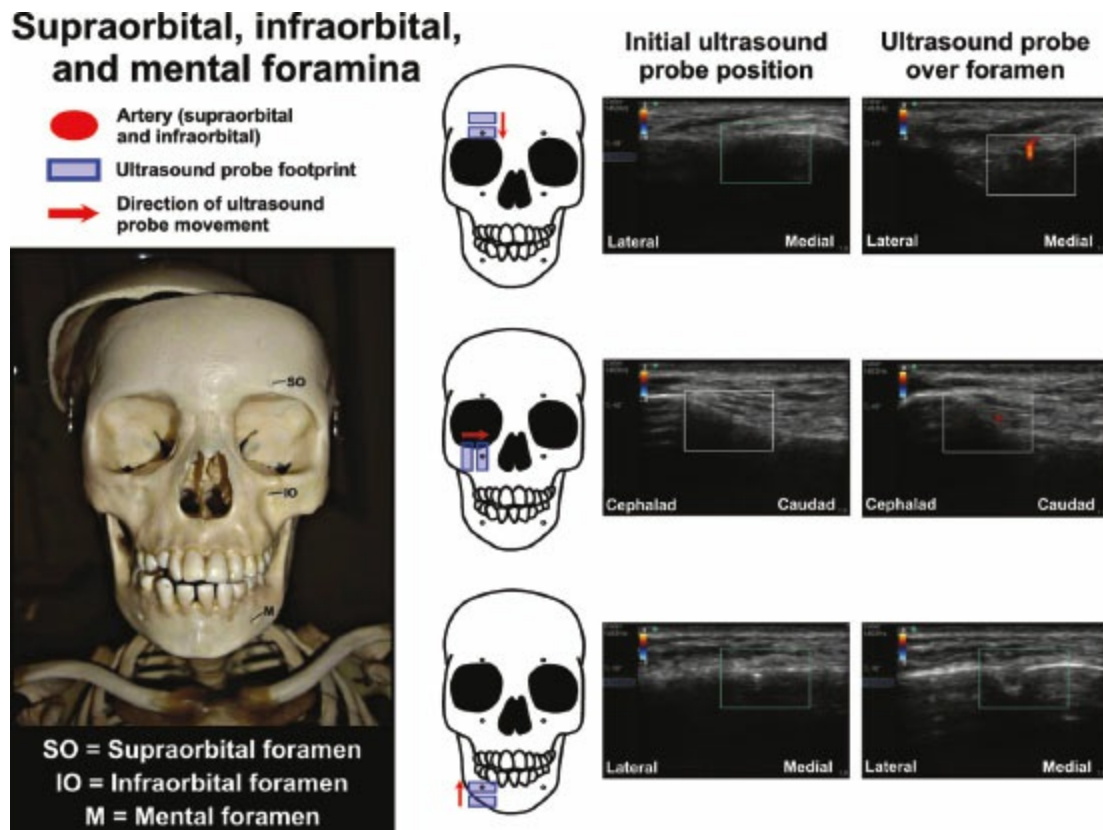

### *Superficial Trigeminal Nerve Branch Block*

Trigeminal block can be performed easily by injection of the three individual terminal superficial branches (supraorbital, infraorbital, mental nerves). Each nerve is associated closely with their respective foramina, and all foramina lie in the same sagittal plane on each side of the face (approximately 2.5 cm lateral to the mid-facial line passing through the pupil) (Fig. 36-16) and are easily located by US.<sup>87</sup> These foramina are readily palpable, and the nerves can be blocked with superficial injections of small quantities of local anesthetic. The bony landmarks are usually sufficient themselves for routine anesthetic purposes. However, paresthesias are desirable when performing neurolytic blocks with alcohol. An additional block of the supratrochlear nerve is required if the field of anesthesia is to cross the midline. Generally, fine, short needles (e.g., 24 to 26 gauge, 25 to 40 mm) and small syringes (1 to 5 mL) will be suitable for these blocks. The block is usually performed with the patient in the supine position.

### **Procedure**

- *Supraorbital nerve (terminal nerve of ophthalmic branch)*. The supraorbital notch can be easily palpated at the medial upper angle of the orbit or located by US as shown in Figure 36-16. The needle is inserted, and local anesthetic (see Clinical Pearls) is injected slowly after aspiration, slightly outside the notch, producing anesthesia of the ipsilateral forehead.
- *Supratrochlear nerve (terminal nerve of ophthalmic branch)*. Anesthesia of the supratrochlear nerve is obtained with superficial infiltration of the upper internal angle of the orbital rim. This is needed if the field of anesthesia is to cross the midline.
- *Infraorbital nerve (terminal branch of maxillary nerve)*. The infraorbital foramen lies about 1 cm below the middle of the lower orbital margin. If the foramen cannot be palpated directly, it can be identified by locating the discontinuity of the hyperechoic line on US (Fig. 36-16).<sup>87</sup> The needle should be introduced in a cranial direction through a skin wheal approximately 0.5 cm below the expected opening. After making contact with the bone and withdrawing slightly, injection of a small quantity of local anesthetic is performed. This block produces anesthesia of the middle third of the ipsilateral face.
- *Mental nerve (sensory terminal branch of mandibular nerve)*. The mental nerve emerges from its foramen, which lies inferior to the outer lip at

the level of the second premolar, midway between the upper and lower borders of the mandible. The mental canal angles medially and inferiorly; therefore, needle insertion should start approximately 0.5 cm above and 0.5 cm lateral to the anticipated location of the orifice if it cannot be palpated directly. Again, the use of US can aid identification of the foramen (Fig. 36-16). Slow injection after aspiration at the opening of the canal produces anesthesia of the mandibular area. Injection directly into the canal should be avoided to reduce the risk of neural injury.

**Figure 36-16** Ultrasound scanning of the supraorbital, infraorbital, and mental foramina. Discontinuation of the hyperechoic bony line indicates the position of the foramen.

### Clinical Pearls

- Choice of local anesthetic for all blocks will depend on the purpose of the block and the duration of anesthesia required (e.g., 1% mepivacaine for shorter procedures and 0.75% ropivacaine for longer procedures). For surgical anesthesia, 2 to 5 mL of local anesthetic may be used, whereas diagnostic or therapeutic volumes or volumes for infants will be much smaller (0.5 to 1 mL).
- Blocks should be followed by local compression to prevent hematoma formation.
- PNB of the terminal branches of the trigeminal nerve offers a safe and effective alternative to local infiltration for soft-tissue injury of the

face. Despite this, local infiltration is often required to rectify incomplete anesthesia, especially of the supraorbital and infraorbital nerves.<sup>88</sup>

- Infraorbital nerve block may be performed for postoperative analgesia after cleft lip repair. Palpating anatomic landmarks for this block can be difficult in the neonate due to the developing facial configuration.
- Skull nerve blocks can be used for craniotomy procedures and are also recommended to attenuate postoperative pain.<sup>89</sup> The nerves blocked to achieve successful anesthesia for craniotomy include the supraorbital and supratrochlear nerves, the greater and lesser occipital nerves, the auriculotemporal nerves, and the great auricular nerve.
- Supraorbital nerve blocks often require supplementation, perhaps due to the anatomic variation of the nerve. The nerve may exit the skull undivided, or its medial and lateral branches may exit separately. For frame pin placement during stereotactic neurosurgery, failure to block the lateral branch may account for inadequate coverage.<sup>90</sup>
- During mental nerve block in older patients, resorption of the superior margin of the mandible will make the foramen appear to lie more superiorly along the ramus.

### *Maxillary Nerve Block*

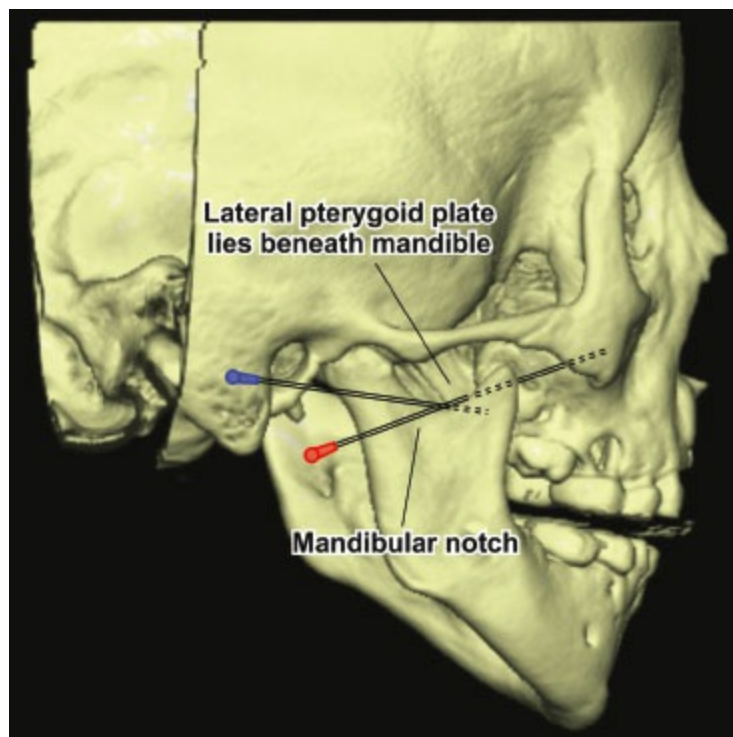

This block should be performed by practitioners with related and adequate experience. It is required when superficial block of the infraorbital nerve does not produce adequate anesthesia or when anesthesia of the more proximal superior dental nerves is required. This can be performed by a lateral approach to the sphenopalatine fossa.

### **Procedure**

- The patient either sits with the mouth slightly open or lies supine with a small towel under the occiput and the head turned slightly away from the side to be blocked.
- Above the zygomatic arch: The center of the upper zygomatic arch is marked. A 60- to 90-mm needle is introduced at 45 degrees caudally and medially, toward the contralateral molar teeth. After paresthesia is elicited at the nostril, upper lip, and cheek, the needle is withdrawn slightly, and local anesthetic is injected slowly and incrementally and with frequent aspiration.
- Below the zygomatic arch ([Fig. 36-17](#)): The zygomatic arch is marked along its course, and the patient is asked to open and close the mouth slowly so that the curved upper border of the mandible can be identified. The mandibular fossa is palpated between the condylar and coronoid processes. The lowest point of the mandibular notch is

palpated, and an “X” is marked at this spot, which is usually at the midpoint of the zygoma. A local anesthetic skin wheal is raised at the “X” after appropriate skin preparation.

- With the patient’s jaw in the open position, a 60- to 90-mm needle is introduced through the “X” at a 45-degree angle toward the dorsal part of the eyeball (cephalad and slightly anterior).
- The needle should contact the lateral portion of the pterygoid process (pterygoid plate) at a depth of 4 to 5 cm. The needle is then withdrawn and redirected slightly cephalad and anteriorly until it passes beyond the pterygoid plate and enters the pterygopalatine fossa at an additional depth of no more than 1 cm. A paresthesia in the nose or the upper teeth confirms nerve localization. The pterygopalatine fossa is highly vascular, so care must be exercised to avoid intravascular injection.
- Anesthesia can be achieved by injecting 5 mL into the pterygopalatine fossa, either upon obtaining the paresthesia or blindly by advancing 1 cm beyond the plate.

**Figure 36-17** Lateral view of a computed tomography-scanned skull showing the bony landmarks and final needle insertion angles for the maxillary (*red needle*) and mandibular (*blue needle*) nerves. Each block procedure involves first reaching the lateral pterygoid plate (see text for details).

### Clinical Pearls

- One concern during this block is spread of local anesthetic to adjacent structures, especially to the nerves in the orbit. If pain occurs in the

region of the orbit during the procedure, the injection should be stopped, and the needle should be withdrawn.

- Although the mainstay of treatment for trigeminal neuralgia continues to be pharmacologic or neuroablative, maxillary nerve block with extraoral mandibular nerve block has been reported to provide relief in some settings.<sup>91</sup>

### *Mandibular Nerve Block*

This nerve can be blocked for dental and maxillary surgery or for inferior dental pain, trigeminal neuralgia in the third branch, or temporomandibular joint dysfunction. It is the only branch of the trigeminal nerve where anesthesia carries the risk of loss of motor (mastication) function.

### **Procedure**

- The patient lies supine with the face in profile. Landmarks for location of the mandibular fossa are the same as those described for maxillary nerve blockade.
- A 60- to 90-mm needle is introduced through the skin wheal and directed perpendicularly to the skin, without the cephalad angulation required for maxillary nerve anesthesia.
- When the pterygoid plate is contacted, the depth should be noted. The needle is then redirected posteriorly until it passes beyond the pterygoid plate. It should contact the nerve 0.5 to 1 cm deep from the point where the pterygoid plate was contacted (Fig. 36-17).
- Paresthesia of the lower jaw, lower lip, and lower incisors at a depth of approximately 4 to 4.5 cm confirms proximity to the nerve. Gentle exploration in a cephalad and caudad direction, from the initial point where the needle passes posterior to the plate, may be required. After slight needle withdrawal, 5 to 10 mL of solution is injected incrementally with repeated aspiration to avoid intravascular injection. As with maxillary blockade, paresthesias can be painful to the patient.

### **Clinical Pearls**

- Anesthesia of the auriculotemporal nerve is often delayed.
- Facial nerve anesthesia can occasionally be seen when large volumes are injected to block the mandibular nerve. This is of little consequence unless neurolytic agents are used.
- A more serious complication is the possibility of intravascular injection in this highly vascular area. Injection should be performed incrementally with small quantities, and there should be constant observation for signs of toxicity.
- For patients with abnormal anatomy or accessory innervation to the

mandible, alternatives to the standard mandibular block include the Gow-Gates and Akinosi–Vazirani blocks.<sup>92</sup>

## Cervical Plexus Blocks

Anesthesia of either the deep or superficial cervical plexus or both can be used for procedures of the lateral or anterior neck such as parathyroidectomy and carotid endarterectomy. During carotid surgery, local infiltration of the carotid bifurcation may be necessary to block reflex hemodynamic changes associated with glossopharyngeal stimulation.

### *Deep Cervical Plexus Block*

#### Procedure

- The patient is placed supine with a small towel under the head, which is turned 45 degrees to the opposite side with slight neck extension.
- Landmarks include the posterior edge of the sternocleidomastoid muscle, the caudal portion of the mastoid process, the angle of the jaw, and the transverse processes of cervical vertebrae C2–C5 (about 1.5 cm apart). If all transverse processes cannot be palpated, the most prominent tubercle of C6 (Chassaignac's) is marked. A line is drawn from the mastoid process along the sternocleidomastoid muscle to reach the transverse process of C6. Each transverse process of C2–C5 is marked approximately 0.5 to 1 cm behind the line; the transverse process of C2 lies about 1.5 cm inferior to the mastoid process.
- Skin infiltration is carried out at the “X” marks of C2–C4, and three needles (22 gauge, 3.5 to 5 cm) are introduced perpendicular to the skin and advanced about 30 degrees caudally with a slight posterior orientation (Fig. 36-8).
- After confirming contact with the transverse process, the needle is withdrawn slightly and a syringe is connected to the needle. Two to three milliliters of local anesthetic solution are injected per segment for therapeutic or diagnostic purposes or for blocks in children, whereas 5 to 10 mL per segment may be sufficient for surgical block (limiting the total to approximately 20 mL if superficial blocks are also performed).

#### Clinical Pearls

- The deep block may be performed by single injection at C3 or C4 as originally described by Winnie et al.<sup>93</sup> or by a standard three-injection technique.
- A recent anatomic study demonstrated that the longus capitis muscle is a suitable landmark for US-guided deep cervical plexus block.<sup>94</sup> With

this approach, both the deep cervical plexus and sympathetic trunk can be blocked.

- Paresthesia occurring during these blocks has been associated with more effective anesthesia.<sup>95</sup>
- Anesthesia for carotid endarterectomy may involve performing combined superficial and deep cervical plexus blocks, yet the benefit of combined over superficial block alone has been questioned.<sup>96,97</sup> There appears to be no difference between these two approaches in the amount of supplemental local anesthesia required.
- There are several life-threatening complications that may arise from deep cervical plexus block; in fact, this block is administered rarely. Injection may occur into the vertebral artery, and subarachnoid or epidural injections are possible if the needle is advanced too far medially into the vertebral foramen. This is more likely in the cervical region because of the longer dural sleeves that accompany these nerve branches. Careful monitoring of the patient should continue for 60 minutes after the block has been performed.
- Phrenic nerve palsy leading to hemidiaphragmatic paresis is a common occurrence with deep cervical plexus block.<sup>98</sup> This block is not indicated in any patient who depends on the diaphragm for tidal ventilation, nor is bilateral blockade ever recommended.
- Other well-described side effects include Horner syndrome (if the superior cervical or cervicothoracic ganglion is blocked),<sup>99</sup> stellate ganglion block,<sup>100</sup> and hoarseness due to recurrent laryngeal nerve block.

### *Superficial Cervical Plexus Block*

This block is performed in a position similar to deep cervical plexus block and results in anesthesia only of the sensory fibers of the plexus.

#### **Procedure**

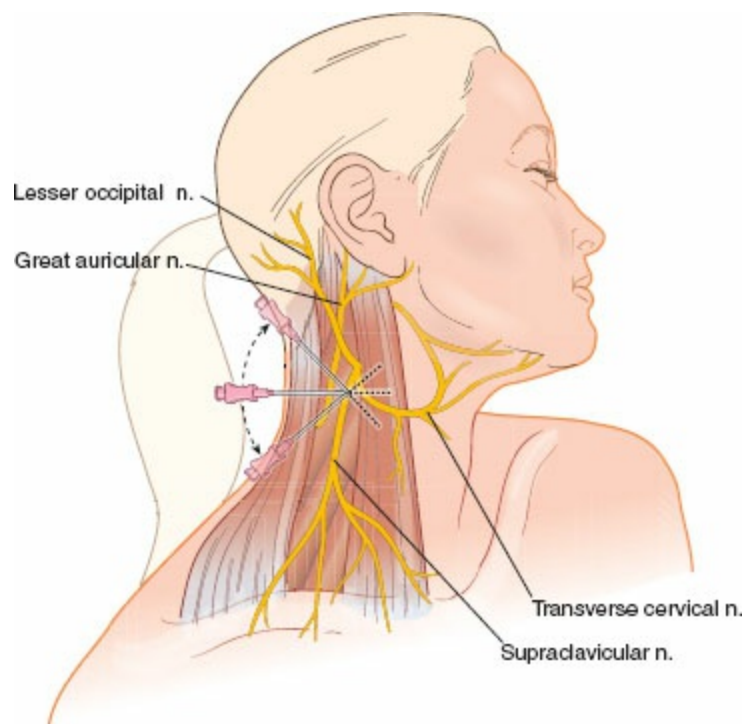

- An “X” is made at the midpoint of the posterior border of the sternocleidomastoid muscle.
- Local skin infiltration is performed with a fan-like injection using 10 to 20 mL of local anesthetic (0.1 to 0.2 mL/kg for children) along the posterior border of the sternocleidomastoid muscle 4 cm above and below the level of the midpoint (Fig. 36-18).

#### **Clinical Pearls**

- The most common approach for minimally invasive parathyroidectomy (involving a small unilateral incision rather than bilateral neck exploration) includes a combination of C2–C4 superficial cervical

plexus block, infiltration along the incision line and infiltration of the upper thyroid pedicle.<sup>101</sup> This approach can result in shorter anesthetic and operative times, leading to earlier hospital discharge, as well as significantly better postoperative pain relief.<sup>101,102</sup>

- Initial studies of US-guided superficial cervical plexus block showed no added benefit over the blind technique,<sup>103</sup> although US guidance may be helpful in emergency situations.<sup>104</sup>
- Using a modified surgical approach, thyroid surgery has been performed under superficial cervical plexus block in combination with anterior field block.<sup>105</sup>
- Minimally invasive surgery may require conversion to general anesthesia when there is difficulty ensuring adequate protection of the recurrent laryngeal nerve or when intraoperative diagnosis of parathyroid carcinoma or multiglandular parathyroid hyperplasia occurs.
- Phrenic nerve paralysis leading to diaphragmatic dysfunction,<sup>95</sup> vagus nerve block with resultant recurrent nerve paralysis,<sup>106</sup> and inadvertent intravascular injection<sup>107</sup> have all been reported.

**Figure 36-18** Lateral view of the head and neck, showing block needle insertion angles needed to perform superficial cervical plexus block. Initially, the needle is inserted perpendicular to the skin at the midpoint of the lateral border of the sternocleidomastoid muscle (where it is crossed by the external jugular vein). The needle can then be repositioned to superior and inferior angulations to reach the entire cervical plexus.

## Occipital Nerve Blocks

The greater and lesser occipital nerves can be blocked by superficial injection at the points on the posterior skull where they emerge from below the muscles of the neck. This block is rarely used for surgical procedures and is more often applied as a diagnostic step in evaluating head and neck pain complaints.

### *Procedure*

- The patient sits with their head tilted forward slightly to expose the prominent nuchal ridge of bone at the posterior base of the skull.
- The inferior nuchal line is palpated at one-third of the distance between the external occipital protuberance and the foramen magnum. A mark is placed on the nuchal line at the lateral border of the insertion of the erector muscles of the neck, usually 2.5 cm from the midline. At this point, the branches of the greater occipital nerve usually pass laterally from behind the muscle to cross the nuchal line. The nerve is located directly lateral to the easily palpated occipital artery. During its ascent along the posterior skull, the lesser occipital nerve can be located an additional 2.5 cm away from the greater occipital nerve along the inferior nuchal line; a mark should be placed here as well (Fig. 36-9).
- A short, fine needle (e.g., 25 mm 25 gauge) is introduced with a slight cranial angulation at each mark to the depth of the skull itself. After slight withdrawal, local anesthetic is injected (e.g., 0.5 to 1 mL of 1% lidocaine for diagnostic procedures or 1 to 3 mL of 0.75% ropivacaine for therapeutic procedures). Paresthesias are occasionally encountered but are not essential for obtaining simple skin anesthesia.
- If more anterior anesthesia of the scalp is required, the lesser occipital nerve branches can also be blocked by advancing the needle subcutaneously from this point in an anterior direction toward the mastoid process. A band of anesthetic solution is deposited along the line between skin entry and the mastoid process using 2 to 3 mL of local anesthetic.

### *Clinical Pearls*

- Blockade of the lesser occipital and great auricular nerves (both blocked by subcutaneous injection from the angle of the mandible to the mastoid process) has been successful in providing postoperative analgesia after otoplasty.<sup>108</sup> Reducing the requirement for opioid analgesia (with its associated nausea and vomiting) is essential due to the high incidence of pain and vomiting on the first postoperative day related to the surgical procedure alone.
- Greater occipital nerve block is commonly used for primary headache

syndromes. For chronic syndromes, the anterior region involving the trigeminal nerve is also blocked.<sup>109</sup> It has been reported for use with cervicogenic headache, occipital neuralgia, migraine, and cluster headache.<sup>110</sup>

- Complications with this technique are rare. Care must be taken not to advance the needle anteriorly under the skull, as the foramen magnum might be entered unintentionally with a long needle. Local hematoma may be produced with superficial injection, but this is only a temporary problem.

## Upper Extremity

Although many approaches to the brachial plexus have been described, there are traditionally four anatomic locations where local anesthetics are placed: (1) the interscalene groove near the cervical transverse processes, (2) the subclavian sheath at the first rib, (3) near the coracoid process in the infraclavicular fossa, and (4) surrounding the axillary artery in the axilla. The introduction of US imaging has increased the use of blocks at the supraclavicular fossa, as visualization of the subclavian artery and lung make these critical structures easier to avoid. It is important to stress that clear visibility of the needle is essential for this block (and generally for all blocks of the brachial plexus). The appropriate choice of approach depends not only on the patient's anatomy but also on the site of surgery and the method used to locate nerve structures.

The terminal branches of the brachial plexus can also be anesthetized by local anesthetic injection along their peripheral course as they cross joint spaces, where they lie proximal to easily identifiable structures (Table 36-1), or by injection of a dilute local anesthetic solution intravenously below a pneumatic tourniquet on the upper arm ("intravenous regional" or Bier block). The use of US may increase the number of locations where the terminal nerves can be successfully blocked. For example, the ulnar nerve can be blocked effectively at the medial surface of the mid-forearm, which may reduce the risk of ulnar nerve palsy posed by block at the elbow near the cubital tunnel. As stated in the introduction to Specific Techniques, the use of combined US- and NS-guided technique is stressed in the figures, and, for simplicity of viewing, the necessary sterile precautions are not shown.

### Brachial Plexus Block

#### *Interscalene Block*

This block, as described by Winnie<sup>111</sup> in 1970, is indicated mostly for surgical anesthesia of the shoulder, upper arm, and forearm but is often insufficient

for the hand. Frequently, it spares the lowest branches of the plexus, the C8 and T1 fibers, which innervate the caudad (ulnar) border of the forearm. Nevertheless, recent reports provide evidence that a low interscalene block (below C6, just superior to the clavicle) may provide sufficient anesthesia and analgesia for procedures on the lower arm.<sup>112,113</sup> The patient is positioned supine, with their head faced slightly to the contralateral side. The main surface landmark used for this block—the sternocleidomastoid muscle—can be accentuated by asking the patient to reach for the ipsilateral knee and by rotating the head approximately 45 degrees to the nonoperative side. The head should also be elevated slightly, and the patient should be instructed to take a deep breath since contraction of the scalenus muscles accentuates the interscalene groove. This groove lies immediately behind the lateral border of the clavicular head of the sternocleidomastoid muscle at the level of the cricoid cartilage (C6). As for all procedures of the upper extremity, prepare the needle insertion site and other applicable skin areas with an antiseptic solution and, if using US imaging, ensure sterility of the US probe with a standard sleeve cover or transparent dressing.

### **Procedure Using Nerve Stimulation Technique**

- Landmarks: Using the maneuvers described earlier, the interscalene groove is palpated by rolling the fingers posteriorly off the lateral border of the sternocleidomastoid muscle; mark the groove as high as possible. After the patient relaxes, the prominent transverse process of C6 can often be felt directly in the groove and should be marked.
- Needling: A skin wheal is raised in the interscalene groove at the level of the cricoid. A 22-gauge, 36- to 50-mm insulated needle (shorter for pediatric patients) is introduced through the wheal. The needle is directed medially, caudally, and slightly posteriorly in the direction of the C6 transverse process. The caudad tilt of the needle is important to avoid either entering the neural foramen or injection into the dural nerve root sheath, increasing the risk of high-spinal anesthesia or spinal cord injury.<sup>114</sup> Avoiding medial placement by using a mostly caudad and posterior direction may reduce the risks even more. The superficial structures of the plexus have been shown to be located at an average, shallow depth of 5.5 mm.<sup>115</sup> Due to compact arrangement of neck anatomy in children, an angled insertion may be needed (as opposed to perpendicular in adults) to avoid puncture of the vertebral artery or epidural/subarachnoid space.
- Nerve localization: Applying an initial current of 0.8 mA is sufficient for stimulation of the plexus (usually at a depth of 1 to 3 cm), and the current is reduced to aim for a threshold current of 0.4 mA before injection after obtaining an appropriate motor response. Diaphragmatic

or trapezius twitches should be avoided, as they are associated with **6** cervical plexus stimulation. A diaphragmatic response indicates that the phrenic nerve is being stimulated and that the needle is too anterior.

- **Injection:** After careful aspiration, 25- to 30-mL local anesthetic is injected in small increments to detect intraneural or intravascular placement of the needle.

### **Procedure Using Ultrasound Guidance (Fig. 36-19)**

- **Scanning:** Two scanning techniques are recommended for viewing the brachial plexus at the interscalene level: (1) beginning anteriorly at the cricoid cartilage level (C6) with movement from anterior and medial to posterior and lateral toward the interscalene groove, and (2) scanning proximally from the supraclavicular fossa to the interscalene location.
- **Appearance:** At the supraclavicular fossa, the brachial plexus (trunks/divisions) can be seen in short axis as a tightly enclosed cluster (i.e., honeycomb-like), superior and lateral to the subclavian artery (Fig. 36-20). After tracing the nerves in a proximal fashion toward the interscalene groove, the nerve structures (roots/trunks) are visualized in a sagittal oblique section as three (usually) or up to five round or oval-shaped hypoechoic (see Common Techniques: Nerve Stimulation and Ultrasound Imaging section) structures, sometimes with a few internal punctate echoes, lying between the scalenus anterior and medius muscles. The C8 and T1 roots may be difficult to identify because of their depth.<sup>116,117</sup>
- **Needling:** After infiltration of local anesthetics to the skin at the anticipated needle puncture site, a 22-gauge, 50-mm needle (insulated is recommended) is introduced either OOP (see Common Techniques section) or IP to the probe (Fig. 36-19) and advanced to a maximum of 3 cm for most patients. For OOP needle insertion technique, the clinician stands beside or cephalad to the probe and places the initial needle puncture site cranial to the probe. The needle is typically angled somewhat caudally toward the US beam plane. For IP needle insertion technique, the needle is moved from lateral to medial (still slightly caudad) and will first penetrate the scalenus medius muscle before entering the interscalene groove. It is recommended to use NS to enable further nerve localization. Note that, in children, the brachial plexus roots are located relatively superficial at the interscalene level compared to adults. In infants, the roots may be only millimeters below the skin surface.
- **Local anesthetic spread:** A test injection of D5W is recommended and will help further confirm nerve localization with NS and estimate the

pattern of local anesthetic spread. Local anesthetic should be deposited in the midst of the neural structures so that it spreads to surround the nerves circumferentially. Local anesthetic distention in this compartment can be seen by US as a hypoechoic (fluid) expansion.

**Figure 36-19** Arrangement of relevant anatomy for ultrasound-guided interscalene brachial plexus block. The block is performed using an IP needle alignment to a linear, high frequency probe. The needle is directed lateral medial with slight caudal angulation to avoid the intervertebral foramen. The roots/trunks of the plexus are usually seen as three or more round or oval-shaped hypoechoic structures sandwiched between the scalenus anterior and medius muscles in the interscalene groove. Note that the vertebral artery lies medial and deep to the brachial plexus.

## Clinical Pearls

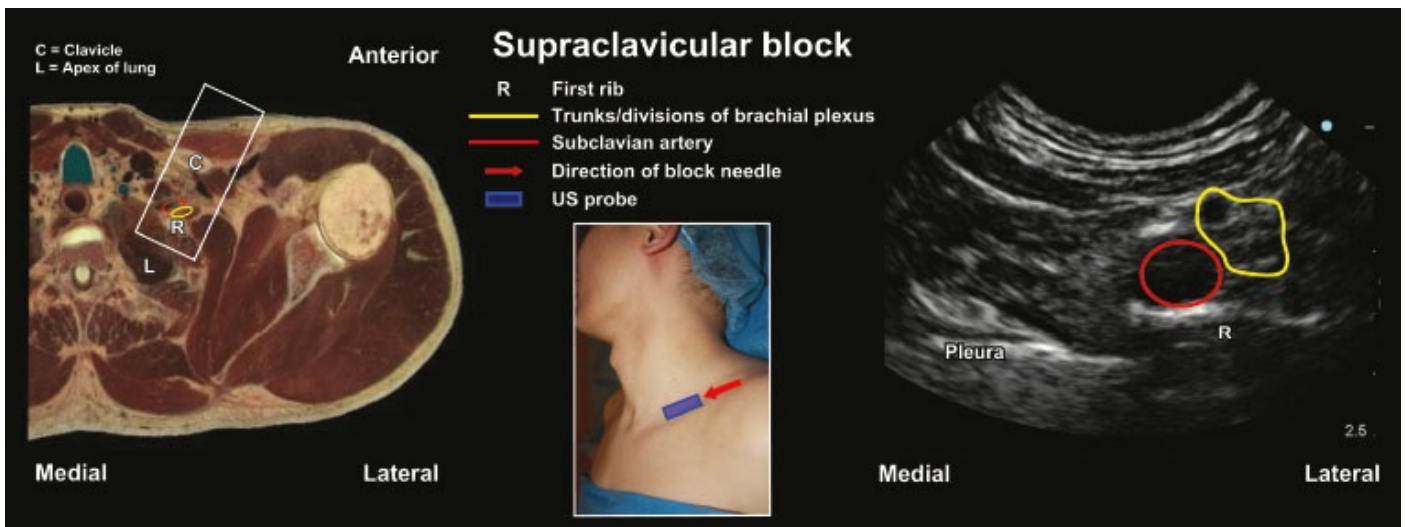

- The use of long-acting local anesthetics may provide analgesia for 10 to 12 hours. For longer analgesia, insertion of a continuous catheter is effective for procedures such as total shoulder replacement, although securing the catheters in the mobile neck tissues is a challenge.
- Equal success has been achieved when any of the appropriate muscle responses are elicited as a positive stimulating test. Palpation of the muscle may confirm the motor response.
- Despite the fact that subarachnoid or intraneural injection can occur even when the threshold current is more than 0.4 mA, it is advisable to avoid injecting when the current responses are less than 0.4 mA.
- If a continuous block is indicated, the needle entry point may be moved a centimeter cephalad for the OOP approach, making the corresponding angle of insertion a little steeper and more tangential to the course of the plexus. The bevel of the introducing needle should be directed laterally. Placement of a stimulating catheter may be aided by dilating the perineural space with D5W, which will allow the user to

monitor the catheter's advancement to a location where motor response is maintained at less than 0.5 mA.

- Securing catheters in the freely mobile neck is a challenge. Some prefer to secure the catheter by tunneling 3 to 4 cm below the skin by passing it back through an intravenous catheter that has been introduced subcutaneously near the entry site.
- During OOP US-guided technique, more than 45-degree needle angulation should be avoided, as the needle may be inserted too deep and directed toward the spinal cord.
- Complications from this approach are related to the structures located in the vicinity of the tubercle. The cupola of the lung is close, particularly on the right side, and can be contacted if the needle is directed too far caudally. Pneumothorax should be considered if cough or chest pain is produced while exploring for the nerve. If the needle is allowed to pass directly medially, it may enter the intervertebral foramen, and injection of local anesthetic may produce spinal or epidural anesthesia. The vertebral artery passes posteriorly at the level of the sixth vertebra to lie in its canal in the transverse process that can be seen as a pulsatile structure deep to the plexus; direct injection into this vessel can rapidly produce central nervous system toxicity and convulsions. Careful aspiration and incremental injections are important to help avoid both of these potential problems.
- Even with appropriate injection, local anesthetic solution can spread to contiguous nerves. It may produce cervical plexus block, including motor fibers to the diaphragm, which may be a problem in patients with respiratory insufficiency. A case report described an optimal spread of local anesthetic and the possibility of using saline dilution technique should phrenic nerve block occur.<sup>118</sup>
- Horner syndrome is common because of spread to the sympathetic chain on the anterior vertebral body.
- Neuropathy of the C6 root is a potential problem because the needle may unintentionally pin the nerve root against the tubercle and predispose to intraneural injection. The needle should be withdrawn slightly if the first injection produces the characteristic “crampy” pain sensation.
- An alternative technique for blocking the roots of the brachial plexus is to perform a cervical paravertebral block,<sup>119</sup> which can utilize the bony landmarks of the vertebral column. This is a high quality but advanced block and should be performed using US guidance. A lateral US view of the brachial plexus at the level of C6 allows visualization of the needle as it passes lateral to the C6 transverse process and into the interscalene space. This view avoids the challenges of attempting to

view the brachial plexus from a posterior approach, where the bony structures may obscure the view of the needle and plexus.

**Figure 36-20** Arrangement of relevant anatomy for ultrasound-guided supraclavicular brachial plexus block. The block is performed using IP needle alignment to a small footprint curved probe with the needle inserted lateral to medial in a slightly sagittal plane. Color Doppler can be valuable to quickly locate the subclavian artery inferomedial to the plexus trunks/divisions.

### *Supraclavicular Block*

The supraclavicular block targets the trunks and/or divisions of the brachial plexus, depending on the location of the injection site and the patient's anatomy. Similar to the interscalene block, the patient is positioned supine with the head turned approximately 45 degrees to the contralateral side. Prepare the needle insertion site and other applicable skin areas with an antiseptic solution, and ensure sterility of the US probe with a standard sleeve cover or transparent dressing.

**Procedure Using Nerve Stimulation Technique (Note that most clinicians prefer to perform this block under US guidance to minimize potential complications; some may use NS as an adjunct method with US.)**

- Landmarks: The outline of the clavicle is drawn on the skin, and the midpoint of the clavicle is marked. An "X" is placed posterior to this midpoint in the interscalene groove, usually 1 cm behind the clavicle. Since the plexus lays immediately cephaloposterior to the subclavian artery, its pulse serves as a reliable landmark in thinner individuals.
- Needling: Local infiltration is performed at the site of the nerve, and a 2.5- to 5-cm, 22-gauge needle is introduced in the parasagittal plane at the superior border of the clavicle at the lateral edge of the sternocleidomastoid muscle insertion. An initial insertion angle of 45

degrees cephalad is recommended, with subsequent reductions in angle as necessary,<sup>120</sup> although an angle of less than 20 degrees may lead to the needle contacting the pleura and/or subclavian vein prior to the plexus. The rib may be contacted, with subsequent anteroposterior needle adjustment to contact the plexus, but avoiding rib contact may be most prudent. Careful lateral or medial exploration may be needed, but probing too medially increases the risk of contacting the pleura. For children, a weight-dependent guide can help in determining needle insertion depth. In general, for a 10-kg child, the needle is inserted 10 mm; depth of insertion increases 3 mm for every 10 kg increase in weight until 50 kg. For children above this weight, insertion advances 1 mm for every 10 kg increase in weight (maximum depth should not be >35 mm). However, it would be much preferable to use US as a guide.

- Nerve localization: Responses to NS can be useful for confirmation of needle proximity to the separate trunks. Twitches of pectoralis, deltoid, biceps (upper trunk), triceps (upper/middle trunk), forearm (upper/middle trunk), and hand (lower trunk) muscles with current intensity of 0.4 mA (0.1 to 0.3 milliseconds) are acceptable. Distal responses (hand or wrist flexion or extension) are best to confirm placement within the fascia. Multiple nerve responses are not required.
- Injection: If a nerve response is produced during the course of exploration, the anesthetic solution can be injected while the needle is fixed in position. Twenty-five to forty milliliters of local anesthetic will produce adequate analgesia. In children, the fascia surrounding the nerve trunks is less adherent than in adults, which may lead to greater spread of local anesthetic.

### **Procedure Using Ultrasound Imaging (Fig. 36-20)**

- Scanning: The probe is first placed in a coronal oblique plane at the lateral end and just above the upper border of the clavicle. It is then moved medially until an image of the subclavian artery appears on the screen. Some dorsal and ventral rotations of the probe may be necessary. With the subclavian artery in the middle of the screen, the plexus is located superolateral to the artery, and the neurovascular structures lie above the first rib. Small-footprint probes are generally used for scanning children since they offer better needle movement around the probe.
- Appearance: The subclavian artery is anechoic, hypodense, pulsatile, and round; its identity can be further confirmed by color Doppler. Trunks/divisions of the brachial plexus appear as a cluster of hypoechoic “grape-like” structures consisting of usually three (more as one moves distally) hypoechoic nodules, all surrounded by a

hyperechoic lining (presumably the connective tissues). With the probe in a coronal oblique plane, the plexus depth has been shown with MRI to equal 1.65 cm in males and 1.45 cm in females.<sup>120,121</sup> Medial and deep to the artery, the rib may be seen as a hyperechoic line with dorsal shadowing. The anechoic subclavian vein may be seen inferomedial to the artery.

- **Needling:** The selected needle insertion site is often more lateral with the US-guided technique than when using NS techniques. The skin is infiltrated with local anesthetic, and a 22-gauge, 50-mm (or less) needle (insulated is recommended) is introduced with IP needle alignment to a curved, small footprint (Fig. 36-20) or linear probe. The needle is inserted immediately above the clavicle in a lateral-to-medial direction with a slight cephalad angle. It is recommended to have the concurrent use of NS for additional confirmation of nerve localization and as an additional monitor to prevent intraneural injection by having the threshold stimulation more than 0.2 mA. See earlier for acceptable motor responses to NS.
- **Local anesthetic spread:** It is best to deposit a local anesthetic next to the nerve structures immediately lateral to the subclavian artery on top of the first rib. Injection in this location will often lift the nerve structures superiorly away from the first rib and subclavian artery. The hypoechoic spread of local anesthetic surrounding the nerves may be seen on the US screen.

### **Clinical Pearls**

- It is recommended to use US imaging combined with NS technique during this block to help avoid puncturing the pleura. When using US, it is critical to be able to visualize both the first rib and the pleura and to optimize the image such that the first rib covers the pleura, especially just lateral to the subclavian artery where the target of the needle tip is. It is critical to measure and be aware of the skin–pleura distance with US prior to needle insertion. The responses to NS can be useful for confirmation of needle proximity to the separate trunks.
- The major challenge with US imaging in this region is the presence of a bony prominence (clavicle) and curved soft tissue contour that can interfere with imaging of the brachial plexus in short axis. Despite the advantages of commercially available, low to moderate frequency curved array probes (e.g., C11, Titan or MicroMaxx, Sonosite Inc., Bothell, WA), a curved array probe with a small footprint is extremely useful in this compact area.
- The lateral-to-medial IP needle approach will ensure that the needle approaches the nerve structures before reaching the subclavian artery

(i.e., less chance of inadvertent vascular puncture). However, using a slightly sagittal plane (Fig. 36-20) may reduce the risk of pleural puncture. The needle should be viewed at all times when using a lateral-to-medial approach.

- The greatest risk when using this technique is pneumothorax, as the cupola of the lung lies just medial to the first rib, not far from the plexus. The risk of pneumothorax is greater on the right side as the cupola of the lung is higher on that side. The risk is also greater in tall, thin patients. In children, the brachial plexus at this level is relatively superficial and close to the pleura; careful needle insertion must be exercised to avoid the risk of pneumothorax.
- This method does not introduce any more complications than other methods of brachial plexus block.
- When using a catheter-over-needle method, a medial-to-lateral approach is indicated to reduce the risk of dislodgement.<sup>122</sup> This approach will place the needle tip in the corner immediately lateral to the subclavian artery and above the first rib.

### *Infraclavicular Block*

Infraclavicular block targets the cords of the brachial plexus, and the nerves can be blocked next to the second part of the axillary artery at the level of the coracoid process. Brachial plexus block in the infraclavicular area offers excellent analgesia of the entire arm and allows introduction of continuous catheters to provide prolonged postoperative pain relief. The infraclavicular approach blocks the musculocutaneous and axillary nerves more consistently because they often branch off high in the axilla and can be missed with the axillary block approach. However, multiple injections may be required for successful infraclavicular and axillary blocks.

Infraclavicular blocks are indicated for forearm, elbow, and hand surgeries. The patient is supine with the head turned approximately 45 degrees to the nonoperative side, and their arm may be either at their side with hand on the abdomen or abducted with their palm placed behind their head. When preparing for this block, it is common to have the patient's elbow flexed and the hand resting on the abdomen to facilitate observation of motor responses generated with NS. Alternatively, externally rotating the arm and placing the hand behind the head stretches the cords and brings the nerves closer around the axillary artery, which may facilitate local anesthetic spread around the nerves. As always, prepare the needle insertion site and other applicable skin areas with an antiseptic solution and ensure sterility of the US probe with a standard sleeve cover or transparent dressing.

### **Procedure Using Nerve Stimulation Technique**

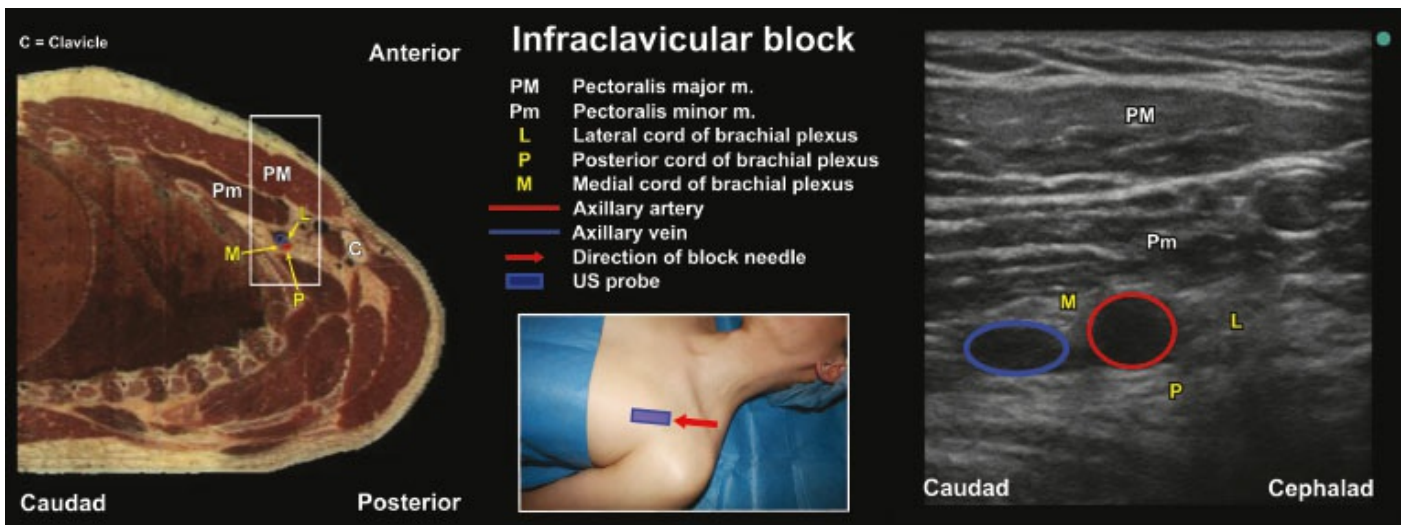

Several approaches have been described for infraclavicular block, all with various needle puncture sites and angles of insertion.<sup>123–128</sup> Here we describe a lateral approach,<sup>124</sup> which may improve plexus cord localization and reduce risk of puncture to both the pleura and axillary artery.<sup>129,130</sup>

- Landmarks: With the patient's arm adducted and their hand resting on their abdomen, the medial aspect of the coracoid process is palpated as one slips their finger off the clavicle.
- Needling: After skin preparation and skin wheal, a 50- to 90-mm, 18- to 22-gauge needle is inserted where the clavicle meets the medial aspect of the coracoid process, generally directed 0 to 15 degrees posterior to the horizontal plane (Fig. 36-21 illustrates this needle insertion when using US guidance). The 15-degree trajectory will likely increase the chances of contacting the more posteriorly located posterior or medial cords which may improve analgesia. A greater angle may be required to achieve adequate responses to NS, since local anesthetic injection at more than one cord may be beneficial. The cords should be approximately 4 to 6 cm deep (insertion of more than 7.5 cm may risk pleural puncture).<sup>124</sup> The needle puncture site may be adjusted slightly caudad to this location, as with the technique of Kapral et al.<sup>123</sup> If the needle is placed 2.5 cm caudad to the coracoid process, a laterally projected needle directed toward the axillary artery may be effective.<sup>124</sup>
- Nerve localization: The first response (elbow flexion) obtained is usually the musculocutaneous nerve arising from the lateral cord. For complete anesthesia of the hand, a separate distal response needs to be obtained from the medial (distal flexors) and posterior (distal and proximal extensors) cords.<sup>131</sup> A simplified approach to determining the specific cord distal responses during infraclavicular block has been described.<sup>132</sup> A close examination of the movements of the fifth digit (pinkie) can be useful to differentiate the cords, with lateral movement (i.e., pronation) representing the lateral cord, medial movement (i.e., flexion) representing the medial cord, and dorsal movement (i.e., extension) representing the posterior cord.<sup>132</sup> Some practitioners also advocate that eliciting a forearm response (pronation via the lateral cord) is essential for a complete block.<sup>133</sup> The artery may be punctured easily at this point, and careful aspiration is required to prevent intravascular injection.
- Injection: If a musculocutaneous nerve response is obtained, the nerve or lateral cord can be blocked by an injection of 5 to 10 mL of local anesthetic. Once responses in the hand are obtained, a further 25 mL of local anesthetic can be injected along the posterior and medial cords.

### Procedure Using Ultrasound Imaging (Fig. 36-21)

- **Scanning:** Immediately medial and inferior to the coracoid process, position a linear or curved lower frequency transducer (4 to 7 MHz), depending on body habitus, in a parasagittal plane, and capture the best possible short-axis view of the brachial plexus cords and axillary vessels. If the patient is quite thin or if using a more medial location (not described here) where the nerves are more superficial, a higher frequency probe may be used.
- **Appearance:** The pectoralis major and minor muscles are separated by a hyperechoic lining (perimysium); the pectoralis major lies superficial and lateral to the pectoralis minor. Approximately 4 to 5 cm deeper lies the axillary neurovascular bundle. The large axillary vein lies medial and caudad to the artery. The lateral cord of the plexus is often readily visualized as a hyperechoic oval structure, although the medial and posterior cords may not be easily identified since the medial cord lies between the axillary artery and vein, whereas the posterior cord can be hidden deep to an axillary artery acoustic shadow. In addition, the medial cord can be posterior or even slightly cephalad to the axillary artery. It is important to realize that there is a great deal of individual anatomic variation in cord location around the artery. The nerve structures now appear hyperechoic, rather than hypoechoic as seen more proximally, presumably due to an increase in the number of fascicles and amount of (hyperechoic-appearing) connective tissue.<sup>75</sup>
- **Needling:** The skin is infiltrated with local anesthetic. For single-injection technique, a 50- to 90-mm, 18- to 22-gauge insulated needle is suitable if using NS, whereas a 90-mm, 17- to 20-gauge needle can be used for catheter placement. Using an IP needle alignment will be most suitable in most cases; however, in young children, this may be difficult due to the limited space between the clavicle and US probe. The block needle is inserted cephalad to the probe and is then advanced caudally and posteriorly at approximately 30 degrees to the skin (IP insertion caudad to the probe is acceptable for young children in whom there is limited space cephalad to the probe). The cords should be found at a depth of 4 to 6 cm.<sup>134</sup> It is recommended to combine US with NS for accurate nerve localization (e.g., musculocutaneous nerve or specific cord), due to the high variability of cord location.
- **Local anesthetic spread:** Aim to place the needle and local anesthetic posterior to the axillary artery next to the posterior cord (spread from this location is optimal for complete block success). Performing a test dose with D5W is recommended prior to local anesthetic injection to visualize spread and confirm nerve localization. Inject 20 to 25 mL of local anesthetic around the posterior cord. If local anesthetic spread is

deemed inadequate to surround all cords, reposition the needle before injecting any additional local anesthetic.

**Figure 36-21** Arrangement of relevant anatomy for ultrasound-guided infraclavicular brachial plexus block. The block is performed using IP needle alignment to a linear probe and directing the needle 15 degrees posteriorly in a cephalad-to-caudad direction. In contrast to the more proximal blocks, the nerves (cords) appear hyperechoic due to higher fascial content and the relatively hyperechoic surrounding tissue (muscle).

## Clinical Pearls

- In the past, numerous techniques were developed with modifications to localize nerves and avoid vessel and pleural punctures. Real-time guidance with US addresses some of these issues, although US-guided blocks are still undergoing a rapid development process to determine the safest and most successful approaches.
- Techniques that incorporate multiple injections may be easier and potentially safer under combined US and NS guidance, which provides direct visualization of the anatomic structures.
- If a catheter is to be threaded, the aim should be to elicit motor responses in the hand itself. The tip of the Tuohy needle (90 mm, 17 to 20 gauge) should be directed laterally to allow the catheter to run in the direction of the nerves.
- Compared to blocks at more proximal locations, the infraclavicular block has the advantage of lower risk of blocking the phrenic nerve or stellate ganglion. However, in some cases, continuous catheters may lie along one cord and fail to provide complete anesthesia and analgesia of the entire brachial plexus with small volume infusions. This may be overcome to some degree by intermittent boluses of larger volumes of local anesthetic.

- Vessel puncture is a potential complication; therefore, frequent aspiration should be performed. Lateral needle insertion will help avoid the risk of pneumothorax.

### *Axillary Block*

The nerves targeted for axillary block course distally with the axillary artery and vein along the humerus from the apex of the axilla (Fig. 36-11). This block is useful for surgery of the elbow, forearm, and hand. The ulnar, median, and radial nerves are the primary targets. The musculocutaneous nerve often leaves the plexus (via the lateral cord) proximal to this point and may be blocked separately during the axillary block (in the coracobrachialis muscle) or at mid-humeral locations (along its diagonal course through or beyond the coracobrachialis muscle). Relative to the third part of the axillary artery, the usual course of the terminal nerves is as follows: the median nerve lies anterior and medial, the ulnar nerve lies posterior and medial, the musculocutaneous nerve lies anterior and lateral, and the radial nerve lies posterior and lateral. Because the single sheath may be broken up into separate compartments by fascial septa surrounding individual nerves in the axilla, some practitioners advocate that local anesthetic should be injected at multiple sites in the axilla, in contrast to the single injections possible with proximal approaches. The patient is positioned supine with the arm abducted at 70 to 80 degrees and externally rotated with the elbow flexed at 90 degrees.

### **Procedure Using Nerve Stimulation Technique**

- Landmarks: The axillary artery is marked as high in its course through the axilla as is practical. It is usually felt in the intramuscular groove between the coracobrachialis and the triceps muscles. It also passes between the insertions of the pectoralis major and the latissimus dorsi muscles on the humerus.
- Needling: A 30- to 50-mm, 22-gauge insulated needle is suitable for this block. After aseptic preparation, a skin wheal is raised over the proximal portion of the artery. The index and middle fingers of the nondominant hand straddle the artery just below this point, both locating the pulsation and compressing the neurovascular bundle below the intended site of injection. The needle is inserted in a slight cephalad direction, followed by a two-step, four-injection process with puncture at locations just superior and inferior to the artery.
- Nerve localization: With NS technique, ideally, the nerves serving the area of proposed surgery are sought first. The median and the musculocutaneous nerves lie on the superior aspect of the artery (as viewed by the operator), whereas the ulnar and radial nerves lie below

and behind the vessel. Obtaining a direct musculocutaneous nerve response (elbow flexion) indicates localization of this particular nerve but not necessarily all nerves.

- Injection: Experience has shown that a multiple injection technique around each individual nerve is the most reliable approach (10 to 15 mL at each nerve location). Less volume may be required, but the minimum required dose/volume per nerve is currently unknown.

### Procedure Using Ultrasound Imaging (Fig. 36-22)

- Scanning: High-frequency, linear probes are generally recommended (10 to 15 MHz) for imaging since the nerves are superficial (1 to 2 cm) below the skin. Small footprint probes are recommended for young children. The most proximal location at the apex of the axilla may be the best for viewing all of the terminal branches of the brachial plexus. The probe is positioned perpendicular to the anterior axillary fold and in cross-section to the humerus at the bicipital sulcus (and at the level of the axillary pulse) to capture the transverse, or short-axis, view of the neurovascular bundle.
- Appearance: In cross-section:
- The coracobrachialis and the biceps brachii muscles are seen laterally; the teres major and the triceps brachii muscles lay medially, the latter being deeper than the biceps brachii muscle.
  - The anechoic and circular axillary artery lies centrally, adjacent to both the biceps brachii and coracobrachialis muscles and is surrounded by the nerves.
  - The nerves appear round-to-oval in short axis, generally appearing as hyperechoic masses due to the large amount of connective tissue (epi- and perineurium) interspersed within the hypoechoic nerve fascicles.
  - The *median* nerve is often located superficial and between the artery and the biceps brachii muscle; the *ulnar* nerve is usually located medial and superficial to the artery; the *radial* nerve lies deep to the artery at the midline (clock-wise: median, ulnar, radial—but there are many variations).
  - The *musculocutaneous* nerve is commonly located in the hyperechoic plane between the biceps brachii and coracobrachialis muscles.
- Needling: A 50-mm, 22-gauge insulated needle (combined US and NS technique is recommended) is suitable. Both IP and OOP needle approaches can be used for axillary block. An OOP approach, with the needle distal to the probe and in transverse axis to the nerve, is similar to the traditional blind procedure, except that the needle will be

aligned at an angle rather than perpendicularly to optimize its visibility. An angle of 30 to 45 degrees from the skin, with the needle placed approximately 1 to 2 cm caudad to the probe, may allow optimal needle visibility (see description of the walk-down technique in the section on Common Techniques: Nerve Stimulation and Ultrasound Imaging). The IP approach involves inserting the needle at an acute angle (20 to 30 degrees) to the skin in a lateral-to-medial direction (Fig. 36-22). Typically, the block needle is advanced to contact the median nerve. It is then crossed over the axillary artery to contact the ulnar nerve superficially and then finally behind the artery to the deeper radial nerve. Follow NS procedure if using this technique.

- Local anesthetic spread: Performing a test dose with D5W is recommended prior to local anesthetic application to visualize spread and confirm nerve localization. A proper injection is indicated by fluid spread completely around the nerve structure, with nerve movement away from the needle tip. Improper injection (e.g., injection outside the sheath) appears as partial asymmetrical fluid expansion not immediately adjacent to the nerve structure.

**Figure 36-22** Arrangement of relevant anatomy for ultrasound-guided axillary brachial plexus block. The block is performed using IP needle alignment to a linear, high frequency probe. Typically, the block needle is advanced in sequence to reach each of the median, ulnar, and radial nerves.

### Clinical Pearls

- Although a multiple-injection NS technique has been used extensively for this and other blocks, it is important to consider that some spread of the local anesthetic solution will occur, and hypesthesia can occur in an unpredictable fashion, limiting the identification of subsequent nerves. A recent evaluation of a two-injection technique—with one

injection posterior to the axillary artery and the other to the musculocutaneous nerve—demonstrated that this approach may be as effective as blocking each of the ulnar, median, radial, and musculoskeletal nerves separately,<sup>135</sup> potentially minimizing unwanted spread to adjacent nerves.

- If forearm anesthesia is required and the musculocutaneous nerve was not localized previously, supplementary anesthesia of the musculocutaneous nerve should be attained using some reliable means of nerve localization (i.e., NS and/or US guidance) rather than blind injection into the coracobrachialis muscle. US imaging 1 to 2 cm distal to the axillary block location can identify the muscle and usually the nerve.
- Intercostobrachial and medial brachial cutaneous nerve blocks can be achieved by subcutaneous injections (5 mL in total) on the medial surface of the upper arm all the way from the biceps to triceps muscles. Both of these nerves are relatively small and can be difficult to visualize under US; however, local anesthetics can be infiltrated superficially above the median nerve toward the triceps.
- Perivascular infiltration and transarterial approaches are also traditionally performed for axillary block, although these techniques have been replaced by advanced technologies such as NS and US.
- For continuous nerve blocks, a 17- to 18-gauge Tuohy needle is required to facilitate catheter placement. Securing the catheter in the axilla may be challenging and may require a short tunnel to stabilize the catheter.
- Axillary approaches to the brachial plexus are associated with minimal complications compared to more proximal brachial plexus blocks. Neuropathy from needle puncture or intraneural injection of local anesthetic is the foremost consideration, although this may be reduced with US imaging and careful attention to injection pressures during the block. Hematoma can occur if the axillary artery is punctured, but this is a self-limiting complication.

### **Terminal Upper Extremity Nerve Blocks**

Upper extremity PNBs are of particular value as rescue blocks to supplement incomplete surgical anesthesia and to provide long-lasting selective analgesia in the postoperative period. The peripheral nerves may be individually blocked at upper mid-humeral, elbow, or wrist locations, depending on the specific nerve. If using US guidance, the elbow and forearm regions appear to be the most suitable block regions, and blocks at these sites may improve the accuracy of nerve localization and local anesthetic spread. The wrist is highly

populated with tendons and fascial tissues (e.g., flexor and extensor retinacula) which, on US, can be difficult to distinguish from nerves and which may also obscure visualization of nerves. With the help of color Doppler, US can be used to identify the nerves at many desirable locations, as they are often situated near blood vessels ([Table 36-1](#)). This chapter will focus on blocks for which NS and US imaging are most amenable but will also  comment on nerve blocks at the wrist. Musculocutaneous nerve block at the upper mid-humeral level is discussed in the section on Axillary Block. [Figures 36-11](#) and [36-12](#) illustrate the courses and cutaneous innervation of the terminal nerves of the upper extremity.

### *Radial Nerve*

The radial nerve can be blocked at the anterosuperior aspect of the lateral epicondyle of the humerus. The radial nerve supplies the posterior compartments of the arm and forearm, including the skin and subcutaneous tissues. It also innervates skin on the posterior aspect of the hand laterally near the base of the thumb and the dorsal aspect of the index and the lateral half of the ring finger up to the distal interphalangeal crease. For radial nerve blocks, the patient is positioned supine with their arm slightly abducted and laterally rotated and with the elbow extended.

#### **Procedure Using Nerve Stimulation Technique**

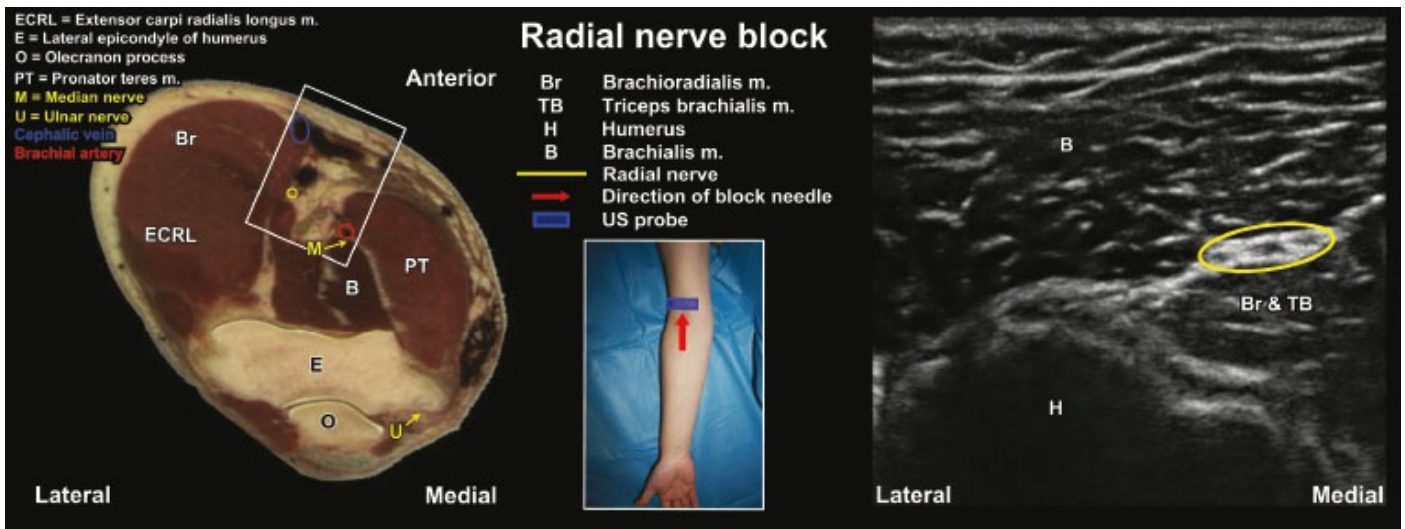

- Landmarks: A line is drawn on the anterior elbow between the medial and lateral epicondyles of the humerus. The radial nerve is located beneath this intercondylar line, approximately 1 to 2 cm lateral to the biceps tendon. This position should be marked with an “X.”
- Needling: A 30- to 50-mm, 22- to 24-gauge insulated needle is used and a skin wheal is raised at the “X.” The needle is then inserted perpendicular to the plane passing through the humeral epicondyles.
- Nerve localization: The correct response to radial NS at this location is extension (dorsiflexion) of the wrist and digits on the operative side. Elbow extension should not be elicited since the branch to the long head of the triceps has diverged proximally.
- Injection: Approximately 5 mL of local anesthetic are injected under low pressure.

#### **Procedure Using Ultrasound Imaging ([Fig. 36-23](#))**

- Scanning: A linear probe in the frequency range of 5 to 10 MHz is suitable for scanning in most cases, although high frequency (10 to 15 MHz) probes are recommended for children due to the short distance between the skin and the nerve. The radial nerve can first be located proximally at the level of the spiral (radial) groove of the humerus

where it lies immediately adjacent to the humerus and posteromedial to the deep brachial (*profunda brachii*) artery of the arm. The patient's arm should be internally rotated and placed with the hand over the abdomen on the opposite side of the body. The spiral groove lies immediately distal and posterior to the deltoid tubercle. Subsequent tracing of the nerve from this humeral location to the anterolateral elbow may facilitate its precise localization. The probe can be rotated slowly to scan the nerve both in the longitudinal and transverse planes at the elbow for confirmation of its location.

- **Appearance:** At the spiral groove of the humerus, the bone is quite superficial and appears deep to the hypoechoic triceps brachii muscle as a clearly demarcated hyperechoic oval shape with dark shadowing in its interior (not shown). The nerve appears oval and predominantly hyperechoic and is located in the posterior aspect of the humerus and immediately adjacent to the small, pulsatile deep brachial (*profunda brachii*) artery (as verified with Doppler). At a point just proximal to the anterior compartment of the elbow, the humerus appears to have changed shape and appears smaller and almost rectangular in cross-section. The hyperechoic radial nerve now lies at some distance from the humerus, is sandwiched between the brachialis and brachioradialis muscles, and appears oval-shaped.
- **Needling:** A 30- to 50-mm, 22-gauge insulated needle is suitable if using NS. The needle can be aligned using both IP and OOP ([Fig. 36-23](#)) approaches to block the nerve at the anterosuperior aspect of the lateral epicondyle of the humerus. The nerve should be blocked slightly above the elbow since it divides into deep and superficial branches approximately 2 cm above the elbow. The block needle is advanced to approach the target nerve on its side, preferably avoiding direct needle contact with the nerve.
- **Local anesthetic spread:** Performing a test dose with D5W is recommended prior to local anesthetic application to visualize spread and confirm nerve localization. The aim is to inject approximately 5 mL of local anesthetic and observe spread around the nerve circumferentially.

**Figure 36-23** Arrangement of relevant anatomy for ultrasound-guided radial nerve block. The block is performed using an OOP needle alignment to a linear probe at the anterolateral elbow. The ideal placement will be a few centimeters above the elbow where the nerve has not yet divided into superficial and deep branches.

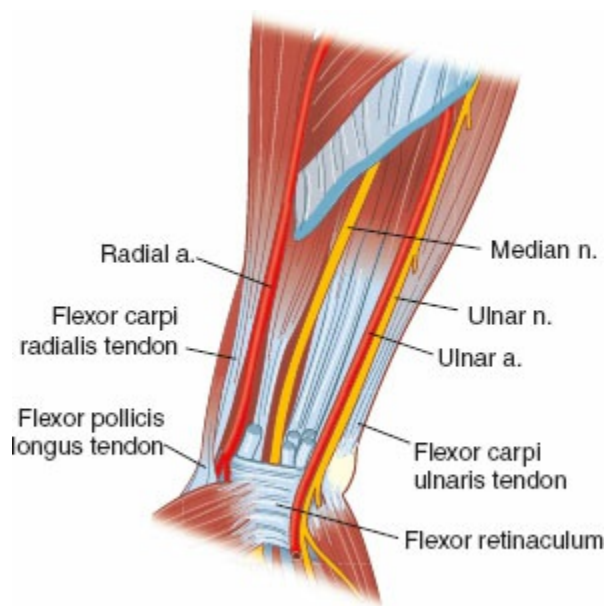

### Clinical Pearls

- Needle contact with the humerus indicates that the needle is too deep, whereas deep needle penetration without bone contact indicates that the needle is lateral to the humerus (beyond the bone).
- The radial nerve can be blocked at the wrist or even lateral distal forearm adjacent to the radial artery. At the wrist, 3 mL of solution is injected into the “anatomic snuffbox” formed by the tendons of the extensor pollicis longus and extensor pollicis brevis tendons. A subcutaneous wheal is then raised from this point, extending over the dorsum of the wrist 3 to 4 cm onto the back of the hand. This approach is suboptimal for most procedures since the nerve divides immediately beyond the elbow and continues as the superficial radial (sensory) and deep posterior interosseous (motor) nerves.

### Median Nerve

The median nerve can be blocked at the midline of the anterior elbow or at the mid-to-distal aspect of the anterior forearm (Fig. 36-24). The nerve is located adjacent (medial) to the brachial artery at the elbow, facilitating its localization here. In the forearm, the nerve can be located at its position lateral to the ulnar nerve. The median nerve supplies the skin anteriorly on the medial surface of the thumb, palm, and digits two to four, and posteriorly on the distal third of the second to fourth digits. It causes flexion at the metacarpophalangeal joints and extension at the interphalangeal joints of digits two and three. The nerve innervates muscles which produce flexion and opposition of the thumb, middle, and index fingers and pronation and flexion

of the wrist. For blocks at the anterior wrist or anterior distal forearm, the patient's arm should be positioned next to the torso, with the elbow flexed slightly and the hand free to allow a wrist or thumb flexion response elicited by NS.

**Figure 36-24** Illustration of the anterior forearm showing the courses of the median and ulnar nerves. The ulnar artery is a reliable landmark to localize the ulnar nerve when using ultrasound imaging.

## Procedure Using Nerve Stimulation Technique

At the elbow:

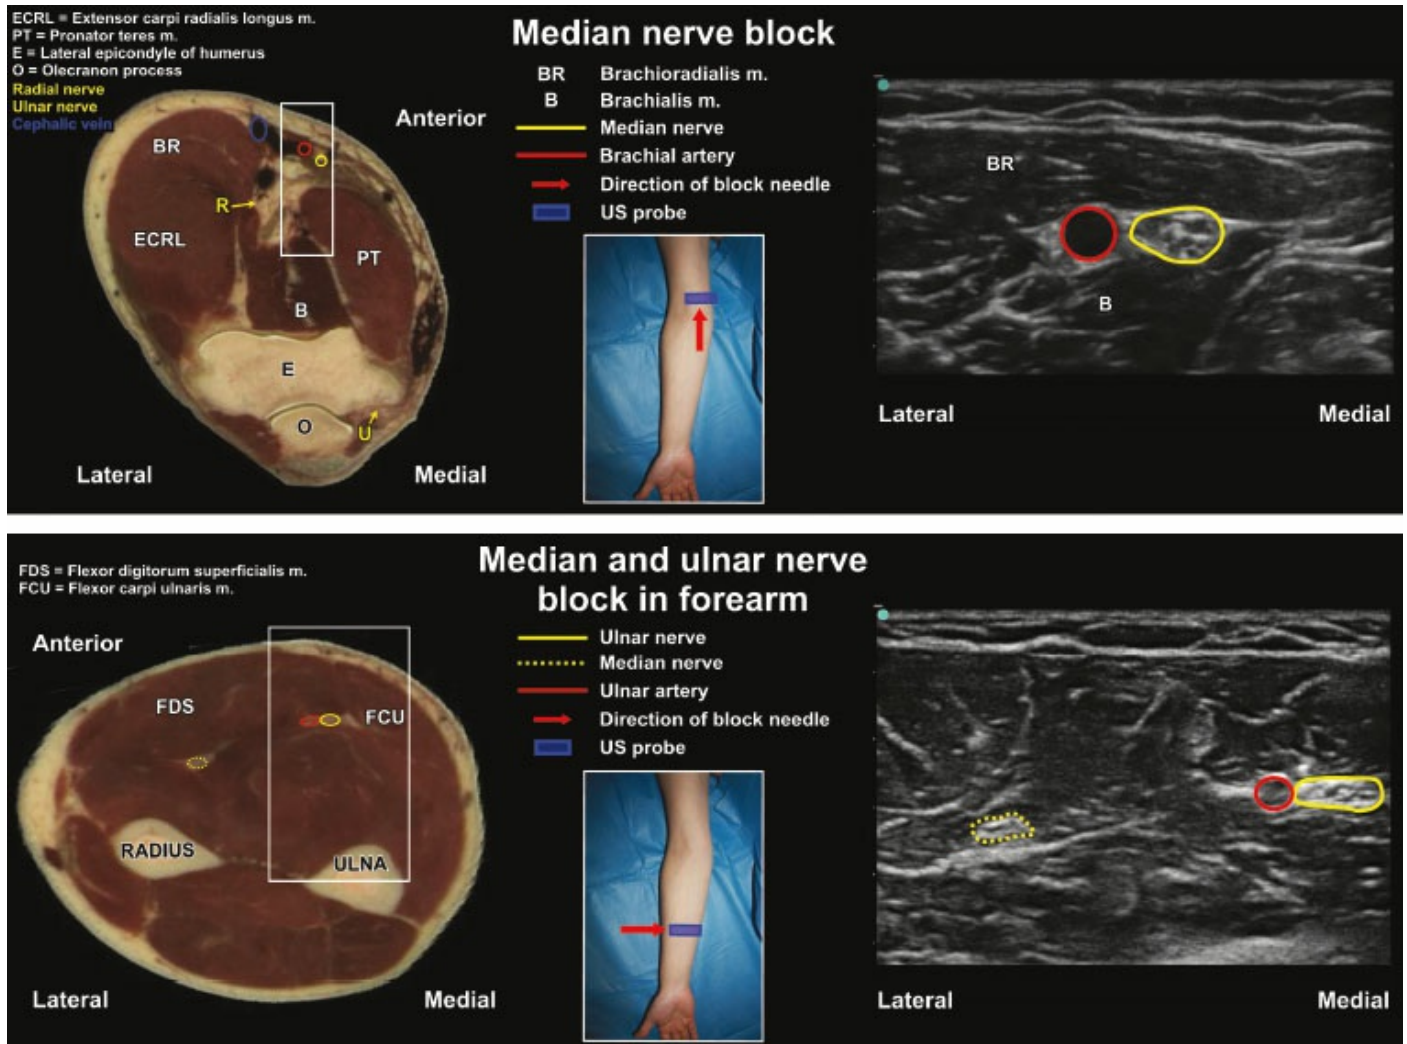

- Landmarks: As with radial nerve block, an intercondylar line is drawn, and the nerve is located where this line crosses the pulsation of the brachial artery, usually 1 cm to the ulnar side of the biceps brachii tendon.
- Needling: Using a 30- to 50-mm insulated needle, a skin wheal is raised at the point identified with landmarks (see earlier), and the needle is introduced perpendicularly at this point.
- Nerve localization: Nerve responses to electrical stimulation are sought immediately adjacent to the artery. The optimal NS response for median nerve block at the elbow location is any one of the following or a combination thereof: flexion and opposition of the thumb, middle, and index fingers; flexion of the wrist; and pronation of the forearm.
- Injection: Injection of 5 mL local anesthetic should be sufficient to block this nerve. Care should be taken to avoid intravascular and intraneural injection.

In the forearm:

- It may be difficult to locate this nerve blindly in the forearm using NS, although the technique of transcutaneous electrical stimulation<sup>17</sup> or,

similarly, percutaneous electrode guidance<sup>18,136</sup> can be used to locate the nerve with a probe placed on or indenting the skin's surface. Once the nerve has been localized, an insulated needle is inserted perpendicular to the plane of the forearm and NS responses are sought. A similar volume of local anesthetic should suffice.

**Figure 36-25** Arrangement of relevant anatomy for ultrasound-guided median and ulnar nerve block. **Top:** Ultrasound-guided median nerve block at the medial aspect of the elbow using an OOP approach. **Bottom:** Ultrasound-guided ulnar nerve block in the mid-distal forearm using an IP needle aligned to a small footprint, linear (“hockey stick”) probe. For ulnar nerve block, the ideal location to avoid arterial puncture is where the nerve has yet to fully approach the ulnar artery.

### Procedure Using Ultrasound Imaging (Fig. 36-25)

- **Scanning:** A high-frequency (10 to 15 MHz) linear probe can be used to capture a transverse view of the nerve and to localize the brachial artery, both at the elbow, where the nerve lies medial to both the artery and then the tendon of the biceps brachii muscle. At the anterolateral forearm, the nerve lies lateral to the ulnar nerve and

artery (localizing the ulnar nerve first will help identify the median nerve). Color Doppler may be used to confirm the location of the above-named arteries.

- **Appearance:** At the elbow, the median nerve can be identified at approximately 1 to 2 cm in depth as a hyperechoic yet distinctly honeycomb-like structure, lying medial to the anechoic pulsatile brachial artery. Deep to the neurovascular structures lies the musculature of the superior aspect of the elbow (pronator teres and brachialis muscles) as a hypoechoic homogeneous mass. At the forearm, the nerve appears oval-shaped and lateral to the ulnar artery.
- **Needling:** Both OOP and IP techniques can be used for either block location. For OOP needling at the elbow (not shown), after adjusting the US image to place the nerve in the middle of the screen, insert a 30- to 50-mm insulated needle perpendicular to the transversely placed probe at a 45- to 60-degree angle. If using combined technique, NS procedure should be followed. An IP technique with the needle in a medial to lateral direction may be advantageous at the elbow to allow easy tracking of the needle to ensure it avoids puncturing the brachial artery.
- **Local anesthetic spread:** After performing a test dose with D5W, the aim is to spread approximately 5 mL of local anesthetic around the nerve in a circular fashion, avoiding nerve contact and obtaining complete blockade.

### **Clinical Pearls**

- The median nerve lies deep to the flexor retinaculum at the wrist, and there is always the potential risk of causing carpal tunnel syndrome due to elevated pressure within the tunnel following injection. For this reason, the elbow or forearm locations for blocking the median nerve are the more logical choices.
- At the wrist, the median nerve lies between the tendons of the palmaris longus and the flexor carpi radialis muscles. If only the palmaris longus muscle can be felt, the nerve lies just to the radial side of its tendon. A skin wheal is raised, and a needle is inserted until it pierces the deep fascia. An injection of 3 to 5 mL of local anesthetic is sufficient to produce anesthesia.
- Aspiration of blood into the tubing during elbow block indicates brachial artery puncture. In this case, the needle should be reinserted after applying pressure to the puncture site until hemostasis is achieved. Contact with the humerus indicates that the needle is too deep. Localized contraction of the arm muscles (e.g., elbow flexion and/or forearm pronation) indicates stimulation of the local muscles

and also that the needle is likely too deep.

### *Ulnar Nerve*

In the periphery, the ulnar nerve can be blocked at the elbow, forearm, or wrist. Ulnar nerve block may be used for rescue analgesia or surgical anesthesia for surgery on the fifth digit. At the junction of the distal third and proximal two-thirds of the medial forearm, the nerve is commonly located just medial to the pulsatile ulnar artery (Fig. 36-24). US-guided technique is advised when using this block location in order to avoid the artery and localize the nerve accurately. The ulnar nerve supplies muscles that produce flexion of the ring (fourth) and little (fifth) fingers and ulnar deviation of wrist. It innervates the skin over the medial surface (anterior and posterior) of the hand and digits four and five. Before performing the block, the patient's arm should be flexed at the elbow by 30 degrees and the forearm supinated. The forearm can rest on an arm board with an additional pillow under the wrist.

### **Procedure Using Nerve Stimulation Technique**

At the elbow:

- Anesthetizing the ulnar nerve at the elbow may be uncomfortable for the patient. NS is not routinely used for localizing the ulnar nerve at the elbow, since the nerve is easily located (and palpated) in the cubital tunnel (ulnar groove) between the medial epicondyle of the humerus and the olecranon process of the ulna. Only a small volume (1 to 4 mL) of local anesthetic should be injected if performing the block at this location.

In the forearm:

- Similar to the median nerve, it may be difficult to blindly locate this nerve in the forearm using NS. Transcutaneous electrical stimulation<sup>17</sup> or percutaneous electrode guidance<sup>18,19</sup> can be used to locate the nerve. Once the nerve has been localized, an insulated needle attached to a nerve stimulator is inserted perpendicular to the plane of the forearm, and appropriate motor responses are sought. The appropriate responses for ulnar nerve block at this location are flexion of the ring (fourth) and little (fifth) fingers and ulnar deviation of the wrist. Injection of 5 mL local anesthetic is sufficient to block the nerve at the forearm. Combined US- and NS-guided technique provides good localization and accuracy with local anesthetic spread.

### **Procedure Using Ultrasound Imaging (Forearm, Fig. 36-25)**

- Scanning: A high-frequency (10 to 15 MHz) linear probe is often used for this block. The probe is placed transversely just above the mid-

forearm level to view the ulnar nerve in short axis as it approaches the ulnar artery. The nerve is positioned above the ulna and the belly of the flexor carpi ulnaris, on the anterior surface of the arm, rather than medially to contact the bone. The operator should scan downward slowly until the nerve and pulsatile artery are viewed adjacent to each other (Doppler may be valuable here) and retract the scanhead slightly so the artery and nerve appear clearly as separate structures (Fig. 36-25).

- **Appearance:** The nerve in short axis is seen as a honeycomb-like, oval-shaped structure, including hypoechoic fascicular structures surrounded by hyperechoic tissue. The adjacent ulnar artery appears anechoic and roughly similar in size to the nerve and lateral to it. The median nerve may be seen at the lateral edge of the image and appears similar to the ulnar nerve in size and shape.
- **Needling:** During IP needling, the image should be adjusted so that the nerve is toward the most lateral edge of the screen for good visibility of the needle shaft (not shown in Fig. 36-25). A short (20 to 30 mm) needle can be used in a medial-to-lateral direction to reduce the risk of vascular puncture.
