NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

PREFACE

Perhaps there was once a time when most of pharmacological knowledge could fit into a relatively small volume, but that time has surely passed. Even as old knowledge has been pared, the addition of new knowledge has caused pharmacology textbooks to expand. Thanks to aggressive editing, the 11th edition of *Goodman & Gilman's The Pharmacological Basis of Therapeutics* is 5% shorter than its predecessor, yet the volume still weighs 4 kg. It's a wonderful book but clearly too heavy to carry around. Hence, this shorter, more portable version, *Goodman & Gilman's Manual of Pharmacology and Therapeutics*. The editors hope that this *Manual*, will affordably provide the essentials of medical pharmacology to a wide audience. The format of the parent text has been retained but the editors have tried to focus on core material, happy in the knowledge that the full text of the 11th edition, with its historical aspects, many chemical and clinical details, additional figures, and references, is available in print as well as online (at <http://www.accessmedicine.com/>), where updates are also published.

The editors of this volume thank the contributors and editors of the 11th edition of *Goodman & Gilman's*, which formed the basis of this manual. We are grateful to our editors at McGraw-Hill, James Shanahan and Christie Naglieri, to project manger Arushi Chawla, and to the long line of contributors and editors who have worked on *Goodman & Gilman's* since its original publication in 1941. It is a tribute to Alfred Gilman and Louis Goodman that their book is alive and vigorous after 66 years.

PHARMACOKINETICS AND PHARMACODYNAMICS

The Dynamics of Drug Absorption, Distribution, Action, and Elimination

PHYSICOCHEMICAL FACTORS IN TRANSFER OF DRUGS ACROSS MEMBRANES

The absorption, distribution, metabolism, and excretion of a drug all involve its passage across cell membranes (Figure 1–1).

The plasma membrane consists of a bilayer of amphipathic lipids with their hydrocarbon chains oriented inward to the center of the bilayer to form a continuous hydrophobic phase and their hydrophilic heads oriented outward. Individual lipid molecules in the bilayer vary according to the particular membrane and can move laterally and organize themselves with cholesterol (e.g., sphingolipids), endowing the membrane with fluidity, flexibility, organization, electrical resistance, and relative impermeability to highly polar molecules. Membrane proteins embedded in the bilayer serve as receptors, ion channels, and transporters to transduce electrical or chemical signaling pathways; many of these proteins are targets for drugs. Cell membranes are relatively permeable to water and bulk flow of water can carry with it small drug molecules (<200 Da). Paracellular transport through intercellular gaps is sufficiently large that passage across most capillaries is limited by blood flow (e.g., glomerular filtration). Capillaries of the central nervous system (CNS) and a variety of epithelial tissues have tight intercellular junctions that limit paracellular transport.

PASSIVE MEMBRANE TRANSPORT

In passive transport, the drug molecule usually penetrates by diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. Such transfer is directly proportional to the magnitude of the concentration gradient across the membrane, to the lipid–water partition coefficient of the drug, and to the membrane surface area exposed to the drug. After a steady state is attained, the concentration of the unbound drug is the same on both sides of the membrane if the drug is a nonelectrolyte. For ionic compounds, the steady-state concentrations depend on the electrochemical gradient for the ion and on differences in pH across the membrane, which may influence the state of ionization of the molecule disparately on either side of the membrane.

WEAK ELECTROLYTES AND INFLUENCE OF pH Most drugs are weak acids or bases that are present in solution as both the lipid-soluble and diffusible nonionized form, and the relatively lipid-insoluble nondiffusible ionized species. Therefore, the transmembrane distribution of a weak electrolyte is determined by its pK_a (pH at which 50% is ionized) and the pH gradient across the membrane (see Figure 1–2). The ratio of nonionized to ionized drug at each pH is readily calculated from the Henderson–Hasselbalch equation:

$$\log \frac{[\text{Protonated form}]}{[\text{Unprotonated form}]} = pK_a - \text{pH} \quad (1-1)$$

This equation relates the pH of the medium around the drug and the drug's acid dissociation constant (pK_a) to the ratio of the protonated (HA or BH^+) and unprotonated (A^- or B) forms, where $\text{HA} \rightarrow \text{A}^- + \text{H}^+$ ($K_a = [\text{A}^-][\text{H}^+]/[\text{HA}]$) describes the dissociation of an acid, and $\text{BH}^+ \rightarrow \text{B} + \text{H}^+$ ($K_a = [\text{B}][\text{H}^+]/[\text{BH}^+]$) describes the dissociation of the protonated form of a base. At steady state, an acidic drug will accumulate on the more basic side of the membrane and a basic drug on the more acidic side—a phenomenon termed *ion trapping*.

DRUG ABSORPTION, BIOAVAILABILITY, AND ROUTES OF ADMINISTRATION

Absorption is the movement of a drug from its site of administration into the central compartment (Figure 1–1) and the extent to which this occurs. For solid dosage forms, absorption first

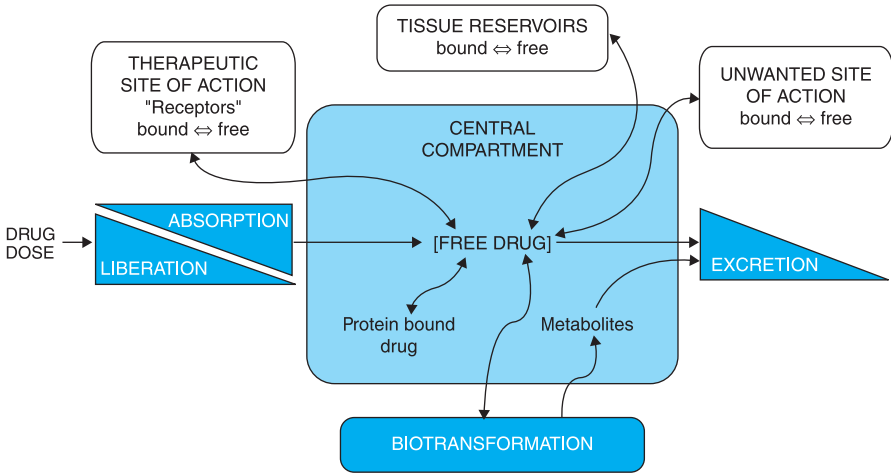

FIGURE 1-1 The interrelationship of the absorption, distribution, binding, metabolism, and excretion of a drug and its concentration at its sites of action. Possible distribution and binding of metabolites in relation to their potential actions at receptors are not depicted.

requires dissolution of the tablet or capsule, thus liberating the drug to be absorbed into the local circulation from which it will distribute to its sites of action. *Bioavailability* indicates the fractional extent to which a dose of drug reaches its site of action, taking into account, for example, the effects of hepatic metabolism and biliary excretion that may occur before a drug taken orally enters the systemic circulation. If hepatic elimination of the drug is large, bioavailability will be reduced substantially (the *first-pass effect*). This decrease in availability is a function of the anatomical site from which absorption takes place; other anatomical, physiological, and pathological factors can influence bioavailability (see below), and the choice of the route of drug administration must be based on an understanding of these conditions.

ORAL INGESTION

Absorption from the gastrointestinal (GI) tract is governed by factors such as surface area for absorption, blood flow to the site of absorption, the physical state of the drug (solution, suspension, or solid dosage form), its water solubility, and concentration at the site of absorption. For

FIGURE 1-2 Influence of pH on the partitioning of a weak acid ($pK_a = 4.4$) between plasma ($pH = 7.4$) and gastric juice ($pH = 1.4$) separated by a lipid barrier. The gastric mucosal membrane behaves as a lipid barrier permeable only to the lipid-soluble, nonionized form of the acid. The ratio of nonionized to ionized drug at each pH is readily calculated from the Henderson–Hasselbalch equation that relates the pH of the medium and the drug’s dissociation constant (pK_a) to the ratio of the protonated (HA) and unprotonated (A^-) forms. The same principles apply to drugs that are weak bases ($BH^+ \rightleftharpoons B + H^+$).

drugs given in solid form, the rate of dissolution may be the limiting factor in their absorption. Since most drug absorption from the GI tract occurs by passive diffusion, absorption is favored when the drug is in the nonionized and more lipophilic form. The epithelium of the stomach is lined with a thick mucous layer, and its surface area is small; by contrast, the villi of the upper intestine provide an extremely large surface area (~200 m²). Accordingly, the rate of absorption of a drug from the intestine will be greater than that from the stomach even if the drug is predominantly ionized in the intestine and largely nonionized in the stomach. Thus, any factor that accelerates gastric emptying will be likely to increase the rate of drug absorption, whereas any factor that delays gastric emptying is expected to have the opposite effect. Gastric emptying is highly variable and influenced by numerous factors.

Drugs that are destroyed by gastric secretions or that cause gastric irritation sometimes are administered in dosage forms with an enteric coating that prevents dissolution in the acidic gastric contents. The use of enteric coatings is helpful for drugs such as aspirin that can cause significant gastric irritation.

Controlled-Release Preparations

A slow rate of dissolution of a drug in GI fluids is the basis for controlled-release, extended-release, sustained-release, and prolonged-action preparations that are designed to produce slow, uniform absorption of the drug for 8 hours or longer. Such preparations are offered for medications in all major drug categories. Potential advantages are reduction in the frequency of administration of the drug as compared with conventional dosage forms (possibly with improved compliance by the patient), maintenance of a therapeutic effect overnight, and decreased incidence and/or intensity of both undesired effects (by elimination of the peaks in drug concentration) and nontherapeutic blood levels of the drug (by elimination of troughs in concentration) that occur after administration of immediate-release dosage forms. Controlled-release dosage forms, while more expensive, are most appropriate for drugs with short $t_{1/2}$ (<4 hours) where patient non-compliance becomes a determinant of therapeutic failure.

SUBLINGUAL ADMINISTRATION

Venous drainage from the mouth is to the superior vena cava, which protects highly soluble drugs like nitroglycerin from rapid hepatic first-pass metabolism. If a tablet of nitroglycerin were swallowed, the accompanying hepatic metabolism would be sufficient to prevent the appearance of any active nitroglycerin in the systemic circulation.

TRANSDERMAL ABSORPTION

Absorption of drugs able to penetrate the intact skin is dependent on the surface area over which they are applied and their lipid solubility (see Chapter 63). The dermis is freely permeable to many solutes; consequently, systemic absorption of drugs occurs much more readily through inflamed, abraded, burned, or denuded skin. Unwanted effects can be produced by absorption through the skin of highly lipid-soluble substances (e.g., a lipid-soluble insecticide in an organic solvent). Transdermal absorption can be enhanced by suspending the drug in an oily vehicle and rubbing the resulting preparation into the skin. Hydration of the skin with an occlusive dressing may facilitate absorption.

RECTAL ADMINISTRATION

The rectal route, though less predictable, can be used when oral ingestion is precluded because the patient is unconscious or when vomiting is present. Approximately 50% of the drug that is absorbed from the rectum will bypass the liver, thus reducing the hepatic first-pass effect.

PARENTERAL INJECTION

Intravenous

Factors relevant to absorption are circumvented by intravenous injection of drugs because bioavailability is rapid and complete. Also, drug delivery is controlled, can be adjusted to the response of the patient and is achieved with an accuracy and immediacy not possible by any other procedure. Irritating solutions can be given only in this manner because the drug, if injected slowly, is greatly diluted by the blood. Occasionally, a drug is injected directly into an artery to localize its effect. Diagnostic agents sometimes are administered by this route (e.g., technetium-labeled human serum albumin).

Unfavorable reactions can occur when transiently high concentrations of a drug or its vehicle are attained rapidly in plasma and tissues. There are therapeutic circumstances where it is advisable to administer a drug by bolus injection (e.g., tissue plasminogen activator) and other circumstances where slower administration of drug is advisable (e.g., antibiotics).

Subcutaneous

Injection of a drug into a subcutaneous site can be used only for drugs that are not irritating to tissue; otherwise, severe pain, necrosis, and tissue sloughing may occur. The rate of absorption following subcutaneous injection of a drug often is sufficiently constant and slow to provide a prolonged effect. Moreover, altering the period over which a drug is absorbed may be varied intentionally, as is accomplished with insulin for injection using particle size, protein complexation, and pH. Absorption of drugs implanted under the skin in a solid pellet form occurs slowly over a period of weeks or months; some hormones (e.g., contraceptives) are administered effectively in this manner.

Intramuscular

Drugs in aqueous solution are absorbed rapidly after intramuscular injection depending on the rate of blood flow to the injection site and the fat versus muscular composition of the site. This may be modulated to some extent by local heating, massage, or exercise. Generally, the rate of absorption following injection of an aqueous preparation into the deltoid or vastus lateralis is faster than when the injection is made into the gluteus maximus. The rate is particularly slower for females after injection into the gluteus maximus. Slow, constant absorption from the intramuscular site results if the drug is injected in solution, oil, or various other repository (depot) vehicles.

Intrathecal

The blood–brain barrier and the blood–cerebrospinal fluid (CSF) barrier often preclude or slow the entrance of drugs into the CNS. Therefore, when local and rapid effects on the meninges or cerebrospinal axis are desired, drugs sometimes are injected directly into the spinal subarachnoid space. Brain tumors may be treated by direct intraventricular drug administration.

PULMONARY ABSORPTION

Gaseous and volatile drugs may be inhaled and absorbed through the pulmonary epithelium and mucous membranes of the respiratory tract. Access to the circulation is rapid by this route because the lung's surface area is large (~140 m²) and first-pass metabolism is avoided. The principles governing absorption and excretion of anesthetic and other therapeutic gases are discussed in Chapters 13 and 15.

TOPICAL APPLICATION**Mucous Membranes**

Drugs are applied to the mucous membranes of the conjunctiva, nasopharynx, oropharynx, vagina, colon, urethra, and urinary bladder primarily for their local effects.

Eye

Topically applied ophthalmic drugs are used for their local effects (see Chapter 63) requiring absorption of the drug through the cornea; corneal infection or trauma thus may result in more rapid absorption. Ophthalmic delivery systems that provide prolonged duration of action (e.g., suspensions and ointments) are useful, as are ocular inserts providing continuous delivery of drug.

BIOEQUIVALENCE

Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredients and are identical in strength or concentration, dosage form, and route of administration. Two pharmaceutically equivalent drug products are considered to be bioequivalent when the rates and extents of bioavailability of the active ingredient in the two products are not significantly different under suitable test conditions.

DISTRIBUTION OF DRUGS

Following absorption or systemic administration into the bloodstream, a drug distributes into interstitial and intracellular fluids depending on the particular physicochemical properties of the drug. Cardiac output, regional blood flow, capillary permeability, and tissue volume determine the rate of delivery and potential amount of drug distributed into tissues. Initially, liver, kidney, brain, and other well-perfused organs receive most of the drug, whereas delivery to muscle, most viscera, skin, and fat is slower. This second distribution phase may require minutes to several hours before the concentration of drug in tissue is in equilibrium with that in blood. The second phase also involves a far larger fraction of body mass than does the initial phase and generally accounts for most of the extravascularly distributed drug. With exceptions such as the brain,

diffusion of drug into the interstitial fluid occurs rapidly. Thus, tissue distribution is determined by the partitioning of drug between blood and the particular tissue.

PLASMA PROTEINS Many drugs circulate in the bloodstream reversibly bound to plasma proteins. Albumin is a major carrier for acidic drugs; α_1 -acid glycoprotein binds basic drugs. Non-specific binding to other plasma proteins generally occurs to a much smaller extent. In addition, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of *thyroid hormone* to thyroxin-binding globulin.

The fraction of total drug in plasma that is bound is determined by the drug concentration, the affinity of binding sites for the drug, and the number of binding sites. For most drugs, the therapeutic range of plasma concentrations is limited; thus the extent of binding and the unbound fraction are relatively constant. The extent of plasma protein binding may be affected by disease-related factors (e.g., hypoalbuminemia). Conditions resulting in the acute-phase reaction response (e.g., cancer, arthritis, myocardial infarction, and Crohn's disease) lead to elevated levels of α_1 -acid glycoprotein and enhanced binding of basic drugs.

Many drugs with similar physicochemical characteristics can compete with each other and with endogenous substances for protein binding. Drug toxicities based on competition between drugs for binding sites is not of clinical concern for most therapeutic agents. Steady-state unbound concentrations of drug will change significantly only when either input (dosing rate) or clearance of unbound drug is changed [see Equation (1–2)]. Thus, steady-state unbound concentrations are independent of the extent of protein binding. However, for narrow-therapeutic-index drugs, a transient change in unbound concentrations occurring immediately following the dose of a competing drug could be of concern, such as with the anticoagulant warfarin.

Importantly, binding of a drug to plasma proteins limits its concentration in tissues and at its site of action because only unbound drug is in equilibrium across membranes. Accordingly, after distribution equilibrium is achieved, the concentration of active, unbound drug in intracellular water is the same as that in plasma except when carrier-mediated transport is involved. Binding of a drug to plasma protein also limits the drug's glomerular filtration because this process does not immediately change the concentration of free drug in the plasma (water is also filtered). Drug transport and metabolism also are limited by binding to plasma proteins, except when these are especially efficient, and drug clearance, calculated on the basis of unbound drug, exceeds organ plasma flow.

TISSUE BINDING Many drugs accumulate in tissues at higher concentrations than those in the extracellular fluids and blood. Tissue binding of drugs usually occurs with cellular constituents such as proteins, phospholipids, or nuclear proteins and generally is reversible. A large fraction of drug in the body may be bound in this fashion and serve as a reservoir that prolongs drug action in that same tissue or at a distant site reached through the circulation. Such tissue binding and accumulation also can produce local toxicity.

Fat as a Reservoir

Many lipid-soluble drugs are stored by physical solution in the neutral fat. In obese persons, the fat content of the body may be as high as 50%, and even in lean individuals it constitutes 10% of body weight; hence, fat may serve as a reservoir for lipid-soluble drugs. Fat is a rather stable reservoir because it has a relatively low blood flow.

REDISTRIBUTION Termination of drug effect after withdrawal of a drug may result from redistribution of the drug from its site of action into other tissues or sites. Redistribution is a factor primarily when a highly lipid-soluble drug that acts on the brain or cardiovascular system is administered rapidly by intravenous injection or by inhalation. The highly lipid-soluble drug reaches its maximal concentration in brain within seconds of its intravenous injection; the plasma concentration then falls as the drug diffuses into other tissues, such as muscle. The concentration of the drug in brain follows that of the plasma because there is little binding of the drug to brain constituents. Thus, the onset of action is rapid, and its termination is rapid, related directly to the concentration of drug in the brain.

CENTRAL NERVOUS SYSTEM AND CEREBROSPINAL FLUID Brain capillary endothelial cells have continuous tight junctions; therefore, drug penetration into the brain depends on transcellular rather than paracellular transport. The unique characteristics of brain capillary endothelial cells and pericapillary glial cells constitute the blood–brain barrier. At the choroid plexus, a similar blood–CSF barrier is present based on epithelial tight junctions. The

lipid solubility of the nonionized and unbound species of a drug is therefore an important determinant of its uptake by the brain; the more lipophilic a drug is, the more likely it is to cross the blood–brain barrier. Drugs may penetrate into the CNS by specific uptake transporters (Chapter 2).

PLACENTAL TRANSFER OF DRUGS The transfer of drugs across the placenta is of critical importance because drugs may cause anomalies in the developing fetus. Lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are important general determinants in drug transfer across the placenta. The fetal plasma is slightly more acidic than that of the mother (pH 7.0–7.2 vs. 7.4), so that ion trapping of basic drugs occurs. The view that the placenta is an absolute barrier to drugs is, however, completely inaccurate, in part because a number of influx transporters are also present. The fetus is to some extent exposed to all drugs taken by the mother.

EXCRETION OF DRUGS

Drugs are eliminated from the body either unchanged by the process of excretion or converted to metabolites (*see* Chapters 2 and 3). Excretory organs, the lung excluded, eliminate polar compounds more efficiently than substances with high lipid solubility. Lipid-soluble drugs thus are not readily eliminated until they are metabolized to more polar compounds.

The kidney is the most important organ for excreting drugs and their metabolites. Substances excreted in the feces are principally unabsorbed orally ingested drugs or drug metabolites excreted either in the bile or secreted directly into the intestinal tract and not reabsorbed. Excretion of drugs in breast milk is important not because of the amounts eliminated, but because the excreted drugs will have unwanted pharmacological effects in the nursing infant. Excretion from the lung is important mainly for the elimination of anesthetic gases (*see* Chapter 13).

RENAL EXCRETION Excretion of drugs and metabolites in the urine involves three distinct processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption. Changes in overall renal function generally affect all three processes to a similar extent. In neonates, renal function is low compared with body mass but matures rapidly within the first few months after birth. During adulthood, there is a slow decline in renal function, ~1% per year, so that in elderly patients a substantial degree of functional impairment may be present.

The amount of drug entering the tubular lumen by filtration depends on the glomerular filtration rate and the extent of plasma binding of the drug; only unbound drug is filtered. In the proximal renal tubule, active, carrier-mediated tubular secretion also may add drug to the tubular fluid. Transporters such as P-glycoprotein and the multidrug-resistance-associated protein type 2 (MRP2), localized in the apical brush-border membrane, are responsible for the secretion of amphipathic anions and conjugated metabolites (*e.g.*, glucuronides, sulfates, and glutathione adducts), respectively (*see* Chapters 2 and 3). Adenosine triphosphate (ATP)-binding cassette (ABC) transporters that are more selective for organic cationic drugs are involved in the secretion of organic bases. Membrane transporters, mainly located in the distal renal tubule, also are responsible for any active reabsorption of drug from the tubular lumen back into the systemic circulation.

In the proximal and distal tubules, the nonionized forms of weak acids and bases undergo net passive reabsorption. The concentration gradient for back-diffusion is created by the reabsorption of water with Na⁺ and other inorganic ions. Since the tubular cells are less permeable to the ionized forms of weak electrolytes, passive reabsorption of these substances depends on the pH. When the tubular urine is made more alkaline, weak acids are largely ionized and thus are excreted more rapidly and to a greater extent. When the tubular urine is made more acidic, the fraction of drug ionized is reduced, and excretion is likewise reduced. Alkalinization and acidification of the urine have the opposite effects on the excretion of weak bases. In the treatment of drug poisoning, the excretion of some drugs can be hastened by appropriate alkalization or acidification of the urine (*see* Chapter 64).

METABOLISM OF DRUGS

Renal excretion of unchanged drug plays only a modest role in the overall elimination of most therapeutic agents because lipophilic compounds filtered through the glomerulus are largely reabsorbed into the systemic circulation during passage through the renal tubules. The metabolism of drugs and other xenobiotics into more hydrophilic metabolites is essential for their elimination from the body, as well as for termination of their biological and pharmacological activity. In general, biotransformation reactions generate more polar, inactive metabolites that are readily excreted from the body. However, in some cases, metabolites with potent biological activity or toxic properties are generated.

Drug metabolism or biotransformation reactions are classified as either phase 1 functionalization reactions or phase 2 biosynthetic (conjugation) reactions. The enzyme systems involved in the biotransformation of drugs are localized primarily in the liver, although every tissue examined has some metabolic activity (see Chapter 3 for details of drug metabolism).

CLINICAL PHARMACOKINETICS

Clinical pharmacokinetics relies on a relationship between the pharmacological effects of a drug and a measurable concentration of the drug (e.g., in blood or plasma). For some drugs, no clear or simple relationship has been found between pharmacological effect and concentration in plasma, whereas for other drugs, routine measurement of drug concentration is impractical as part of therapeutic monitoring. In most cases, the concentration of drug at its sites of action will be related to the concentration of drug in the systemic circulation. The pharmacological effect that results may be the clinical effect desired, or an adverse or toxic effect. Clinical pharmacokinetics provides a framework within which drug dose adjustments can be made.

The physiological and pathophysiological variables that dictate adjustment of dosage in individual patients often do so as a result of modification of pharmacokinetic parameters. The four most important parameters governing drug disposition are *clearance*, a measure of the body's efficiency in eliminating drug; *volume of distribution*, a measure of the apparent space in the body available to contain the drug; *elimination $t_{1/2}$* , a measure of the rate of removal of drug from the body; and *bioavailability*, the fraction of drug absorbed as such into the systemic circulation.

Clearance

Clearance is the most important concept to consider when designing a rational regimen for long-term drug administration. The clinician usually wants to maintain steady-state concentrations of a drug within a *therapeutic window* associated with therapeutic efficacy and a minimum of toxicity for a given agent. Assuming complete bioavailability, the steady-state concentration of drug in the body will be achieved when the rate of drug elimination equals the rate of drug administration. Thus:

$$\text{Dosing rate} = CL \cdot C_{ss} \quad (1-2)$$

where CL is clearance of drug from the systemic circulation and C_{ss} is the steady-state concentration of drug.

Metabolizing enzymes and transporters (see Chapters 2 and 3) usually are not saturated, and thus the absolute rate of elimination of the drug is essentially a linear function (first-order) of its concentration in plasma, where a constant fraction of drug in the body is eliminated per unit of time. If mechanisms for elimination of a given drug become saturated, the kinetics approach zero order, in which a constant amount of drug is eliminated per unit of time. Clearance of a drug is its rate of elimination by all routes normalized to the concentration of drug in some biological fluid where measurement can be made:

$$CL = \text{rate of elimination}/C \quad (1-3)$$

Thus, when clearance is constant, the rate of drug elimination is directly proportional to drug concentration. Clearance is the volume of biological fluid such as blood or plasma from which drug would have to be completely removed to account for the clearance (e.g., ml/min/kg). Clearance can be defined further as blood clearance (CL_b), plasma clearance (CL_p), depending on the measurement made (C_b , C_p).

Clearance of drug by several organs is additive. Elimination of drug may occur as a result of processes that occur in the GI tract, kidney, liver, and other organs. Division of the rate of elimination by each organ by a concentration of drug (e.g., plasma concentration) will yield the respective clearance by that organ. Added together, these separate clearances will equal systemic clearance:

$$CL_{renal} + CL_{hepatic} + CL_{other} = CL \quad (1-4)$$

Systemic clearance may be determined at steady state by using Equation (1-2). For a single dose of a drug with complete bioavailability and first-order kinetics of elimination, systemic clearance may be determined from mass balance and the integration of Equation (1-3) over time:

$$CL = \text{Dose}/AUC \quad (1-5)$$

where AUC is the total area under the curve that describes the measured concentration of drug in the systemic circulation as a function of time (from zero to infinity) as in Figure 1-5.

HEPATIC CLEARANCE

For a drug that is removed efficiently from the blood by hepatic processes (metabolism and/or excretion of drug into the bile), the concentration of drug in the blood leaving the liver will be low, the extraction ratio will approach unity, and the clearance of the drug from blood will become limited by hepatic blood flow (e.g., drugs with systemic clearances >6 mL/min/kg).

RENAL CLEARANCE

Renal clearance of a drug results in its appearance in the urine. The rate of filtration of a drug depends on the volume of fluid that is filtered in the glomerulus and the unbound concentration of drug in plasma because drug bound to protein is not filtered. The rate of secretion of drug by the kidney will depend on the drug's intrinsic clearance by the transporters involved in active secretion as affected by the drug's binding to plasma proteins, the degree of saturation of these transporters, and the rate of delivery of the drug to the secretory site. In addition, processes involved in drug reabsorption from the tubular fluid must be considered. These factors are altered in renal disease.

DISTRIBUTION

VOLUME OF DISTRIBUTION The volume of distribution (V) relates the amount of drug in the body to the concentration of drug (C) in the blood. This volume does not necessarily refer to an identifiable physiological volume but rather to the fluid volume that would be required to contain all the drug in the body at the same concentration measured in the blood:

$$\text{Amount of drug in body} / V = C, \text{ or } V = \text{amount of drug in body} / C \quad (1-6)$$

A drug's volume of distribution therefore reflects the extent to which it is present in extravascular tissues and not in the plasma. The plasma volume of a typical 70-kg man is 3 L, blood volume is about 5.5 L, extracellular fluid volume outside the plasma is 12 L, and the volume of total-body water is approximately 42 L.

Many drugs exhibit volumes of distribution far in excess of these values (see Appendix II in the 11th edition of the parent text). For drugs that are bound extensively to plasma proteins but that are not bound to tissue components, the volume of distribution will approach that of the plasma volume because drug bound to plasma protein is measurable. In contrast, certain drugs have high volumes of distribution even though the drug in the circulation is bound to albumin because these drugs are also sequestered elsewhere.

The volume of distribution may vary widely depending on the relative degrees of binding to high-affinity receptor sites, plasma and tissue proteins, the partition coefficient of the drug in fat, and accumulation in poorly perfused tissues. The volume of distribution for a given drug can differ according to patient's age, gender, body composition, and presence of disease. Total-body water of infants younger than 1 year of age, for example, is 75–80% of body weight, whereas that of adult males is 60% and that of adult females is 55%.

The volume of distribution defined in Equation 1–6 considers the body as a single homogeneous compartment. In this one-compartment model, all drug administration occurs directly into the central compartment, and distribution of drug is instantaneous throughout the volume (V). Clearance of drug from this compartment occurs in a first-order fashion; i.e., the amount of drug eliminated per unit of time depends on the amount (concentration) of drug in the body compartment. Figure 1–3A and Equation 1–7 describe the decline of plasma concentration with time for a drug introduced into this central compartment:

$$C = (\text{dose}/V) \cdot \exp(-kt) \quad (1-7)$$

where k is the rate constant for elimination that reflects the fraction of drug removed from the compartment per unit of time. This rate constant is inversely related to the $t_{1/2}$ of the drug ($k = 0.693/t_{1/2}$).

The idealized one-compartment model does not describe the entire time course of the plasma concentration. That is, certain tissue reservoirs can be distinguished from the central compartment, and the drug concentration appears to decay in a manner that can be described by multiple exponential terms (Figure 1–3B). Nevertheless, the one-compartment model is sufficient to apply to most clinical situations for most drugs and the drug $t_{1/2}$ in the central compartment dictates the dosing interval for the drug.

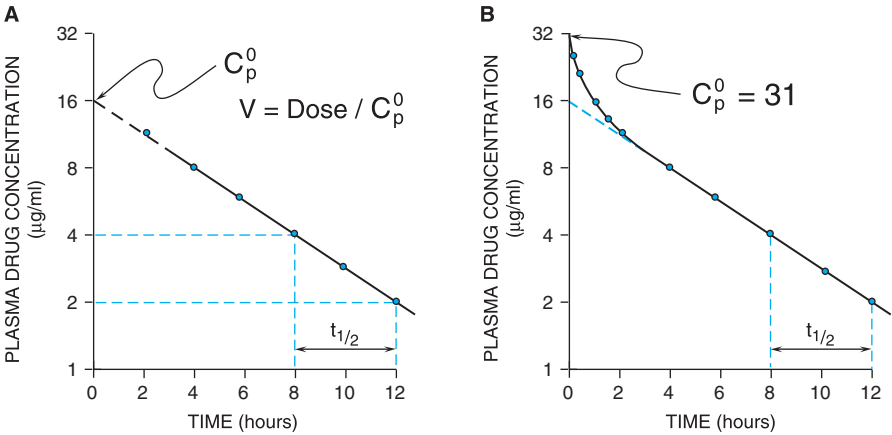

FIGURE 1-3 Plasma concentration–time curves following intravenous administration of a drug (500 mg) to a 70-kg patient. **A.** Drug concentrations are measured in plasma at 2-hour intervals following drug administration. The semi-logarithmic plot of plasma concentration (C_p) versus time appears to indicate that the drug is eliminated from a single compartment by a first-order process (Equation 1–7) with a $t_{1/2}$ of 4 hours ($k = 0.693/t_{1/2} = 0.173 \text{ hr}^{-1}$). The volume of distribution (V) may be determined from the value of C_p obtained by extrapolation to $t = 0$ ($C_p^0 = 16 \mu\text{g/mL}$). Volume of distribution (Equation 1–6) for the one-compartment model is 31.3 L, or 0.45 L/kg ($V = \text{dose}/C_p^0$). The clearance for this drug is 90 mL/min; for a one-compartment model, $CL = kV$. **B.** Sampling before 2 hours indicates that, in fact, the drug follows multiexponential kinetics. The terminal disposition half-life is 4 hours, clearance is 84 mL/min (Equation 1–5), V_{area} is 29 L (Equation 1–7), and V_{ss} is 26.8 L. The initial or “central” distribution volume for the drug ($V_1 = \text{dose}/C_p^0$) is 16.1 L. The example chosen indicates that multicompartment kinetics may be overlooked when sampling at early times is neglected. In this particular case, there is only a 10% error in the estimate of clearance when the multicompartment characteristics are ignored. For many drugs, multicompartment kinetics may be observed for significant periods of time, and failure to consider the distribution phase can lead to significant errors in estimates of clearance and in predictions of the appropriate dosage. Also, the difference between the “central” distribution volume and other terms reflecting wider distribution is important in deciding a loading dose strategy. The multi-compartment model of drug disposition can be viewed as though the blood and highly perfused lean organs such as heart, brain, liver, lung, and kidneys cluster as a single central compartment, whereas more slowly perfused tissues such as muscle, skin, fat, and bone behave as the final compartment (*i.e.*, the tissue compartment). If the ratio of blood flow to various tissues changes within an individual or differs among individuals, rates of drug distribution to tissues will change. Changes in blood flow may cause some tissues that were originally in the “central” volume to equilibrate so slowly as to appear only in the “final” volume. This means that central volumes will appear to vary with disease states that cause altered regional blood flow (*e.g.*, liver cirrhosis). After an intravenous bolus dose, drug concentrations in plasma may be higher in individuals with poor perfusion (*e.g.*, shock). These higher systemic concentrations, in turn, may cause higher concentrations (and greater effects) in highly perfused tissues such as brain and heart. Thus, the effect of a drug at various sites of action can vary depending on perfusion of these sites.

Rate of Drug Distribution

In many cases, groups of tissues with similar perfusion–partition ratios all equilibrate at essentially the same rate such that only one apparent phase of distribution is seen (rapid initial fall of concentration of intravenously injected drug, as in Figure 1–3B). It is as though the drug starts in a “central” volume (Figure 1–1), which consists of plasma and tissue reservoirs that are in rapid equilibrium with it, and distributes to a “final” volume, at which point concentrations in plasma decrease in a log-linear fashion with a rate constant of k (Figure 1–3B).

The volume of distribution at steady state (V_{ss}) represents the volume in which a drug would appear to be distributed during steady state if the drug existed throughout that volume at the same concentration as that in the measured fluid (plasma or blood). V_{ss} also may be appreciated as shown in Equation (1–8), where V_c is the volume of distribution of drug in the central compartment and V_T is the volume term for drug in the tissue compartment:

$$V_{\text{ss}} = V_c + V_T \quad (1-8)$$

Half-Life

The $t_{1/2}$ is the time it takes for the plasma concentration or the amount of drug in the body to be reduced by 50%. For the simplest case, the one-compartment model (Figure 1–3A), $t_{1/2}$ may be determined readily by inspection and used to make decisions about drug dosage. However, drug concentrations in plasma often follow a multi-exponential pattern of decline (*see* Figure 1–3B); two or more $t_{1/2}$ terms thus may be calculated. Such prolonged half times can represent drug elimination from storage sites or poorly perfused tissue spaces and can be linked to drug toxicity.

A useful approximate relationship between the clinically relevant $t_{1/2}$, clearance, and volume of distribution at steady state is given by

$$t_{1/2} \cong 0.693 \cdot V_{ss} / CL \quad (1-9)$$

As clearance of a drug decreases, owing to a disease process, for example, $t_{1/2}$ would be expected to increase as long as volume of distribution remains unchanged. However, increases in $t_{1/2}$ can result from changes in volume of distribution, *e.g.*, when changes in protein binding of a drug affect its clearance and lead to unpredictable changes in $t_{1/2}$. The $t_{1/2}$ provides a good indication of the time required to reach steady state after a dosage regimen is initiated or changed (*i.e.*, four half-lives to reach ~94% of a new steady state), the time for a drug to be removed from the body, and a means to estimate the appropriate dosing interval (*see* below).

STEADY STATE Equation (1–2) indicates that a steady-state concentration eventually will be achieved when a drug is administered at a constant rate (Dosing rate = $CL \cdot C_{ss}$). At this point, drug elimination will equal the rate of drug availability. This concept also extends to regular intermittent dosage (*e.g.*, 250 mg of drug every 8 hours). During each interdose interval, the concentration of drug rises with absorption and falls by elimination. At steady state, the entire cycle is repeated identically in each interval (*see* Figure 1–4). Equation (1–2) still applies for intermittent dosing, but it now describes the average steady-state drug concentration (C_{ss}) during an interdose interval.

Extent and Rate of Bioavailability

BIOAVAILABILITY It is important to distinguish between the rate and extent of drug absorption and the amount of drug that ultimately reaches the systemic circulation. This depends not only on the administered dose but also on the fraction of the dose (F) that is absorbed and escapes any first-pass elimination. This fraction is the drug's *bioavailability*.

If the hepatic blood clearance for the drug is large relative to hepatic blood flow, the extent of availability will be low when the drug is given orally (e.g., lidocaine or propranolol). This reduction in availability is a function of the physiological site from which absorption takes place, and no modification of dosage form will improve the availability under conditions of linear kinetics. Incomplete absorption and/or intestinal metabolism following oral dosing will, in practice, reduce this predicted maximal value of F . When drugs are administered by a route that is subject to first-pass loss, the equations presented above that contain the terms dose or dosing rate also must include the bioavailability term F . For example, Equation (1–2) is modified to

$$F \cdot \text{dosing rate} = CL \cdot C_{ss} \quad (1-10)$$

where the value of F is between 0 and 1. The value of F varies widely for drugs administered by mouth and successful therapy can still be achieved for some drugs with F values as low as 0.03 (e.g., etidronate).

RATE OF ABSORPTION Although the rate of drug absorption does not, in general, influence the average steady-state concentration of the drug in plasma, it may still influence drug therapy. If a drug is absorbed rapidly (*e.g.*, a dose given as an intravenous bolus) and has a small “central” volume, the concentration of drug initially will be high. It will then fall as the drug is distributed to its “final” (larger) volume (Figure 1–3B). If the same drug is absorbed more slowly (*e.g.*, by slow infusion), it will be distributed while it is being administered, and peak concentrations will be lower and will occur later. Controlled-release preparations are designed to provide a slow and sustained rate of absorption in order to produce smaller fluctuations in the plasma concentration–time profile during the dosage interval compared with more immediate-release formulations. Since the beneficial, nontoxic effects of drugs are based on knowledge of an ideal or desired plasma concentration range, maintaining that range while avoiding large swings between peak and trough concentrations can improve therapeutic outcome.

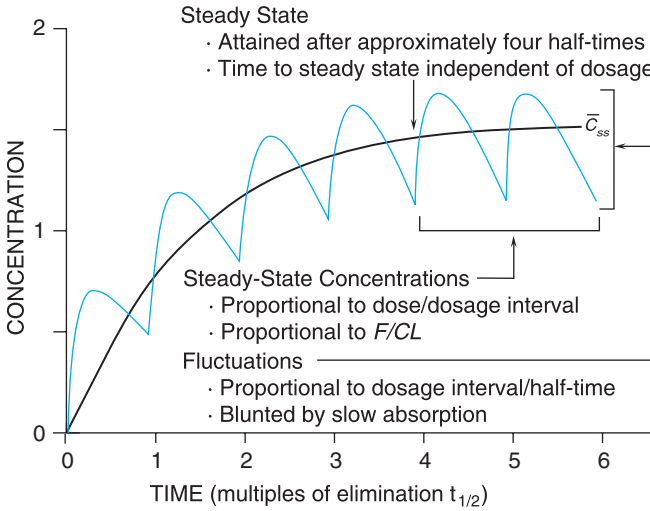

FIGURE 1-4 *Fundamental pharmacokinetic relationships for repeated administration of drugs.* The blue line is the pattern of drug accumulation during repeated administration of a drug at intervals equal to its elimination $t_{1/2}$ when drug absorption is 10 times as rapid as elimination.

As the rate of absorption increases, the concentration maxima approach 2 and the minima approach 1 during the steady state. The black line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based on the one-compartment model. Average concentration (\bar{C}_{ss}) when the steady state is attained during intermittent drug administration is

$$\bar{C}_{ss} = \frac{F \cdot \text{dose}}{CL \cdot T}$$

where F is fractional bioavailability of the dose and T is dosage interval (time). By substitution of infusion rate for $F \cdot \text{dose}/T$, the formula is equivalent to Equation (1-2) and provides the concentration maintained at steady state during continuous intravenous infusion.

Nonlinear Pharmacokinetics

Nonlinearity in pharmacokinetics (i.e., changes in such parameters as clearance, volume of distribution, and $t_{1/2}$ as a function of dose or concentration of drug) usually is due to saturation of either protein binding, hepatic metabolism, or active renal transport of the drug.

SATURABLE PROTEIN BINDING

As the concentration of drug increases, the unbound fraction eventually also must increase (as all binding sites become saturated when drug concentrations in plasma are in the range of 10s to 100s of $\mu\text{g}/\text{mL}$). For a drug that is metabolized by the liver with a low intrinsic clearance-extraction ratio, saturation of plasma-protein binding will cause both V and CL to increase; $t_{1/2}$ thus may remain constant (Equation 1-9). For such a drug, C_{ss} will not increase linearly as the rate of drug administration is increased. For drugs that are cleared with high intrinsic clearance-extraction ratios, C_{ss} can remain linearly proportional to the rate of drug administration. In this case, hepatic clearance will not change, and the increase in V will increase the $t_{1/2}$ by reducing the fraction of the total drug in the body that is delivered to the liver per unit of time. Most drugs fall between these two extremes.

SATURABLE ELIMINATION

All active processes are undoubtedly saturable, but they will appear to be linear if values of drug concentrations encountered in practice are much less than K_m . When drug concentrations exceed K_m , nonlinear kinetics are observed. The major consequences of saturation of metabolism or transport are the opposite of those for saturation of protein binding. Saturation of metabolism or transport may decrease CL . Saturable metabolism causes oral first-pass metabolism to be less than

expected (higher F), and there is a greater fractional increase in C_{ss} than the corresponding fractional increase in the rate of drug administration.

$$C_{ss} = \frac{\text{dosing rate} \cdot K_m}{v_m - \text{dosing rate}} \quad (1-11)$$

As the dosing rate approaches the maximal elimination rate (v_m), the denominator approaches zero, and C_{ss} increases disproportionately. Because saturation of metabolism should have no effect on the volume of distribution, clearance and the relative rate of drug elimination decrease as the concentration increases; therefore, the log C_p time curve is concave-decreasing until metabolism becomes sufficiently desaturated and first-order elimination is present. Thus, the concept of a constant $t_{1/2}$ is not applicable to nonlinear metabolism occurring in the usual range of clinical concentrations. Consequently, changing the dosing rate for a drug with nonlinear metabolism is unpredictable because the resulting steady state is reached more slowly, and importantly, the effect is disproportionate to the alteration in the dosing rate.

Design and Optimization of Dosage Regimens

The intensity of a drug's effect is related to its concentration above a minimum effective concentration, whereas the duration of this effect reflects the length of time the drug level is above this value (Figure 1-5). These considerations, in general, apply to both desired and undesired

FIGURE 1-5 Temporal characteristics of drug effect and relationship to the therapeutic window (e.g., single dose, oral administration). A lag period is present before the plasma drug concentration (C_p) exceeds the minimum effective concentration (MEC) for the desired effect. Following onset of the response, the intensity of the effect increases as the drug continues to be absorbed and distributed. This reaches a peak, after which drug elimination results in a decline in C_p and in the effect's intensity. Effect disappears when the drug concentration falls below the MEC. Accordingly, the duration of a drug's action is determined by the time period over which concentrations exceed the MEC. An MEC exists for each adverse response, and if drug concentration exceeds this, toxicity will result. The therapeutic goal is to obtain and maintain concentrations within the therapeutic window for the desired response with a minimum of toxicity. Drug response below the MEC for the desired effect will be subtherapeutic; above the MEC for an adverse effect, the probability of toxicity will increase. Increasing or decreasing drug dosage shifts the response curve up or down the intensity scale and is used to modulate the drug's effect. Increasing the dose also prolongs a drug's duration of action but at the risk of increasing the likelihood of adverse effects. Unless the drug is nontoxic (e.g., penicillins), increasing the dose is not a useful strategy for extending the duration of action. Instead, another dose of drug should be given, timed to maintain concentrations within the therapeutic window. The area under the blood concentration-time curve (area under the curve, or AUC, shaded in gray) can be used to calculate the clearance (see Equation 1-5) for first-order elimination. The AUC is also used as a measure of bioavailability (defined as 100% for an intravenously administered drug). Bioavailability will be <100% for orally administered drugs, due mainly to incomplete absorption and first-pass metabolism and elimination. Thus, the therapeutic goal is to maintain steady-state drug levels within the therapeutic window. The application of pharmacokinetic monitoring to drug treatment in cases where the therapeutic index of a drug is narrow is beneficial since successful therapy is associated with a target blood level at steady-state.

(adverse) drug effects, and as a result, a therapeutic window exists reflecting a concentration range that provides efficacy without unacceptable toxicity. Similar considerations apply after multiple dosing associated with long-term therapy, and they determine the amount and frequency of drug administration to achieve an optimal therapeutic effect. In general, the lower limit of the therapeutic range is approximately equal to the drug concentration that produces about half the greatest possible therapeutic effect, and the upper limit of the therapeutic range is such that no more than 5–10% of patients will experience a toxic effect. For some drugs, this may mean that the upper limit of the range is no more than twice the lower limit. Of course, these figures can be highly variable, and some patients may benefit greatly from drug concentrations that exceed the therapeutic range, whereas others may suffer significant toxicity at much lower values (e.g., digoxin).

For a limited number of drugs, some effect of the drug is easily measured (e.g., blood pressure, blood glucose), and this can be used to optimize dosage using a trial-and-error approach. Even in an ideal case, certain quantitative issues arise, such as how often to change dosage and by how much. These usually can be settled with simple rules of thumb based on the principles discussed (e.g., change dosage by no more than 50% and no more often than every three to four half-lives). Alternatively, some drugs have very little dose-related toxicity, and maximum efficacy usually is desired. For these drugs, doses well in excess of the average required will ensure efficacy (if this is possible) and prolong drug action. Such a “maximal dose” strategy typically is used for penicillins.

For many drugs, however, the effects are difficult to measure (or the drug is given for prophylaxis), toxicity and lack of efficacy are potential dangers, or the therapeutic index is narrow. In these circumstances, doses must be titrated carefully, and drug dosage is limited by toxicity rather than efficacy.

MAINTENANCE DOSE

In most clinical situations, drugs are administered in a series of repetitive doses or as a continuous infusion to maintain a steady-state concentration of drug associated with the therapeutic window. Calculation of the appropriate maintenance dosage is a primary goal. To maintain the chosen steady-state or target concentration, the rate of drug administration is adjusted such that the rate of input equals the rate of loss. This relationship is expressed here in terms of the desired target concentration:

$$\text{Dosing rate} = \text{target } C_p \cdot CL/F \quad (1-12)$$

If the clinician chooses the desired concentration of drug in plasma and knows the clearance and bioavailability for that drug in a particular patient, the appropriate dose and dosing interval can be calculated.

Dosing Interval for Intermittent Dosage

In general, marked fluctuations in drug concentrations between doses are not desirable. If absorption and distribution were instantaneous, fluctuations in drug concentrations between doses would be governed entirely by the drug's elimination $t_{1/2}$. If the dosing interval T were chosen to be equal to the $t_{1/2}$, then the total fluctuation would be twofold; this is often a tolerable variation.

Pharmacodynamic considerations modify this. For drugs with a narrow therapeutic range, it may be important to estimate the maximal and minimal concentrations that will occur for a particular dosing interval. The minimal steady-state concentration $C_{ss, \min}$ may be reasonably determined by the use of Equation (1-13):

$$C_{ss, \min} = \frac{F \cdot \text{dose} / V_{ss}}{1 - \exp(-kT)} \cdot \exp(-kT) \quad (1-13)$$

where k equals 0.693 divided by the clinically relevant plasma $t_{1/2}$ and T is the dosing interval. The term $\exp(-kT)$ is, in fact, the fraction of the last dose (corrected for bioavailability) that remains in the body at the end of a dosing interval.

LOADING DOSE

A loading dose is one dose or a series of doses given at the onset of therapy with the aim of achieving the target concentration rapidly. The appropriate magnitude for the loading dose is:

$$\text{Loading dose} = \text{target } C_p \cdot V_{ss} / F \quad (1-14)$$

A loading dose may be desirable if the time required to attain steady state (and efficacy) by the administration of drug at a constant rate (four half-lives) is long relative to the demands of the condition being treated as is the case with the treatment of arrhythmias or cardiac failure.

The use of a loading dose also has significant disadvantages. The patient may be exposed abruptly to a toxic concentration of a drug that may take a long time to fall (i.e., long $t_{1/2}$). Loading doses tend to be large, and they are often given parenterally and rapidly; this can be particularly dangerous if toxic effects occur as a result of actions of the drug at sites that are in rapid equilibrium with the high concentration in plasma. It is therefore usually advisable to divide the loading dose into a number of smaller fractional doses administered over time, or to administer the loading dose as a continuous intravenous infusion over a period of time using computerized infusion pumps.

Therapeutic Drug Monitoring

The major use of measured concentrations of drugs (at steady state) is to refine the estimate of CL/F for the patient being treated [using Equation (1–10) as rearranged below]:

$$CL/F(\text{patient}) = \text{dosing rate}/C_{ss}(\text{measured}) \quad (1-15)$$

The new estimate of CL/F can be used in Equation (1–12) to adjust the maintenance dose to achieve the desired target concentration.

PHARMACODYNAMICS

MECHANISMS OF DRUG ACTION AND THE RELATIONSHIP BETWEEN DRUG CONCENTRATION AND EFFECT

Pharmacodynamics—the study of the biochemical and physiological effects of drugs and their mechanisms of action—can provide the basis for the rational therapeutic use of a drug and the design of new and superior therapeutic agents.

Mechanisms of Drug Action

The effects of most drugs result from their interaction with macromolecular components of the organism. These interactions alter the function of the pertinent component and thereby initiate the biochemical and physiological changes that are characteristic of the response to the drug. The term *receptor* denotes the component of the organism with which the drug is presumed to interact.

Drug Receptors

Quantitatively proteins form the most important class of drug receptors. Examples include the receptors for hormones, growth factors, transcription factors, and neurotransmitters; the enzymes of crucial metabolic or regulatory pathways (e.g., dihydrofolate reductase, acetylcholinesterase, and cyclic nucleotide phosphodiesterases); proteins involved in transport processes (e.g., Na^+ , K^+ -ATPase); secreted glycoproteins (e.g., Wnts); and structural proteins (e.g., tubulin). Specific binding properties of other cellular constituents also can be exploited for therapeutic purpose. Thus, nucleic acids are important drug receptors, particularly for cancer chemotherapeutic agents.

A particularly important group of drug receptors consists of proteins that normally serve as receptors for endogenous regulatory ligands. Many drugs act on such physiological receptors and often are particularly selective because physiological receptors are specialized to recognize and respond to individual signaling molecules with great selectivity. Drugs that bind to physiological receptors and mimic the regulatory effects of the endogenous signaling compounds are termed *agonists*. Other drugs, termed *antagonists*, bind to receptors without regulatory effect, but their binding, blocks the binding of the endogenous agonist. Agents that are only partly as effective as agonists no matter the dose employed are termed *partial agonists*; those that stabilize the receptor in its inactive conformation are termed *inverse agonists* (Figure 1–6).

The strength of the reversible interaction between a drug and its receptor, as measured by their dissociation constant, is defined as the *affinity* of one for the other. Both the affinity of a drug for its receptor and its intrinsic activity are determined by its chemical structure.

CELLULAR SITES OF DRUG ACTION Drugs act by altering the activities of their receptors. The sites at which drugs act and the extent of this action are determined by the location and functional capacity of receptors. Selective localization of drug action within an organism therefore

FIGURE 1-6 Regulation of receptor activity by conformation-selective drugs. The ordinate is some activity of the receptor produced by R_a , the active receptor conformation (e.g., stimulation of adenylyl cyclase). If a drug D selectively binds to R_a , it will produce a maximal response. If D has equal affinity for R_i and R_a , it will not perturb the equilibrium between them and will have no effect on net activity; D would appear as an inactive compound. If the drug selectively binds to R_a , then the net amount of R_a will be diminished. If D can bind to receptor in an active conformation R_a but also bind to inactive receptor R_i with lower affinity, the drug will produce a partial response; D will be a partial agonist. If there is sufficient R_a to produce an elevated basal response in the absence of ligand (agonist-independent constitutive activity), then a drug binding to R_i will reduce activity; D will be an inverse agonist. Inverse agonists selectively bind to the inactive form of the receptor and shift the conformational equilibrium toward the inactive state. In systems that are without net constitutive activity, inverse agonists will behave like competitive antagonists. Receptors that have constitutive activity and are sensitive to inverse agonists include benzodiazepine, histamine, opioid, cannabinoid, dopamine, β adrenergic, calcitonin, bradykinin, and adenosine receptors.

does not necessarily depend on selective distribution of the drug. If a drug acts on a receptor that serves functions common to most cells, its effects will be widespread. If the function is a vital one, the drug may be particularly difficult or dangerous to use. Nevertheless, such a drug may be important clinically.

If a drug interacts with receptors that are unique to only a few types of differentiated cells, its effects are more specific. Hypothetically, the ideal drug would cause its therapeutic effect by such a discrete action. Side effects would be minimized, but toxicity might not be. If the differentiated function were a vital one, this type of drug also could be very dangerous. Even if the primary action of a drug is localized, the consequent physiological effects of the drug may be widespread.

Receptors for Physiological Regulatory Molecules

Postulating two functions of a receptor, ligand binding and message propagation (i.e., signaling), suggests the existence of functional domains within the receptor: a *ligand-binding domain* and an *effector domain*. The structure and function of these domains often can be deduced from high-resolution structures of receptor proteins and by analysis of the behavior of intentionally mutated receptors.

The regulatory actions of a receptor may be exerted directly on its cellular target(s), *effector protein(s)*, or may be conveyed by intermediary cellular signaling molecules called *transducers*. The receptor, its cellular target, and any intermediary molecules are referred to as a *receptor-effector system* or *signal-transduction pathway*. Frequently, the proximal cellular effector protein is not the ultimate physiological target but rather is an enzyme or transport protein that creates, moves, or degrades a small metabolite (e.g., a cyclic nucleotide or inositol trisphosphate) or ion (e.g., Ca^{2+}) known as a *second messenger*. Second messengers can diffuse in the proximity of their binding sites and convey information to a variety of targets, which can respond simultaneously to the output of a single receptor binding a single agonist molecule. Even though these second messengers originally were thought of as freely diffusible molecules within the cell, their diffusion and their intracellular actions are constrained by compartmentation—selective localization of

receptor–transducer–effector–signal termination complexes—established *via* protein–lipid and protein–protein interactions.

Receptors and their associated effector and transducer proteins also act as integrators of information as they coordinate signals from multiple ligands with each other and with the metabolic activities of the cell. An important property of physiological receptors that also makes them excellent targets for drugs is that they act catalytically. The catalytic nature of receptors is obvious when the receptor itself is an enzyme, but all known physiological receptors are formally catalysts. When, for example, a single agonist molecule binds to a receptor that is an ion channel, hundreds of thousands to millions of ions flow through the channel every second. Similarly, a single steroid hormone molecule binds to its receptor and initiates the transcription of many copies of specific mRNAs, which, in turn, can give rise to multiple copies of a single protein.

PHYSIOLOGICAL RECEPTORS: STRUCTURAL AND FUNCTIONAL FAMILIES

Receptors for physiological regulatory molecules can be assigned to a relatively few functional families whose members share both common mechanisms of action and similar molecular structures (Figure 1–7). For each receptor superfamily, there is now a context for understanding the structures of ligand-binding domains and effector domains and how agonist binding influences the regulatory activity of the receptor. The relatively small number of biochemical mechanisms and structural formats used for cellular signaling is fundamental to the ways in which target cells integrate signals from multiple receptors to produce additive, sequential, synergistic, or mutually inhibitory responses.

Receptors as Enzymes: Receptor Protein Kinases and Guanylyl Cyclases

A large group of receptors with intrinsic enzymatic activity consists of cell surface protein kinases, which exert their regulatory effects by phosphorylating diverse effector proteins at the inner face of the plasma membrane. Protein phosphorylation is a common mechanism for altering the biochemical activities of an effector or its interactions with other proteins. Most receptors that are protein kinases phosphorylate tyrosine residues in their substrates. A few receptor protein kinases phosphorylate serine or threonine residues. The most structurally simple receptor protein kinases are composed of an agonist-binding domain on the extracellular surface of the plasma membrane, a single membrane-spanning element, and a protein kinase domain on the inner membrane face. Many variations on this basic architecture exist, including assembly of multiple subunits in the mature receptor, obligate oligomerization of the liganded receptor, and the addition of multiple regulatory or protein-binding domains to the intracellular protein kinase domain that permit association of the liganded receptor with additional effector molecules and with substrates.

Another family of receptors, protein kinase–associated receptors, lack the intracellular enzymatic domains but, in response to agonists, bind or activate distinct protein kinases on the cytoplasmic face of the plasma membrane.

For the receptors that bind atrial natriuretic peptides and the peptides guanylin and uroguanylin, the intracellular domain is not a protein kinase but rather a guanylyl cyclase that synthesizes the second messenger cyclic guanosine monophosphate (cyclic GMP), which activates a cyclic GMP–dependent protein kinase (PKG) and can modulate the activities of several cyclic nucleotide phosphodiesterases, among other effectors.

Protease-Activated Receptor Signaling

Proteases that are anchored to the plasma membrane or that are soluble in the extracellular fluid (e.g., thrombin) can cleave ligands or receptors at the surface of cells to either initiate or terminate signal transduction. Peptide agonists often are processed by proteolysis to become active at their receptors. Targeting the proteolytic regulation of receptor mechanisms has produced successful therapeutic strategies, such as the use of angiotensin-converting enzyme (ACE) inhibitors in the treatment of hypertension (see Chapters 30 and 32) and the generation of new anticoagulants targeting the action of thrombin (see Chapter 54).

Ion Channels

Receptors for several neurotransmitters form agonist-regulated ion-selective channels in the plasma membrane, termed ligand-gated ion channels or receptor operated channels, that convey their signals by altering the cell's membrane potential or ionic composition. This group includes the nicotinic cholinergic receptor, the γ -aminobutyric acid A (GABA_A) receptor, and receptors for glutamate, aspartate, and glycine (see Chapters 9, 12, and 16). They are all multisubunit proteins, with each subunit predicted to span the plasma membrane several times. Symmetrical association of the subunits allows each to form a segment of the channel wall, or pore, and to cooperatively

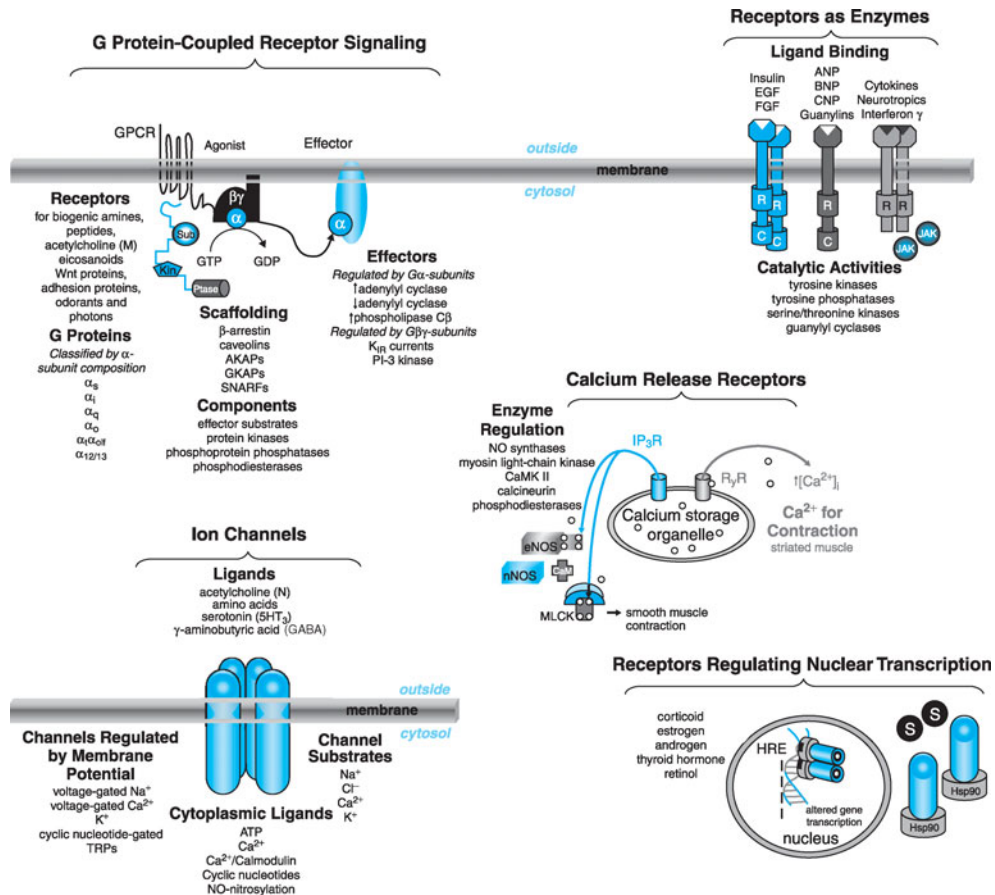

FIGURE 1-7 Structural motifs of physiological receptors and their relationships to signaling pathways. Detailed descriptions of these signaling pathway are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

control channel opening and closing. Agonist binding may occur on a particular subunit that may be represented more than once in the assembled multimer (e.g., the nicotinic acetylcholine receptor) or may be conferred by a separate single subunit of the assembled channel, as is the case with the sulfonylurea receptor (SUR) that associates with a K^+ channel ($K_{ir,6.2}$) to regulate the ATP-dependent K^+ channel (K_{ATP}) (see Chapter 60). Openers of the same channel (minoxidil) are used as vascular smooth muscle relaxants. Receptor-operated channels also are regulated by other receptor-mediated events, such as protein kinase activation following activation of G protein-coupled receptors (GPCRs) (see below). Phosphorylation of the channel protein on one or more of its subunits can confer both activation and inactivation depending on the channel and the nature of the phosphorylation.

G Protein-Coupled Receptors

A large superfamily of receptors that accounts for many known drug targets interacts with distinct heterotrimeric GTP-binding regulatory proteins known as G proteins. G proteins are signal transducers that convey information (i.e., agonist binding) from the receptor to one or more effector proteins. GPCRs include those for a number of biogenic amines, eicosanoids and other lipid-signaling molecules, peptide hormones, opioids, amino acids such as GABA, and many other peptide and protein ligands. G protein-regulated effectors include enzymes such as adenylyl cyclase, phospholipase C, phosphodiesterases, and plasma membrane ion channels selective for Ca^{2+} and K^+ (Figure 1–7). Because of their number and physiological importance, GPCRs are the targets for many drugs; perhaps half of all nonantibiotic prescription drugs are directed toward these receptors that make up the third largest family of genes in humans.

GPCRs span the plasma membrane as a bundle of seven α -helices. G proteins, composed of a GTP-binding α subunit, which confers specific recognition by receptor and effector, and an associated dimer of β and γ subunits that can confer both membrane localization of the G protein (e.g., via myristoylation) and direct signaling such as activation of inward rectifier K^+ (GIRK) channels and binding sites for G protein receptor kinases (GRKs), bind to the cytoplasmic face of the receptors promoting the binding of GTP to the G protein α subunit. GTP activates the G protein and allows it, in turn, to activate the effector protein. The G protein remains active until it hydrolyzes the bound GTP to GDP. Activation of the G_α subunit by GTP allows it to regulate an effector protein and to drive the release of $G_{\beta\gamma}$ subunits, which can also regulate effectors (e.g., K^+ channels), and which ultimately reassociate with GDP-liganded G_α , returning the system to the basal state.

Central to the effect of many GPCRs is release of Ca^{2+} from intracellular stores. For example, α receptors for norepinephrine activate G_q specific for the activation of phospholipase C_β . Phospholipase C_β (PLC $_\beta$) is a membrane-bound enzyme that hydrolyzes a membrane phospholipid, phosphatidylinositol-4,5-bisphosphate, to generate inositol-1,4,5-trisphosphate (IP_3) and the lipid, diacylglycerol. IP_3 binds to receptors on Ca^{2+} release channels in the IP_3 -sensitive Ca^{2+} stores of the endoplasmic reticulum, triggering the release of Ca^{2+} and rapidly raising $[Ca^{2+}]_i$. The elevation of $[Ca^{2+}]_i$ is transient owing to its avid reuptake into stores. Ca^{2+} can bind to and directly regulate ion channels (e.g., large conductance Ca^{2+} -activated K^+ channels). Ca^{2+} can also bind to calmodulin; the resulting Ca^{2+} -calmodulin complex then can modulate a variety of effectors, including ion channels (e.g., the small conductance Ca^{2+} -activated K^+ channels), and cellular enzymes (e.g., Ca^{2+} -calmodulin-dependent protein kinases and PDEs).

Receptor-ligand interactions alone do not regulate all GPCR signaling. It is now clear that GPCRs undergo both homo- and heterodimerization and possibly oligomerization. Heterodimerization can result in receptor units with altered pharmacology compared with either individual receptor. Evidence is emerging that dimerization of receptors may regulate the affinity and specificity of the complex for G protein and regulate the sensitivity of the receptor to phosphorylation by receptor kinases and the binding of arrestin, events important in termination of the action of agonists and removal of receptors from the cell surface. Dimerization also may permit binding of receptors to other regulatory proteins such as transcription factors. Thus, the receptor-G protein effector systems are complex networks of convergent and divergent interactions involving both receptor-receptor and receptor-G protein coupling that permits extraordinarily versatile regulation of cell function.

Transcription Factors

Receptors for steroid hormones, thyroid hormone, vitamin D, and the retinoids are soluble DNA-binding proteins that regulate the transcription of specific genes. These receptors act as both hetero- and homo-dimers with homologous cellular proteins, but may be regulated by higher-order oligomerization with other modulators, often bound to these modulatory proteins in the cytoplasm, retaining them in an inactive state. Regulatory sites in DNA where agonists bind are

receptor-specific: the sequence of a “glucocorticoid-response element,” with only slight variation, is associated with each glucocorticoid-response gene, whereas a “thyroid-response element” confers specificity of the actions of the thyroid hormone nuclear receptor.

CYTOPLASMIC SECOND MESSENGERS

Binding of an agonist to a receptor provides the first message in receptor signal transduction to effector to affect cell physiology. The first messenger promotes the cellular production or mobilization of a second messenger, which initiates cellular signaling through a specific biochemical pathway. Physiological signals are integrated within the cell as a result of interactions between and among second-messenger pathways. Compared with the number of receptors and cytosolic signaling proteins, there are relatively few recognized cytoplasmic second messengers. However, their synthesis or release and degradation or excretion reflects the activities of many pathways. Well-studied second messengers include cyclic AMP, cyclic GMP, cyclic ADP-ribose, Ca^{2+} , inositol phosphates, diacylglycerol, and nitric oxide (NO). Second messengers influence each other both directly, by altering the other's metabolism, and indirectly, by sharing intracellular targets. This pattern of regulatory pathways allows the cell to respond to agonists, singly or in combination, with an integrated array of cytoplasmic second messengers and responses.

Cyclic AMP

Cyclic AMP, the prototypical second messenger, is synthesized by adenylyl cyclase under the control of many GPCRs; stimulation is mediated by G_s ; inhibition, by G_i . There are nine membrane-bound isoforms of adenylyl cyclase (AC). The membrane-bound ACs are 120 kDa glycoproteins with six membrane-spanning helices; and two large cytoplasmic domains. Membrane-bound ACs exhibit basal enzymatic activity that is modulated by binding of GTP-liganded α subunits of stimulatory and inhibitory G proteins (G_s and G_i). ACs are catalogued based on their structural homology and their distinct regulation by G protein α and $\beta\gamma$ subunits, Ca^{2+} , protein kinases, and the actions of the diterpene forskolin. Because each AC isoform has its own tissue distribution and regulatory properties, different cell types respond differently to similar stimuli.

The role of drugs interacting at GPCRs as agonists is to accelerate the exchange of GDP for GTP on the α subunits of these G proteins. Once activated by α_s -GTP, AC remains activated until α_s hydrolyzes the bound GTP to GDP, which returns the system to its ground state. A single AC activation produces many molecules of cyclic AMP, which, in turn, can activate PKA. Cyclic AMP is eliminated by a combination of hydrolysis, catalyzed by cyclic nucleotide phosphodiesterases, and extrusion by several plasma membrane transport proteins.

Phosphodiesterase

Phosphodiesterases (PDEs) are regulated by controlled transcription as well as by second messengers (cyclic nucleotides and Ca^{2+}) and interactions with other signaling proteins such as β -arrestin and protein kinases. PDEs are responsible for the hydrolysis of the cyclic 3',5'-phosphodiester bond found in cyclic AMP and cyclic GMP. PDEs comprise a superfamily with 11 subfamilies distinguished on the basis of amino acid sequence, substrate specificity, pharmacological properties, and allosteric regulation. The substrate specificities of the PDEs include enzymes that are specific for cyclic AMP, cyclic GMP, and both. PDEs play a highly regulated role that is important in controlling the intracellular levels of cyclic AMP and cyclic GMP. The importance of the PDEs as regulators of signaling is evident from their development as drug targets in diseases such as asthma and chronic obstructive pulmonary disease, cardiovascular diseases such as heart failure and atherosclerotic peripheral arterial disease, neurological disorders, and erectile dysfunction.

Cyclic GMP

Cyclic GMP is generated by two distinct forms of guanylyl cyclase (GC). NO stimulates soluble guanylyl cyclase (sGC), and the natriuretic peptides, guanylns, and heat-stable Escherichia coli enterotoxin stimulate members of the membrane-spanning GCs (e.g., particulate GC).

Actions of Cyclic Nucleotides

In most cases, cyclic AMP functions by activating the isoforms of cyclic AMP-dependent protein kinase (PKA), and cyclic GMP activates a PKG. Recently, a number of additional actions of cyclic nucleotides have been described, all with pharmacological relevance.

Cyclic Nucleotide-Dependent Protein Kinases

PKA holoenzyme consists of two catalytic (C) subunits reversibly bound to a regulatory (R) subunit dimer. The holoenzyme is inactive. Binding of four cyclic AMP molecules, two to each R subunit,

dissociates the holoenzyme, liberating two catalytically active C subunits that phosphorylate serine and threonine residues on specific substrate proteins.

PKA diversity lies in both its R and C subunits. Molecular cloning has revealed α and β isoforms of both the classically described PKA regulatory subunits (RI and RII), as well as three C subunit isoforms C α , C β , and C γ . The R subunits exhibit different binding affinities for cyclic AMP, giving rise to PKA holoenzymes with different thresholds for activation. In addition to differential expression of R and C isoforms in various cells and tissues, PKA function is modulated by subcellular localization mediated by A-kinase-anchoring proteins (AKAPs).

PKA can phosphorylate both final physiological targets (metabolic enzymes or transport proteins) and numerous protein kinases and other regulatory proteins in multiple signaling pathways. This latter group includes transcription factors that allow cyclic AMP to regulate gene expression in addition to more acute cellular events.

Cyclic GMP activates a protein kinase, PKG, that phosphorylates some of the same substrates as PKA and some that are PKG-specific. Unlike PKA, PKG does not disassociate upon binding cyclic GMP. PKG is known to exist in two homologous forms. PKGI, with an acetylated N terminus, is associated with the cytoplasm and known to exist in two isoforms (I α and I β) that arise from alternate splicing. PKGII, with a myristylated N terminus, is membrane-associated and may be compartmented by PKG-anchoring proteins in a manner similar to that known for PKA. Pharmacologically important effects of elevated cyclic GMP include modulation of platelet activation and regulation of smooth muscle contraction.

Cyclic Nucleotide-Gated Channels

In addition to activating protein kinases, cyclic AMP and cyclic GMP also bind to and directly regulate the activity of plasma membrane cation channels referred to as cyclic nucleotide-gated (CNG) channels. CNG ion channels have been found in kidney, testis, heart, and the CNS. These channels open in response to direct binding of intracellular cyclic nucleotides and contribute to cellular control of the membrane potential and intracellular Ca²⁺ levels. The CNG ion channels are multisubunit pore-forming channels that share structural similarity with the voltage-gated K⁺ channels.

Calcium

The entry of Ca²⁺ into the cytoplasm is mediated by diverse channels: Plasma membrane channels regulated by G proteins, membrane potential, K⁺ or Ca²⁺ itself, and channels in specialized regions of endoplasmic reticulum that respond to IP₃ or, in excitable cells, to membrane depolarization and the state of the Ca²⁺ release channel and its Ca²⁺ stores in the sarcoplasmic reticulum. Ca²⁺ is removed both by extrusion (Na⁺-Ca²⁺ exchanger and Ca²⁺ ATPase) and by reuptake into the endoplasmic reticulum (SERCA pumps). Ca²⁺ propagates its signals through a much wider range of proteins than does cyclic AMP, including metabolic enzymes, protein kinases, and Ca²⁺-binding regulatory proteins (e.g., calmodulin) that regulate still other ultimate and intermediary effectors that regulate cellular processes as diverse as exocytosis of neurotransmitters and muscle contraction. Drugs such as chlorpromazine (an antipsychotic agent) are calmodulin inhibitors.

Regulation of Receptors

Receptors not only initiate regulation of biochemical events and physiological function but also are themselves subject to many regulatory and homeostatic controls. These controls include regulation of the synthesis and degradation of the receptor by multiple mechanisms, covalent modification, association with other regulatory proteins, and/or relocation within the cell. Transducer and effector proteins are regulated similarly. Modulating inputs may come from other receptors, directly or indirectly, and receptors are almost always subject to feedback regulation by their own signaling outputs.

Continued stimulation of cells with agonists generally results in a state of *desensitization* (also referred to as *adaptation*, *refractoriness*, or *down-regulation*) such that the effect that follows continued or subsequent exposure to the same concentration of drug is diminished. This phenomenon, called *tachyphylaxis*, occurs rapidly and is important therapeutically; an example is attenuated response to the repeated use of β receptor agonists as bronchodilators for the treatment of asthma (see Chapters 10 and 27).

Desensitization can result from temporary inaccessibility of the receptor to agonist or from fewer receptors synthesized and available at the cell surface (e.g., down-regulation of receptor number). Phosphorylation of the receptor by specific GPCR kinases (GRKs) plays a key role in triggering rapid desensitization. Phosphorylation of agonist-occupied GPCRs by GRKs facilitates the binding of cytosolic proteins termed arrestins to the receptor, resulting in the uncoupling of

G protein from the receptor. The β -arrestins recruit proteins such as PDE4 (which limits cyclic AMP signaling), and others such as clathrin and β_2 -adaptin, promoting sequestration of receptor from the membrane (internalization) and providing a scaffold that permits additional signaling steps.

Predictably, supersensitivity to agonists also frequently follows chronic reduction of receptor stimulation. Such situations can result, for example, following withdrawal from prolonged receptor blockade (e.g., the long-term administration of β receptor antagonists such as propranolol (see Chapter 10) or in the case where chronic denervation of a preganglionic fiber induces an increase in neurotransmitter release per pulse, indicating postganglionic neuronal supersensitivity. Supersensitivity can be the result of tissue response to pathological conditions, such as it happens in cardiac ischemia and is due to synthesis and recruitment of new receptors to the surface of the myocyte.

DISEASES RESULTING FROM RECEPTOR MALFUNCTION Alteration in receptors and their immediate signaling effectors can be the cause of disease. The loss of a receptor in a highly specialized signaling system may cause a relatively limited, if dramatic, phenotypic disorder (e.g., deficiency of the androgen receptor and androgen insensitivity syndrome; see Chapter 58). Deficiencies in widely employed signaling pathways have broad effects, as are seen in myasthenia gravis and some forms of insulin-resistant diabetes mellitus, which result from autoimmune depletion of nicotinic cholinergic receptors (see Chapter 9) or insulin receptors (see Chapter 60), respectively.

The expression of aberrant or ectopic receptors, effectors, or coupling proteins potentially can lead to supersensitivity, subsensitivity, or other untoward responses. Among the most significant events is the appearance of aberrant receptors as products of oncogenes that transform otherwise normal cells into malignant cells. Virtually any type of signaling system may have oncogenic potential (Chapter 51).

SIGNIFICANCE OF RECEPTOR SUBTYPES

Molecular cloning has accelerated discovery of novel receptor subtypes, and their expression as recombinant proteins has facilitated discovery of subtype-selective drugs. Distinct but related receptors may, but may not, display distinctive patterns of selectivity among agonist or antagonist ligands. When selective ligands are not known, the receptors are more commonly referred to as isoforms rather than as subtypes. The distinction between classes and subtypes of receptors, however, often is arbitrary or historical. The α_1 , α_2 , and β receptors differ from each other both in ligand selectivity among drugs and in coupling to G proteins (G_β , G_γ , and G_δ , respectively), yet α and β are considered receptor classes and α_1 and α_2 are considered subtypes. The α_{1A} , α_{1B} , and α_{1C} receptor isoforms differ little in their biochemical properties, although their tissue distributions are distinct. The β_1 , β_2 , and β_3 adrenergic receptor subtypes exhibit both differences in tissue distribution and phosphorylation by either GRKs or PKA.

Pharmacological differences among receptor subtypes are exploited therapeutically through the development and use of receptor-selective drugs. Such drugs may be used to elicit different responses from a single tissue when receptor subtypes initiate different intracellular signals, or they may serve to differentially modulate different cells or tissues that express one or another receptor subtype. Increasing the selectivity of a drug among tissues or among responses elicited from a single tissue may determine whether the drug's therapeutic benefits outweigh its unwanted effects.

Actions of Drugs Not Mediated by Receptors

Some drug effects do not occur *via* macromolecular receptors, such as therapeutic neutralization of gastric acid by a base (antacid). Drugs such as *mannitol* act according to colligative properties, increasing the osmolarity of various body fluids and causing changes in the distribution of water to promote diuresis, catharsis, expansion of circulating volume in the vascular compartment, or reduction of cerebral edema (see Chapter 28). The introduction of cholesterol-binding agents orally (e.g., *cholestyramine resin*) can be used to decrease dietary cholesterol absorption.

QUANTITATION OF DRUG-RECEPTOR INTERACTIONS AND EFFECTS Receptor Pharmacology

Receptor occupancy theory, in which it is assumed that response emanates from a receptor occupied by a drug, has its basis in the law of mass action. The basic currency of receptor pharmacology is the dose-response curve, a depiction of the observed effect of a drug as a function of its

FIGURE 1-8 Graded responses expressed as a function of the concentration of drug A present at the receptor. The hyperbolic shape of the curve in panel A becomes sigmoid when plotted semi-logarithmically, as in panel B. The concentration of drug that produces 50% of the maximal response quantifies drug activity and is referred to as the EC₅₀ (effective concentration for 50% response). The range of concentrations needed to usefully depict the dose–response relationship ($\sim 3 \log_{10}[10]$ units) is too wide to be useful in the linear format of Figure 1-8A; thus, most dose–response curves use $\log[D]$ on the abscissa (Figure 1-8B). Dose–response curves presented in this way are sigmoidal in shape and have three basic properties: threshold, slope, and maximal asymptote. These parameters characterize and quantitate the activity of the drug. The sigmoidal curve also depicts the law of mass action as expressed in Equation 1-16.

concentration in the receptor compartment. Figure 1-8A shows a typical dose–response curve; it reaches a maximal asymptotic value when the drug occupies all the receptor sites.

Some drugs cause low-dose stimulation and high-dose inhibition of response. These U-shaped relationships for some receptor systems are said to display hormesis. Several drug–receptor systems can display this property (e.g., prostaglandins, endothelin, and purinergic and serotonergic agonists, among others), which is likely to be at the root of drug toxicity.

Potency and Relative Efficacy

In general, the drug–receptor interaction is characterized first by binding of drug to receptor and second by generation of a response in a biological system. The first function is governed by the chemical property of *affinity*, ruled by the chemical forces that cause the drug to associate reversibly with the receptor.

This simple relationship, permits an appreciation of the reliance of the interaction of drug (D) with receptor (R) on both the forward or association rate (k_1) and the reverse or dissociation rate (k_2). At any given time, the concentration of agonist–receptor complex [DR] is equal to the product of $k_1[D][R]$ minus the product $k_2[DR]$. At equilibrium (*i.e.*, when $\delta[DR]/\delta\tau = 0$), $k_1[D][R] = k_2[DR]$. The equilibrium dissociation constant (K_D) is then described by ratio of the off-rate and the on-rate (k_2/k_1).

$$\text{At equilibrium, } K_D = \frac{[D][R]}{[DR]} = \frac{k_2}{k_1} \quad (1-17)$$

The affinity constant is the reciprocal of the equilibrium dissociation constant (affinity constant = $K_D = 1/K_A$). A high affinity means a small K_D . As a practical matter, the affinity of a drug is influenced most often by changes in its off-rate (k_2) rather than its on-rate (k_1). Although a number of assumptions are made in this analysis, it is generally useful for considering the interactions of drugs with their receptors. Using this simple model of Equation 1-17 permits us to write an expression of the fractional occupancy (f) of receptors by agonist:

$$f = \frac{[\text{drug-receptor complexes}]}{[\text{total receptors}]} = \frac{[DR]}{[R] + [DR]} \quad (1-18)$$

This can be expressed in terms of K_A (or K_D) and $[D]$:

$$f = \frac{K_A [D]}{1 + K_A [D]} = \frac{[D]}{[D] + K_D} \quad (1-19)$$

Thus, when $[D] = K_D$, a drug will occupy 50% of the receptors present. Potent drugs are those which elicit a response by binding to a critical number of a particular receptor type at low concentrations (high affinity) compared with other drugs acting on the same system and having lower affinity and thus requiring more drug to bind to the same number of receptors.

The generation of a response from the drug–receptor complex is governed by a property described as efficacy. Where agonism is the information encoded in a drug’s chemical structure that causes the receptor to change conformation to produce a physiological or biochemical response when the drug is bound, efficacy is that property intrinsic to a particular drug that determines how “good” an agonist the drug is. Historically, efficacy has been treated as a proportionality constant that quantifies the extent of functional change imparted to a receptor-mediated response system on binding a drug. Thus, a drug with high efficacy may be a full agonist eliciting, at some concentration, a full response, whereas a drug with a lower efficacy at the same receptor may not elicit a full response at any dose. When it is possible to describe the relative efficacy of drugs at a particular receptor, a drug with a low intrinsic efficacy will be a partial agonist.

QUANTIFYING AGONISM When the relative potency of two agonists of equal efficacy is measured in the same biological system, downstream signaling events are the same for both drugs, and the comparison yields a relative measure of the affinity and efficacy of the two agonists (Figure 1–9A). It is convenient to describe agonist response by determining the half-maximally effective concentration (EC_{50}) for producing a given effect. Thus, measuring agonist potency by comparison of EC_{50} values is one method of measuring the capability of different agonists to induce a response in a test system and for predicting comparable activity in another. Another method of estimating agonist activity is to compare maximal asymptotes in systems where the agonists do not produce maximal response (Figure 1–9B). The advantage of using maxima is that this property depends solely on efficacy, whereas potency is a mixed function of both affinity and efficacy.

QUANTIFYING ANTAGONISM Characteristic patterns of antagonism are associated with certain mechanisms of blockade of receptors. One is straightforward *competitive antagonism*, whereby a drug that lacks intrinsic efficacy but retains affinity competes with the agonist for the binding site on the receptor. The characteristic pattern of such antagonism is the concentration-dependent production of a parallel shift to the right of the agonist dose–response curve with no change in the maximal response (Figure 1–10A). The magnitude of the rightward shift of the curve depends on the concentration of the antagonist and its affinity for the receptor.

FIGURE 1–9 *Two ways of quantifying agonism. A.* The relative potency of two agonists (drug x, gray line; drug y, blue line) obtained in the same tissue is a function of their relative affinities and intrinsic efficacies. The half-maximal effect of drug x occurs at a concentration that is one-tenth the half-maximally effective concentration of drug y. Thus, drug x is more potent than drug y. *B.* In systems where the two drugs do not both produce the maximal response characteristic of the tissue, the observed maximal response is a nonlinear function of their relative intrinsic efficacies. Drug x is more efficacious than drug y; their asymptotic fractional responses are 100% (drug x) and 50% (drug y).

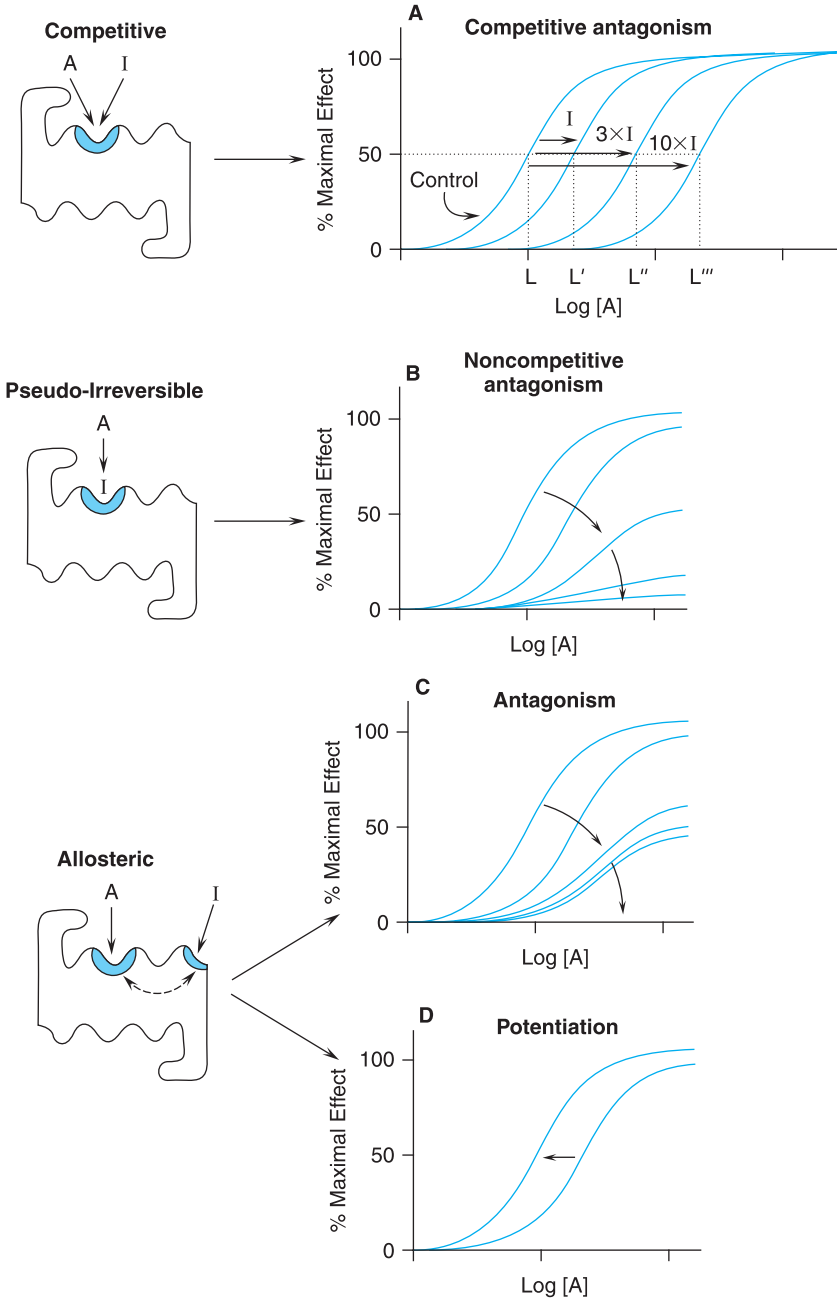

FIGURE 1-10 Mechanisms of receptor antagonism. **A.** Competitive antagonism occurs when the agonist A and antagonist I compete for the same binding site on the receptor. Response curves for the agonist are shifted to the right in a concentration-related manner by the antagonist such that the EC₅₀ for the agonist increases (e.g., L versus L', L'', and L''') with the concentration of the antagonist. **B.** If the antagonist binds to the same site as the agonist but does so irreversibly or pseudo-irreversibly (slow dissociation but no covalent bond), it causes a shift of the dose-response curve to the right, with further depression of the maximal response. Allosteric effects occur when the ligand I binds to a different site on the receptor to either inhibit response (see panel C) or potentiate response (see panel D). This effect is saturable; inhibition reaches a limiting value when the allosteric site is fully occupied.

A partial agonist similarly can compete with a “full” agonist for binding to the receptor. However, increasing concentrations of a partial agonist will inhibit response to a finite level characteristic of the drug’s intrinsic efficacy; a competitive antagonist will reduce the response to zero. Partial agonists thus can be used therapeutically to buffer a response by inhibiting untoward stimulation without totally abolishing the stimulus from the receptor.

An antagonist may dissociate so slowly from the receptor as to be essentially irreversible in its action. Under these circumstances, the maximal response to the agonist will be depressed at some antagonist concentrations (Figure 1–10B). Operationally, this is referred to as *noncompetitive antagonism*, although the molecular mechanism of action really cannot be inferred unequivocally from the effect. An irreversible antagonist competing for the same binding site as the agonist also can produce the pattern of antagonism shown in Figure 1–10B.

Noncompetitive antagonism can be produced by another type of drug, referred to as an allosteric antagonist. This type of drug produces its effect by binding a site on the receptor distinct from that of the primary agonist and thereby changing the affinity of the receptor for the agonist. In the case of an allosteric antagonist, the affinity of the receptor for the agonist is decreased by the antagonist (Figure 1–10C). In contrast, some allosteric effects could potentiate the effects of agonists (Figure 1–10D).

MEMBRANE TRANSPORTERS AND DRUG RESPONSE

Transporters are membrane proteins that control the influx of essential nutrients and ions and the efflux of cellular waste, environmental toxins, and other xenobiotics. Approximately 6% of genes in the human genome encode transporters or transporter-related proteins. Drug-transporting proteins contribute to both therapeutic and adverse effects of drugs (Figure 2-1).

Two major superfamilies dominate the area of drug transporters: ATP-binding cassette (ABC) and solute carrier (SLC) transporters. Most ABC proteins are primary active transporters, which rely on adenosine triphosphate (ATP) hydrolysis to actively pump their substrates across membranes. The 49 known genes for ABC proteins are grouped into seven subclasses or families (ABCA to ABCG). Well known examples are P-glycoprotein (encoded by *ABCB1*) and the cystic fibrosis transmembrane regulator (CFTR, encoded by *ABCC7*). The SLC superfamily includes genes that encode facilitated transporters and ion-coupled secondary active transporters, 43 SLC families with ~300 transporters. Many mediate drug absorption and disposition. Prominent SLC transporters include the serotonin transporter (SERT, encoded by *SLC6A4*) and the dopamine transporter (DAT, encoded by *SLC6A3*).

MEMBRANE TRANSPORTERS IN THERAPEUTIC DRUG RESPONSES

PHARMACOKINETICS Important transporters located in intestinal, renal, and hepatic epithelia function in concert with metabolism of drugs in the selective absorption and elimination of endogenous substances and drugs (Figure 2-2). In addition, transporters mediate tissue-specific drug distribution (drug targeting); conversely, transporters also may serve as protective barriers to particular organs and cell types, controlling tissue distribution as well as the absorption and elimination of drugs.

PHARMACODYNAMICS: TRANSPORTERS AS DRUG TARGETS Membrane transporters are the targets of many drugs. For example, neurotransmitter transporters are the targets for drugs used in the treatment of neuropsychiatric disorders. SERT (*SLC6A4*) is a target for the selective serotonin reuptake inhibitors (SSRIs), a major class of antidepressant drugs. Other neurotransmitter reuptake transporters serve as drug targets for the tricyclic antidepressants, amphetamines (including amphetamine-like drugs used in the treatment of attention deficit disorder in children), and anticonvulsants. These transporters also may be involved in the pathogenesis of neuropsychiatric disorders, including Alzheimer's and Parkinson's diseases. Transporters that are nonneuronal also may be potential drug targets (*e.g.*, cholesterol transporters in cardiovascular disease, nucleoside transporters in cancers, glucose transporters in metabolic syndromes, and Na⁺-H⁺ antiporters in hypertension).

DRUG RESISTANCE Membrane transporters play critical roles in the development of resistance to anticancer drugs, antiviral agents, and anticonvulsants. P-glycoprotein, which exports many chemotherapeutics from cells, is overexpressed in tumor cells after exposure to cytotoxic anticancer agents. Other transporters (*e.g.*, breast cancer resistance protein [BCRP], organic anion transporters, and several nucleoside transporters) also have been implicated in resistance to anticancer drugs.

MEMBRANE TRANSPORTERS AND ADVERSE DRUG RESPONSES

Through import and export mechanisms, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs and thereby play critical roles in the cellular toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into three categories (Figure 2-3).

Transporters expressed in the liver and kidney—as well as metabolic enzymes—are key determinants of drug exposure (Figure 2-3, *top panel*) because they control the total clearance of drugs and thus influence the plasma concentration profiles and subsequent exposure to the toxicological target.

Transporters expressed in tissues that may be targets for drug toxicity (*e.g.*, brain) or in barriers to such tissues (*e.g.*, the blood-brain barrier [BBB]) can tightly control local drug concentrations and thus control the drug exposure of these tissues (Figure 2-3, *middle panel*). Drug-induced toxicity sometimes is caused by the concentrative tissue distribution mediated by influx transporters.

Transporters for endogenous ligands may be modulated by drugs and thereby exert adverse effects (Figure 2-3, *bottom panel*). If severe, these effects can lead to withdrawal of the drug

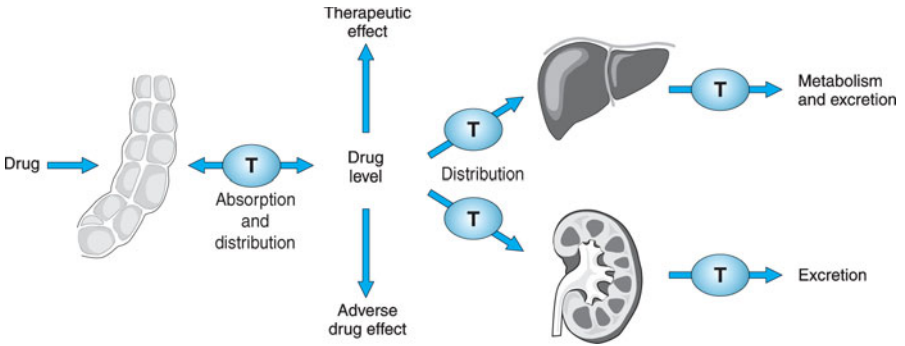

FIGURE 2-1 Roles of membrane transporters in pharmacokinetic pathways. Membrane transporters (T) play roles in pharmacokinetic pathways (drug absorption, distribution, metabolism, and excretion), thereby setting systemic drug levels. Drug levels often drive therapeutic and adverse drug effects.

(e.g., the thiazolidinedione troglitazone). Thus, uptake and efflux transporters determine the plasma and tissue concentrations of endogenous compounds and xenobiotics, thereby influencing either systemic or site-specific drug toxicity.

BASIC MECHANISMS OF MEMBRANE TRANSPORT

TRANSPORTERS VERSUS CHANNELS

Both channels and transporters facilitate the membrane permeation of inorganic ions and organic compounds. Channels have two primary states, open and closed, that are stochastic phenomena. Only in the open state do channels act as pores for their selected ions, allowing permeation across the plasma membrane. After opening, channels return to the closed state as a function of time.

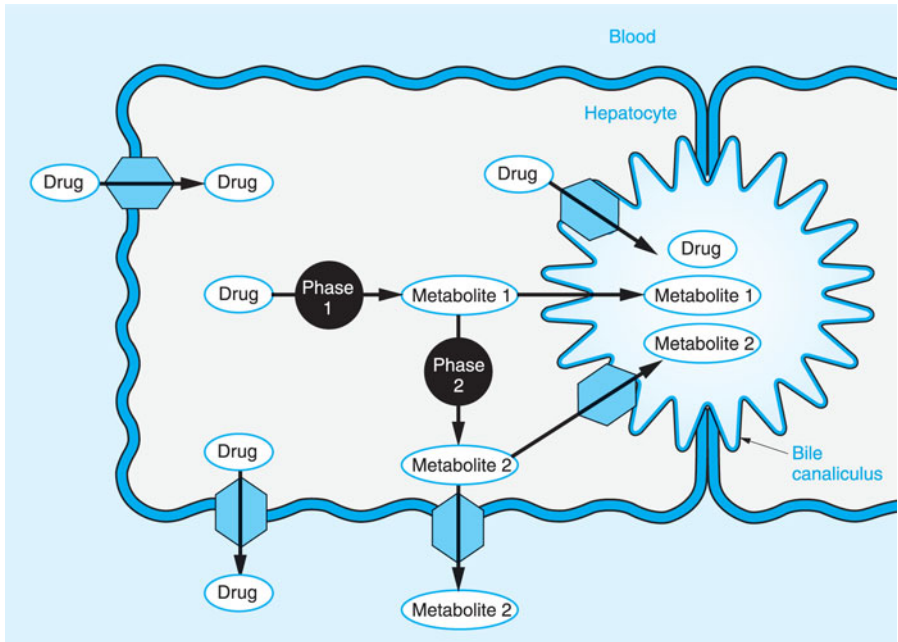

FIGURE 2-2 Hepatic drug transporters. Membrane transporters, shown as hexagons with arrows, work in concert with phase 1 and phase 2 drug-metabolizing enzymes in the hepatocyte to mediate the uptake and efflux of drugs and their metabolites.

FIGURE 2-3 Major mechanisms by which transporters mediate adverse drug responses. Three cases are given. The left panel of each case provides a cartoon representation of the mechanism; the right panel shows the resulting effect on drug levels. (Top panel) Increase in the plasma concentrations of drug due to a decrease in the uptake and/or secretion in clearance organs such as the liver and kidney. (Middle panel) Increase in the concentration of drug in toxicological target organs due either to the enhanced uptake or to reduced efflux of the drug. (Bottom panel) Increase in the plasma concentration of an endogenous compound (e.g., a bile acid) due to a drug's inhibiting the influx of the endogenous compound in its eliminating or target organ. The diagram also may represent an increase in the concentration of the endogenous compound in the target organ owing to drug-inhibited efflux of the endogenous compound.

In contrast, a transporter forms an intermediate complex with the substrate (solute); thereafter, a conformational change in the transporter induces substrate translocation to the other side of the membrane. Because of these different mechanisms, turnover rates differ markedly between channels and transporters. Turnover rate constants of typical channels are 10^6 – 10^8 s^{-1} , whereas those of transporters are, at most, 10^1 – 10^3 s^{-1} . Because transporters form intermediate complexes with specific compounds, transporter-mediated membrane transport is characterized by saturability and inhibition by substrate analogs.

The basic mechanisms involved in solute transport across the plasma membrane include passive diffusion, facilitated diffusion, and active transport. Active transport can be further subdivided into primary and secondary active transport. These mechanisms are depicted in Figure 2-4.

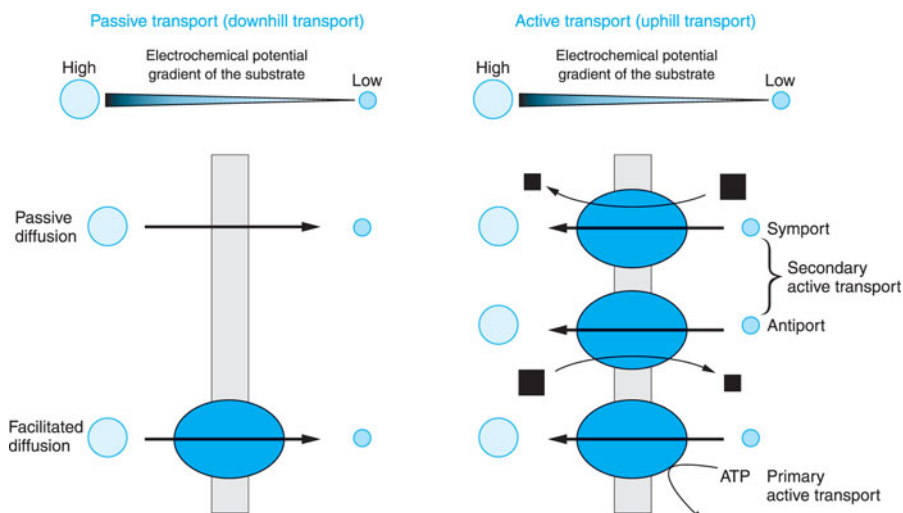

FIGURE 2-4 Classification of membrane transport mechanisms. Light blue circles depict the substrate. Size of the circles is proportional to the concentration of the substrate. Arrows show the direction of flux. Black squares represent the ion that supplies the driving force for transport (size is proportional to the concentration of the ion). Dark blue ovals depict transport proteins.

PASSIVE DIFFUSION Simple diffusion of a solute across the plasma membrane involves three processes: partition from the aqueous to the lipid phase, diffusion across the lipid bilayer, and repartition into the aqueous phase on the opposite side. Diffusion of any solute (including drugs) occurs down an electrochemical potential gradient of the solute and is dependent on both its chemical and electrical potential.

FACILITATED DIFFUSION Membrane transporters may facilitate diffusion of ions and organic compounds across the plasma membrane; this facilitated diffusion does not require energy input. Just as in passive diffusion, the transport of ionized and nonionized compounds across the plasma membrane occurs down their electrochemical potential gradient. Therefore, steady state will be achieved when the electrochemical potentials of the compound on both sides of the membrane become equal.

ACTIVE TRANSPORT Active transport requires energy input and transports solutes against their electrochemical gradients, leading to the concentration of solutes on one side of the plasma membrane and the creation of potential energy in the electrochemical gradient formed. Active transport plays an important role in the uptake and efflux of drugs and other solutes. Depending on the driving force, active transport can be subdivided into primary and secondary active transport (Figure 2-4).

Primary Active Transport Membrane transport that directly couples with ATP hydrolysis is called *primary active transport*. ABC transporters are examples of primary active transporters. They contain one or two highly conserved ATP binding cassettes that exhibit ATPase activity. ABC transporters mediate the unidirectional efflux of many solutes across biological membranes.

Secondary Active Transport In secondary active transport, the transport across the plasma membrane of one solute S_1 against its concentration gradient is driven energetically by the transport of another solute S_2 in accordance with its concentration gradient. The driving force for this type of transport therefore is stored in the electrochemical potential created by the concentration difference of S_2 across the plasma membrane. Depending on the transport direction of the solute, secondary active transporters are classified as either symporters or antiporters. *Symporters*, also termed *cotransporters*, transport S_2 and S_1 in the same direction, whereas *antiporters*, also termed *exchangers*, move their substrates in opposite directions (Figure 2-4).

KINETICS OF TRANSPORT

The flux of a substrate (rate of transport) across the plasma membrane *via* transporter-mediated processes is characterized by saturability. The relationship between the flux v and substrate concentration C in a transporter-mediated process is analogous to the rate of product formed by an enzyme and the concentration of substrate. The maximum transport rate (V_{\max}) is proportional to the density of transporters on the plasma membrane, and the K_m represents the substrate concentration at which the flux is half maximal. When C is small compared with the K_m , the flux is increased in proportion to the substrate concentration (roughly linearly). If C is large compared with the K_m value, the flux approaches the maximal value (V_{\max}). The K_m and V_{\max} values can be determined by examining the flux at different substrate concentrations.

Transporter-mediated membrane transport of a substrate is also characterized by inhibition by other compounds. As with enzyme or receptor inhibition, this inhibition can be categorized as one of three types: competitive, noncompetitive, and uncompetitive.

Competitive inhibition occurs when substrates and inhibitors share a common binding site on the transporter, resulting in an increase in the apparent K_m value. *Noncompetitive* inhibition occurs when the inhibitor allosterically affects the transporter in a manner that does not inhibit the formation of an intermediate complex of substrate and transporter but does inhibit the subsequent translocation process. *Uncompetitive* inhibition assumes that inhibitors form a complex only with an intermediate substrate-transporter complex and inhibit subsequent translocation.

VECTORIAL TRANSPORT

The SLC transporters mediate either drug uptake or efflux, whereas ABC transporters mediate only unidirectional efflux. Asymmetrical transport across a monolayer of polarized cells, such as the epithelial and endothelial cells of brain capillaries, is called *vectorial transport* (Figure 2–5). Vectorial transport is important in the efficient transfer of solutes across epithelial or endothelial barriers; it plays a major role in hepatobiliary and urinary excretion of drugs from the blood to the lumen and in the intestinal absorption of drugs and nutrients. In addition, efflux of drugs from the brain *via* brain endothelial cells and brain choroid plexus epithelial cells involves vectorial transport.

For lipophilic compounds with sufficient membrane permeability, ABC transporters alone can achieve vectorial transport by extruding their substrates to the outside of cells without the help of influx transporters. For relatively hydrophilic organic anions and cations, coordinated uptake and efflux transporters in the polarized plasma membranes are necessary to achieve the vectorial movement of solutes across an epithelium. Common substrates of coordinated transporters are transferred efficiently across the epithelial barrier. In the liver, a number of transporters with different substrate specificities are localized on the sinusoidal membrane (facing blood). These transporters are involved in the uptake of bile acids, amphipathic organic anions, and hydrophilic organic cations into hepatocytes. Similarly, ABC transporters on the canalicular membrane (facing bile) export such compounds into the bile. Overlapping substrate specificities between the uptake

FIGURE 2–5 *Trans epithelial or trans endothelial flux.* Transepithelial or transendothelial flux of drugs requires distinct transporters at the two surfaces of the epithelial or endothelial barriers. These are depicted diagrammatically for transport across the small intestine (absorption), the kidney and liver (elimination), and the brain capillaries that comprise the blood–brain barrier.

transporters (Na^+ /taurocholate cotransporting polypeptide [NTCP] and organic anion transporting polypeptide [OATP] family) and efflux transporters (BSEP, MRP2, P-glycoprotein, and BCRP) make the vectorial transport of organic anions highly efficient. Similar transport systems also are present in the intestine, renal tubules, and endothelial cells of the brain capillaries (Figure 2–5).

REGULATION OF TRANSPORTER EXPRESSION

*Transporter expression can be regulated transcriptionally in response to drug treatment and pathophysiological conditions, resulting in induction or down-regulation of transporter mRNAs. A number of nuclear receptors form heterodimers with the 9-cis-retinoic acid receptor (RXR) in regulating drug-metabolizing enzymes and transporters. Such receptors include pregnane X receptor (PXR/NR1I2), constitutive androstane receptor (CAR/NR1I3), farnesoid X receptor (FXR/NR1H4), peroxisome proliferator-activated receptor α (PPAR α), and retinoic acid receptor (RAR). Except for CAR, these are ligand-activated nuclear receptors that, as heterodimers with RXR, bind specific elements in the enhancer regions of target genes. CAR has constitutive transcriptional activity that is antagonized by inverse agonists such as androstenol and androstanol and induced by barbiturates. PXR (SXR in humans) is activated by synthetic and endogenous steroids, bile acids, and drugs such as clotrimazole, phenobarbital, rifampin, sulfapyrazone, ritonavir, carbamazepine, phenytoin, sulfadimidine, taxol, and hyperforin (a constituent of *St. John's wort*). Table 2–1 summarizes the effects of drug activation of nuclear receptors on transporter expression. There is an overlap of substrates between CYP3A4 and P-glycoprotein, and PXR mediates coinduction of CYP3A4 and P-glycoprotein, supporting their cooperation in efficient detoxification.*

TRANSPORTER SUPERFAMILIES IN THE HUMAN GENOME

SLC TRANSPORTERS The SLC superfamily includes 43 families and contains ~300 human genes. Many of these genes are associated with genetic diseases (Table 2–2). SLC transporters transport diverse ionic and nonionic endogenous compounds and xenobiotics, acting either as facilitated transporters or as secondary active symporters or antiporters.

ABC SUPERFAMILY The ABC superfamily consists of 49 genes, each containing one or two conserved ABC regions. The ABC region—the core catalytic domain of ATP hydrolysis—contains Walker A and B sequences and an ABC transporter-specific signature C sequence. The ABC regions of these proteins bind and hydrolyze ATP, and the proteins use the energy for uphill transport of their substrates across the membrane. Although some ABC superfamily transporters contain only a single ABC motif, they form homodimers (BCRP/ABCG2) or heterodimers (ABCG5 and ABCG8) that exhibit a transport function. ABC transporters in prokaryotes are involved in the import of essential compounds that cannot be obtained by passive diffusion (e.g., sugars, vitamins, and metals). Most ABC genes in eukaryotes transport compounds from the cytoplasm to the outside or into an intracellular compartment (e.g., endoplasmic reticulum, mitochondria, and peroxisomes).

ABC transporters are divided into seven groups based on their sequence homology (Table 2–3). They are essential for many cellular processes, and mutations in at least 13 of the genes cause or contribute to human genetic disorders.

In addition to conferring multidrug resistance, an important pharmacological aspect of these transporters is xenobiotic export from healthy tissues. In particular, MDR1/ABCB1, MRP2/ABCC2, and BCRP/ABCG2 have been shown to be involved in overall drug disposition.

Properties of ABC Transporters Related to Drug Action

The tissue distribution of drug-related ABC transporters is summarized in Table 2–4, together with information about typical substrates.

TISSUE DISTRIBUTION OF DRUG-RELATED ABC TRANSPORTERS

MDR1 (ABCB1), MRP2 (ABCC2), and BCRP (ABCG2) are all expressed in the apical side of the intestinal epithelia, where they extrude xenobiotics, including many clinically relevant drugs. Key to the vectorial excretion of drugs into urine or bile, ABC transporters are expressed in polarized tissues, such as kidney and liver: MDR1, MRP2, and MRP4 (ABCC4) on the brush-border membrane of renal epithelia, and MDR1, MRP2, and BCRP on the bile canalicular membrane of hepatocytes. Some ABC transporters are expressed specifically on the blood side of the endothelial or epithelial cells that form barriers to the free entrance of toxic compounds into tissues: the BBB (MDR1 and MRP4 on the luminal side of brain capillary endothelial cells), the blood–cerebrospinal fluid (CSF) barrier (MRP1 and MRP4 on the basolateral blood side of choroid plexus epithelia), the blood–testis barrier (MRP1 on the basolateral membrane of mouse Sertoli

cells and *MDR1* in several types of human testicular cells), and the blood–placenta barrier (*MDR1*, *MRP2*, and *BCRP* on the luminal maternal side and *MRP1* on the antiluminal fetal side of placental trophoblasts).

MRP/ABCC Family

The substrates of transporters in the *MRP/ABCC* family are mostly organic anions. Both *MRP1* and *MRP2* accept glutathione and glucuronide conjugates, sulfated conjugates of bile salts, and nonconjugated organic anions of an amphipathic nature (at least one negative charge and some degree of hydrophobicity). They also transport neutral or cationic anticancer drugs, such as vinca alkaloids and anthracyclines, possibly via a cotransport or symport mechanism with reduced glutathione. *MRP3* also has a substrate specificity that is similar to that of *MRP2* but with a lower transport affinity for glutathione conjugates compared with *MRP1* and *MRP2*. *MRP3* is expressed on the sinusoidal side of hepatocytes and is induced under cholestatic conditions. *MRP3* functions to return toxic bile salts and bilirubin glucuronides into the blood circulation. *MRP4* and *MRP5* pump nucleotide analogs and clinically important anti–human immunodeficiency virus (HIV) drugs. No substrates for *MRP6* have been identified that explain *MRP6*-associated pseudoxanthoma.

ABC TRANSPORTERS IN DRUG ABSORPTION AND ELIMINATION

Systemic exposure to orally administered digoxin is increased by coadministration of *MDR1* inducers and negatively correlated with *MDR1* protein expression in the intestine. *MDR1* is also expressed on the brush-border membrane of renal epithelia, and its function can be monitored using digoxin (>70% excreted in the urine). *MDR1* inhibitors (e.g., quinidine, verapamil, vasopar, spironolactone, clarithromycin, and ritonavir) all markedly reduce renal digoxin excretion. In view of this, drugs with narrow therapeutic windows (e.g., digoxin) should be used with great care if *MDR1*-based drug–drug interactions are likely.

NOTE: Representative substrates and cytotoxic drugs with increased resistance (*) are included in this table (cytotoxicity with increased resistance is usually caused by the decreased accumulation of the drugs). Although MDR3 (ABCB4), BSEP (ABCB11), ABCG5, and ABCG8 are not directly involved in drug disposition, inhibition of these physiologically important ABC transporters will lead to unfavorable side effects.

Little clinically applicable information regarding MRP2 and BCRP drug-handling is available. Most MRP2 or BCRP substrates also can be transported by the OATP family transporters on the sinusoidal membrane.

GENETIC VARIATION IN MEMBRANE TRANSPORTERS: IMPLICATIONS FOR CLINICAL DRUG RESPONSE

Inherited disorders of membrane transport have been identified (Tables 2–2 and 2–3), and polymorphisms in membrane transporters that play a role in drug response are yielding new insights in pharmacogenetics (see Chapter 4). The most widely studied drug transporter is P-glycoprotein (MDR1, *ABCB1*); the *ABCB1* genotype is associated with responses to anticancer drugs, antiviral agents, immunosuppressants, antihistamines, cardiac glycosides, and anticonvulsants. *ABCB1* SNPs also have been associated with tacrolimus and nortriptyline neurotoxicity and susceptibility for developing ulcerative colitis, renal cell carcinoma, and Parkinson's disease.

TRANSPORTERS INVOLVED IN PHARMACOKINETICS

Hepatic Transporters

HMG-CoA REDUCTASE INHIBITORS

Statins are cholesterol-lowering agents that reversibly inhibit HMG-CoA reductase, which catalyzes a rate-limiting step in cholesterol biosynthesis (see Chapter 35). Most of the statins in the acid form are substrates of uptake transporters that mediate hepatic uptake and enterohepatic circulation (Figures 2–5 and 2–6). In this process, hepatic uptake transporters such as OATP1B1 and efflux transporters such as MRP2 cooperate to produce vectorial transcellular transport of bisubstrates in the liver. The efficient first-pass hepatic uptake of statins by OATP1B1 helps them to exert their pharmacological effect and also minimizes the systemic drug distribution, thereby minimizing adverse effects in smooth muscle. Recently, two common SNPs in *SLCO1B1* (OATP1B1) have been associated with elevated plasma levels of pravastatin.

DRUG-DRUG INTERACTIONS INVOLVING TRANSPORTER-MEDIATED HEPATIC UPTAKE Transporter-mediated hepatic uptake can cause drug-drug interactions among drugs that are actively taken up into the liver and metabolized and/or excreted in the bile. When an inhibitor of drug-metabolizing enzymes is highly concentrated in hepatocytes by active transport,

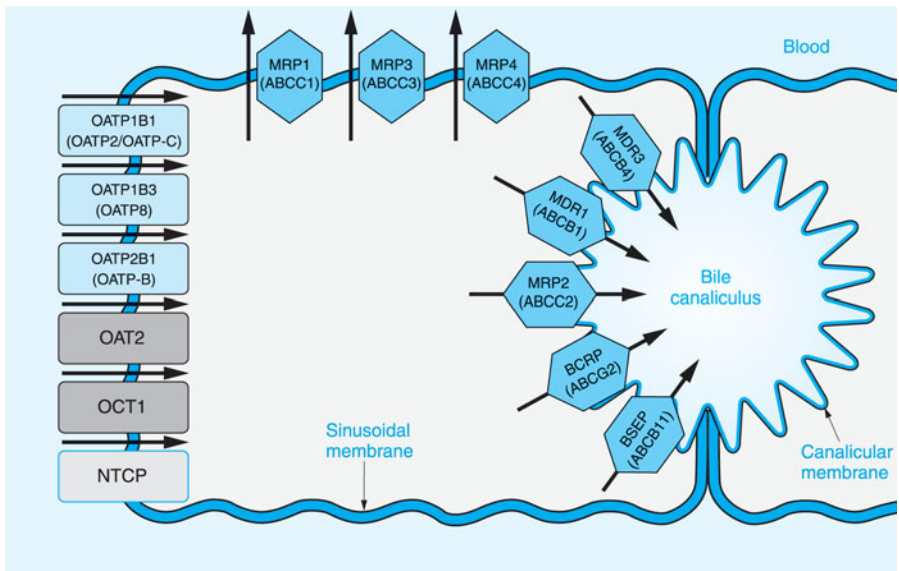

FIGURE 2–6 Transporters in the hepatocyte that function in the uptake and efflux of drugs across the sinusoidal membrane and efflux of drugs into the bile across the canalicular membrane. See text for details of the transporters pictured.

extensive inhibition of the drug-metabolizing enzymes may be observed because of the high concentration of the inhibitor in the vicinity of the drug-metabolizing enzymes.

Renal Transporters

ORGANIC CATION TRANSPORT Structurally diverse organic cations are secreted in the proximal tubule. Many secreted organic cations are endogenous compounds (e.g., choline, *N*-methylnicotinamide, and dopamine), and renal secretion appears to be important in eliminating excess concentrations of these substances. However, a primary function of organic cation secretion is to rid the body of xenobiotics, including many positively charged drugs and their metabolites (e.g., *cimetidine*, *ranitidine*, metformin, *procaïnamide*, and *N-acetylprocaïnamide*), and toxins from the environment (e.g., *nicotine*). Organic cations that are secreted by the kidney may be either hydrophobic or hydrophilic. Hydrophilic organic drug cations generally have molecular weights of <400; a current model for their secretion in the proximal tubule of the nephron is shown in Figure 2–7.

For the transepithelial flux of a compound (e.g., secretion), it is essential for the compound to traverse two membranes sequentially, the basolateral membrane facing the blood side and the apical membrane facing the tubular lumen. Distinct transporters on each membrane mediate the sequential steps of transport. Organic cations cross the basolateral membrane by three distinct transporters in the SLC family 22 (SLC22): OCT1 (SLC22A1), OCT2 (SLC22A2), and OCT3 (SLC22A3). Organic cations are transported across this membrane down their electrochemical gradient (–70 mV). The SLC22 members have 12 putative transmembrane domains with N-linked glycosylation sites.

Transport of organic cations from cell to tubular lumen across the apical membrane occurs via an electroneutral proton–organic cation exchange mechanism. Transporters on the apical

Circles show transporters in the same family, SLC22A4 (OCTN1) and SLC22A5 (OCTN2). MDR1 (ABCB1) is depicted as a dark blue oval. Carn, carnitine; OC⁺, organic cation.

membrane are in the SLC22 family and termed novel organic cation transporters (OCTNs) OCTN1 (SLC22A4) and OCTN2 (SLC22A5). These bifunctional transporters mediate both organic cation secretion and carnitine reabsorption. In the reuptake mode, the transporters function as Na^+ cotransporters, relying on the inwardly driven Na^+ gradient created by Na^+, K^+ -ATPase to move carnitine from tubular lumen into the cell. In the secretory mode, the transporters function as proton–organic cation exchangers: protons move from tubular lumen to cell interior in exchange for organic cations, which move from cytosol to tubular lumen.

OCT1 has four splice variants, one of which is functionally active, OCT1G/L554. OCT1 is expressed primarily in the liver, with some expression in heart, intestine, and skeletal muscle. In humans, very modest levels of OCT1 transcripts are detected in the kidney. The transport mechanism of OCT1 is electrogenic and saturable for transport of small-molecular-weight organic cations including tetraethylammonium (TEA) and dopamine. OCT1 also can mediate organic cation–organic cation exchange. Organic cations can trans-inhibit OCT1. When present on the cytosolic side of a membrane, the hydrophobic organic cations quinine and quinidine, which are poor substrates of OCT1, can trans-inhibit influx of organic cations via OCT1.

Human OCT1 (SLC22A1) accepts a wide array of monovalent organic cations with molecular weights of <400, including many drugs (e.g., procainamide, metformin, and pindolol). Inhibitors of OCT1 are generally more hydrophobic. Since OCT1 mammalian orthologs have >80% amino acid identity, evolutionarily nonconserved residues among mammalian species clearly are involved in specificity differences.

OCT2 is located adjacent to OCT1 on chromosome 6 (6q26). A single splice variant of human OCT2, termed OCT2-A, in the kidney is a truncated form of OCT2 that appears to have a lower K_m for substrates than OCT2. In the kidney, OCT2 is localized to the proximal tubule, distal tubules, and collecting ducts. In the proximal tubule, OCT2 is restricted to the basolateral membrane. The transport mechanism of OCT2 is similar to that of OCT1.

Like OCT1, OCT2 generally accepts a wide array of monovalent organic cations with molecular weights of <400. OCT2 is also present in neuronal tissues and may play a housekeeping role in neurons, taking up excess concentrations of neurotransmitters and recycling neurotransmitters by taking up breakdown products that then reenter monoamine synthetic pathways.

Human OCT3 is expressed in the liver, kidney (weakly), intestine, and placenta. Like OCT1 and OCT2, OCT3 appears to support electrogenic potential-sensitive organic cation transport. Some studies have suggested that OCT3 is the extraneuronal monoamine transporter based on its substrate specificity and potency of interaction with monoamine neurotransmitters. Because of its relatively low abundance in the kidney, OCT3 may play only a limited role in renal drug elimination.

OCTN1 (SLC22A4) is expressed in the kidney, trachea, and bone marrow and operates as an organic cation–proton exchanger. OCTN1 likely functions as a bidirectional pH- and ATP-dependent transporter at the apical membrane in renal tubular epithelial cells.

OCTN2 (SLC22A5) is expressed predominantly in the renal cortex, with very little expression in the medulla, and is localized to the apical membrane of the proximal tubule. OCTN2 transports L-carnitine with high affinity in a Na^+ -dependent manner, whereas, Na^+ does not influence OCTN2-mediated transport of organic cations. Thus, OCTN2 is thought to function as both a Na^+ -dependent carnitine transporter and a Na^+ -independent organic cation transporter. Mutations in OCTN2 cause primary systemic carnitine deficiency.

ORGANIC ANION TRANSPORT Structurally diverse organic anions are secreted in the proximal tubule. The primary function of organic anion secretion appears to be the removal from the body of xenobiotics, including many weakly acidic drugs (e.g., pravastatin, captopril, p-aminohippurate [PAH], and penicillins) and toxins (e.g., ochratoxin).

Two primary transporters on the basolateral membrane (Figure 2–8) mediate the flux of organic anions from interstitial fluid to tubule cells: OAT1 (SLC22A6) and OAT3 (SLC22A8). Hydrophilic organic anions are transported across the basolateral membrane against an electrochemical gradient in exchange with intracellular α -ketoglutarate, which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α -ketoglutarate is maintained by a basolateral Na^+ -dicarboxylate transporter (NaDC3). The Na^+ gradient that drives NaDC3 is maintained by Na^+, K^+ -ATPase.

TRANSPORTERS INVOLVED IN PHARMACODYNAMICS: DRUG ACTION IN THE BRAIN

Neurotransmitters are packaged in vesicles in presynaptic neurons, released in the synapse by vesicle fusion with the plasma membrane, and—except for acetylcholine—are then taken back into the presynaptic neurons or postsynaptic cells (see Chapter 6). Transporters involved in the neuronal

reuptake of neurotransmitters and the regulation of their levels in the synaptic cleft belong to two major superfamilies, SLC1 and SLC6. Transporters in both families play roles in reuptake of γ -aminobutyric acid (GABA), glutamate, and the monoamine neurotransmitters norepinephrine, serotonin, and dopamine. These transporters may serve as pharmacologic targets for neuropsychiatric drugs.

SLC6 family members localized in the brain and involved in neurotransmitter reuptake into presynaptic neurons include the norepinephrine transporter (NET, *SLC6A2*), the dopamine transporter (DAT, *SLC6A3*), the serotonin transporter (SERT, *SLC6A4*), and several GABA reuptake transporters (GAT1, GAT2, and GAT3). Each of these transporters appears to have 12 transmembrane domains and a large extracellular loop with glycosylation sites between transmembrane domains 3 and 4. Typically, these proteins are ~600 amino acids in length. SLC6 family members depend on the Na⁺ gradient to actively transport their substrates into cells. Cl⁻ is also required, although to a variable extent depending on the family member.

Through reuptake mechanisms, the neurotransmitter transporters in the SLC6A family regulate the concentrations and persistence of neurotransmitters in the synaptic cleft; the extent of transmitter uptake also influences subsequent vesicular storage of transmitters. Further, the transporters can function in the reverse direction by exporting neurotransmitters in a Na⁺-independent fashion. Many of these transporters also are present in other tissues (e.g., kidney and platelets), where they may serve other roles.

SLC6A1 (GAT1), SLC6A11 (GAT3), AND SLC6A13 (GAT2) GAT1 is the most important GABA transporter in the brain; it predominantly is expressed in presynaptic GABAergic neurons. GAT1 is found in abundance in the neocortex, cerebellum, basal ganglia, brainstem, spinal cord,

retina, and olfactory bulb. GAT3 is found only in the brain, largely in glial cells. GAT2 is found in peripheral tissues, including the kidney and liver, and in the choroid plexus and meninges within the CNS. The presence of GAT2 in the choroid plexus and its absence in presynaptic neurons suggest that this transporter may play a primary role in maintaining GABA homeostasis in the CSF. GAT1 is the target of the antiepileptic drug *tiagabine*, which presumably acts to increase GABA levels in the synaptic cleft of GABAergic neurons by inhibiting the reuptake of GABA. GAT3 is the target for the nipecotic acid derivatives that are anticonvulsants.

SLC6A2 (NET) NET is expressed in central and peripheral nervous tissues and adrenal chromaffin cells. In the brain, NET colocalizes with neuronal markers, consistent with a role in reuptake of monoamine neurotransmitters. The transporter functions in the Na⁺-dependent reuptake of norepinephrine and dopamine and as a higher-capacity norepinephrine channel. A major role of NET is to limit the synaptic dwell time of norepinephrine and to terminate its actions, salvaging norepinephrine for subsequent repackaging. NET participates in the regulation of many neurological functions, including memory and mood. NET is a drug target for the antidepressant *desipramine*, other tricyclic antidepressants, and *cocaine*. Orthostatic intolerance, a rare familial disorder characterized by an abnormal blood pressure and heart rate response to postural changes, has been associated with a mutation in NET.

SLC6A3 (DAT) DAT is located primarily in the brain in dopaminergic neurons. The primary function of DAT is the reuptake of dopamine, terminating its actions. Although present on presynaptic neurons at the synaptic junction, DAT is also present in abundance away from the synaptic cleft, suggesting that DAT may play a role in clearing excess dopamine in the vicinity of neurons. Physiologically, DAT is involved in the various functions that are attributed to the dopaminergic system, including mood, behavior, reward, and cognition. Drugs that interact with DAT include cocaine and its analogs, *amphetamines*, and the neurotoxin *MPTP*.

SLC6A4 (SERT) SERT plays a role in the reuptake and clearance of serotonin in the brain. Like the other SLC6A family members, SERT transports its substrates in a Na⁺-dependent fashion and is dependent on Cl⁻ and possibly on the countertransport of K⁺. Substrates of SERT include serotonin (5-HT), various tryptamine derivatives, and neurotoxins such as *3,4-methylenedioxymethamphetamine* (MDMA; ecstasy) and *fenfluramine*. SERT is the specific target of the selective serotonin reuptake inhibitors (*e.g.*, *fluoxetine* and *paroxetine*) and one of several targets of tricyclic antidepressants (*e.g.*, *amitriptyline*). Genetic variants of SERT have been associated with an array of behavioral and neurological disorders. The precise mechanism by which a reduced activity of SERT, caused by either a genetic variant or an antidepressant, ultimately affects mood and behavior is not known.

BLOOD–BRAIN AND BLOOD–CSF BARRIERS

Drugs acting in the CNS must either cross the BBB or the blood–CSF barrier, which are formed by brain capillary endothelial cells or epithelial cells of the choroid plexus, respectively. Efflux transporters play a role in these dynamic barriers. P-glycoprotein extrudes its substrate drugs on the luminal membrane of the brain capillary endothelial cells into the blood, complicating CNS therapy for some drugs (*see* Chapter 1). Other transporters in the BBB and the blood–CSF barrier include members of organic anion transporting polypeptide (OATP1A4 and OATP1A5) and organic anion transporter (OAT3) families, which facilitate the uptake of organic compounds such as β -lactam antibiotics, statins, PAH, H₂-receptor antagonists, and bile acids on the plasma membrane facing the brain–CSF. Further understanding of influx and efflux transporters in these barriers should translate into more effective delivery of drugs to the CNS while avoiding undesirable CNS side effects and may help to define the mechanisms of drug–drug interactions and interindividual differences in the therapeutic CNS effects.

DRUG METABOLISM

Substances foreign to the body, or xenobiotics, are metabolized by the same enzymatic pathways and transport systems that are utilized for dietary constituents. Xenobiotics to which humans are exposed include environmental pollutants, food additives, cosmetic products, agrochemicals, processed foods, and drugs. Many xenobiotics are lipophilic chemicals that, in the absence of metabolism, would not be efficiently eliminated and would accumulate in the body, possibly causing toxicity. Most xenobiotics are subjected to metabolic pathways that convert these hydrophobic chemicals into more hydrophilic derivatives that are readily eliminated in urine or bile.

The processes of drug metabolism that lead to elimination also play a major role in diminishing the biological activity of drugs. For example, *phenytoin*, an anticonvulsant used in the treatment of epilepsy, is virtually insoluble in water. Metabolism by phase 1 cytochrome P450 enzymes (CYPs) makes 4-OH-phenytoin, which is a substrate for phase 2 uridine diphosphate-glucuronosyltransferases (UGTs) that produce a water soluble 4-glucuronate adduct that is readily eliminated. Metabolism also terminates the biological activity of the drug.

Paradoxically, these same enzymes can also convert certain chemicals to highly reactive toxic and carcinogenic metabolites. Depending on the structure of the chemical substrate, xenobiotic-metabolizing enzymes produce electrophilic metabolites that can react with nucleophilic cellular macromolecules such as DNA, RNA, and protein. Reaction of these electrophiles with DNA can sometimes result in cancer through the mutation of genes such as oncogenes or tumor suppressor genes. This potential for carcinogenic activity makes testing the safety of drug candidates of vital importance, particularly for drugs that will be used chronically.

THE PHASES OF DRUG METABOLISM Xenobiotic metabolism consists of phase 1 reactions (oxidation, reduction, or hydrolytic reactions) and phase 2 reactions, in which enzymes form a conjugate of the phase 1 product (Table 3–1). Phase 1 enzymes introduce functional groups (*e.g.*, -OH, -COOH, -SH, -O-, or NH_2) into the compound; these moieties do little to increase the water solubility of the drug but usually lead to drug inactivation. Metabolism, usually the hydrolysis of an ester or amide linkage, sometimes results in bioactivation of a drug. Inactive drugs that undergo metabolism to an active drug are called *prodrugs*. The antitumor drug *cyclophosphamide* is bioactivated to a cell-killing electrophilic derivative (*see* Chapter 51). Phase 2 enzymes facilitate the elimination of drugs and the inactivation of electrophilic and potentially toxic metabolites produced by oxidation. While many phase 1 reactions result in drug inactivation, phase 2 reactions produce a metabolite with improved water solubility and increased molecular weight, thereby facilitating drug elimination.

Phase 1 oxidation reactions are catalyzed by the superfamilies of CYPs, flavin-containing monooxygenases (FMOs), and epoxide hydrolases (EHs). The CYPs and FMOs comprise superfamilies containing multiple genes. The phase 2 enzymes include several superfamilies of conjugating enzymes, such as the glutathione-S-transferases (GSTs), UDP-glucuronosyltransferases (UGTs), sulfotransferases (SULTs), *N*-acetyltransferases (NATs), and methyltransferases (MTs). These conjugation reactions usually require the substrate to have oxygen (hydroxyl or epoxide groups), nitrogen, or sulfur atoms that serve as acceptor sites for a hydrophilic moiety (*e.g.*, glutathione, glucuronic acid, sulfate, or an acetyl group) that is covalently conjugated to an acceptor site on the molecule, as in the example of phenytoin. In general, oxidation by phase 1 enzymes either adds or exposes a functional group, permitting the products to then serve as substrates for phase 2 conjugating or synthetic enzymes.

SITES OF DRUG METABOLISM Xenobiotic-metabolizing enzymes are expressed in most tissues in the body; the highest levels are found in the gastrointestinal (GI) tract (*e.g.*, liver, small intestine, and colon). The high concentration of xenobiotic-metabolizing enzymes in GI epithelium mediates the initial metabolic processing of most oral drugs and is the initial site for first-pass metabolism of drugs. Absorbed drug then enters the portal circulation and transits to the liver, which is the major “metabolic clearing house” for both endogenous chemicals (*e.g.*, cholesterol, steroid hormones, fatty acids, and proteins) and xenobiotics. While some active drug may escape first-pass metabolism in the GI tract and liver, subsequent passes through the liver result in further metabolism of the parent drug until it is eliminated. Other organs that contain significant xenobiotic-metabolizing enzymes include the nasal mucosa and lung, which play important roles in the first-pass metabolism of airborne pollutants and of drugs that are administered as aerosols.

Xenobiotic Metabolizing Enzymes

Enzymes	Reactions
<i>Phase 1 “oxygenases”</i>	
Cytochrome P450s (P450 or CYP)	C and O oxidation, dealkylation, others
Flavin-containing monooxygenases (FMO)	N, S, and P oxidation
Epoxide hydrolases (mEH, sEH)	Hydrolysis of epoxides
<i>Phase 2 “transferases”</i>	
Sulfotransferases (SULT)	Addition of sulfate
UDP-glucuronosyltransferases (UGT)	Addition of glucuronic acid
Glutathione-S-transferases (GST)	Addition of glutathione
<i>N</i> -acetyltransferases (NAT)	Addition of acetyl group
Methyltransferases (MT)	Addition of methyl group
<i>Other enzymes</i>	
Alcohol dehydrogenases	Reduction of alcohols
Aldehyde dehydrogenases	Reduction of aldehydes
NADPH-quinone oxidoreductase (NQO)	Reduction of quinones

mEH and sEH are microsomal and soluble epoxide hydrolase. UDP, uridine diphosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

The phase 1 CYPs, FMOs, and EHs, and some phase 2 conjugating enzymes, notably the UGTs, are located in the endoplasmic reticulum (ER) of the cell (Figure 3-1). The ER lumen is physically distinct from the rest of the cytosolic components and is ideally suited for the metabolic function of these enzymes: hydrophobic molecules enter the cell and embed in the lipid bilayer, where they encounter the phase 1 enzymes. Once oxidized, drugs are conjugated in the membrane by the UGTs

FIGURE 3-1 Location of CYPs in the cell. The figure shows increasingly microscopic levels of detail, sequentially expanding the areas within the black boxes. CYPs are embedded in the phospholipid bilayer of the endoplasmic reticulum (ER). Most of the enzyme is located on the cytoplasmic surface of the ER. A second enzyme, NADPH-cytochrome P450 oxidoreductase, transfers electrons to the CYP where it can, in the presence of O_2 , oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single NADPH-CYP oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains a molecule of iron-protoporphyrin IX that functions to bind and activate O_2 . Substituents on the porphyrin ring are methyl (M), propionyl (P), and vinyl (V) groups.

or by the cytosolic transferases such as GST and SULT. The metabolites are then transported out of the cell and into the bloodstream. Hepatocytes, which constitute >90% of the cells in the liver, carry out most drug metabolism and produce conjugated substrates that can also be transported through the bile canalicular membrane into the bile for elimination in the gut (*see* Chapter 2).

THE CYPs CYPs are heme proteins (Figure 3–1). The heme iron binds oxygen in the CYP active site, where oxidation of substrates occurs. Electrons are supplied by the enzyme NADPH-cytochrome P450 oxidoreductase and its cofactor, NADPH. Metabolism of a substrate by a CYP consumes one molecule of O₂ and produces an oxidized substrate and a molecule of water. Depending on the nature of the substrate, the reaction for some CYPs is partially “uncoupled,” consuming more O₂ than substrate metabolized and producing “activated oxygen” or O₂⁻. The O₂⁻ is usually converted to water by the enzyme superoxide dismutase.

Among the diverse reactions carried out by mammalian CYPs are *N*-dealkylation, *O*-dealkylation, aromatic hydroxylation, *N*-oxidation, *S*-oxidation, deamination, and dehalogenation (Table 3–2). CYPs are involved in the metabolism of dietary and xenobiotic agents, as well as the synthesis of endogenous compounds that are derived from cholesterol (*e.g.*, steroid hormones and bile acids).

The CYPs that carry out xenobiotic metabolism have the capacity to metabolize a large number of structurally diverse chemicals. This is due both to multiple forms of CYPs and to the capacity of a single CYP to metabolize structurally dissimilar chemicals. A single compound can be metabolized by multiple CYPs and CYPs can metabolize a single compound at multiple positions. This promiscuity of CYPs (Table 3–2), due to their large and fluid substrate binding sites, occurs at the cost of relatively slow catalytic rates. Eukaryotic CYPs metabolize substrates at a fraction of the rate of more typical enzymes involved in intermediary metabolism and mitochondrial electron transfer. As a result, drugs generally have half-lives in the range of 3–30 hours, while endogenous compounds have half-lives of seconds to minutes.

The broad substrate specificity of CYPs is one of the underlying reasons for the high frequency of drug interactions. When two coadministered drugs are both metabolized by a single CYP, they compete for binding to the enzyme’s active site. This can result in the inhibition of metabolism of one or both of the drugs, leading to elevated plasma levels. For drugs with a narrow therapeutic index, the elevated serum levels may elicit unwanted toxicities. Drug-drug interactions are among the leading causes of adverse drug reactions.

THE NAMING OF CYPs

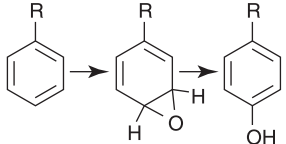

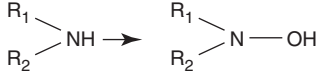

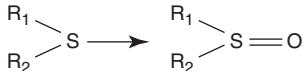

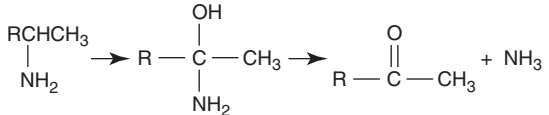

There are 57 functional CYP genes and 58 pseudogenes in humans. These genes are grouped into families and subfamilies. CYPs are named with the root “CYP” followed by a number designating the family, a letter denoting the subfamily, and a second number designating the CYP isoform. Thus, CYP3A4 is family 3, subfamily A, and gene number 4. In humans, 12 CYPs in families 1–3 (CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5) are primarily responsible for xenobiotic metabolism. The liver contains the greatest abundance of xenobiotic-metabolizing CYPs; CYPs also are expressed throughout the GI tract, and, in lower amounts, in lung, kidney, and the central nervous system (CNS). The most important CYPs for drug metabolism are those in the CYP2C, CYP2D, and CYP3A subfamilies. CYP3A4—the most abundantly expressed—is involved in the metabolism of ~50% of clinically used drugs (Figure 3–2A). The CYP1A, CYP1B, CYP2A, CYP2B, and CYP2E subfamilies are rarely involved in the metabolism of therapeutic drugs, but they catalyze the metabolic activation of many protoxins and procarcinogens.

There are large interindividual variations in CYP activity due to genetic polymorphisms and differences in gene regulation (see below). Several human CYP genes exhibit polymorphisms, including CYP2A6, CYP2C9, CYP2C19, and CYP2D6.

DRUG-DRUG INTERACTIONS Interactions at the level of drug metabolism form the basis of many drug interactions. Most commonly, an interaction occurs when two drugs (*e.g.*, a statin and a macrolide antibiotic or antifungal) are metabolized by the same enzyme and affect each other’s metabolism. Thus, it is important to determine the identity of the CYP that metabolizes a particular drug and to avoid coadministering drugs that are metabolized by the same CYP. Some drugs can also inhibit CYPs independently of being substrates. For example, the common antifungal agent, *ketoconazole* (NIZORAL) is a potent inhibitor of CYP3A4 and other CYPs. Coadministration of ketoconazole with the anti-HIV viral protease inhibitors reduces the clearance of the protease inhibitor and increases its plasma concentration and the risk of toxicity. For most drugs, the package insert lists the CYP that carries out its metabolism and notes the potential for drug interactions. Some drugs are CYP inducers that can induce not only their own metabolism but also the metabolism of coadministered

drugs (*see* below and Figure 3–5). Steroid hormones and herbal products such as St. John's wort can increase hepatic levels of CYP3A4, thereby increasing the metabolism of many drugs. Drug metabolism can also be influenced by diet. CYP inhibitors and inducers are commonly found in foods and in some cases these can influence drug toxicity and efficacy. Components of grapefruit juice are potent inhibitors of CYP3A4; thus, drug inserts may warn that taking a medication with grapefruit juice could increase the drug's bioavailability. The antihistamine *terfenadine* was withdrawn from the market because its metabolism was blocked by CYP3A4 substrates such as *erythromycin* and grapefruit juice. Terfenadine is a prodrug that requires oxidation by CYP3A4 to its active metabolite, and at high doses the parent compound causes arrhythmias. Thus, elevated levels of parent drug in the plasma as a result of CYP3A4 inhibition caused ventricular tachycardia in some individuals. Interindividual differences in drug metabolism are significantly influenced by polymorphisms in CYPs. The CYP2D6 polymorphism has led to the withdrawal of several drugs (*e.g.*, *debrisoquine* and *perhexiline*) and the cautious use of others that are CYP2D6 substrates (*e.g.*, *encainide* and *flecainide* [antiarrhythmics], *desipramine* and *nortriptyline* [antidepressants], and *codeine*).

FLAVIN-CONTAINING MONOOXYGENASES (FMOs) FMOs are another superfamily of phase 1 enzymes that are expressed at high levels in the liver and localized to the ER. There are six families of FMOs, with FMO3 being most abundant in liver. FMOs are minor contributors to drug metabolism and generally produce benign metabolites. FMOs are not induced by any of the xenobiotic receptors (*see* below) or easily inhibited; thus, in distinction to CYPs, FMOs are less involved in drug interactions. This distinction has practical consequences, as illustrated by two drugs used in the control of gastric motility, *itopride* and *cisapride*. Itopride is metabolized by FMO3; cisapride is metabolized by CYP3A4. Thus, itopride is less likely to be involved in drug interactions than is cisapride. CYP3A4 participates in drug interactions through induction and inhibition of metabolism, whereas FMO3 is not induced or inhibited by any clinically used drugs (although FMOs may become important as new drugs are developed). FMO3 metabolizes nicotine as well as H₂-receptor antagonists (*cimetidine* and *ranitidine*), antipsychotics (*clozapine*), and antiemetics (*itopride*).

HYDROLYTIC ENZYMES Epoxides are highly reactive electrophiles that can bind to cellular nucleophiles found in protein, RNA, and DNA, resulting in cell toxicity and transformation. Two forms of *epoxide hydrolase* (EH) hydrolyze epoxides produced by CYPs: a soluble form (sEH) is expressed in the cytosol and a microsomal form (mEH) is localized to the ER membrane. These EHs participate in the deactivation of potentially toxic derivatives generated by CYPs. The antiepileptic drug *carbamazepine* (Chapter 19) is a prodrug that is converted to its pharmacologically active derivative, *carbamazepine-10,11-epoxide* by CYP3A4. This metabolite is efficiently hydrolyzed by mEH to a dihydrodiol, resulting in drug inactivation. The tranquilizer *valnoctamide* and anticonvulsant *valproic acid* inhibit mEH, resulting in clinically significant drug interactions with carbamazepine by causing elevations of the active derivative. This has led to the development of new antiepileptic drugs (*e.g.*, *gabapentin* and *levetiracetam*) that are metabolized by CYPs but not by EHs.

The *carboxylesterase* superfamily catalyzes the hydrolysis of ester- and amide-containing compounds. These enzymes are found in both the ER and cytosol of many cell types and are involved in detoxification or metabolic activation of drugs, environmental toxins, and carcinogens. Carboxylesterases also catalyze the activation of prodrugs to their respective free acids. For example, the prodrug and cancer chemotherapeutic agent *irinotecan* is bioactivated by plasma and intracellular carboxylesterases to the potent topoisomerase inhibitor SN-38.

PHASE 2 METABOLISM: CONJUGATING ENZYMES The phase 2 conjugation reactions are synthetic in nature. The contributions of different phase 2 reactions to drug metabolism are shown in Figure 3–2B. Two of the reactions, glucuronidation and sulfation, result in the formation of metabolites with significantly increased hydrophilicity. Glucuronidation also markedly increases the molecular weight of the compound, which favors biliary excretion. Characteristic of the phase 2 reactions is the participation of cofactors such as UDP-glucuronic acid (UDP-GA) for UGTs and 3'-phosphoadenosine-5'-phosphosulfate (PAPS) for SULTs; these cofactors react with functional groups on the substrates that often are generated by the phase 1 CYPs. With the exception of glucuronidation, which is localized to the luminal side of the ER, all phase 2 reactions are carried out in the cytosol. The catalytic rates of phase 2 reactions are significantly faster than the rates of the CYPs. Thus, if a drug is targeted for phase 1 oxidation through the CYPs followed by a phase 2 conjugation reaction, the rate of elimination usually will depend on the phase 1 reaction.

FIGURE 3–2 The fraction of clinically used drugs metabolized by the major phase 1 and phase 2 enzymes. The relative size of each pie section represents the estimated percentage of drugs metabolized by the major phase 1 (panel **A**) and phase 2 (panel **B**) enzymes. In some cases, more than a single enzyme is responsible for metabolism of a single drug. CYP, cytochrome P450; DPYD, dihydropyrimidine dehydrogenase; GST, glutathione-S-transferase; NAT, N-acetyltransferase; SULT, sulfotransferase, TPMT, thiopurine methyltransferase; UGT, UDP-glucuronosyltransferase.

GLUCURONIDATION UGTs catalyze the transfer of glucuronic acid from the cofactor UDP-GA to a substrate to form β -D-glucopyranosiduronic acids (glucuronides), metabolites that are sensitive to cleavage by β -glucuronidase. The generation of glucuronides can be formed through alcoholic and phenolic hydroxyl groups, carboxyl, sulfuryl, and carbonyl moieties, as well as through primary, secondary, and tertiary amine linkages. Examples of glucuronidation reactions are shown in Table 3–2. The broad specificity of UGTs assures that most clinically used drugs are excreted as glucuronides. There are 19 human genes that encode the UGT proteins; nine are encoded by the *UGT1* locus on chromosome 2; ten are encoded by the *UGT2* gene cluster on chromosome 4. Both families of proteins are involved in the metabolism of drugs and xenobiotics, while the UGT2 family appears to have greater specificity for the glucuronidation of endogenous substances such as steroids.

UGTs are expressed in a tissue-specific and often inducible fashion, with the highest concentration in the GI tract and liver. Based upon their physicochemical properties, glucuronides are excreted by the kidneys into the urine or through active transport processes through the apical surface of the liver hepatocytes into the bile ducts and thence to the duodenum with bile. Many drugs that are glucuronidated and excreted in the bile reenter the circulation by “enterohepatic recirculation”: β -D-glucopyranosiduronic acids are targets for β -glucuronidase activity found in strains of

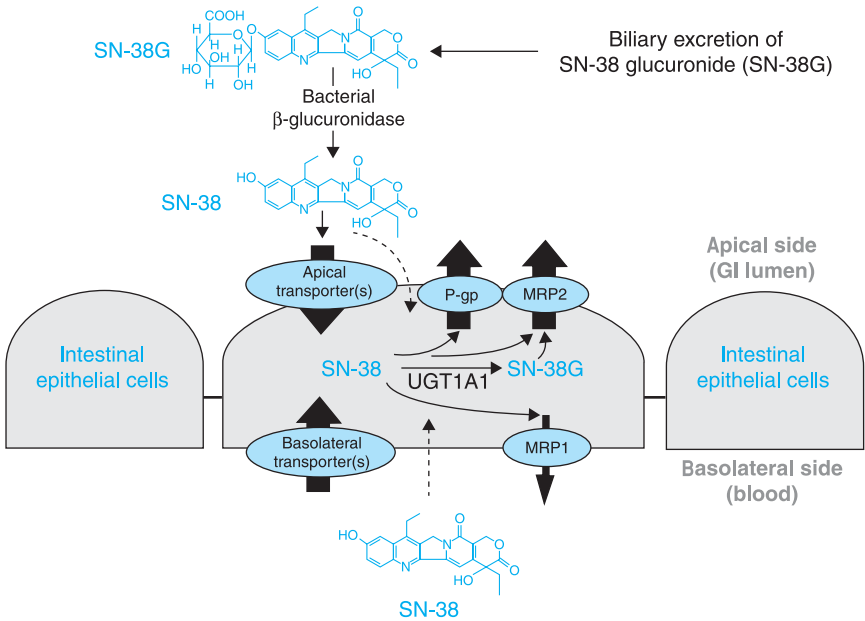

FIGURE 3–3 Routes of SN-38 transport and exposure to intestinal epithelial cells. SN-38 is transported into the bile following glucuronidation by liver UGT1A1 and extrahepatic UGT1A7. Following cleavage of luminal SN-38 glucuronide (SN-38G) by bacterial β -glucuronidase, reabsorption into epithelial cells can occur by passive diffusion (indicated by the dashed arrows entering the cell) as well as by apical transporters. Movement into epithelial cells may also occur from the blood by basolateral transporters. Intestinal SN-38 can efflux into the lumen through P-glycoprotein (P-gp) and multidrug resistance protein 2 (MRP2) and into the blood via MRP1. Excessive accumulation of the SN-38 in intestinal epithelial cells, resulting from reduced glucuronidation, can lead to cellular damage and toxicity.

bacteria that are common in the lower GI tract; the result is the liberation of free drug into the intestinal lumen; free drug is transported by passive diffusion or through apical transporters back into the intestinal epithelial cells, and enters the portal circulation (Figure 3–3).

UGT1A1 is of great importance in drug metabolism. For instance, the glucuronidation of bilirubin by UGT1A1 is the rate-limiting step in assuring efficient bilirubin clearance; this rate can be affected by both genetic variation and competing substrates (drugs). Bilirubin is the breakdown product of heme, 80% of which originates from circulating hemoglobin and 20% from other heme-containing proteins such as the CYPs. Bilirubin must be metabolized further by glucuronidation to assure its elimination. The failure to efficiently metabolize bilirubin by glucuronidation leads to elevated serum levels (hyperbilirubinemia). There are more than 50 genetic lesions in the UGT1A1 gene that can lead to inherited unconjugated hyperbilirubinemia. Two UGT1A1 deficiencies are Crigler-Najjar syndrome type I, diagnosed as a complete lack of bilirubin glucuronidation, and Crigler-Najjar syndrome type II, differentiated by the detection of low amounts of bilirubin glucuronides in duodenal secretions. These rare syndromes result from mutations in the UGT1A1 gene and the consequent production of little or no functional UGT1A1 protein.

Gilbert's syndrome is a generally benign condition, present in up to 10% of the population, that is diagnosed clinically because circulating bilirubin levels are 60–70% higher than those in normal subjects. The most common genetic polymorphism associated with Gilbert's syndrome is a mutation in the UGT1A1 gene promoter, which leads to reduced expression of UGT1A1. Subjects with Gilbert's syndrome may be predisposed to adverse drug reactions resulting from a reduced capacity to metabolize drugs by UGT1A1. In these patients, there is competition for drug metabolism with bilirubin glucuronidation, resulting in pronounced hyperbilirubinemia as well as reduced formation of the glucuronide metabolites of drugs. Gilbert's syndrome alters patient responses to irinotecan. Irinotecan, a prodrug used in chemotherapy of solid tumors (see Chapter 51), is metabolized to its active form SN-38 by serum carboxylesterases. SN-38, a potent topoisomerase inhibitor, is inactivated by UGT1A1 and excreted in the bile (Figure 3–3). Once in

the lumen of the intestine, the SN-38 glucuronide undergoes cleavage by bacterial β -glucuronidase and reenters the circulation through intestinal absorption. Elevated levels of SN-38 in the blood lead to hematological toxicities characterized by leukopenia and neutropenia, and damage to the intestinal epithelial cells, resulting in severe diarrhea. Patients with Gilbert's syndrome who are receiving irinotecan therapy are predisposed to hematological and GI toxicities resulting from elevated serum levels of SN-38, the net result of insufficient UGT1A activity and consequent accumulation of a toxic drug in the GI epithelium.

SULFATION The sulfotransferases (SULTs) are located in the cytosol and conjugate sulfate derived from 3'-phosphoadenosine-5'-phosphosulfate (PAPS) to the hydroxyl groups of aromatic and aliphatic compounds. In humans, 11 SULT isoforms have been identified. SULTs metabolize a wide variety of endogenous and exogenous substrates and play important roles in normal human homeostasis. For example, SULT1B1 is the predominant form expressed in skin and brain, carrying out sulfation of cholesterol and thyroid hormones; cholesterol sulfate is an essential regulator of keratinocyte differentiation and skin development. SULT1A3 is highly selective for catecholamines, while estrogens are sulfated by SULT1E1 and dehydroepiandrosterone (DHEA) is sulfated by SULT2A1; as a consequence, significant fractions of circulating catecholamines, estrogens, iodothyronines, and DHEA exist in the sulfated form.

The SULT1 family isoforms are the major SULT forms involved in drug metabolism, with SULT1A1 being the most important. SULT1C2 and SULT1C4 are expressed abundantly in fetal tissues and decline in abundance in adults; little is known about their substrate specificities. SULT1E catalyzes the sulfation of endogenous and exogenous steroids, and has been found localized in liver as well as in hormone-responsive or producing tissues such as the testis, breast, adrenal gland, and placenta.

Metabolism of drugs through sulfation often leads to the generation of chemically reactive metabolites, where the sulfate is electron withdrawing and may be heterolytically cleaved, leading to the formation of an electrophilic cation. Examples of the generation by sulfation of a carcinogenic or toxic response in mutagenicity assays occur with chemicals derived from the environment or from food mutagens generated from well-cooked meat. Thus, it is important to understand whether human SULT polymorphisms are associated with cancers related to environmental exposure. Since SULT1A1 is the most abundant form in human tissues and displays broad substrate specificity, the polymorphic profiles associated with this gene and the onset of various human cancers are of considerable interest.

GLUTATHIONE CONJUGATION The glutathione-S-transferases (GSTs) catalyze the transfer of glutathione to reactive electrophiles, a function that serves to protect cellular macromolecules from interacting with electrophilic heteroatoms (-O, -N, and -S). The cosubstrate in the reaction is the tripeptide glutathione (γ -glutamic acid, cysteine, and glycine (see Figure 3-4). Cellular glutathione may be oxidized (GSSG) or reduced (GSH), and the ratio of GSH:GSSG is critical in maintaining a cellular environment in the reduced state. In addition to affecting xenobiotic

FIGURE 3-4 Glutathione as a cosubstrate in the conjugation of a drug or xenobiotic (X) by glutathione-S-transferase (GST).

conjugation with GSH, a severe reduction in GSH content can predispose cells to oxidative damage, a state linked to a number of disease states.

The formation of glutathione conjugate generates a thioether linkage of drug or xenobiotic to the cysteine moiety of the tripeptide. Since the concentration of glutathione in hepatic cells is high, typically in the 10 mM range, many drugs and xenobiotics can react nonenzymatically with glutathione. However, the GSTs have been found to comprise up to 10% of the total cellular protein, assuring efficient enzymic conjugation of glutathione to reactive electrophiles. The high concentration of GSTs also provides a reservoir of intracellular binding sites that facilitates non-covalent and sometimes covalent interactions with compounds that are not substrates for glutathione conjugation. The cytosolic pool of GSTs has been shown to bind steroids, bile acids, bilirubin, cellular hormones, and environmental toxicants, in addition to complexing with other cellular proteins.

The 20+ human GSTs are divided into two subfamilies that differ in their substrate specificities. The cytosolic forms predominate in the metabolism of drugs and xenobiotics, whereas the microsomal GSTs metabolize endogenous compounds such as leukotrienes and prostaglandins. Despite the apparent overcapacity of GSTs and GSH, there is always concern that some reactive intermediates will escape detoxification, bind to cellular components, and cause toxicity. The potential for such an occurrence is heightened if GSH is depleted or if a specific polymorphism of GST is less active. While it is difficult to deplete cellular GSH levels, drugs that require large doses to be clinically efficacious have the greatest potential to lower cellular GSH levels. Acetaminophen, which normally is metabolized by glucuronidation and sulfation, is also a substrate for oxidative metabolism by CYP2E1 to generate the toxic metabolite N-acetyl-p-benzoquinone imine (NAPQI). An overdose of acetaminophen can deplete cellular GSH levels, increase NAPQI levels, and enhance the potential for NAPQI to interact with other cellular components.

*The GSTs are all polymorphic, and several of the polymorphic forms express a null phenotype. Individuals who carry these polymorphisms are predisposed to toxicities by agents that are selective substrates for the GSTs. The allele GSTM1*0 is observed in 50% of the Caucasian population and has been associated with human malignancies of the lung, colon, and bladder. Null activity in the GSTT1 gene has been associated with adverse side effects and toxicity in cancer chemotherapy with cytostatic drugs; the toxicities result from insufficient drug clearance via GSH conjugation. Expression of the null genotype can reach 60% in Chinese and Korean populations. Activities of GSTs in cancerous tissues also have been linked to the development of drug resistance toward chemotherapeutic agents.*

N-ACETYLATION The cytosolic N-acetyltransferases (NATs) are responsible for the metabolism of drugs and environmental agents containing an aromatic amine or hydrazine group. The addition of the acetyl group from the cofactor acetyl-coenzyme A often leads to a metabolite that is less water soluble because the ionizable amine is neutralized by covalent addition of an acetyl group. NATs are among the most polymorphic of all human xenobiotic drug-metabolizing enzymes. There are two functional NAT genes in humans, *NAT1* and *NAT2*. Over 25 allelic variants of *NAT1* and *NAT2* have been characterized, and homozygous genotypes for at least two variant alleles are required to predispose to lowered drug metabolism. Slow acetylation patterns are attributed mostly to *NAT2* polymorphisms.

Following the introduction of *isoniazid* for the treatment of tuberculosis, toxicities were noted in 5–15% of the patients (see Chapter 47) Individuals suffering from the toxic effects of isoniazid excreted large amounts of unchanged drug and low amounts of acetylated isoniazid. Pharmacogenetic studies led to the classification of “rapid” and “slow” acetylators, with the “slow” phenotype being predisposed to toxicity. Molecular analysis of the *NAT2* gene revealed polymorphisms that correspond to the “slow” and “fast” acetylator phenotypes. Polymorphisms in the *NAT2* gene and their association with the slow acetylation of isoniazid provided the first link between pharmacogenetic phenotype and a genetic polymorphism.

Drugs that are subject to acetylation and their known toxicities are listed in Table 3–3. Many classes of clinically used drugs contain an aromatic amine or a hydrazine group that can be acetylated. If a drug is known to be subject to such modification, the acetylation phenotype of an individual patient can be important. Adverse drug reactions in a slow acetylator resemble drug overdose; thus, a “slow acetylator” requires dose reduction or an increased dosing interval. Several drugs that are acetylated (e.g., sulfonamides) have been implicated in idiosyncratic hypersensitivity reactions. Sulfonamides are transformed into hydroxylamines that interact with cellular proteins, generating haptens that can elicit autoimmune responses. Individuals who are slow acetylators are predisposed

Indications and Unwanted Side Effects of Drugs Metabolized by N-Acetyltransferases

Drug	Indication	Major Side Effects
Acebutolol	Arrhythmias, hypertension	Drowsiness, weakness, insomnia
Amantadine	Influenza A, parkinsonism	Appetite loss, dizziness, headache, nightmares
Aminobenzoic acid	Skin disorders, sunscreens	Stomach upset, contact sensitization
Aminoglutethimide	Adrenal cortex carcinoma, breast cancer	Clumsiness, nausea, dizziness, agranulocytosis
Aminosalicilyc acid	Ulcerative colitis	Allergic fever, itching, leukopenia
Amonafide	Prostate cancer	Myelosuppression
Amrinone	Advanced heart failure	Thrombocytopenia, arrhythmias
Benzocaine	Local anesthesia	Dermatitis, itching, rash, methemoglobinemia
Caffeine	Neonatal respiratory distress syndrome	Dizziness, insomnia, tachycardia
Clonazepam	Epilepsy	Ataxia, dizziness, slurred speech
Dapsone	Dermatitis, leprosy, AIDS-related complex	Nausea, vomiting, hyperexcitability, methemoglobinemia, dermatitis
Dipyron (metamizole)	Analgesic	Agranulocytosis
Hydralazine	Hypertension	Hypotension, tachycardia, flushing, headache
Isoniazid	Tuberculosis	Peripheral neuritis, hepatotoxicity
Nitrazepam	Insomnia	Dizziness, somnolence
Phenelzine	Depression	CNS excitation, insomnia, orthostatic hypotension, hepatotoxicity
Procainamide	Ventricular tachyarrhythmia	Hypotension, systemic lupus erythematosus
Sulfonamides	Antibacterial agents	Hypersensitivity, hemolytic anemia, fever, lupus-like syndromes

to such drug-induced reactions. Thus, knowledge of a patient's acetylating phenotype can be important in avoiding drug toxicity.

Tissue-specific NAT expression can affect toxicity of environmental pollutants. NAT1 is ubiquitously expressed in human tissues, whereas NAT2 is found in liver and the GI tract. Both enzymes have a capacity to form N-hydroxy-acetylated metabolites from bicyclic aromatic hydrocarbons, a reaction that leads to the nonenzymatic release of the acetyl group and the generation of highly reactive nitrenium ions. Thus, N-hydroxy acetylation is thought to activate certain environmental toxicants. In contrast, direct N-acetylation of the environmentally generated bicyclic aromatic amines is stable and leads to detoxification. NAT2 fast acetylators efficiently metabolize and detoxify bicyclic aromatic amine through liver-dependent acetylation. Slow acetylators (NAT2 deficient) accumulate bicyclic aromatic amines, which are metabolized by CYPs to N-OH metabolites that are eliminated in the urine. In bladder epithelium, NAT1 efficiently catalyzes the N-hydroxy acetylation of bicyclic aromatic amines, a process that leads to deacetylation and the formation of the mutagenic nitrenium ion. Slow acetylators due to NAT2 deficiency are predisposed to bladder cancer if exposed to environmental bicyclic aromatic amines.

METHYLATION In humans, xenobiotics can undergo O-, N-, and S-methylation. Methyltransferases (MTs) are identified by substrate and methyl conjugate. Humans express three N-methyltransferases, one catechol-O-methyltransferase (COMT), a phenol-O-methyltransferase (POMT), a thiopurine S-methyltransferase (TPMT), and a thiol methyltransferase (TMT). All MTs use S-adenosyl-methionine as the methyl donor. Except for a conserved signature sequence, there is limited overall sequence conservation among the MTs, indicating that each MT has evolved to display a unique catalytic function. Although all MTs generate methylated products, the substrate specificity of each is high.

Nicotinamide N-methyltransferase (NNMT) methylates serotonin, tryptophan, and pyridine-containing compounds such as nicotinamide and nicotine. Phenylethanolamine N-methyltransferase (PNMT)

is responsible for the methylation of norepinephrine to form epinephrine; the histamine *N*-methyltransferase (HNMT) metabolizes substances containing an imidazole ring (e.g., histamine). COMT methylates neurotransmitters containing a catechol moiety (e.g., dopamine and norepinephrine, methyl dopa, and drugs of abuse such as ecstasy). The most important MT clinically may be TPMT, which catalyzes the *S*-methylation of aromatic and heterocyclic sulfhydryl compounds, including the thiopurine drugs azathioprine (AZA), 6-mercaptopurine (6-MP), and thioguanine. AZA and 6-MP are used for inflammatory bowel disease (see Chapter 38) and autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. Thioguanine is used in acute myeloid leukemia, and 6-MP is used to treat childhood acute lymphoblastic leukemia (see Chapter 51). Because TPMT is responsible for the detoxification of 6-MP, a genetic deficiency in TPMT can result in severe toxicities in patients taking these drugs. The toxic side effects arise when a lack of 6-MP methylation by TPMT causes accumulation of 6-MP, resulting in the generation of toxic levels of 6-thioguanine nucleotides. Tests for TPMT activity have made it possible to identify individuals who are predisposed to the toxic side effects of 6-MP therapy, who therefore should receive a decreased dose.

INDUCTION OF DRUG METABOLISM Xenobiotics can influence the extent of drug metabolism by activating transcription and inducing the expression of genes encoding drug-metabolizing enzymes. Thus, a drug may induce its own metabolism. One potential consequence of this is a decrease in plasma drug concentration as the autoinduced metabolism of the drug exceeds the rate at which new drug enters the body, resulting in loss of efficacy. Ligands and the receptors through which they induce drug metabolism are shown in Table 3–4. Figure 3–5 shows the scheme by which a drug may interact with nuclear receptors to induce its own metabolism. A particular receptor, when activated by a ligand, can induce the transcription of a battery of target genes, including CYPs and drug transporters. Any drug that is a ligand for a receptor that induces CYPs and transporters could cause altered drug metabolism and drug interactions.

The aryl hydrocarbon receptor (AHR) is a basic helix-loop-helix transcription factor that induces expression of genes encoding CYP1A1 and CYP1A2, which metabolically activate chemical carcinogens, including environmental contaminants and carcinogens derived from food. Many of these substances are inert unless metabolized by CYPs. Induction of CYPs by AHR could result in an increase in the toxicity and carcinogenicity of these procarcinogens. For example, *omeprazole*, a proton pump inhibitor used to treat ulcers (see Chapter 36), is an AHR ligand and can induce CYP1A1 and CYP1A2, possibly activating toxins/carcinogens.

Another induction mechanism involves members of the nuclear receptor superfamily. Many of these receptors were originally termed “orphan receptors” because they had no known endogenous ligands. The nuclear receptors relevant to drug metabolism and drug therapy include the pregnane X receptor (PXR), constitutive androstane receptor (CAR), and the peroxisome proliferator activated receptor (PPAR). PXR is activated by a number of drugs, including antibiotics (*rifampin* and *troleandomycin*), Ca²⁺ channel blockers (*nifedipine*), statins (*mevastatin*), antidiabetic drugs (*rosiglitazone*), HIV protease inhibitors (*ritonavir*), and anti-cancer drugs (*paclitaxel*). Hyperforin, a component of St. John’s wort, also activates PXR. This activation is thought to be the basis for the decreased efficacy of oral contraceptives in individuals taking St. John’s wort: activated PXR induces CYP3A4, which can metabolize steroids found in oral contraceptives. PXR also induces the expression of genes encoding certain drug

FIGURE 3–5 Induction of drug metabolism by nuclear receptor–mediated signal transduction. When a drug such as atorvastatin (Ligand) enters the cell, it can bind to a nuclear receptor such as the pregnane X receptor (PXR). PXR then forms a complex with the retinoid X receptor (RXR), binds to DNA upstream of target genes, recruits coactivator (which binds to the TATA box binding protein, TBP), and activates transcription. Among PXR target genes are CYP3A4, which can metabolize the atorvastatin and decrease its cellular concentration. Thus, atorvastatin induces its own metabolism, undergoing both ortho- and para-hydroxylation.

transporters and phase 2 enzymes including SULTs and UGTs. Thus, PXR facilitates the metabolism and elimination of xenobiotics, including drugs, with notable consequences (see legend to Figure 3–5).

The nuclear receptor CAR was discovered based on its capacity to activate genes in the absence of ligand. Steroids such as *androstanol*, the antifungal agent *clotrimazole*, and the antiemetic *meclizine* are inverse agonists that inhibit gene activation by CAR, while the pesticide 1,4-bis (2-[3,5-dichloropyridyloxy]) benzene, the steroid 5 β -pregnane-3,20-dione, and probably other endogenous compounds are agonists that activate gene expression when bound to CAR. Genes induced by CAR include those encoding CYP2B6, CYP2C9, and CYP3A4, various phase 2 enzymes (including GSTs, UGTs, and SULTs), and drug and endobiotic transporters. CYP3A4 is induced by both PXR and CAR; thus, its level is highly influenced by a number of drugs and other xenobiotics. In addition to a potential role in inducing drug degradation, CAR may function in the control of bilirubin degradation, the process by which the liver decomposes heme. As with the xenobiotic-metabolizing enzymes, species differences also exist in the ligand specificities of these nuclear receptors. For example, rifampin activates human PXR but not mouse or rat PXR, while meclizine preferentially activates mouse CAR but inhibits gene induction by human CAR.

The PPAR family has three members, α , β , and γ . PPAR α is the target for the fibrate hyperlipidemic drugs (e.g., *gemfibrozil* and *fenofibrate*). While PPAR α activation induces target genes encoding fatty acid metabolizing enzymes that lower serum triglycerides, it also induces CYP4 enzymes that carry out the oxidation of fatty acids and drugs with fatty acid–containing side chains, such as *leukotrienes* and *arachidonic acid* analogs.

DRUG METABOLISM, DRUG DEVELOPMENT, AND THE SAFE AND EFFECTIVE USE OF DRUGS Drug metabolism influences drug efficacy and safety. A substantial percentage (~50%) of drugs associated with adverse responses are metabolized by xenobiotic-metabolizing enzymes, notably the CYPs. Many of these CYPs are subject both to induction and inhibition by drugs, dietary factors, and other environmental agents. This can result in decreases in drug efficacy and half life; conversely, changes in CYP activity can result in drug accumulation to toxic levels. Thus, before a new drug application is filed with the FDA, the routes of metabolism and the enzymes involved in this metabolism must be established, so that relevant

polymorphisms of metabolic enzymes are identified and potential drug interactions can be predicted and avoided.

Historically, drug candidates have been administered to rodents at doses well above the human target dose in order to predict acute toxicity. For drug candidates that will be used chronically in humans, long-term carcinogenicity studies are carried out in rodent models. For determination of metabolism, the compound is subjected to interaction with human liver cells or extracts from these cells that contain the drug-metabolizing enzymes. Such studies determine how humans will metabolize a particular drug, and to a limited extent, predict its rate of metabolism. If a CYP is involved, a panel of recombinant CYPs can be used to determine which CYP predominates in the metabolism of the drug. If a single CYP, such as CYP3A4, is found to be the sole CYP that metabolizes a drug candidate, then a decision can be made about the likelihood of drug interactions. Interactions arise when multiple drugs are simultaneously administered, for example in elderly patients, who on a daily basis may take prescribed anti-inflammatory drugs, cholesterol-lowering drugs, blood pressure medications, a gastric-acid suppressant, an anticoagulant, and a number of over-the-counter medications. Ideally, a candidate drug would be metabolized by several CYPs, so that variability in expression levels of one CYP or drug-drug interactions would not significantly impact its overall metabolism and pharmacokinetics.

Similar studies can be carried out with phase 2 enzymes and drug transporters in order to predict the metabolic fate of a drug. In addition to the use of recombinant human xenobiotic-metabolizing enzymes in predicting drug metabolism, human receptor-based (PXR and CAR) systems should also be used to determine whether a particular drug candidate could be a ligand for PXR, CAR, or PPAR α .

PHARMACOGENETICS

Pharmacogenetics is the study of the genetic basis for variation in drug response; it also encompasses pharmacogenomics, which employs tools for surveying the entire genome to assess multi-genetic determinants of drug response. Technical advances in genomics permit genotype-to-phenotype analyses in which genomic polymorphisms are exploited to assess whether a particular genomic variability translates into phenotypic variability of drug response.

Importance of Pharmacogenetics to Variability in Drug Response

An individual's response to a given drug depends on a complex interplay among many environmental and genetic factors (Figure 4-1). Genetic factors account for most of the variation in metabolic rates for many drugs. Heritability can account for 75–85% of the variability in pharmacokinetic half-lives for drugs that are eliminated by metabolism. Cytotoxicity of drugs also appears to be heritable.

Several genetic polymorphisms of drug-metabolizing enzymes result in monogenic traits in which genotype predicts phenotype. In retrospective analyses, half of adverse drug reactions were associated with drugs that are substrates for polymorphic drug-metabolizing enzymes. Thus, drugs metabolized by enzymes that exhibit polymorphic activity, which make up only 22% of all drugs, disproportionately account for adverse drug reactions. Prospective genotype determinations of these enzymes may allow us to avoid many adverse drug reactions.

GENOMIC BASIS OF PHARMACOGENETICS

Types of Genetic Variants

A *polymorphism* is a variation in the DNA sequence that is present at an allele frequency of 1% or greater in a population. Two major types of sequence variation have been associated with variation in human phenotype: *single nucleotide polymorphisms* (SNPs) and *insertions/deletions* (indels) (Figure 4-2). SNPs are present in the human genome at approximately one SNP every few hundred to a thousand base pairs, depending on the gene region. Indels are much less frequent, particularly in coding regions of genes.

SNPs in the coding region are termed *cSNPs* and are further classified as nonsynonymous (or *missense*) if the base pair change results in an amino acid substitution, synonymous (or *sense*) if the base pair substitution within a codon does not alter the encoded amino acid, and *nonsense* if they introduce a stop codon. Typically, substitutions of the third base pair in a codon, the *wobble position*, do not alter the encoded amino acid. In addition, about 10% of SNPs can have more than two possible alleles (*e.g.*, a C can be replaced by either an A or G), so that the same polymorphic site can be associated with amino acid substitutions in some alleles but not others.

Polymorphisms in noncoding regions of genes may occur in the 5' and 3' untranslated regions, in promoter or enhancer regions, in intronic regions, or in large intergenic regions between genes. Intronic polymorphisms found near exon-intron boundaries are often treated as a distinct category from other intronic polymorphisms, since they may affect splicing and thereby affect function. Noncoding SNPs in promoters/enhancers or in 5' and 3' untranslated regions may affect gene transcription or transcript stability. Noncoding SNPs in introns or exons may create alternative splicing sites, and the altered transcript may have fewer or more exons, or shorter or larger exons, than the wild-type transcript. Introduction or deletion of exonic sequence can cause a frame shift in the translated protein and thereby change protein structure or function, or can result in an early stop codon, producing an unstable or nonfunctional protein. Because 95% of the genome is intergenic, most polymorphisms are unlikely to directly affect the encoded transcript or protein. However, intergenic polymorphisms may have biological consequences by affecting DNA tertiary structure, interaction with chromatin and topoisomerases, or DNA replication. Thus, intergenic polymorphisms cannot be assumed to be pharmacogenetically insignificant.

A remarkable degree of diversity is evident in the types of insertions/deletions that are tolerated as germline polymorphisms. One common polymorphism in glutathione-S-transferase M1 (*GSTM1*) is caused by a 50-kilobase (kb) germline deletion; the null allele has a population frequency of 0.3–0.5, depending on race/ethnicity. In biochemical studies, homozygous null individuals have only ~50% of the liver glutathione conjugating capacity of those with at least one copy of the *GSTM1* gene. In the *UGT1A1* promoter, the number of TA repeats affects the quantitative

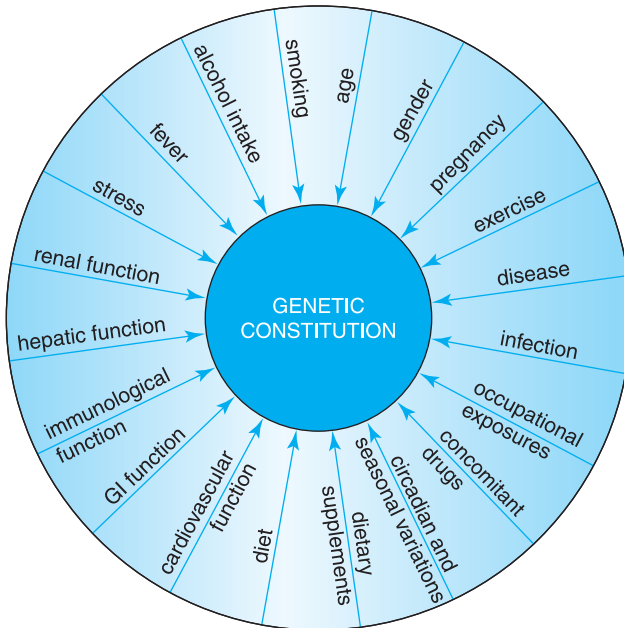

FIGURE 4-1 Exogenous and endogenous factors contribute to variation in drug response.

expression of this crucial glucuronosyl transferase in liver. Finally, a common 68 base pair indel polymorphism in cystathionine β -synthase has been linked to folate levels.

A *haplotype*, defined as a series of linked polymorphisms on a chromosome, specifies the DNA sequence variation on one chromosome. For example, consider two SNPs in *ABCB1* encoding the P-glycoprotein multidrug resistance protein: a T to A base pair substitution at position 3421 and a C to T change at position 3435. Possible haplotypes are $T_{3421}C_{3435}$, $T_{3421}T_{3435}$, $A_{3421}C_{3435}$, and $A_{3421}T_{3435}$. For any gene, individuals will have two haplotypes, one maternal and one paternal in origin, which may or may not be identical. Haplotypes are important because they are the functional unit of the gene. That is, a haplotype represents the constellation of variants that occur together for the gene on each chromosome. In some cases, this constellation of variants, rather than the individual variant or allele, may be functionally important. In others, however, a single mutation may be functionally important regardless of other variants within the haplotype(s).

Ethnic Diversity

Polymorphisms differ in their frequencies within human populations. Among coding region SNPs, synonymous SNPs are present, on average, at higher frequencies than nonsynonymous SNPs. For most genes, the nucleotide diversity, which reflects the number and the frequency of the SNPs, is greater for synonymous than for nonsynonymous SNPs. This reflects selective pressures (termed *negative* or *purifying selection*) that act to preserve the functional activity, and hence the amino acid sequence, of proteins. In human population studies using whole genome scanning, polymorphisms have been classified as either cosmopolitan (*i.e.*, present in all ethnic groups) or population (or race and ethnic) specific. Cosmopolitan polymorphisms are present in all ethnic groups, although frequencies may differ among ethnic groups; they usually are found at higher allele frequencies in comparison to population-specific polymorphisms and are evolutionarily older.

African Americans have the highest number of population-specific polymorphisms in comparison to European Americans, Mexican Americans, and Asian Americans. Africans are believed to be the oldest population and therefore carry both recently derived, population-specific polymorphisms, and older cosmopolitan polymorphisms that occurred before migrations out of Africa.

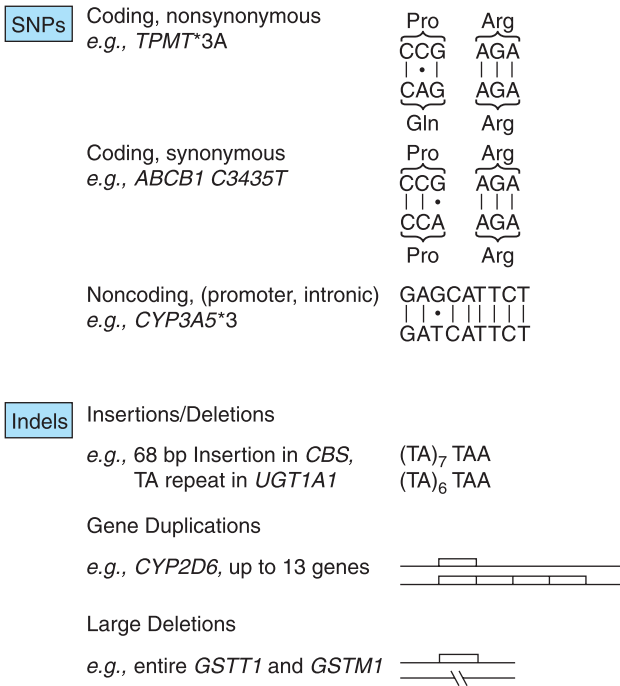

FIGURE 4–2 Molecular mechanisms of genetic polymorphisms. The most common genetic variants are single nucleotide polymorphism substitutions (SNPs). *Coding nonsynonymous* SNPs result in a nucleotide substitution that changes the amino acid codon (here proline to glutamine), which could change protein structure, stability, substrate affinities, or introduce a stop codon. *Coding synonymous* SNPs do not change the amino acid codon, but may have functional consequences (transcript stability, splicing). Noncoding SNPs may be in promoters, introns, or other regulatory regions that may affect transcription factor binding, enhancers, transcript stability, or splicing. The second major types of polymorphism are *indels* (*insertion/deletions*). Indels can have any of the same effects as SNP substitutions: short repeats in the promoter (which can affect transcript amount), or larger insertions/deletions that add or subtract amino acids. Indels can also involve gene duplications, stably transmitted inherited germline gene replication that causes increased protein expression and activity, or gene deletions that result in the complete lack of protein production. All of these mechanisms have been implicated in common germline pharmacogenetic polymorphisms. TPMT, thiopurine methyltransferase; ABCB1, the multidrug resistance transporter (P-glycoprotein); CYP, cytochrome P450; CBS, cystathionine β -synthase; UGT, UDP-glucuronyl transferase; GST, glutathione-S-transferase.

Consider the coding region variants of two membrane transporters (Figure 4–3). Shown are nonsynonymous and synonymous SNPs; population-specific nonsynonymous cSNPs are indicated in the figure. The multidrug resistance associated protein, MRP2, has a large number of nonsynonymous cSNPs. There are fewer synonymous variants than nonsynonymous variants, but the allele frequencies of the synonymous variants are greater than those of the nonsynonymous variants. By comparison, the dopamine transporter DAT has a number of synonymous variants but no nonsynonymous variants, suggesting that selective pressures have acted against substitutions that led to changes in amino acids.

In a survey of coding region haplotypes in ~300 different genes in 80 ethnically diverse DNA samples, most genes were found to have between 2 and 53 haplotypes, with the average number of haplotypes in a gene being 14. Like SNPs, haplotypes may be cosmopolitan or population specific and ~20% of the over 4000 identified haplotypes were cosmopolitan. Considering the frequencies of the haplotypes, cosmopolitan haplotypes actually accounted for over 80% of all haplotypes, whereas population-specific haplotypes accounted for only 8%.

Polymorphism Selection

Genetic variations sometimes cause a “disease” phenotype. Due to the disease, some evolutionary selection against these single-gene polymorphisms is present. Cystic fibrosis, sickle-cell anemia,

FIGURE 4-3 Coding region polymorphisms in two membrane transporters. Shown are the dopamine transporter, DAT (encoded by *SLCGA3*) and multidrug resistance associated protein, MRP2 (encoded by *ABCC2*). Coding region variants were identified in 247 ethnically diverse DNA samples (100 African Americans, 100 European Americans, 30 Asians, 10 Mexicans, and 7 Pacific Islanders). Shown in light gray are synonymous variants, and in black, nonsynonymous variants.

and Crigler-Najjar syndrome are examples of inherited diseases caused by single gene defects. Crigler-Najjar syndrome is a severe genetic disorder caused by rare inactivating mutations in *UGT1A1*. More common and less deleterious polymorphisms in *UGT1A1* are associated with modest hyperbilirubinemia and altered drug clearance. Polymorphisms in other genes are highly penetrant in subjects challenged with certain drugs; these polymorphisms thus are the causes of monogenic pharmacogenetic traits. Because they are not deleterious in the constitutive state, there is unlikely to be any selective pressure for or against these polymorphisms. Most genetic polymorphisms have a modest impact on the affected genes, are part of a large array of multigenic factors that impact drug effect, or affect genes whose products play a minor role in drug action relative to large nongenetic effects. For example, phenobarbital induction of metabolism may be such an overwhelming “environmental” effect that polymorphisms in the affected transcription factors and drug-metabolizing enzymes have relatively modest effects.

PHARMACOGENETIC STUDY DESIGN CONSIDERATIONS

Pharmacogenetic Measures

A *pharmacogenetic trait* is any measurable or discernible trait associated with a drug, including enzyme activity, drug or metabolite levels in plasma or urine, effects on blood pressure or lipid

levels, and drug-induced gene expression patterns. Directly measuring a trait (*e.g.*, enzyme activity) has the advantage that the net effect of the contributions of all genes that influence the trait is reflected in the phenotypic measure but the disadvantage is that it also reflects nongenetic influences (*e.g.*, diet, drug interactions, diurnal, or hormonal fluctuation) and thus, may be “unstable.” For example, if a patient is given an oral dose of *dextromethorphan*, and the urinary ratio of parent drug to metabolite is assessed, the phenotype reflects the CYP2D6 genotype. If dextromethorphan instead is given with *quinidine*, a potent CYP2D6 inhibitor, the ratio may indicate a poor metabolizer genotype even though the subject carries wild-type CYP2D6 alleles. In other words, quinidine coadministration may result in a drug-induced enzymatic deficiency, and the false assignment to a CYP2D6 poor metabolizer phenotype. Lack of consistency for a given subject in a phenotypic measure, such as the erythromycin breath test for CYP3A, indicates that the phenotype is influenced by nongenetic factors and may indicate a multigenic or weakly penetrant effect of a monogenic trait. Because most pharmacogenetic traits are multigenic rather than monogenic (Figure 4–4), considerable effort is being made to identify the important genes and their polymorphisms that influence variability in drug response.

Most genotyping methods use genomic DNA that is extracted from somatic, diploid cells, usually white blood cells or buccal cells due to their ready accessibility. DNA is extremely stable if appropriately extracted and stored; unlike many laboratory tests, genotyping need be performed only once because DNA sequence is generally constant throughout an individual’s lifetime. Although tremendous progress has been made in molecular biological techniques to determine genotypes, relatively few pharmacogenetic tests are used routinely in patient care. Genotyping tests are directed at each specific known polymorphic site using a variety of strategies that generally depend at some level on the specific and avid annealing of at least one oligonucleotide to a region of DNA flanking or overlapping the polymorphic site. Because genomic variability is so common (with polymorphic sites every few hundred nucleotides), “cryptic” or unrecognized polymorphisms may interfere with oligonucleotide annealing, thereby resulting in false-positive or false-negative genotype assignments. Full integration of genotyping into therapeutics will require high standards for genotyping technology, perhaps with more than one method required for each polymorphic site.

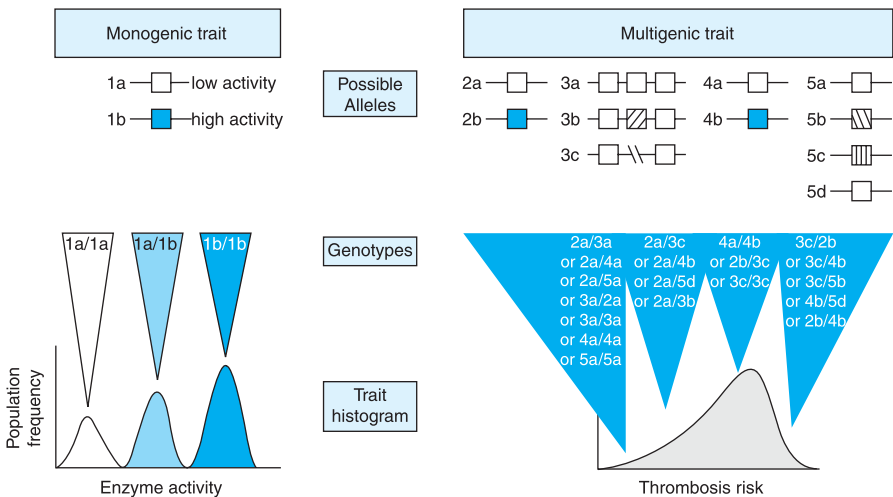

FIGURE 4–4 *Monogenic versus multigenic pharmacogenetic traits.* Possible alleles for a monogenic trait (*upper left*), in which a single gene has a low-activity (1a) and a high-activity (1b) allele. The population frequency distribution of a monogenic trait (*bottom left*), here depicted as enzyme activity, may exhibit a trimodal frequency distribution with relatively distinct separation among low activity (homozygous for 1a), intermediate activity (heterozygous for 1a and 1b), and high activity (homozygous for 1b). This is contrasted with multigenic traits (*e.g.*, an activity influenced by up to four different genes, genes 2 through 5), each of which has 2, 3, or 4 possible alleles (a through d). The population histogram for activity is unimodal-skewed, with no distinct differences among the genotypic groups. Multiple combinations of alleles coding for low activity and high activity at several of the genes can translate into low-, medium-, and high-activity phenotypes.

Because polymorphisms are so common, the allelic structure that indicates whether polymorphisms within a gene are on the same or different alleles (their haplotype) may also be important. Experimental methods to unambiguously confirm whether polymorphisms are allelic are technically challenging so statistical probability is often used to assign putative or inferred haplotypes.

Candidate Gene *versus* Genome-Wide Approaches

After genes in drug response pathways are identified, the next step in the design of a candidate gene association pharmacogenetic study is to identify genetic polymorphisms that are most likely to contribute to the therapeutic and/or adverse responses. There are several databases that contain information on polymorphisms and mutations in human genes (Table 4–1) that allow the investigator to search by gene for reported polymorphisms. Some databases, such as the Pharmacogenetics and Pharmacogenomics Knowledge Base, include phenotypic and genotypic data.

Because it is currently impractical to analyze all polymorphisms in a candidate gene association study, it is important to select polymorphisms that most likely are associated with the drug-response phenotype. For this purpose, there are two categories of polymorphisms. Some polymorphisms do not directly alter function of the expressed protein (*e.g.*, they don't affect the enzyme that metabolizes the drug or the drug receptor). Rather, these polymorphisms are linked to the variant allele that alters function. If they are very tightly linked with the causative polymorphism, these polymorphisms nonetheless may serve as surrogates for drug-response phenotype.

The second type of polymorphism is the *causative polymorphism*, which directly produces the phenotype. Whenever possible, it is desirable to select polymorphisms for pharmacogenetic studies that are likely to be causative. If biological information indicates that a particular polymorphism alters function, this polymorphism is an excellent candidate to use in an association study.

A potential drawback of the candidate gene approach is that the wrong genes may be studied. Genome-wide approaches, using gene expression arrays, genome-wide scans, or proteomics, can complement the candidate gene approach by providing a relatively unbiased survey of the genome to identify previously unrecognized candidate genes. For example, RNA, DNA, or protein from patients who have unacceptable toxicity from a drug can be compared with corresponding material from identically treated patients who did not exhibit such toxicity. Patterns of gene expression, clusters of polymorphisms or heterozygosity, or relative amounts of proteins can be ascertained using computational tools, to identify genes, genomic regions, or proteins that can be further assessed for germline polymorphisms differentiating the phenotype. Gene expression and proteomic approaches have the advantage that the abundance of signal may itself directly reflect some of the relevant genetic variation; however, both types of expression are highly influenced by the tissue studied, and the most relevant tissue (*e.g.*, brain) may not be readily available. DNA has the advantage that it is readily available and independent of tissue type, but the vast majority of genomic variation is not

in genes, and the large number of SNPs raises the danger of type I error (finding differences that are false-positives).

Functional Studies of Polymorphisms

For most polymorphisms, functional information is not available. Therefore, it is important to predict whether a given polymorphism may result in a change in protein function, stability, or subcellular localization. One approach to understanding the functional effects of various types of genomic variations is to survey the mutations that have been associated with human Mendelian disease. DNA variations associated with diseases or traits most frequently are missense and non-sense mutations, followed by deletions. Of amino acid replacements associated with human disease, there is a high representation at residues that are most conserved evolutionarily. More radical changes in amino acids also are more likely to be associated with disease than more conservative changes; substitution of a charged amino acid (Arg) for a nonpolar, uncharged amino acid (Cys) is more likely to affect function than substitution of residues that are more chemically similar (*e.g.*, Arg to Lys).

With an increasing number of SNPs being identified by large-scale SNP discovery projects, computational methods are needed to predict the functional consequences. To this end, predictive algorithms have been developed to identify potentially deleterious amino acid substitutions. These methods can be classified into two groups. The first group relies on sequence comparisons alone to identify and score substitutions according to their degree of conservation across multiple species. The second group of methods relies on mapping of SNPs onto protein structures, in addition to sequence comparisons.

For many proteins—including enzymes, transporters, and receptors—the mechanisms by which amino acid substitutions alter function have been characterized in kinetic studies. Figure 4–5 shows simulated curves depicting the rate of metabolism of a substrate by two amino acid variants of an enzyme and the most common genetic form of the enzyme. The metabolism of substrate by one variant enzyme, Variant A, is characterized by an increased K_m . Such an effect can occur if the amino acid substitution alters the binding site of the enzyme leading to a decreased affinity for the substrate. An amino acid variant may also alter the maximum rate of substrate metabolism (V_{max}) by the enzyme, as exemplified by Variant B. Such reductions in V_{max} generally reflect reduced expression of the enzyme, which may occur because of decreased protein stability or changes in protein trafficking or recycling.

In contrast to studies with coding region SNPs, predicting the function of SNPs in noncoding regions of genes represents a major challenge in human genetics and pharmacogenetics. The principles of evolutionary conservation that have been validated in predicting the function of

FIGURE 4–5 Simulated concentration–dependence curves showing the rate of metabolism of a hypothetical substrate by the common genetic form of an enzyme and two nonsynonymous variants. Variant A exhibits an increased K_m and likely reflects a change in the substrate binding site of the protein by the substituted amino acid. Variant B exhibits a change in the maximum rate of metabolism (V_{max}) of the substrate. This may be due to reduced expression level of the enzyme or to a decrease in its catalytic efficiency. Altered K_m and V_{max} may also be coexpressed in a single variant (not shown).

nonsynonymous variants in the coding region need to be refined and tested as predictors of function of SNPs in noncoding regions.

Pharmacogenetic Phenotypes

Candidate genes for therapeutic and adverse response can be divided into three categories: pharmacokinetic, receptor/target, and disease-modifying.

PHARMACOKINETICS Germline variability in genes that encode factors that determine the pharmacokinetics of a drug, in particular enzymes and transporters, affect drug concentrations and are therefore major determinants of therapeutic and adverse drug response (Table 4–2). Multiple enzymes and transporters may affect the pharmacokinetics of a given drug. Several polymorphisms in drug metabolizing enzymes are monogenic phenotypic trait variations and thus are referenced using their phenotypic designations (*e.g.*, slow *vs.* fast acetylation, extensive *vs.* poor metabolizers of debrisoquine or *sparteine*) rather than using genotypic designations that reference the gene that is the target of polymorphisms in each case (*e.g.*, NAT2 and CYP2D6, respectively). A large number of medications (~15–25% of all medicines in use) are known substrates for CYP2D6 (Table 4–2). The molecular and phenotypic characterization of multiple racial and ethnic groups has shown that seven variant alleles account for >90% of the “poor metabolizer” low-activity CYP2D6 alleles in most racial groups, that the frequency of variant alleles varies with geographic origin, and that a small percentage of individuals carry stable duplications of CYP2D6, with “ultra-rapid” metabolizers having up to 13 copies of the active gene. Phenotypic consequences of the deficient CYP2D6 phenotype include increased risk of toxicity of antidepressants or antipsychotics (catabolized by the enzyme), and lack of analgesic effect of codeine (anabolized by the enzyme); conversely, the ultra-rapid phenotype is associated with extremely rapid clearance and thus decreased efficacy of antidepressants.

CYP2C19, historically termed mephenytoin hydroxylase, displays pharmacogenetic variability, with just a few SNPs accounting for the majority of the deficient, poor metabolizer phenotype. The deficient phenotype is much more common in Chinese and Japanese populations. Several proton pump inhibitors (*e.g.*, omeprazole and lansoprazole) are inactivated by CYP2C19. Thus, the deficient patients have higher exposure to active parent drug, a greater pharmacodynamic effect (higher gastric pH), and a higher probability of ulcer cure than heterozygotes or homozygous wild-type individuals.

The anticoagulant *warfarin* is catabolized by CYP2C9. Inactivating polymorphisms in *CYP2C9* are common—with 2–10% of most populations being homozygous for low-activity variants—and are associated with lower *warfarin* clearance, lower dose requirements, and a higher risk of bleeding complications.

Thiopurine methyltransferase (TPMT) methylates thiopurines such as *mercaptopurine* (an antileukemic drug that is also the product of *azathioprine* metabolism). One in 300 individuals is homozygous deficient, 10% are heterozygotes, and about 90% are homozygous for wild-type *TPMT* alleles. Three SNPs account for over 90% of the inactivating alleles. Because methylation of mercaptopurine competes with activation of the drug to thioguanine nucleotides, the concentration of the active (but also toxic) thioguanine metabolites is inversely related to TPMT activity and directly related to the probability of pharmacologic effects. Dose reductions (from that appropriate for the “average” population) may be required to avoid myelosuppression in 100% of homozygous deficient patients, 35% of heterozygotes, and only 7–8% of those with homozygous wild-type activity. Mercaptopurine has a narrow therapeutic range, and dosing by trial and error can place patients at higher risk of toxicity; thus, prospective adjustment of thiopurine doses based on *TPMT* genotype has been proposed, both for leukemia and for nonmalignant diseases such as Crohn’s disease and transplant rejection.

PHARMACOGENETICS AND DRUG TARGETS Gene products that are direct drug targets have important roles in pharmacogenetics. Whereas highly penetrant genetic variants with profound functional consequences may cause disease phenotypes that confer negative selective pressure, more subtle variations in the same genes can persist in the population without causing disease but nonetheless affecting drug response. Methylene tetrahydrofolate reductase (MTHFR), the target of several antifolate drugs, interacts with folate-dependent one-carbon synthesis reactions. Complete inactivation *via* rare point mutations in *MTHFR* causes severe mental retardation and premature cardiovascular disease. Whereas rare variants in *MTHFR* may result in the severe phenotype, the C677T SNP causes an amino acid substitution that is maintained in the population at a high frequency. The T variant is associated with modestly lower MTHFR activity (~30% less than the 677C allele) and modest, but significantly elevated, plasma homocysteine concentrations. This polymorphism does not alter

Vitamin D receptor	Estrogen	Bone mineral density

FIGURE 4-6 Pharmacodynamics and pharmacogenetics. The proportion of patients requiring a dosage decrease for the antidepressant drug paroxetine was greater ($p = 0.001$) in the approximately one-third of patients who have the C/C genotype for the serotonin 2A receptor ($5HT_{2A}$) compared to the two-thirds of patients who have either the T/C or T/T genotype at position 102. The major reason for dosage decreases in paroxetine was the occurrence of adverse drug effects.

drug pharmacokinetics but apparently modulates pharmacodynamics by predisposing to GI toxicity of the antifolate drug *methotrexate* in transplant recipients. Following prophylactic treatment with methotrexate for graft-versus-host disease, mucositis was three times more common in patients homozygous for the 677T allele than in those homozygous for the 677C allele.

Many polymorphisms in drug targets predict responsiveness to drugs (Table 4-2). Serotonin receptor polymorphisms predict not only the responsiveness to antidepressants (Figure 4-6), but also the overall risk of depression. β adrenergic receptor polymorphisms have been linked to asthma responsiveness after β agonist therapy, renal function following angiotensin-converting enzyme (ACE) inhibitors, and heart rate following β -blockers. Polymorphisms in 3-hydroxy-3-methylglutaryl coenzyme A reductase have been linked to the degree of lipid lowering following statins, which are inhibitors of this enzyme (*see* Chapter 35), and to the degree of elevation of high-density lipoproteins among women on estrogen replacement therapy (Figure 4-7).

FIGURE 4-7 Effect of genotype on response to estrogen hormone replacement therapy. Depicted are pretreatment (base line) and posttreatment (follow-up) high-density lipoprotein (HDL) cholesterol levels in women of the C/C vs. C/T or T/T HMG-CoA reductase genotype.

POLYMORPHISM-MODIFYING DISEASES AND DRUG RESPONSES Some genes may affect the underlying disease being treated without directly interacting with the drug. Modifier polymorphisms are important for the *de novo* risk of some events and for the risk of drug-induced events. The *MTHFR* polymorphism, for example, is linked to homocysteinemia, which in turn affects thrombosis risk. The risk of a drug-induced thrombosis is dependent not only on the use of prothrombotic drugs, but on environmental and genetic predisposition to thrombosis, which may be affected by germline polymorphisms in *MTHFR*, factor V, and prothrombin. These polymorphisms do not directly affect the pharmacokinetics or pharmacodynamics of prothrombotic drugs, such as glucocorticoids, estrogens, and asparaginase, but may modify the risk of the phenotypic event (thrombosis) in the presence of the drug.

Likewise, polymorphisms in ion channels (*e.g.*, *HERG*, *KvLQT1*, *Mink*, and *MIRP1*) may affect the overall risk of cardiac dysrhythmias, which may be accentuated in the presence of a drug that can prolong the QT interval (*e.g.*, macrolide antibiotics, antihistamines). These modifier polymorphisms may impact on the risk of “disease” phenotypes even in the absence of drug challenges; in the presence of drug, the “disease” phenotype may be elicited.

In addition to the underlying germline variation of the host, tumors also harbor somatically-acquired mutations, and the efficacy of some anticancer drugs depends on the genetics of both the host and the tumor. For example, non-small-cell lung cancer is treated with inhibitors of epidermal growth factor receptor (EGFR), such as *gefitinib*. Patients whose tumors have activating mutations in the tyrosine kinase domain of *EGFR* appear to respond better to gefitinib than those without such mutations. Thus, the receptor is altered, and at the same time, individuals with the activating mutations may be considered to have a distinct category of non-small-cell lung cancer.

Pharmacogenetics and Drug Development

Pharmacogenetics will likely impact drug development in several ways. Genome-wide approaches hold promise for identification of new drug targets and new drugs. In addition, accounting for genetic/genomic interindividual variability may lead to genotype-specific development of new drugs and to genotype-specific dosing regimens.

Pharmacogenetics may identify subsets of patients who will have a very high or a very low likelihood of responding to an agent. This will permit testing of the drug in a selected population that is more likely to respond, minimizing the possibility of adverse events in patients who derive no benefit, and more tightly defining the parameters of response in the subset more likely to benefit.

A related role for pharmacogenomics in drug development is to identify genetic subsets of patients who are at highest risk for a serious adverse drug effect and to avoid testing the drug in that subset of patients. For example, the identification of HLA subtypes associated with hypersensitivity to the HIV-1 reverse transcriptase inhibitor *abacavir* could theoretically identify a subset of patients who should receive alternative therapy, and thereby minimize or even abrogate hypersensitivity as an adverse effect of this agent. Following intensively timed antileukemic therapy, children with acute myeloid leukemia who are homozygous for germline deletions in GSH transferase (*GSTT1*) are almost three times as likely to die of toxicity as those patients who have at least one wild-type copy of *GSTT1*; this difference is not seen after “usual” doses of therapy. These results suggest an important principle: pharmacogenetic testing may help to identify patients who require altered dosages of medications, but may not completely preclude the use of the agents.

Pharmacogenetics in Clinical Practice

Three major types of evidence are needed to implicate a polymorphism in clinical care: screens of tissues from multiple humans linking the polymorphism to a trait; complementary preclinical functional studies indicating that the polymorphism is plausibly linked with the phenotype; and multiple supportive clinical phenotype/genotype studies. Because of the high probability of error in genotype/phenotype association studies, replication is essential.

Adjusting drug dosages for variables such as renal or liver dysfunction is accepted in drug dosing. Even though there are many examples of significant effects of polymorphisms on drug disposition (*e.g.*, Table 4–2), there is much more hesitation from clinicians to adjust doses based on genetic testing than on indirect clinical measures of renal and liver function. Existing resources permit clinicians to access information on pharmacogenetics (*see* Table 4–1).

The high frequency of functionally important polymorphisms ensures that dosing complexity will increase. Even if only one polymorphism were considered when dosing a drug, the scale of

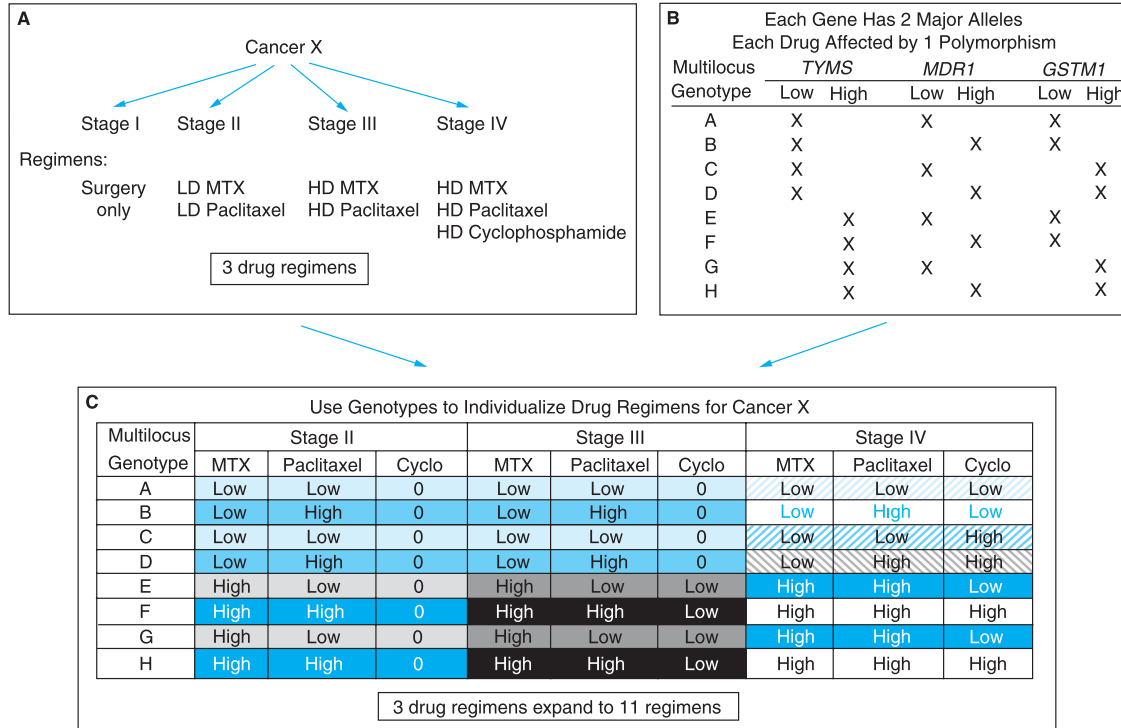

FIGURE 4-8 Potential impact of incorporation of pharmacogenetics into dosing of drugs for a relatively simple therapeutic regimen. The traditional approach to treatment for a disease (A), in this case a cancer, is based purely on stage of the cancer. Up to three different drugs are used in combination, with intensity of dosing dependent on the stage of the cancer. With this strategy, some with stage II disease are not receiving as much drug as they could tolerate; some patients with stage III or IV disease are undertreated and some are overtreated. Panel B illustrates a hypothetical patient population with eight different multilocus genotypes. It is assumed that each of the three drugs is affected by just one genetic polymorphism (*TYMS* for methotrexate [MTX], *MDR1* for paclitaxel, and *GSTM1* for cyclophosphamide), and each polymorphism has just two important genotypes (one coding for low and one for high activity). The possible multilocus genotypes are designated by the letters A to H, and the combinations of *TYMS*, *MDR1* and *GSTM1* genotypes giving rise to those multilocus genotypes are indicated in the table. If these three genotypes, along with stage of cancer, are used to individualize dosages (C), so that those with low activity receive lower doses and those with higher activity receive higher doses of the relevant drug, what began as a total of three drug regimens in the absence of pharmacogenetics becomes 11 regimens (distinguished by different backgrounds and font colors) by using pharmacogenetics for dosage individualization.

complexity could be large. Many individuals take multiple drugs simultaneously for different diseases, while many therapeutic regimens for a single disease include multiple agents. All of this translates into a plethora of possible drug-dose combinations. The promise of human genomics has emphasized the potential to discover individualized “magic bullets”, while ignoring the reality of the added complexity of additional testing and need for interpretation of results to capitalize on individualized dosing. This is illustrated in Figure 4–8. In this case, a traditional anticancer treatment regimen is replaced with one that incorporates pharmacogenetic information with the stage of the cancer determined by a variety of standardized pathological criteria. Assuming just one important genetic polymorphism for each of the three different anticancer drugs, 11 individual drug regimens are generated.

The potential utility of pharmacogenetics in drug therapy is great. Once adequate genotype/phenotype studies have been conducted, molecular diagnostic tests will be developed that detect >95% of the important genetic variants for the most polymorphisms; such genetic tests have the advantage that they need only be conducted once in a given individual. Continued incorporation of pharmacogenetics into clinical trials will identify important genes and polymorphisms demonstrate whether dosage individualization can improve outcomes and decrease adverse effects. Significant covariates will be identified to refine dosing in the context of drug interactions and disease influences. Although the challenges are substantial, accounting for the genetic basis of variability in response to medications is likely to be a fundamental component of disease diagnosis and pharmacotherapy.

THE SCIENCE OF DRUG THERAPY

Optimal therapeutic decisions are based on an evaluation of the patient and assessment of the evidence for efficacy and safety of treatment. Therapy must be guided by an understanding of drug pharmacokinetics and pharmacodynamics that is integrated with patient-focused information. Well-designed and executed clinical trials provide the scientific evidence that informs most therapeutic decisions; they may be supplemented by *observational studies*, particularly in assessing adverse effects that elude detection in clinical trials.

Clinical Trials

In clinical trials, random assignment of patients or volunteers to the control group or the group receiving the experimental therapy is the optimal method for distributing the known and unknown variables that affect outcome between the treatment and control groups. Randomized clinical trials may be impossible to use studying all experimental therapies; for patients who cannot—by regulation, ethics, or both—be studied with this design (*e.g.*, children or fetuses) or for disorders with a typically fatal outcome (*e.g.*, rabies), it may be necessary to use historical controls.

Concealing participant assignment is referred to as *blinding* or *masking*. Participants in the control group will receive an inactive replica of the drug, a *placebo*. In a *single-blind study*, participants are blinded to treatment assignment, but investigators are not. In a *double-blind study*, neither the participants nor the investigators know whether the active agent is being given. Blinding the investigators not only removes bias in patient management and outcome interpretation but also eliminates selectivity in the enthusiasm for therapy typically conveyed by clinicians. By eliminating participant and observer bias, the randomized, double-blind, placebo-controlled trial has the highest likelihood of revealing the truth about the effects of a drug. This design permits evaluation of subjective end points, such as pain, that are powerfully influenced by the administration of placebo. Striking examples include pain in labor, where a placebo produces ~40% of the relief provided by the opioid analgesic *meperidine* with a remarkably similar time course, angina pectoris, where as much as a 60% improvement in symptoms is achieved with placebo, and depression, where the response to placebo is often 60–70% as great as that of an active antidepressant drug.

The existence of a therapy known to improve disease outcome provides an ethical basis for comparing a new drug with the established treatment rather than placebo. If the aim is to show that the new drug is as effective as the comparator, then the size of the trial must be sufficiently large to have the statistical power needed to demonstrate a meaningful difference. Trials conducted against comparators as controls can be misleading if they claim equal efficacy based on the lack of a statistical difference between the drugs in a trial that was too small to demonstrate such a difference. When trials against comparator drugs examine the relative incidence of side effects, it also is important that equally effective doses of the drugs are used.

A clear hypothesis should guide the selection of a *primary endpoint*, which should be specified before the trial is initiated. Ideally, this primary endpoint will measure a clinical outcome, either a disease-related outcome, such as improvement of survival or reduction of myocardial infarction, or a symptomatic outcome, such as pain relief or quality of life. Examination of a single, prospectively selected endpoint will most likely yield a valid result. A few additional (secondary) endpoints also may be designated in advance; the greater the number of such endpoints examined, the greater the likelihood that apparently significant changes in one of them will occur by chance. The least rigorous examination of trial results comes from retrospective selection of endpoints after viewing the data. This introduces a selection bias and increases the probability of a chance result; retrospective selection therefore should be used only as the basis to generate hypotheses that then can be tested prospectively.

Therapeutic decisions sometimes must be based on trials evaluating surrogate endpoints—measures such as clinical signs or laboratory findings that are correlated with but do not directly measure clinical outcome. Such surrogate endpoints include measurements of blood pressure (for antihypertensive drugs), plasma glucose (drugs for diabetes), and level of viral RNA in plasma (for antiretroviral drugs). The extent to which surrogate endpoints predict clinical outcome varies, and two drugs with the same effect on a surrogate endpoint may have different effects on clinical outcome. The effect of a drug on a surrogate endpoint may lead to erroneous conclusions about the clinical consequences of drug administration. In one compelling example, the CAST study showed that—despite the ability of certain antiarrhythmics to suppress ventricular ectopy after myocardial

infarction—the drugs actually increased the frequency of sudden cardiac death. Thus, the ultimate test of a drug's efficacy must arise from actual clinical outcomes rather than surrogate markers.

The *sample* of patients selected for a clinical trial may not be representative of the entire *population* of patients with that disease. Patients entered into a trial usually are selected according to the severity of their disease and other characteristics (*inclusion criteria*) or are excluded because of coexisting disease, concurrent therapy, or specific features of the disease itself (*exclusion criteria*). It always is important to ascertain that the clinical characteristics of an individual patient correspond with those of patients in the trial. For example, the Randomized Aldactone Evaluation Study (RALES) showed that treatment with the mineralocorticoid-receptor antagonist *spironolactone* was associated with a 30% reduction in death in patients with severe congestive heart failure. Hyperkalemia, a potential adverse effect, was seen only rarely in this study, which excluded patients with serum creatinine levels >2.5 mg/dL. With the expanded use of spironolactone after RALES was published, numerous patients, many of whom did not meet the RALES inclusion criteria, developed severe hyperkalemia. Therefore, knowledge of the criteria for selecting the patients in a trial must inform the application of study results to a given patient.

Determination of efficacy and safety is an ongoing process usually based on results from multiple randomized, double-blind, controlled trials. A *meta-analysis* of similarly designed studies that measured the same endpoint can be used to better assess possible significance of drug treatment; by narrowing confidence limits; they can strengthen the likelihood that an apparent effect is (or is not) due to the drug rather than chance.

Observational Studies

Important but infrequent adverse drug effects may escape detection in the randomized, controlled trials that demonstrate efficacy and form the basis for approval of drugs for marketing (*e.g.*, COX-2 inhibitors, *see* Chapter 26). The number of patient-years of drug exposure during a clinical trial is small relative to exposure after the drug is marketed. Furthermore, some adverse effects may have a long latency or may affect patients not included in the controlled trials. Observational studies therefore are used to examine those adverse effects that only become apparent with widespread, prolonged use.

The quality of information derived from observational studies varies with the design and depends highly on the selection of controls and the accuracy of the information on medication use. *Cohort studies* compare the occurrence of events in users and nonusers of a drug; this is the more powerful of the observational study designs. *Case-control studies* compare drug exposure among patients with an adverse outcome *versus* that in control patients. Because the control and treatment groups in an observational study are not selected randomly, they may be different in unknown ways that determine outcome independent of drug use. Because of the limitations of observational studies, their validity cannot be equated with that of randomized, controlled trials (Table 5–1). Observational studies raise questions and pose hypotheses about adverse reactions; if it is not feasible to test these hypotheses in controlled trials, then clinical decisions may be made from replicated findings from observational studies.

PATIENT-CENTERED THERAPEUTICS

Interindividual differences in drug delivery to its site(s) of action can profoundly influence therapeutic effectiveness and adverse effects. Some of the determinants of interindividual variation are

indicated in Figure 5-1. Therapeutic success and safety result from integrating evidence of efficacy and safety with knowledge of the individual factors that determine response in a given patient.

Drug History

The starting point in the drug history is the documentation of current prescription drug use. It often is very helpful for patients to bring all current medications with them to the clinical encounter. Specific prompting is required to elicit the use of over-the-counter drugs and herbal supplements. Similarly, information about medications that are used only sporadically (*e.g.*, *sildenafil* for erectile dysfunction) may not be volunteered. With cognitively impaired patients, it may be necessary to include caregivers and pharmacy records in the drug history process. Adverse reactions to drugs should be documented with specifics regarding severity. It is revealing to ask whether patients or their physicians have discontinued any medications in the past. A review of current drug profile and list of adverse effects are required for each patient encounter, both during hospital rounds and during outpatient visits, to maximize effectiveness and safety of treatment.

DETERMINANTS OF INTERINDIVIDUAL VARIATION IN RESPONSE TO DRUGS

Disease-Induced Alterations in Pharmacokinetics

IMPAIRED RENAL CLEARANCE OF DRUGS If a drug is cleared primarily by the kidney, dose modification should be considered in patients with renal dysfunction. When renal clearance is diminished, the desired effect can be maintained either by decreasing the dose or lengthening the dose interval. Estimation of the glomerular filtration rate (GFR) based on serum creatinine, ideal body weight, and age provides an approximation of the renal clearance of many drugs.

With knowledge of the GFR, initial dosing reductions can be estimated. The accuracy of initial dosing should be monitored by clinical assessment and plasma drug concentration where feasible.

Drug metabolites that may accumulate with impaired renal function may be pharmacologically active or toxic. Although *meperidine* is not dependent on renal function for elimination, its metabolite *normeperidine* is cleared by the kidney and accumulates when renal function is impaired. Because normeperidine has greater convulsant activity than meperidine, its high levels in renal failure probably account for the central nervous system (CNS) excitation, with irritability, twitching, and seizures, that can occur when multiple doses of meperidine are given to patients with impaired renal function (*see* Chapter 21).

IMPAIRED HEPATIC CLEARANCE OF DRUGS The effect of liver disease on the hepatic biotransformation of drugs cannot be predicted from any measure of hepatic function. Thus, even though the metabolism of some drugs is decreased with impaired hepatic function, there is no quantitative basis for dose adjustment other than assessment of the clinical response and plasma concentration. The oral bioavailability of drugs with extensive first-pass hepatic clearance (*e.g.*, *morphine*, *meperidine*, *midazolam*, and *nifedipine*) may be increased in liver disease.

CIRCULATORY INSUFFICIENCY OWING TO CARDIAC FAILURE OR SHOCK In circulatory failure, neuroendocrine compensation can substantially reduce renal and hepatic blood flow, thereby reducing elimination of many drugs. Particularly affected are drugs with high hepatic extraction ratios, such as *lidocaine*, whose clearance is a function of hepatic blood flow; in this setting, only half the usual infusion rate of lidocaine is required to achieve therapeutic plasma levels.

ALTERED DRUG BINDING TO PLASMA PROTEINS When a drug is highly bound to plasma proteins, its egress from the vascular compartment is limited to the unbound (free) drug. Hypoalbuminemia owing to renal insufficiency, hepatic disease, or other causes can reduce the extent of binding of acidic and neutral drugs; in these conditions, measurement of free drug provides a more accurate guide to therapy than does analysis of total drug. Changes in protein binding are particularly important for drugs that are >90% bound to plasma protein, where a small change in the extent of binding produces a large change in the level of free drug. Metabolic clearance of such highly bound drugs also is a function of the unbound fraction of drug. Thus, clearance is increased in those conditions that reduce protein binding; shorter dosing intervals therefore must be employed to maintain therapeutic plasma levels.

INTERACTIONS BETWEEN DRUGS

Marked alterations in the effects of some drugs can result from coadministration with another agent. Such interactions can cause toxicity or inhibit the drug effect and the therapeutic benefit.

Drug interactions always should be considered when unexpected responses to drugs occur. Understanding the mechanisms of drug interaction provides a framework for preventing them. Drug interactions may be *pharmacokinetic* (*i.e.*, the delivery of a drug to its site of action is altered by a second drug) or *pharmacodynamic* (*i.e.*, the response of the drug target is modified by a second drug).

Pharmacokinetic Interactions Caused by Diminished Drug Delivery to the Site of Action

For drugs administered orally, impaired gastrointestinal (GI) absorption is an important consideration. For example, aluminum ions in certain antacids or ferrous ions in oral iron supplements form insoluble chelates of *tetracycline antibiotics*, thereby preventing their absorption. The antifungal *ketoconazole* is a weak base that is only soluble at acid pH. Drugs that inhibit gastric acidity, such as the proton pump inhibitors and histamine H₂ receptor antagonists, impair the dissolution and absorption of ketoconazole.

Many drug interactions involve the CYPs that perform phase 1 metabolism of a large number of drugs (*see* Chapter 3). Their expression can be induced by a plethora of drugs, including antibiotics (*e.g.*, *rifampin*), anticonvulsants (*e.g.*, *phenobarbital*, phenytoin, and *carbamazepine*), nonnucleoside reverse transcriptase inhibitors (*e.g.*, *efavirenz* and *nevirapine*), and herbal supplements (*e.g.*, *St. John's wort*). Although these drugs most potently induce CYP3A4, the expression of CYPs in the 1A, 2B, and 2C families also can be increased. Induction of these enzymes accelerates the metabolism of drugs that are their substrates, including *cyclosporine*, *tacrolimus*, *warfarin*, *verapamil*, *methadone*, *dexamethasone*, *methylprednisolone*, *estrogen*, and the *HIV protease inhibitors*. The decrease in oral bioavailability from increased first-pass metabolism in the liver results in loss of efficacy.

Pharmacokinetic Interactions that Increase Drug Delivery to the Site of Action

INHIBITION OF DRUG-METABOLIZING ENZYMES For drugs whose clearance depends on biotransformation, inhibition of a metabolizing enzyme leads to reduced clearance, prolonged $t_{1/2}$, and drug accumulation during maintenance therapy, sometimes with severe adverse

effects. Knowledge of the CYP isoforms that catalyze the principal pathways of drug metabolism provides a basis for understanding and even predicting drug interactions (see Chapter 3).

Hepatic CYP3A isozymes catalyze the metabolism of many drugs that are subject to significant drug interactions owing to inhibition of metabolism. Drugs metabolized predominantly by CYP3A isozymes include immunosuppressants (e.g., cyclosporine and tacrolimus); HMG-CoA reductase inhibitors (e.g., *lovastatin*, *simvastatin*, and *atorvastatin*); HIV protease inhibitors (e.g., *indinavir*, *nelfinavir*, *saquinavir*, *amprinavir*, and *ritonavir*); Ca²⁺ channel antagonists (e.g., *felodipine*, *nifedipine*, *nisoldipine*, and *diltiazem*); glucocorticoids (e.g., dexamethasone and *methylprednisolone*); benzodiazepines (e.g., *alprazolam*, *midazolam*, and *triazolam*); and lidocaine.

The inhibition of CYP3A isoforms may vary even among structurally related members of a given drug class. For example, the antifungal azoles ketoconazole and *itraconazole* potentially inhibit CYP3A enzymes, whereas the related *fluconazole* inhibits minimally except at high doses or in the setting of renal insufficiency. Similarly, certain macrolide antibiotics (e.g., *erythromycin* and *clarithromycin*) potentially inhibit CYP3A isoforms, but *azithromycin* does not. In one instance, the inhibition of CYP3A4 activity is turned to therapeutic advantage: the HIV protease inhibitor ritonavir inhibits CYP3A4 activity; when coadministered with other protease inhibitors metabolized by this pathway, ritonavir increases their half-lives and permits less frequent dosing.

Drug interactions mediated by CYP3A inhibition can be severe (e.g., nephrotoxicity induced by cyclosporine and tacrolimus and rhabdomyolysis resulting from increased levels of statins). Whenever an inhibitor of the CYP3A isoforms is administered, the clinician must be cognizant of the potential for serious interactions with drugs metabolized by CYP3A.

Drug interactions also can result from inhibition of other CYPs. *Amiodarone* and its active metabolite *desethylamiodarone* promiscuously inhibit several CYPs, including CYP2C9, the principal enzyme that eliminates the active *S*-enantiomer of warfarin. Because many patients treated with amiodarone (e.g., subjects with atrial fibrillation) are also receiving warfarin, the potential exists for major bleeding complications.

Knowledge of the specific pathways of metabolism of a drug and the molecular mechanisms of enzyme induction can help to identify potential interactions; thus, the pathways of drug metabolism often are determined during preclinical drug development. For example, if *in vitro* studies indicate that a compound is metabolized by CYP3A4, studies can focus on commonly used drugs that either inhibit (e.g., ketoconazole) or induce (e.g., rifampin) this enzyme. Other probes for the evaluation of potential drug interactions targeted at human CYPs include midazolam or erythromycin for CYP3A4 and *dextromethorphan* for CYP2D6.

INHIBITION OF DRUG TRANSPORT Drug transporters are key determinants of the availability of certain drugs to their site(s) of action, and clinically significant drug interactions can result from inhibition of drug transporters (see Chapter 2). P-glycoprotein, which actively transports multiple chemotherapeutic drugs out of cancer cells and renders them resistant to drug action, is expressed on the luminal aspect of intestinal epithelial cells (where it functions to inhibit xenobiotic absorption), on the luminal surface of renal tubular cells, and on the canalicular aspect of hepatocytes. Since this transporter is responsible for the elimination of certain drugs (e.g., digoxin), inhibition of P-glycoprotein-mediated transport results in increased plasma levels of drug at steady state. Inhibitors of P-glycoprotein include verapamil, diltiazem, amiodarone, *quinidine*, ketoconazole, *itraconazole*, and erythromycin. P-glycoprotein on the capillary endothelium that forms the blood-brain barrier exports drugs from the brain, and inhibition of P-glycoprotein enhances CNS distribution of some drugs (e.g., HIV protease inhibitors).

Pharmacodynamic Interactions

Combinations of drugs often are employed to therapeutic advantage when their beneficial effects are additive or synergistic or because therapeutic effects can be achieved with fewer drug-specific adverse effects by using submaximal doses of drugs in concert. Combination therapy often constitutes optimal treatment for many conditions, including heart failure (see Chapter 33), hypertension (see Chapter 32), and cancer (see Chapter 51). This section addresses pharmacodynamic interactions that produce adverse effects.

Nitrovasodilators (see Chapter 31) produce vasodilation by NO-dependent elevation of cyclic GMP in vascular smooth muscle. The pharmacologic effects of sildenafil, *tadalafil*, and *vardenafil* result from inhibition of the type 5 cyclic nucleotide phosphodiesterase (PDE5) that hydrolyzes cyclic GMP to 5'GMP in the vasculature. Thus, coadministration of an NO donor (e.g., nitroglycerin) with a PDE5 inhibitor can cause potentially catastrophic hypotension.

The oral anticoagulant warfarin has a narrow margin between therapeutic inhibition of clot formation and bleeding complications and is subject to several important drug interactions (*see* Chapter 54). Nonsteroidal anti-inflammatory drugs cause gastric and duodenal ulcers (*see* Chapter 36), and their concurrent administration with warfarin increases the risk of GI bleeding almost four-fold compared with warfarin alone. By inhibiting platelet aggregation, *aspirin* increases the incidence of bleeding in warfarin-treated patients. Finally, antibiotics that alter the intestinal flora reduce the bacterial synthesis of vitamin K, thereby enhancing the effect of warfarin.

A subset of nonsteroidal anti-inflammatory drugs, including *indomethacin*, *ibuprofen*, *piroxicam*, and the *cyclooxygenase (COX)-2 inhibitors*, can antagonize antihypertensive therapy, especially with regimens employing angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists, and β adrenergic receptor antagonists. The effect on arterial pressure ranges from trivial to severe. In contrast, *aspirin* and *sulindac* produce little, if any, elevation of blood pressure when used concurrently with these antihypertensive drugs.

Antiarrhythmic drugs that block potassium channels, such as *sotalol* and *quinidine*, can cause the polymorphic ventricular tachycardia known as *torsades de pointes* (*see* Chapter 34). The abnormal repolarization that leads to polymorphic ventricular tachycardia is potentiated by hypokalemia, and diuretics that produce potassium loss increase the risk of this drug-induced arrhythmia.

AGE AS A DETERMINANT OF RESPONSE TO DRUGS Most drugs are evaluated in young and middle-aged adults, and data on their use in children and the elderly are sparse. At the extremes of age, drug pharmacokinetics and pharmacodynamics can be altered, possibly requiring substantial alteration in the dose or dosing regimen to safely produce the desired clinical effect.

Children Drug disposition in childhood does not vary linearly with either body weight or body surface area, and there are no reliable, broadly applicable formulas for converting drug doses used in adults to those that are safe and effective in children. An important generality is that pharmacokinetic variability is likely to be greatest at times of physiological change (*e.g.*, the newborn or premature baby or at puberty) such that dosing adjustment, often aided by drug monitoring for drugs with narrow therapeutic indices, becomes critical for safe, effective therapeutics.

Most drug-metabolizing enzymes are expressed at low levels at birth, followed by an isozyme-specific postnatal induction. CYP2E1 and CYP2D6 appear in the first day, followed within 1 week by CYP3A4 and the CYP2C subfamily. CYP2A1 is not expressed until 1–3 months after birth. Some glucuronidation pathways are decreased in the newborn, and an inability of newborns to glucuronidate *chloramphenicol* was responsible for the “gray baby syndrome” (*see* Chapter 46). When adjusted for body weight or surface area, hepatic drug metabolism in children after the neonatal period often exceeds that of adults. Studies using *caffeine* as a model substrate illustrate the developmental changes in CYP1A2 that occur during childhood (Figure 5–2). The mechanisms regulating such developmental changes are uncertain, and other pathways of drug metabolism probably mature with different patterns.

Renal elimination of drugs also is reduced in the neonatal period. Neonates at term have markedly reduced GFR (2–4 mL/min/1.73 m²), and prematurity reduces renal function even further. As a result, neonatal dosing regimens for a number of drugs (*e.g.*, aminoglycosides) must be

FIGURE 5–2 Developmental changes in CYP1A2 activity, assessed as caffeine clearance.

reduced to avoid toxic drug accumulation. GFR (corrected for body surface area) increases progressively to adult levels by 8–12 months of age. Dosing guidelines for children—where they exist—are drug- and age-specific.

Drug pharmacodynamics in children also may differ from those in adults. *Antihistamines* and *barbiturates* that generally sedate adults may be excitatory in children. The enhanced sensitivity to the sedating effects of *propofol* in children has led to the administration of excessive doses that produced myocardial failure, metabolic acidosis, and multiorgan failure. Unique features of childhood development also may provide special vulnerabilities to drug toxicity; for example, tetracyclines can permanently stain developing teeth, and glucocorticoids can attenuate linear growth of bones.

The Elderly As adults age, gradual changes in pharmacokinetics and pharmacodynamics increase the interindividual variability of doses required for a given effect. Pharmacokinetic changes result from changes in body composition and the function of drug-eliminating organs. The reduction in lean body mass, serum albumin, and total-body water, coupled with the increase in percentage of body fat, alters drug distribution in a manner dependent on lipid solubility and protein binding. The clearance of many drugs is reduced in the elderly. Renal function variably declines to ~50% of that in young adults. Hepatic blood flow and drug metabolism also are reduced in the elderly but vary considerably. In general, the activities of hepatic CYPs are reduced, but conjugation mechanisms are relatively preserved. Frequently, the elimination half-lives of drugs are increased as a consequence of larger apparent volumes of distribution of lipid-soluble drugs and/or reductions in the renal or metabolic clearance.

Changes in pharmacodynamics are important factors in treating the elderly. Drugs that depress the CNS produce increased effects at any given plasma concentration due to age-related pharmacokinetic changes, physiological changes, and loss of homeostatic resilience, resulting in increased sensitivity to unwanted effects of drugs (*e.g.*, hypotension from psychotropic medications and hemorrhage from anticoagulants).

The number of elderly in developed nations is increasing rapidly. These individuals have more illnesses than younger people and consume a disproportionate share of prescription and over-the-counter drugs; they also are a population in whom drug use is especially likely to be marred by serious adverse effects and drug interactions. They therefore should receive drugs only when absolutely necessary for well-defined indications and at the lowest effective doses. Appropriate monitoring of drug levels and frequent reviews of the patient's drug history, with discontinuation of those drugs that did not achieve the desired end point or are no longer required, would greatly improve the health of the elderly.

THE PHARMACODYNAMIC CHARACTERISTICS OF A DRUG THAT DETERMINE ITS USE IN THERAPY

When drugs are administered to patients, there is no single characteristic relationship between the drug concentration in plasma and the measured effect; the concentration–effect curve may be concave upward, concave downward, linear, sigmoid, or an inverted-U shape. Moreover, the concentration–effect relationship may be distorted if the response being measured is a composite of several effects, such as the change in blood pressure produced by a combination of cardiac, vascular, and reflex effects. However, such a composite concentration–effect curve often can be resolved into simpler curves for each of its components. These simplified concentration–effect relationships, regardless of their exact shape, can be viewed as having four characteristic variables: *potency*, *maximal efficacy*, *slope*, and *individual variation*. These concepts are discussed in more detail in Chapter 1.

Potency can be viewed as the location of the concentration–effect curve along the concentration axis. Potency can be useful in the design of dosage forms, but more potent drugs are not always superior therapeutic agents. Maximal efficacy is the maximal effect that can be produced by a drug, as determined principally by the properties of the drug and its receptor–effector system and is reflected in the plateau of the concentration–effect curve. In clinical use, undesired effects may limit a drug's dosage such that its true maximal efficacy may not be achievable and clinical efficacy is then seen at a lower concentration. The slope of the concentration–effect curve reflects the mechanism of action of a drug, including the shape of the curve that describes drug binding to its receptor. The steepness of the curve dictates the range of doses that are useful for achieving a clinical effect (Figure 5–3).

Pharmacodynamic Variability

Individuals vary in the magnitude of their response to the same concentration of a single drug or to similar drugs, and a given individual may not always respond in the same way to the same drug

FIGURE 5-3 *The Log concentration–effect relationship.* Representative log concentration–effect curve illustrating its four characterizing variables. Here, the effect is measured as a function of increasing drug concentration in the plasma. Similar relationships also can be plotted as a function of the dose of drug administered. These plots are referred to as dose–effect curves. (See text for further discussion.)

concentration. A concentration–effect curve applies only to a single individual at one time or to an average individual. The intersecting brackets in Figure 5–3 indicate that an effect of varying intensity will occur in different individuals at a specified drug concentration or that a range of concentrations is required to produce an effect of specified intensity in all patients.

Attempts have been made to define and measure individual “sensitivity” to drugs in the clinical setting, and progress has been made in understanding some of the determinants of sensitivity to drugs that act at specific receptors. Drug responsiveness may change because of disease or because of previous drug administration. Receptors are dynamic, and their concentration and function may be up- or down-regulated by endogenous and exogenous factors.

Data on the association of drug levels with efficacy and toxicity must be interpreted in the context of the pharmacodynamic variability in the population (*e.g.*, genetics, age, disease, and other drugs). The variability in pharmacodynamic response in the population may be analyzed by constructing a quantal concentration–effect curve (Figure 5–4A).

The Therapeutic Index

The dose of a drug required to produce a specified effect in 50% of the population is the *median effective dose* (ED_{50} ; Figure 5–4B). In preclinical studies of drugs, the *median lethal dose* (LD_{50}) is determined in experimental animals. The LD_{50}/ED_{50} ratio is an indication of the *therapeutic index*, which is a statement of how selective the drug is in producing its desired *versus* its adverse effects. In clinical studies, the dose, or preferably the concentration, of a drug required to produce toxic effects can be compared with the concentration required for therapeutic effects in the population to evaluate the *clinical therapeutic index*. Since pharmacodynamic variation in the population may be marked, the concentration or dose of drug required to produce a therapeutic effect in most of the population usually will overlap the concentration required to produce toxicity in some of the population, even though the drug’s therapeutic index in an individual patient may be large. Also, the concentration–percent curves for efficacy and toxicity need not be parallel, adding yet another complexity to determination of the therapeutic index in patients. Finally, no drug produces a single effect, and the therapeutic index for a drug will vary depending on the effect being measured.

ADVERSE DRUG REACTIONS AND DRUG TOXICITY

Any drug, no matter how trivial its therapeutic actions, has the potential to do harm. Adverse reactions are a cost of modern medical therapy. Although the mandate of the Food and Drug Administration (FDA) is to ensure that drugs are safe and effective, these terms are relative. The anticipated benefit from any therapeutic decision must be balanced by the potential risks.

It has been estimated that 3–5% of all hospitalizations can be attributed to adverse drug reactions, resulting in 300,000 hospitalizations annually in the U.S. Once hospitalized, patients have about a 30% chance of an untoward event related to drug therapy, and the risk attributable to each course of drug therapy is about 5%. The chance of a life-threatening drug reaction is about 3% per

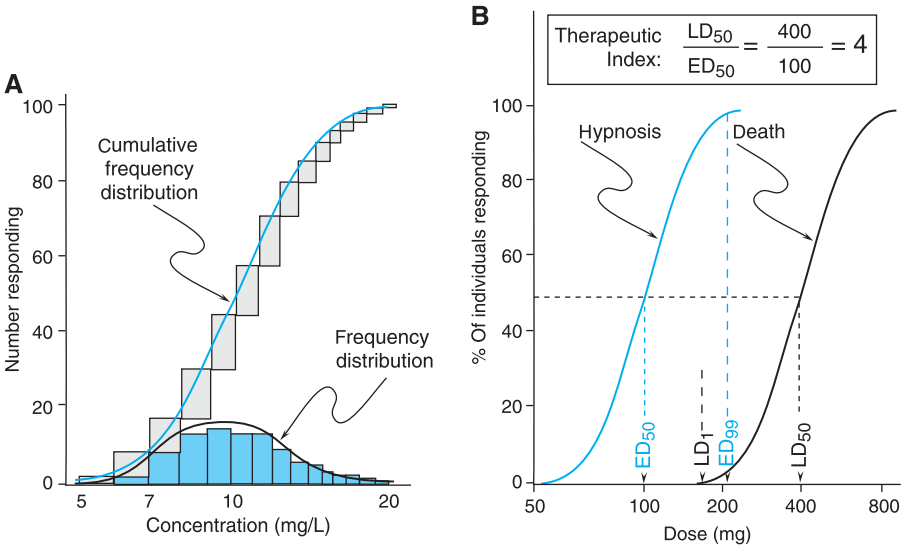

FIGURE 5-4 Frequency distribution curves and quantal concentration–effect and dose–effect curves. **A.** Frequency distribution curves. An experiment was performed on 100 subjects, and the effective plasma concentration that produced a quantal response was determined for each individual. The number of subjects who required each dose is plotted, giving a log-normal frequency distribution (colored bars). The gray bars demonstrate that the normal frequency distribution, when summated, yields the cumulative frequency distribution—a sigmoidal curve that is a quantal concentration–effect curve. **B.** Quantal dose–effect curves. Animals were injected with varying doses of sedative-hypnotic, and the responses were determined and plotted. The calculation of the therapeutic index, the ratio of the LD₅₀ to the ED₅₀, is an indication of how selective a drug is in producing its desired effects relative to its toxicity. (See text for additional explanation.)

patient in the hospital and about 0.4% per each course of therapy. Adverse reactions to drugs are the most common cause of iatrogenic disease.

Mechanism-based adverse drug reactions are extensions of the principal pharmacological action of the drug. These would be expected to occur with all members of a class of drugs having the same mechanism of action.

When an adverse effect is encountered infrequently, it may be referred to as *idiosyncratic* (i.e., it does not occur in the population at large). Idiosyncratic adverse effects may be mechanism-based (e.g., angioedema on angiotensin-converting enzyme inhibitors) or off-target reactions (e.g., anaphylaxis to penicillin). Investigations of idiosyncratic reactions often have identified a genetic or environmental basis for the unique host factors leading to the unusual effects.

THERAPEUTIC DRUG MONITORING

Given the multiple factors that alter drug disposition, measurement of the concentration in body fluids can assist in individualizing therapy with selected drugs. Determination of the concentration of a drug is particularly useful when well-defined criteria are met:

1. A demonstrated relationship exists between the concentration of drug in plasma and the desired therapeutic effect or the toxic effect to be avoided. The range of plasma levels between that required for efficacy and that at which toxicity occurs for a given individual is designated the *therapeutic window*.
2. There is sufficient variability in plasma level that the level cannot be predicted from the dose alone.
3. The drug produces effects, intended or unwanted, that are difficult to monitor.
4. The concentration required to produce the therapeutic effect is close to the level that causes toxicity (i.e., there is a low therapeutic index).

A clear demonstration of the relation of drug concentration to efficacy or toxicity is not achievable for many drugs; even when such a relationship can be determined, it usually predicts only

FIGURE 5-5 The relation of the therapeutic window of drug concentrations to the therapeutic and adverse effects in the population. Ordinate is linear; abscissa is logarithmic.

a probability of efficacy or toxicity. In trials of antidepressant drugs, such a high proportion of patients respond to placebo that it is difficult to determine the plasma level associated with efficacy. There is a quantal concentration–response curve for efficacy and adverse effects (Figure 5–5); for many drugs, the concentration that achieves efficacy in all the population may produce adverse effects in some individuals. Thus, a *population therapeutic window* expresses a range of concentrations at which the likelihood of efficacy is high and the probability of adverse effects is low. It does not guarantee either efficacy or safety. *Therefore, use of the population therapeutic window to adjust dosage of a drug should be complemented by monitoring appropriate clinical and surrogate markers for drug effect.*

THE DYNAMIC INFORMATION BASE

The information available to guide drug therapy is continually evolving. Among the available sources are textbooks of pharmacology and therapeutics, medical journals, published treatment guidelines, analytical evaluations of drugs, drug compendia, professional seminars and meetings, and advertising. A strategy to extract objective and unbiased data is required for the practice of rational, evidence-based therapeutics. Patient-centered acquisition of relevant information is a centerpiece of such a strategy. This requires access to the information in the practice setting and increasingly is facilitated by electronic availability of information resources including the primary medical literature (available via PubMed, www.ncbi.nlm.nih.gov/entrez/query.fcgi).

Depending on their aim and scope, textbooks of pharmacology may provide, in varying proportions, basic pharmacological principles, critical appraisal of useful categories of therapeutic agents, and detailed descriptions of individual drugs or prototypes that serve as standards of reference for assessing new drugs. In addition, pharmacodynamics and pathophysiology are correlated. Therapeutics is considered in virtually all textbooks of medicine but often superficially. The PDR offers industry-collated data and can be used for indication and dosing information. Industry promotion—in the form of direct-mail brochures, journal advertising, displays, professional courtesies, or the detail person or pharmaceutical representative—is intended to be persuasive rather than educational. The pharmaceutical industry cannot, should not, and indeed does not purport to be responsible for the education of physicians in the use of drugs.

DRUG NOMENCLATURE

The existence of many names for each drug, even when the names are reduced to a minimum, has led to a lamentable and confusing situation in drug nomenclature (*see* Appendix I in the 11th edition of the parent text). In addition to its formal *chemical* name, a new drug is usually assigned a *code* name by the pharmaceutical manufacturer. If the drug appears promising and the manufacturer wishes to place it on the market, a *U.S. adopted name* (USAN) is selected by the USAN Council,

which is jointly sponsored by the American Medical Association, the American Pharmaceutical Association, and the United States Pharmacopeial Convention, Inc. This *nonproprietary* name often is referred to as the *generic name*. If the drug is eventually admitted to the *United States Pharmacopeia* (see below), the USAN becomes the *official name*. However, the nonproprietary and official names of an older drug may differ. Subsequently, the drug also will be assigned a *proprietary name*, or *trademark*, by the manufacturer. If more than one company markets the drug, then it may have several proprietary names. If mixtures of the drug with other agents are marketed, each such mixture also may have a separate proprietary name.

There is increasing worldwide adoption of the same *nonproprietary name* for each therapeutic substance. For newer drugs, the USAN is usually adopted for the nonproprietary name in other countries, but this is not true for older drugs. International agreement on drug names is mediated through the World Health Organization and the pertinent health agencies of the cooperating countries.

Except for a few drugs such as *levodopa* and *dextroamphetamine*, nonproprietary names usually give no indication of the drug's stereochemistry. This issue becomes important when a drug's different diastereomers produce different pharmacologic effects, as is the case with *labetalol* (see Chapters 10 and 32).

The nonproprietary or official name of a drug should be used whenever possible, and such a practice has been adopted in this book. The use of the nonproprietary name is clearly less confusing when the drug is available under multiple proprietary names and when the nonproprietary name more readily identifies the drug with its pharmacological class. The facile argument for the proprietary name is that it is frequently more easily pronounced and remembered as a result of advertising. *For purposes of identification, representative proprietary names, designated by SMALLCAP TYPE, appear throughout the text and in the index.* Not all proprietary names for drugs are included because the number of proprietary names for a single drug may be large and because proprietary names differ from country to country.

DRUG DEVELOPMENT AND ITS REGULATION

Drug Regulation

The history of drug regulation in the U.S. reflects the growing involvement of governments in most countries to ensure some degree of efficacy and safety in marketed medicinal agents. The first legislation, the Federal Food and Drug Act of 1906, was concerned with the interstate transport of adulterated or misbranded foods and drugs. There were no obligations to establish drug efficacy and safety. This act was amended in 1938, after the deaths of 105 children that resulted from the marketing of a solution of *sulfanilamide* in diethylene glycol, an excellent but highly toxic solvent. The amended act, the enforcement of which was entrusted to the FDA, was concerned primarily with the truthful labeling and safety of drugs. Toxicity studies, as well as approval of a new drug application (NDA), were required before a drug could be promoted and distributed. However, no proof of efficacy was required, and extravagant claims for therapeutic indications were made commonly.

In this relatively relaxed atmosphere, research in basic and clinical pharmacology burgeoned in industrial and academic laboratories. The result was a flow of new drugs, called "wonder drugs" by the lay press. Because efficacy was not rigorously defined, a number of therapeutic claims could not be supported by data. The risk-to-benefit ratio was seldom mentioned but emerged dramatically early in the 1960s. At that time, *thalidomide*, a hypnotic with no obvious advantage over other drugs in its class, was introduced in Europe. After a short period, it became apparent that the incidence of a relatively rare birth defect, phocomelia, was increasing. It soon reached epidemic proportions, and retrospective epidemiological research firmly established the causative agent to be thalidomide taken early in the course of pregnancy. The reaction to the dramatic demonstration of the teratogenicity of a needless drug was worldwide. In the U.S., it resulted in the Harris-Kefauver Amendments to the Food, Drug, and Cosmetic Act in 1962, which require sufficient pharmacological and toxicological research in animals before a drug can be tested in human beings. The data from such studies must be submitted to the FDA in the form of an application for an investigational new drug (IND) before clinical studies can begin. Three phases of clinical testing have evolved to provide the data that are used to support an NDA. Proof of efficacy is required, as is documentation of relative safety in terms of the risk-to-benefit ratio for the disease entity to be treated.

Drug Development

By the time an IND application has been initiated and a drug reaches the stage of testing in humans, its pharmacokinetic, pharmacodynamic, and toxic properties have been evaluated

in vivo in several species of animals in accordance with regulations and guidelines published by the FDA. Although the value of many requirements for preclinical testing is self-evident, such as those that screen for direct toxicity to organs and characterize dose-related effects, the value of others is controversial, particularly because of the well-known interspecies variation in the effects of drugs.

Trials of drugs in human beings in the U.S. generally are conducted in three phases, which must be completed before an NDA can be submitted to the FDA for review; these are outlined in Figure 5–6. Although assessment of risk is a major objective of such testing, this is far more difficult than is the determination of whether a drug is efficacious for a selected clinical condition. Usually about 2000–3000 carefully selected patients receive a new drug during phase 3 clinical trials. At most, only a few hundred are treated for more than 3–6 months regardless of the likely

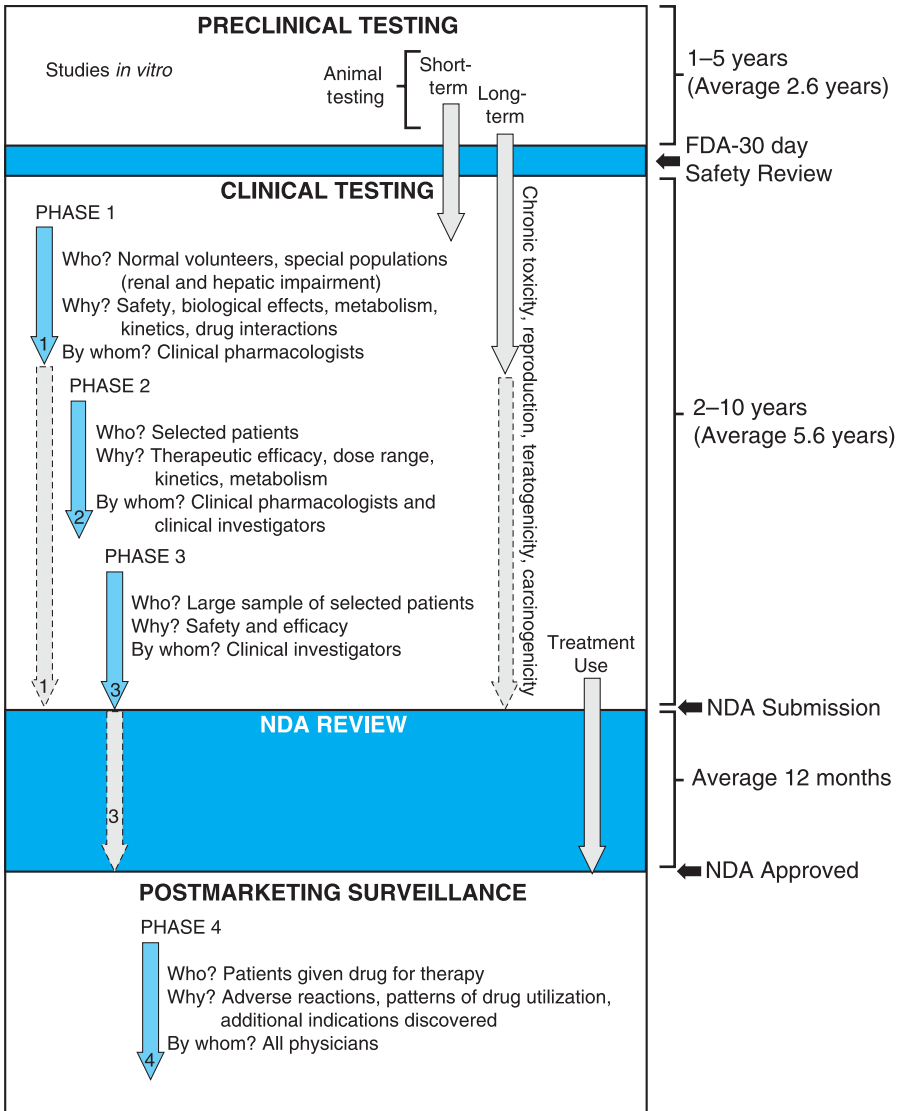

FIGURE 5–6 The phases of drug development in the United States.

duration of therapy that will be required in practice. Thus, the most profound and overt risks that occur almost immediately after the drug is given can be detected in a phase 3 study if they occur more often than once per 100 administrations. Risks that are medically important but delayed or less frequent than 1 in 1000 administrations may not be revealed prior to marketing (e.g., COX-2 inhibitors). Consequently, a number of unanticipated adverse and beneficial effects of drugs are detectable only after the drug is used broadly. Many countries, including the U.S., have established systematic methods for the surveillance of the effects of drugs after they have been approved for distribution (see below).

Postmarketing Surveillance for Adverse Reactions

For idiosyncratic adverse reactions, current approaches to “safety assessment” in clinical trials are problematic. The relative rarity of severe idiosyncratic reactions (e.g., severe dermatological, hematological, or hepatological toxicities) poses an epidemiological challenge. It is clear that a risk of 1 in 1000 is not distributed evenly across the population; some patients, due to unique genetic or environmental factors, are at an extremely high risk, whereas the remainder of the population may be at low or no risk. In contrast to the human heterogeneity underlying idiosyncratic risk, the standard process of drug development, particularly preclinical safety assessment using inbred healthy animals maintained in a defined environment on a defined diet and manifesting predictable habits, limits the identification of risk for idiosyncratic adverse drug reactions in the human population. Understanding the genetic and environmental bases of idiosyncratic adverse events holds the promise of assessing individual rather than population risk, thereby improving the overall safety of pharmacotherapy.

Formal approaches for estimating the magnitude of an adverse drug effect are the follow-up or cohort study of patients who are receiving a particular drug, the case-control study, where the frequency of drug use in cases of adverse reactions is compared with controls, and meta-analyses of pre- and postmarketing studies. Cohort studies can estimate the incidence of an adverse reaction but cannot, for practical reasons, discover rare events. To have any significant advantage over the premarketing studies, a cohort study must follow at least 10,000 patients who are receiving the drug to detect with 95% confidence one event that occurs at a rate of 1 in 3300, and the event can be attributed to the drug only if it does not occur spontaneously in the control population. Meta-analyses combine the data from several studies in an attempt to discern benefits or risks that are sufficiently uncommon that an individual study lacks the power to discover them.

The Key Role of the Clinician in Surveillance for Adverse Reactions

Because of the shortcomings of cohort and case-control studies and meta-analyses, additional approaches are needed. Spontaneous reporting of adverse reactions has proven to be an effective way to generate an early signal that a drug may cause an adverse event. In the past few years, considerable effort has gone into improving the reporting system in the U.S., which is now called MEDWATCH. Still, the voluntary reporting system in the U.S. is deficient compared with the legally mandated systems of many other nations.

NEUROTRANSMISSION: THE AUTONOMIC AND SOMATIC MOTOR NERVOUS SYSTEMS

The autonomic nervous system (ANS) is the primary moment-to-moment regulator of the internal environment of the organism, regulating specific functions that occur without conscious control, for example, respiration, circulation, digestion, body temperature, metabolism, sweating, and the secretions of certain endocrine glands. The endocrine system, in contrast, provides slower, more generalized regulation by secreting hormones into the systemic circulation to act at distant, widespread sites over periods of minutes to hours to days.

In the periphery, the ANS consists of nerves, ganglia, and plexuses that innervate the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues. Based on considerations of anatomy and neurotransmitters, we divide the ANS into sympathetic and parasympathetic branches. The sympathetic branch, including the adrenal medulla, is not essential to life in a controlled environment, but the lack of sympathoadrenal functions becomes evident with stress (e.g., compensatory cardiovascular responses to altered posture and exercise do not occur; fainting ensues). The sympathetic system normally is continuously active, adjusting moment-to-moment to a changing environment. The sympathoadrenal system also can discharge as a unit, particularly during rage and fright, and affect sympathetically-innervated structures over the entire body simultaneously, increasing heart rate and blood pressure, shifting blood flow from skin and splanchnic regions to the skeletal muscles, elevating blood glucose, dilating the bronchioles and pupils, and generally preparing the organism for “fight or flight.”

The parasympathetic system, organized mainly for discrete and localized discharge, slows the heart rate, lowers the blood pressure, stimulates GI movements and secretions, aids absorption of nutrients, protects the retina from excessive light, and empties the urinary bladder and rectum. Many parasympathetic responses are rapid and reflexive. Although the parasympathetic branch of the ANS is concerned primarily with conservation of energy and maintenance of organ function during periods of satiety and minimal activity, its elimination is incompatible with life.

VISCERAL AFFERENT FIBERS

Afferent fibers from visceral structures are the first link in the reflex arcs of the autonomic system. With certain exceptions, such as local axon reflexes, most visceral reflexes are mediated through the central nervous system (CNS). Information on the status of the visceral organs is transmitted to the CNS through the cranial nerve (parasympathetic) visceral sensory system and the spinal (sympathetic) visceral afferent system. The cranial visceral sensory system carries mainly mechanoreceptor and chemosensory information; the afferents of the spinal visceral system principally convey sensations related to temperature and tissue injury of mechanical, chemical, or thermal origin. Cranial visceral sensory information enters the CNS via four cranial nerves: the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X). These four cranial nerves transmit visceral sensory information from the internal face and head (V), tongue (taste, VII), hard palate, upper part of the oropharynx, and carotid body (IX), and lower part of the oropharynx, larynx, trachea, esophagus, and thoracic and abdominal organs (X), with the exception of the pelvic viscera, which are innervated by nerves from the second through fourth sacral spinal segments. The visceral afferents from these four cranial nerves terminate topographically in the solitary tract nucleus (STN).

Sensory afferents from visceral organs also enter the CNS via the spinal nerves. Those concerned with muscle chemosensation may arise at all spinal levels; sympathetic visceral sensory afferents generally arise at the thoracic levels where sympathetic preganglionic neurons are found. Pelvic sensory afferents from spinal segments S2–S4 enter at that level and are important for the regulation of sacral parasympathetic outflow. In general, visceral afferents that enter the spinal nerves convey information concerned with temperature as well as nociceptive visceral inputs.

Neurotransmitters that mediate transmission from sensory fibers have not been characterized unequivocally. Substance P and calcitonin gene-related peptide are leading candidates for

communicating nociceptive stimuli from the periphery to the CNS. Somatostatin, vasoactive intestinal polypeptide (VIP), and cholecystokinin may play a role in the transmission of afferent impulses from autonomic structures. ATP appears to be a neurotransmitter in certain sensory neurons, including those that innervate the urinary bladder. Enkephalins, present in interneurons in the dorsal spinal cord (within an area termed the substantia gelatinosa), have antinociceptive effects that appear to arise from presynaptic and postsynaptic actions to inhibit the release of substance P and diminish the activity of cells that project from the spinal cord to higher centers in the CNS. The excitatory amino acids glutamate and aspartate also play major roles in transmission of sensory responses to the spinal cord.

CENTRAL AUTONOMIC CONNECTIONS

There probably are no purely autonomic or somatic centers of integration; extensive overlap occurs; somatic responses always are accompanied by visceral responses, and vice versa. Autonomic reflexes can be elicited at the level of the spinal cord and are manifested by sweating, blood pressure alterations, vasomotor responses to temperature changes, and reflex emptying of the urinary bladder, rectum, and seminal vesicles. The hypothalamus and the STN are principal loci of integration of ANS functions, including regulation of body temperature, water balance, carbohydrate and fat metabolism, blood pressure, emotions, sleep, respiration, and reproduction. Signals are received through ascending spinobulbar pathways, the limbic system, neostriatum, cortex, and to a lesser extent other higher brain centers.

The CNS can produce a wide range of patterned autonomic and somatic responses. Highly integrated patterns of response generally are organized at the hypothalamic level and involve autonomic, endocrine, and behavioral components. More limited patterned responses are organized at other levels of basal forebrain, brainstem, and spinal cord.

DIVISIONS OF THE PERIPHERAL AUTONOMIC SYSTEM: EFFERENT NERVES

On the efferent side, the ANS consists of two large divisions: (1) the sympathetic or thoracolumbar, and, (2) the parasympathetic or craniosacral (see Figure 6-1).

The neurotransmitter of all preganglionic autonomic fibers, all postganglionic parasympathetic fibers, and a few postganglionic sympathetic fibers is *acetylcholine* (ACh). Adrenergic fibers comprise the majority of the postganglionic sympathetic fibers; here, the transmitter is *norepinephrine* (NE, *noradrenaline*). The terms *cholinergic* and *adrenergic* are used to describe neurons that release ACh or NE, respectively.

SYMPATHETIC BRANCH OF THE ANS

The cells that give rise to the preganglionic fibers of this division lie mainly in the intermediolateral columns of the spinal cord and extend from the first thoracic to the second or third lumbar segment. The axons from these cells are carried in the anterior (ventral) nerve roots and synapse with neurons lying in sympathetic ganglia outside the cerebrospinal axis. Sympathetic ganglia are found in three locations: paravertebral, prevertebral, and terminal.

The 22 pairs of paravertebral sympathetic ganglia form the lateral chains on either side of the vertebral column. The ganglia are connected to each other by nerve trunks and to the spinal nerves by rami communicantes. The white rami are restricted to the segments of the thoracolumbar outflow; they carry the preganglionic myelinated fibers that exit the spinal cord via the anterior spinal roots. The gray rami arise from the ganglia and carry postganglionic fibers back to the spinal nerves for distribution to sweat glands and pilomotor muscles and to blood vessels of skeletal muscle and skin. The prevertebral ganglia lie in the abdomen and the pelvis near the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The terminal ganglia are few in number; lie near the organs they innervate, and include ganglia connected with the urinary bladder and rectum and the cervical ganglia in the region of the neck. Small intermediate ganglia lie outside the conventional vertebral chain, especially in the thoracolumbar region, usually proximally to the communicating rami and the anterior spinal nerve roots.

Preganglionic fibers issuing from the spinal cord may synapse with the neurons of more than one sympathetic ganglion. Their principal ganglia of termination need not correspond to the original level from which the preganglionic fiber exits the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the paravertebral ganglia to form the splanchnic nerves. Most of the splanchnic nerve fibers do not synapse until they reach the celiac ganglion; others directly innervate the adrenal medulla (see below).

Postganglionic fibers arising from sympathetic ganglia innervate visceral structures of the thorax, abdomen, head, and neck. The trunk and the limbs are supplied by the sympathetic fibers in spinal nerves, as described earlier. The prevertebral ganglia contain cell bodies whose axons

Blue, cholinergic; gray, adrenergic; dotted blue, visceral afferent; solid lines, preganglionic; broken lines, postganglionic. In the upper rectangle at the right are shown the finer details of the ramifications of adrenergic fibers at any one segment of the spinal cord, the path of the visceral afferent nerves, the cholinergic nature of somatic motor nerves to skeletal muscle, and the presumed cholinergic nature of the vasodilator fibers in the dorsal roots of the spinal nerves. The asterisk (*) indicates that it is not known whether these vasodilator fibers are motor or sensory or where their cell bodies are situated. In the lower rectangle on the right, vagal preganglionic (solid blue) nerves from the brainstem synapse on both excitatory and inhibitory neurons found in the myenteric plexus. A synapse with a postganglionic cholinergic neuron (blue with varicosities) gives rise to excitation, whereas synapses with purinergic, peptide (VIP), or an NO-generating neuron (black with varicosities) lead to relaxation. Sensory nerves (dotted blue lines) originating primarily in the mucosal layer send afferent signals to the CNS but often branch and synapse with ganglia in the plexus. Their transmitter is substance P or other tachykinins. Other interneurons (white) contain serotonin and will modulate intrinsic activity through synapses with other neurons eliciting excitation or relaxation (black). Cholinergic, adrenergic, and some peptidergic neurons pass through the circular smooth muscle to synapse in the submucosal plexus or terminate in the mucosal layer, where their transmitter may stimulate or inhibit GI secretion.

innervate the glands and smooth muscles of the abdominal and the pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses, such as the cardiac, esophageal, and pulmonary plexuses. The sympathetic distribution to the head and the neck (vasomotor, pupillo dilator, secretory, and pilomotor) is via the cervical sympathetic chain and its three ganglia. All postganglionic fibers in this chain arise from cell bodies located in these three ganglia; all preganglionic fibers arise from the upper thoracic segments of the spinal cord, there being no sympathetic fibers that leave the CNS above the first thoracic level.

The adrenal medulla and other chromaffin tissue are embryologically and anatomically similar to sympathetic ganglia. The adrenal medulla differs from sympathetic ganglia in that its principal catecholamine is epinephrine (Epi, adrenaline), not NE. The chromaffin cells in the adrenal medulla are innervated by typical preganglionic fibers that release ACh.

PARASYMPATHETIC BRANCH OF THE ANS

The parasympathetic branch of the ANS consists of preganglionic fibers that originate in the CNS and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata, and the sacral part of the spinal cord. The midbrain, or tectal, outflow consists of fibers arising from the Edinger–Westphal nucleus of the third cranial nerve and going to the ciliary ganglion in the orbit. The medullary outflow consists of the parasympathetic components of the seventh, ninth, and tenth cranial nerves. The fibers in the seventh (facial) cranial nerve form the chorda tympani, which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the greater superficial petrosal nerve, which innervates the sphenopalatine ganglion. The autonomic components of the ninth (glossopharyngeal) cranial nerve innervate the otic ganglia. Postganglionic parasympathetic fibers from these ganglia supply the sphincter of the iris (pupillary constrictor muscle), the ciliary muscle, the salivary and lacrimal glands, and the mucous glands of the nose, mouth, and pharynx. These fibers also include vasodilator nerves to these same organs. The tenth (vagus) cranial nerve arises in the medulla and contains preganglionic fibers, most of which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. In the intestinal wall, the vagal fibers terminate around ganglion cells in the myenteric and submucosal plexuses. Thus, preganglionic fibers are very long, whereas postganglionic fibers are very short. The vagus nerve also carries a far greater number of afferent fibers (but apparently no pain fibers) from the viscera into the medulla; the cell bodies of these fibers lie mainly in the nodose ganglion.

The parasympathetic sacral outflow consists of axons that arise from cells in the second, third, and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves (nervi erigentes). They synapse in terminal ganglia lying near or within the bladder, rectum, and sexual organs. The vagal and sacral outflows provide motor and secretory fibers to thoracic, abdominal, and pelvic organs (Figure 6–1).

ENTERIC NERVOUS SYSTEM

The activities of the GI tract are controlled locally through a restricted part of the peripheral nervous system called the enteric nervous system (ENS). The ENS is involved in sensorimotor control and consists of both afferent sensory neurons and a number of motor nerves and interneurons that are organized principally into two nerve plexuses: the myenteric (Auerbach's) plexus and the submucosal (Meissner's) plexus. The myenteric plexus, located between the longitudinal and circular muscle layers, plays an important role in the contraction and relaxation of GI smooth muscle. The submucosal plexus is involved with secretory and absorptive functions of the GI epithelium, local blood flow, and neuroimmune activities. The ENS consists of components of the sympathetic and parasympathetic branches of the ANS and has sensory nerve connections through the spinal and nodose ganglia (see Chapter 37).

Parasympathetic input to the GI tract is excitatory; preganglionic neurons in the vagus innervate the parasympathetic ganglia of the enteric plexuses. Postganglionic sympathetic nerves also synapse with the intramural enteric parasympathetic ganglia. Sympathetic nerve activity induces relaxation primarily by inhibiting the release of ACh from the preganglionic fibers.

The intrinsic primary afferent neurons are present in both the myenteric and submucosal plexuses. They respond to luminal chemical stimuli, to mechanical deformation of the mucosa, and to stretch. The nerve endings of the primary afferent neurons can be activated by endogenous substances (e.g., serotonin) arising from local enterochromaffin cells or possibly from serotonergic nerves.

The muscle layers of the GI tract are dually innervated by excitatory and inhibitory motor neurons whose cell bodies are in the gut wall. ACh, in addition to being the transmitter of parasympathetic nerves to the ENS, is the primary excitatory transmitter acting on nicotinic acetylcholine

receptors (nAChRs) in ascending intramural pathways. Pharmacological blockade of cholinergic neurotransmission, however, does not completely abolish this excitatory transmission because cotransmitters, such as substance P and neurokinin A, are coreleased with ACh and contribute to the excitatory response; similarly, ATP acts as an excitatory neurotransmitter via P2X receptors.

Inhibitory neurons of the ENS release a variety of transmitters and cotransmitters, including nitric oxide (NO), ATP (acting on P2Y receptors), VIP, and pituitary adenylyl cyclase-activating peptide (PACAP); NO is a primary inhibitory transmitter. Interstitial cells of Cajal (ICC) relay signals from the nerves to the smooth muscle cells to which they are electrically coupled. The ICC have receptors for both the inhibitory transmitter NO and the excitatory tachykinins. Disruption of the ICC impairs excitatory and inhibitory neurotransmission.

DIFFERENCES AMONGST SYMPATHETIC, PARASYMPATHETIC, AND MOTOR NERVES

A preganglionic sympathetic fiber may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it finally synapses with a postganglionic neuron; also, its terminals contact a large number of postganglionic neurons, and one ganglion cell may be supplied by several preganglionic fibers, such that the ratio of preganglionic axons to ganglion cells may be >1:20. This organization permits a diffuse discharge of the sympathetic system.

The parasympathetic system, in contrast, has terminal ganglia very near or within the organs innervated and thus is more circumscribed in its influences. In some organs, there is a 1:1 relationship between the number of preganglionic and postganglionic fibers (this distinction does not apply to all sites; in the myenteric plexus, this ratio is ~1:8000).

The cell bodies of somatic motor neurons reside in the ventral horn of the spinal cord (see Figure 6-1); the axon divides into many branches, each of which innervates a single muscle fiber, so more than 100 muscle fibers may be supplied by one motor neuron to form a motor unit. At each neuromuscular junction, the axonal terminal loses its myelin sheath and forms a terminal arborization that lies in apposition to a specialized surface of the muscle membrane, the *motor end plate* (see Figure 9-2).

RESPONSES OF EFFECTOR ORGANS TO AUTONOMIC NERVE IMPULSES From the responses of the various effector organs to autonomic nerve impulses and the knowledge of the intrinsic autonomic tone, one can predict the actions of drugs that mimic or inhibit the actions of these nerves. In some instances, the sympathetic and parasympathetic neurotransmitters can be viewed as physiological or functional antagonists. Most viscera are innervated by both divisions of the ANS, and the level of activity at any moment represents the sum of influences of the two components. Effects of sympathetic and parasympathetic stimulation of the heart and the iris show a pattern of functional antagonism in controlling heart rate and pupillary aperture, respectively, whereas their actions on male sexual organs are complementary and are integrated to promote sexual function. The control of peripheral vascular resistance is due primarily, but not exclusively, to sympathetic control of the contraction of arteriolar smooth muscle. The effects of stimulating the sympathetic and parasympathetic nerves to various organs, visceral structures, and effector cells are summarized in Table 6-1.

NEUROTRANSMISSION

Nerve impulses elicit responses by liberating specific chemical neurotransmitters. Understanding the chemical mediation of nerve impulses provides the framework for our knowledge of the mechanism of action of drugs at these sites. The sequence of events involved in neurotransmission is of particular importance because pharmacologically active agents modulate the individual steps.

AXONAL CONDUCTION

Conduction refers to the passage of an impulse along an axon or muscle fiber; transmission refers to the passage of an impulse across a synaptic or neuroeffector junction. Axonal conduction has its basis in transmembrane ionic gradients and in selectively permeable membrane channels. At rest, the interior of the typical mammalian axon is ~70 mV negative to the exterior. The resting potential is essentially a K^+ Nernst potential based on the higher concentration of K^+ [$\sim 40\times$] in the axoplasm versus the extracellular fluid and the relatively high permeability of the resting axonal membrane to K^+ , Na^+ , and Cl^- are present in higher concentrations in the extracellular fluid than in the axoplasm, but the axonal membrane at rest is considerably less permeable to these ions; hence, their contribution to the resting potential is small. These ionic gradients are maintained by the Na^+ , K^+ -ATPase.

In response to depolarization to a threshold level, an action potential (AP) is initiated locally in the membrane. The AP consists of two phases. Following a small gating current resulting from

^bAdrenergic receptors: α_1 , α_2 , and subtypes thereof; β_1 , β_2 , β_3 . Cholinergic receptors: nicotinic (N); muscarinic (M), with subtypes 1–4. The receptor subtypes are described more fully in Chapters 7 and 10 and in Tables 6–2, 6–3 and 6–6. When a designation of subtype is not provided, the nature of the subtype has not been determined unequivocally. Only the principal receptor subtypes are shown. Transmitters other than acetylcholine and norepinephrine contribute to many of the responses.

^cIn the human heart, the ratio of β_1 to β_2 is about 3:2 in atria and 4:1 in ventricles. While M₂ receptors predominate, M₃ receptors are also present.

^dThe predominant α_1 receptor subtype in most blood vessels (both arteries and veins) is α_{1A} (see Table 6–8), although other α_1 subtypes are present in specific vessels. The α_{1D} is the predominant subtype in the aorta.

^eDilation predominates *in situ* owing to metabolic autoregulatory mechanisms.

^fOver the usual concentration range of physiologically released circulating epinephrine, the β -receptor response (vasodilation) predominates in blood vessels of skeletal muscle and liver; the α -receptor response (vasoconstriction) in other abdominal viscera. The renal and mesenteric vessels also contain specific dopaminergic receptors whose activation causes dilation.

^gSympathetic cholinergic neurons cause vasodilation in skeletal muscle beds, but this is not involved in most physiological responses.

^hThe endothelium of most blood vessels releases NO, which causes vasodilation in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to exogenously added muscarinic agonists in the circulation.

ⁱWhile adrenergic fibers terminate at inhibitory β receptors on smooth muscle fibers and at inhibitory α receptors on parasympathetic (cholinergic) excitatory ganglion cells of the myenteric plexus, the primary inhibitory response is mediated *via* enteric neurons through NO, P2Y receptors, and peptide receptors.

^tThere is significant variation among species in the receptor types that mediate certain metabolic responses. All three β adrenergic receptors have been found in human fat cells. Activation of β_3 adrenergic receptors produces a vigorous thermogenic response as well as lipolysis. The significance is unclear. Activation of β adrenergic receptors also inhibits leptin release from adipose tissue. ADH, antidiuretic hormone, arginine vasopressin; AV, atrioventricular; AP, action potential.

depolarization inducing an open conformation of the channel, the initial phase is caused by a rapid increase in the permeability of Na^+ through voltage-sensitive Na^+ channels. The result is inward movement of Na^+ and a rapid depolarization from the resting potential, which continues to a positive overshoot. The second phase results from the rapid inactivation of the Na^+ channel and the delayed opening of a K^+ channel, which permits outward movement of K^+ to terminate the depolarization.

The transmembrane ionic currents produce local circuit currents around the axon. As a result, adjacent resting channels in the axon are activated, exciting an adjacent portion of the axonal membrane and causing propagation of the AP without decrement along the axon. The region that has undergone depolarization remains momentarily in a refractory state. In myelinated fibers, permeability changes occur only at the nodes of Ranvier, thus causing a rapidly progressing type of jumping, or saltatory, conduction. The puffer fish poison tetrodotoxin and a congener found in shellfish, saxitoxin, selectively block axonal conduction by blocking the voltage-sensitive Na^+ channel and preventing the increase in Na^+ permeability associated with the rising phase of the AP. In contrast, batrachotoxin, a potent steroidal alkaloid secreted by a South American frog, produces paralysis through a selective increase in permeability of the Na^+ channel, which induces a persistent depolarization. Scorpion toxins are peptides that cause persistent depolarization by inhibiting the inactivation process. For more details on Na^+ and Ca^{2+} channels, see Chapters 14, 31, and 34.

JUNCTIONAL TRANSMISSION The arrival of the AP at the axonal terminals initiates a series of events that trigger transmission of an excitatory or inhibitory impulse across the synapse or neuroeffector junction (see Figure 6-2):

1. *Release of stored neurotransmitter; prejunctional regulation.* Nonpeptide (small molecule) neurotransmitters are largely synthesized in the axonal terminals and stored there in synaptic

FIGURE 6-2 Steps involved in excitatory and inhibitory neurotransmission. 1. The nerve action potential (AP) consists of a transient self-propagated reversal of charge on the axonal membrane. (The internal potential E_i goes from a negative value, through zero potential, to a slightly positive value primarily through increases in Na^+ permeability and then returns to resting values by an increase in K^+ permeability.) When the AP arrives at the presynaptic terminal, it initiates release of the excitatory or inhibitory transmitter. Depolarization at the nerve ending and entry of Ca^{2+} initiate docking and then fusion of the synaptic vesicle with the membrane of the nerve ending. Docked and fused vesicles are shown. 2. Combination of the excitatory transmitter with postsynaptic receptors produces a localized depolarization, the excitatory postsynaptic potential (EPSP), through an increase in permeability to cations, most notably Na^+ . The inhibitory transmitter causes a selective increase in permeability to K^+ or Cl^- , resulting in a localized hyperpolarization, the inhibitory postsynaptic potential (IPSP). 3. The EPSP initiates a conducted AP in the postsynaptic neuron; this can be prevented, however, by the hyperpolarization induced by a concurrent IPSP. Transmitter action is terminated by enzymatic destruction, by reuptake into the presynaptic terminal or adjacent glial cells, or by diffusion.

vesicles. Peptide neurotransmitters (or precursor peptides) are found in large dense-core vesicles that are transported down the axon from their site of synthesis in the cell body. The arrival of an AP and depolarization of the axonal terminal membrane causes the synchronous release of several hundred quanta of neurotransmitter; a critical step in most but not all nerve endings is the influx of Ca^{2+} , which enters the axonal cytoplasm and promotes fusion between the axoplasmic membrane and those vesicles in close proximity to it. The contents of the vesicles, including enzymes, other proteins, and cotransmitters (e.g., ATP, NPY) then are discharged to the exterior by *exocytosis* (see Figure 6-2).

Receptors on soma, dendrites, and axons of neurons respond to neurotransmitters or modulators released from the same neuron or from adjacent neurons or cells. Soma–dendritic receptors are located on or near the cell body and dendrites; when activated, they primarily modify functions of the soma–dendritic region such as protein synthesis and generation of action potentials. Presynaptic receptors are located on axon terminals or varicosities; when activated, they modify functions such as synthesis and release of transmitters. Two main classes of presynaptic receptors have been identified on most neurons, including sympathetic and parasympathetic terminals. Heteroreceptors are presynaptic receptors that respond to neurotransmitters, neuromodulators, or neurohormones released from adjacent neurons or cells. For example, NE can influence the release of ACh from parasympathetic neurons by acting on α_{2A} , α_{2B} , and α_{2C} receptors, whereas ACh can influence the release of NE from sympathetic neurons by acting on M_2 and M_4 receptors (see below). The other class of presynaptic receptors are autoreceptors, located on axon terminals of a neuron and activated by the neuron's own transmitter to modify subsequent transmitter synthesis and release. For example, NE may interact with α_{2A} and α_{2C} receptors to inhibit neurally-released NE. Similarly, ACh may interact with M_2 and M_4 receptors to inhibit neurally-released ACh. Adenosine, dopamine (DA), glutamate, γ -aminobutyric acid (GABA), prostaglandins, and enkephalins influence neurally-mediated release of neurotransmitters, in part by altering the function of presynaptic ion channels.

2. *Combination of the transmitter with postjunctional receptors and production of the postjunctional potential.* The released transmitter diffuses across the synaptic or junctional cleft and combines with specialized receptors on the postjunctional membrane; this often results in a localized increase in the ionic permeability, or conductance, of the membrane. With certain exceptions (noted below), one of three types of permeability change can occur: (a) a generalized increase in the permeability to cations (notably Na^+ but occasionally Ca^{2+}), resulting in a localized depolarization of the membrane, i.e., an excitatory postsynaptic potential (EPSP); (b) a selective increase in permeability to anions, usually Cl^- , resulting in stabilization or hyperpolarization of the membrane (an inhibitory postsynaptic potential or IPSP); or (c) an increased permeability to K^+ (the K^+ gradient is directed outward; thus, hyperpolarization results, i.e., an IPSP).

Electrical potential changes associated with the EPSP and IPSP generally result from passive fluxes of ions down concentration gradients. The changes in channel permeability that cause these potential changes are specifically regulated by the specialized postjunctional neurotransmitter receptors (see Chapter 12 and below). In the presence of an appropriate neurotransmitter, the channel opens rapidly to a high-conductance state, remains open for about a millisecond, and then closes. A short pulse of current is observed as a result of the channel's opening and closing. The summation of these microscopic events gives rise to the EPSP. High-conductance ligand-gated ion channels usually permit passage of Na^+ or Cl^- ; K^+ and Ca^{2+} are involved less frequently. The preceding ligand-gated channels belong to a large superfamily of ionotropic receptor proteins that includes the nicotinic, glutamate, serotonin (5-HT_3) and P2X receptors, which conduct primarily Na^+ , cause depolarization, and are excitatory, and GABA and glycine receptors, which conduct Cl^- , cause hyperpolarization, and are inhibitory. Neurotransmitters also can modulate the permeability of K^+ and Ca^{2+} channels indirectly, often via receptor-G protein interactions (see Chapter 1). Other receptors for neurotransmitters act by influencing the synthesis of intracellular second messengers (e.g., cyclic AMP, cyclic GMP, IP₃) and do not necessarily cause a change in membrane potential.

3. *Initiation of postjunctional activity.* If an EPSP exceeds a certain threshold value, it initiates an action potential in the postsynaptic membrane by activating voltage-sensitive channels in the immediate vicinity. In certain smooth muscle types in which propagated impulses are minimal, an EPSP may increase the rate of spontaneous depolarization, cause Ca^{2+} release, and enhance muscle tone; in gland cells, the EPSP initiates secretion through Ca^{2+} mobilization. An IPSP, which occurs in neurons and smooth muscle but not in skeletal muscle, will tend to oppose excitatory potentials simultaneously initiated by other neuronal sources. The ultimate response depends on the summation of all the potentials.

4. *Destruction or dissipation of the transmitter and termination of action.* To sustain high frequency transmission and regulation of function, the synaptic dwell-time of the primary neurotransmitter must be relatively short. At cholinergic synapses involved in rapid neurotransmission, high and localized concentrations of *acetylcholinesterase* (AChE) are localized to hydrolyze ACh. When AChE is inhibited, removal of the transmitter occurs principally by diffusion, and the effects of ACh are potentiated and prolonged (*see* Chapter 8).

Termination of the actions of catecholamines occurs by a combination of simple diffusion and reuptake by the axonal terminals of the released transmitter by the SLC6 family of transporters using energy stored in the transmembrane Na^+ gradient (*see* Tables 2–2 and 6–5). Termination of the actions of 5-HT and GABA and other amino acid transmitters also results from their transport into neurons and surrounding glia by SLC1 and SLC6 family members. Peptide neurotransmitters are hydrolyzed by various peptidases and dissipated by diffusion; specific uptake mechanisms have not been demonstrated for these substances.

5. *Nonelectrogenic functions.* During the resting state, there is a continual slow release of isolated quanta of the transmitter that produces electrical responses at the postjunctional membrane [miniature end-plate potentials (*mepps*)] that are associated with the maintenance of physiological responsiveness of the effector organ. A low level of spontaneous activity within the motor units of skeletal muscle is particularly important because skeletal muscle lacks inherent tone. The activity and turnover of enzymes involved in the synthesis and inactivation of neurotransmitters, the density of presynaptic and postsynaptic receptors, and other characteristics of synapses probably are controlled by trophic actions of neurotransmitters or other trophic factors released by the neuron or the target cells.

Cholinergic Transmission

The synthesis, storage, and release of ACh (Figure 6–3) follow a similar life cycle in all cholinergic synapses, including those at skeletal neuromuscular junctions, preganglionic sympathetic and parasympathetic terminals, postganglionic parasympathetic varicosities, postganglionic sympathetic varicosities innervating sweat glands in the skin, and in the CNS.

CHOLINE ACETYLTRANSFERASE

Choline acetyltransferase catalyzes the synthesis of ACh—the acetylation of choline with acetyl coenzyme A (CoA). Choline acetyltransferase, like other protein constituents of the neuron, is synthesized within the perikaryon and then is transported along the length of the axon to its terminal. Axonal terminals contain a large number of mitochondria, where acetyl CoA is synthesized. Choline is taken up from the extracellular fluid into the axoplasm by active transport. The synthetic step occurs in the cytosol; most of the ACh is then sequestered within synaptic vesicles. Inhibitors of choline acetyltransferase have no therapeutic utility, in part because the uptake of choline, not the activity of the acetyltransferase, is rate-limiting in ACh biosynthesis.

CHOLINE TRANSPORT Transport of choline from the plasma into neurons is rate-limiting in ACh synthesis and is accomplished by distinct high- and low-affinity transport systems. The high-affinity system ($K_m = 1\text{--}5\ \mu\text{M}$) is unique to cholinergic neurons, dependent on extracellular Na^+ , and inhibited by *hemicholinium*. Plasma concentrations of choline approximate $10\ \mu\text{M}$. Much of the choline formed from AChE-catalyzed hydrolysis of ACh is recycled into the nerve terminal.

STORAGE OF ACh

After its synthesis, ACh is taken up by storage vesicles principally at the nerve terminals. The vesicles contain both ACh and ATP, at an estimated ratio of 10:1, in the fluid phase with Ca^{2+} and Mg^{2+} , and vesiculín, a negatively charged proteoglycan thought to sequester Ca^{2+} or ACh. In some cholinergic vesicles there are peptides (e.g., VIP) that act as cotransmitters. The vesicular ACh transporter, has considerable concentrating power, is saturable, and is ATP-dependent. The process is inhibited by vesamicol (Figure 6–3). Inhibition by vesamicol is noncompetitive and reversible and does not affect the vesicular ATPase. Estimates of the ACh content of synaptic vesicles range from 1000 to over 50,000 molecules per vesicle; a single motor nerve terminal contains 300,000 or more vesicles.

RELEASE OF ACETYLCHOLINE AND ITS MODULATION BY TOXINS

*The release of ACh and other neurotransmitters by exocytosis is inhibited by botulinum and tetanus toxins from Clostridium. Botulinum toxin acts in the nerve ending to reduce ACh vesicular release (*see* Chapters 9 and 63 for therapeutic uses of botulinum toxin).*

FIGURE 6-3 A cholinergic neuroeffector junction. The synthesis of ACh in the varicosity depends on the uptake of choline *via* a sodium-dependent carrier. This uptake can be blocked by *hemicholinium*. Choline and the acetyl moiety of acetyl coenzyme A, derived from mitochondria, form ACh, a process catalyzed by the enzyme choline acetyltransferase (ChAT). ACh is transported into the storage vesicle by a carrier that can be inhibited by *vesamicol*. ACh is stored in vesicles along with other potential cotransmitters (Co-T) such as ATP and VIP. Release of ACh and the Co-T occurs following depolarization of the membrane, which allows the entry of Ca²⁺ through voltage-dependent Ca²⁺ channels. Elevated [Ca²⁺]_{in} promotes fusion of the vesicular membrane with the cell membrane and exocytosis of vesicular contents. This fusion process involves the interaction of specialized proteins of the vesicular membrane (VAMPs, vesicle-associated membrane proteins) and the membrane of the varicosity (SNAPS, synaptosome-associated proteins). The exocytotic release of ACh can be blocked by *botulinium toxin*. Once released, ACh can interact with the muscarinic receptors (mAChR), which are GPCRs, or nicotinic receptors (nAChR), which are ligand-gated ion channels, to produce the characteristic response of the effector. ACh also can act on presynaptic mAChRs or nAChRs to modify its own release. The action of ACh is terminated by hydrolysis to choline and acetate by acetylcholinesterase (AChE) associated with the effector cell membrane.

By contrast, tetanus toxin primarily has a central action: it is transported in retrograde fashion up the motor neuron to its soma in the spinal cord. From there the toxin migrates to inhibitory neurons that synapse with the motor neuron and blocks exocytosis in the inhibitory neuron. The block of release of inhibitory transmitter gives rise to tetanus or spastic paralysis. The toxin from the venom of black widow spiders (α -latrotoxin) binds to neuroexins, transmembrane proteins that reside on the nerve terminal membrane, resulting in massive synaptic vesicle exocytosis.

ACETYLCHOLINESTERASE (AChE)

ACh must be removed or inactivated within the time limits imposed by the response characteristics of the synapse. At the neuromuscular junction, immediate removal is required to prevent lateral diffusion and sequential activation of adjacent receptors. This removal is accomplished in <1 ms by hydrolysis of ACh by AChE. The K_m of AChE for ACh is ~ 50 – 100 μM . The resulting choline has only 10^{-3} – 10^{-5} the potency of ACh^m at the neuromuscular junction. AChE is found in cholinergic neurons (dendrites, perikarya, and axons) and is highly concentrated at the post-synaptic end plate of the neuromuscular junction. A similar esterase, butyrylcholinesterase (BuChE; also known as pseudocholinesterase), is present in low abundance in glial or satellite cells but is virtually absent in neuronal elements of the central and peripheral nervous systems.

BuChE is synthesized primarily in the liver and is found in liver and plasma. AChE and BuChE typically are distinguished by the relative rates of ACh and butyrylcholine hydrolysis and by effects of selective inhibitors (see Chapter 8). Almost all pharmacological effects of the anti-ChE agents are due to the inhibition of AChE, with the consequent accumulation of endogenous ACh in the vicinity of the nerve terminal.

CHARACTERISTICS OF CHOLINERGIC TRANSMISSION AT VARIOUS SITES

Skeletal Muscle

At the neuromuscular junction (Figure 9–2), ACh interacts with nicotinic ACh receptors and induces an immediate, marked increase in cation permeability. Upon activation by ACh, the nicotinic receptor's intrinsic channel opens for about 1 ms, admitting $\sim 50,000$ Na^+ ions. The channel-opening process is the basis for the localized depolarizing EPP within the end plate, which triggers the muscle AP and leads to contraction.

Autonomic Ganglia

The primary pathway of cholinergic transmission in autonomic ganglia is similar to that at the neuromuscular junction of skeletal muscle. The initial depolarization is the result of activation of nicotinic ACh receptors, which are ligand-gated cation channels with properties similar to those found at the neuromuscular junction. Several secondary transmitters or modulators either enhance or diminish the sensitivity of the postganglionic cell to ACh. Ganglionic transmission is discussed in more detail in Chapter 9.

Autonomic Effectors

Stimulation or inhibition of autonomic effector cells by ACh results from interaction of ACh with muscarinic ACh receptors. In this case, the effector is coupled to the receptor by a G protein (see Chapter 1). In contrast to skeletal muscle and neurons, smooth muscle and the cardiac conduction system (sinoatrial [SA] node, atrium, atrioventricular [AV] node, and the His–Purkinje system) normally exhibit intrinsic activity, both electrical and mechanical, that is modulated but not initiated by nerve impulses. At some smooth muscle, ACh causes a decrease in the resting potential (i.e., the membrane potential becomes less negative) and an increase in the frequency of spike production, accompanied by a rise in tension. A primary action of ACh in initiating these effects through muscarinic receptors is probably partial depolarization of the cell membrane brought about by an increase in Na^+ and, in some instances, Ca^{2+} conductance; activation of muscarinic receptors can also activate the G_q -PLC-IP₃ pathway leading to the mobilization of stored Ca^{2+} . Hence, ACh stimulates ion fluxes across membranes and/or mobilizes intracellular Ca^{2+} to cause contraction.

In the heart, spontaneous depolarizations normally arise from the SA node. In the cardiac conduction system, particularly in the SA and AV nodes, stimulation of the cholinergic innervation or the direct application of ACh causes inhibition, associated with hyperpolarization of the membrane and a marked decrease in the rate of depolarization. These effects are due, at least partly, to a selective increase in permeability to K^+ and are mediated by muscarinic cholinergic receptors.

PREJUNCTIONAL SITES

Both cholinergic and adrenergic nerve terminal varicosities contain autoreceptors and heteroreceptors. ACh release therefore is subject to complex regulation by mediators, including ACh itself acting on M_2 and M_4 autoreceptors, and other transmitters (e.g., NE acting on α_{2A} and α_{2C} adrenergic receptors) or locally-produced substances (e.g., NO). ACh-mediated inhibition of ACh release following activation of M_2 and M_4 autoreceptors is thought to represent a physiological negative-feedback control mechanism. At some neuroeffector junctions (e.g., the myenteric plexus in the GI tract or the SA node in the heart), sympathetic and parasympathetic nerve terminals often are juxtaposed. The opposing effects of NE and ACh, therefore, result not only from the opposite effects of the two transmitters on the smooth muscle or cardiac cells but also from their mutual inhibition of each other's release via actions on heteroreceptors. Muscarinic autoreceptors and heteroreceptors are targets for both agonists and antagonists. Muscarinic agonists can inhibit the electrically-induced release of ACh; antagonists will enhance the evoked release of transmitter. In addition to α_{2A} and α_{2C} adrenergic receptors, other inhibitory heteroreceptors on parasympathetic terminals include A_1 , H_3 , and opioid receptors. Evidence also exists for β_2 adrenergic facilitatory receptors.

EXTRANEURONAL CHOLINERGIC SYSTEMS ACh is present in the vast majority of human cells and organs, including epithelial cells (airways, alimentary tract, epidermis, glandular

tissue), mesothelial and endothelial cells, circulating cells (platelets), and immune cells (mononuclear cells, macrophages). The exact function of nonneuronal ACh is not known; proposed roles include regulation of mitosis, locomotion, automaticity, ciliary activity, cell–cell contact, barrier function, respiration and secretion, and the regulation of lymphocyte function.

CLASSIFICATION OF CHOLINERGIC RECEPTORS

ACh elicits responses similar to those of either nicotine or muscarine, depending on the physiological preparation. Thus, the receptors for ACh are classified as nicotinic or muscarinic. Tubocurarine and atropine block nicotinic and muscarinic effects of ACh, respectively, providing pharmacological evidence of two receptor types for ACh.

Subtypes of Nicotinic Acetylcholine Receptors

The nicotinic ACh receptors (nAChRs) are members of a superfamily of ligand-gated ion channels. The receptors exist at the skeletal neuromuscular junction, autonomic ganglia, adrenal medulla and in the CNS. They are the natural targets for ACh as well as pharmacologically administered drugs, including nicotine. The receptor forms a pentameric structure consisting of homomeric α and β subunits. In humans, 8 α subunits (α_2 through α_7 , α_9 , and α_{10}) and three β subunits (β_2 through β_4) have been cloned. Both the muscle and neuronal nAChRs share structural and functional properties with other ligand-gated channels such as the GABA_A, 5-HT₃, and glycine receptors. The muscle nAChR is the best-characterized form. The muscle nicotinic receptor contains four distinct subunits in a pentameric complex ($\alpha_2\beta\delta\gamma$ or $\alpha_2\beta\delta\epsilon$; see Table 6–2). The muscle and neuronal subunits share the basic topography of a large extracellular N-terminal domain that contributes to agonist binding, four hydrophobic transmembrane domains (TM₁ through TM₄), a large cytoplasmic loop between TM₃ and TM₄, and a short extracellular C terminus. The M₂ transmembrane region is thought to form the ion pore of the nAChR (see Chapter 9). Autonomic ganglia form homomeric α_7 and heteromeric $\alpha_3\beta_4$, with (α_3)₂(β_4)₃ being the most prevalent.

The pentameric structure of the neuronal nAChR and the considerable molecular diversity of its subunits offer the possibility of a large number of nAChRs with different physiological properties. These receptors may subservise a variety of discrete functions and thus represent novel drug targets for a wide variety of therapeutic agents. The stoichiometry of most nAChRs in brain is still uncertain. Distinctions amongst nAChRs are listed in Table 6–2. The structure, function, distribution, and subtypes of nicotinic receptors are described in more detail in Chapter 9.

SUBTYPES OF MUSCARINIC RECEPTORS

In mammals, five distinct subtypes of muscarinic ACh receptors (mAChRs) have been identified, each produced by a different gene. Like the different forms of nicotinic receptors, these variants have distinct anatomical locations in the periphery and CNS and differing chemical specificities. The mAChRs are GPCRs (see Table 6–3). Muscarinic AChRs are present in virtually all organs, tissues, and cell types, although certain subtypes often predominate at specific sites. For example, the M₂ receptor is the predominant subtype in the heart, whereas the M₃ receptor is the predominant subtype in the bladder. In the periphery, mAChRs mediate the classical muscarinic actions of ACh in organs and tissues innervated by parasympathetic nerves; mAChRs are also present at sites that lack parasympathetic innervation (e.g., on endothelial and smooth muscle cells of most blood vessels). In the CNS, mAChRs are involved in regulating a large number of cognitive, behavior, sensory, motor, and autonomic functions. The basic functions of muscarinic cholinergic receptors (Table 6–3) are mediated by interactions with G proteins and thus by G protein–induced changes in the function of distinct member-bound effector molecules. The M₁, M₃, and M₅ subtypes couple through the pertussis toxin–insensitive G_s, G₁₁, and G_{12/13} to stimulate the PLC-IP₃-Ca²⁺ pathway, with activation of Ca²⁺-dependent phenomena such as contraction of smooth muscle and secretion (see Chapter 1). Another product of PLC activation, diacylglycerol, in conjunction with Ca²⁺, activates PKC, resulting in the phosphorylation of numerous proteins and leading to various physiological responses. Activation of M₁, M₃, and M₅ receptors can also cause the activation of phospholipase A₂, leading to the release of arachidonic acid and consequent eicosanoid synthesis, resulting in autocrine/paracrine stimulation of adenylyl cyclase.

Stimulation of M₂ and M₄ cholinergic receptors leads to interaction with other G proteins, (e.g., G_i and G_o) with a resulting inhibition of adenylyl cyclase, a decrease in cyclic AMP, activation of inwardly rectifying K⁺ channels, and inhibition of voltage-gated Ca²⁺ channels, with the functional consequences of hyperpolarization and inhibition of excitability. These are most clear in myocardium, where inhibition of adenylyl cyclase and activation of K⁺ conductances account for the negative chronotropic and inotropic effects of ACh.

*Most organs, tissues, and cells express multiple mAChRs.

†M₁, M₃, and M₅ mAChRs appear to couple to the same G proteins and signal through similar pathways. Likewise, M₂ and M₄ mAChRs couple through similar G proteins and signal through similar pathways.

‡Despite the fact that in many tissues, organs, and cells multiple subtypes of mAChRs coexist, one subtype may predominate in producing a particular function; in others, there may be equal predominance.

ABBREVIATIONS: PLC, phospholipase C; IP₃, inositol-1,4,5-trisphosphate; DAG, diacylglycerol; PLD₂, phospholipase D; AA, arachidonic acid; PLA, phospholipase A; cAMP, cyclic AMP; SA node, sinoatrial node; AV node, atrioventricular node; HR, heart rate; PTX, pertussis toxin; VTA, ventral tegmentum area.

Following activation by agonists, mAChRs can be phosphorylated by a variety of receptor kinases and second-messenger regulated kinases; the phosphorylated mAChR subtypes then can interact with β -arrestin and presumably other adaptor proteins. As a result, the various mAChR signaling pathways may be differentially altered, leading to short- or long-term desensitization of a particular signaling pathway, receptor-mediated activation of the MAP kinase pathway downstream of mAChR phosphorylation, and long-term potentiation of mAChR-mediated PLC stimulation. Agonist activation of mAChRs also may induce receptor internalization and down-regulation.

Adrenergic Transmission

Norepinephrine (NE), dopamine (DA), and epinephrine (Epi) are catecholamines. NE is the principal transmitter of most sympathetic postganglionic fibers and of certain tracts in the CNS. DA is the predominant transmitter of the mammalian extrapyramidal system and of several mesocortical and mesolimbic neuronal pathways. Epi is the major hormone of the adrenal medulla. There are important interactions between the endogenous catecholamines and many of the drugs used in the treatment of hypertension, mental disorders, and a variety of other conditions described in subsequent chapters. The basic physiological, biochemical, and pharmacological features are presented here. Almost every step in the synthesis, storage, release, reuptake/metabolism, and action of catecholamine can be usefully modulated by pharmacological agents.

SYNTHESIS, STORAGE, AND RELEASE OF CATECHOLAMINES *Synthesis*—The steps in the synthesis of DA, NE (known outside the U.S. as noradrenaline), and Epi (known as adrenaline) are shown in Figure 6-4. Tyrosine is sequentially 3-hydroxylated and decarboxylated to form DA. DA is β -hydroxylated to yield NE (the transmitter in postganglionic nerves of the sympathetic branch of the ANS), which is N-methylated in chromaffin tissue to give Epi. The enzymes involved are not completely specific; consequently, other endogenous substances and some drugs are also substrates. 5-hydroxytryptamine (5-HT, serotonin) can be produced from 5-hydroxy-L-tryptophan by aromatic L-amino acid decarboxylase (AAD or dopa decarboxylase). AAD also converts dopa into DA, and methyl-dopa to α -methyl-DA, which is converted to α -methyl-NE by dopamine β -hydroxylase (D β H; Table 6-4).

FIGURE 6-4 The biosynthesis of dopamine, norepinephrine, and epinephrine. The enzymes involved are shown in blue; essential cofactors in italics. The final step occurs only in the adrenal medulla and in a few epinephrine-containing neuronal pathways in the brainstem.

Enzymes for Synthesis of Catecholamines

Enzyme	Occurrence	Subcellular Distribution	Cofactor Requirement	Substrate Specificity	Comments
Tyrosine hydroxylase	Widespread; sympathetic nerves	Cytoplasmic	Tetrahydrobiopterin, O ₂ , Fe ²⁺	Specific for L-tyrosine	Rate-limiting step Inhibition can lead to depletion of NE
Aromatic L-amino acid decarboxylase	Widespread; sympathetic nerves	Cytoplasmic	Pyridoxal phosphate	Nonspecific	Inhibition does not alter tissue NE and Epi appreciably
Dopamine β-hydroxylase	Widespread; sympathetic nerves	Synaptic vesicles	Ascorbic acid, O ₂ (contains copper)	Nonspecific	Inhibition can decrease NE and Epi levels
Phenylethanolamine N-methyltransferase	Largely in adrenal gland	Cytoplasmic	S-Adenosyl methionine (CH ₃ donor)	Nonspecific	Inhibition leads to decrease in adrenal catecholamines; under control of glucocorticoids

Tyrosine hydroxylase, the rate-limiting enzyme, is a substrate for PKA, PKC, and CaM kinase; phosphorylation may increase hydroxylase activity, an important acute mechanism whereby NE and Epi, acting at autoreceptors, enhance catecholamine synthesis in response to elevated nerve stimulation. In addition, there is a delayed increase in tyrosine hydroxylase gene expression after nerve stimulation, occurring at the levels of transcription, RNA processing, regulation of RNA stability, translation, and enzyme stability. Thus, multiple mechanisms maintain the content of catecholamines in response to increased transmitter release. In addition, tyrosine hydroxylase is subject to allosteric feedback inhibition by catecholamines.

The main features of the mechanisms of synthesis, storage, and release of catecholamines and their modifications by drugs are summarized in Figure 6–5. NE or Epi is stored in vesicles with ATP and other cotransmitters (e.g., neuropeptide Y [NPY]), depending on the site. The adrenal medulla has two distinct catecholamine-containing cell types: those with NE and those that express the enzyme phenylethanolamine-N-methyltransferase (PNMT) and contain primarily Epi (in these cells, the NE formed in the granules leaves these structures, is methylated in the cytoplasm to Epi, then reenters the chromaffin granules, where it is stored until released. In adults, Epi accounts for ~80% of the catecholamines of the adrenal medulla. A major factor that controls the rate of synthesis of Epi, and hence the size of the store available for release from the adrenal medulla, is the level of glucocorticoids secreted by the adrenal cortex. The intraadrenal portal vascular system carries the corticosteroids directly to the adrenal medullary chromaffin cells, where they induce the synthesis of PNMT (Figure 6–4). The activities of both tyrosine hydroxylase and DBH also are increased in the adrenal medulla when the secretion of glucocorticoids is stimulated. Thus, any stress that persists sufficiently to evoke an enhanced secretion of corticotropin mobilizes the appropriate hormones of both the adrenal cortex (predominantly cortisol in humans) and medulla (Epi). This relationship occurs only in certain mammals, including humans, in which adrenal chromaffin cells are enveloped by steroid-secreting cortical cells. There is evidence for PMNT expression and extra-adrenal chromaffin tissue in mammalian tissues such as brain, heart, and lung, leading to extra-adrenal Epi synthesis.

In addition to synthesis of new transmitter, NE stores are also replenished by transport of NE previously released to the extracellular fluid by the combined actions of a NE transporter (NET, or uptake 1) that terminates the synaptic actions of released NE and returns NE to the neuronal cytosol, and VMAT-2, the vesicular monoamine transporter; that refills the storage vesicles from the cytosolic pool of NE (see below). In the removal of NE from the synaptic cleft, uptake by the NET is more important than extraneuronal uptake (ENT, uptake 2). The sympathetic nerves as a whole remove ~87% of released NE via NET compared with 5% by extraneuronal ENT and 8% via diffusion to the circulation. By contrast, clearance of circulating catecholamines is primarily by nonneuronal mechanisms, with liver and kidney accounting for >60% of the clearance. Because VMAT-2 has a much higher affinity for NE than does the metabolic enzyme, monoamine oxidase, over 70% of recaptured NE is sequestered into storage vesicles.

STORAGE OF CATECHOLAMINES Vesicular storage of catecholamines ensures their regulated release and protects them from intraneuronal metabolism by oxidative deamination by monoamine oxidase (MAO) (see below and Figure 6–6). The vesicular monoamine transporter (VMAT-2) is driven by a pH gradient established by an ATP-dependent proton pump. Monoamine transporters are relatively promiscuous and transport DA, NE, Epi, and 5-HT. *Reserpine* inhibits VMAT-2, making the catecholamine susceptible to degradation and leading to depletion of catecholamine from sympathetic nerve endings and in the brain.

There are two neuronal membrane transporters for catecholamines, the NE transporter (NET) and the DA transporter (DAT) (see Table 6–5). NET is Na⁺-dependent and is blocked selectively by a number of drugs, including *cocaine* and tricyclic antidepressants such as *imipramine*. This transporter has a high affinity for NE and a somewhat lower affinity for Epi; the synthetic β adrenergic receptor agonist *isoproterenol* is not a substrate for this system. A number of other highly specific, high affinity neurotransmitter transporters have been identified, including those for 5-HT and a variety of amino acid transmitters. These plasma membrane transporters appear to have greater substrate specificity than do vesicular transporters and may be viewed as targets (“receptors”) for specific drugs such as *cocaine* (NET, DAT) or *fluoxetine* (SERT, the serotonin transporter).

Certain sympathomimetic drugs (e.g., ephedrine and tyramine) produce some of their effects indirectly by displacing NE from the nerve terminals to the extracellular fluid by a nonexocytotic mechanism, and then the released NE acts at receptor sites of the effector cells. The mechanisms by which these drugs release NE from nerve endings are complex. All such drugs are substrates for NET. As a result of their transport across the neuronal membrane into the axoplasm, they make carrier

FIGURE 6-5 An adrenergic neuroeffector junction. Tyrosine is transported into the varicosity and converted to DOPA by tyrosine hydroxylase (TH) and DOPA to dopamine via the action of aromatic L-amino acid decarboxylase (AAADC). Dopamine is taken up into storage vesicles by a transporter that can be blocked by reserpine; cytoplasmic NE also can be taken up by this transporter. Dopamine is converted to NE within the vesicle via the action of dopamine- β -hydroxylase (D β H). NE is stored in vesicles along with cotransmitters (e.g., NPY and ATP), depending on the particular neuroeffector junction; different populations of vesicles may preferentially store different proportions of the cotransmitters. Release of the transmitters occurs upon depolarization of the varicosity, which allows entry of Ca^{2+} through voltage-dependent Ca^{2+} channels. Elevated $[Ca^{2+}]_{in}$ promotes fusion of the vesicular membrane with the membrane of the varicosity, with subsequent exocytosis of transmitters. This fusion process involves the interaction of specialized proteins associated with the vesicular membrane (VAMPs, vesicle-associated membrane proteins) and the membrane of the varicosity (SNAPS, synaptosome-associated proteins). Once in the synapse, NE can interact with α - and β -adrenergic receptors to produce the characteristic response of the effector. The adrenergic receptors are GPCRs. α and β receptors also can be located presynaptically where NE can either diminish (α_2), or facilitate (β) its own release and that of the cotransmitters. The principal mechanism by which NE is cleared from the synapse is via a cocaine-sensitive neuronal uptake transporter. Once transported into the cytosol, NE can be restored in the vesicle or metabolized by monoamine oxidase (MAO). NPY produces its effects by activating NPY receptors, of which there are at least five types (Y_1 through Y_5). NPY receptors are GPCRs. NPY can modify its own release and that of the other transmitters via presynaptic receptors of the Y_2 type. NPY is removed from the synapse by the action of peptidases. ATP produces its effects by activating P2X receptors (ligand-gated ion channels) and P2Y receptors (GPCRs). There are multiple subtypes of both P2X and P2Y receptors. As with the other cotransmitters, ATP can act prejunctionally to modify its own release via receptors for ATP or via its metabolic breakdown to adenosine that acts on P_1 (adenosine) receptors. ATP is cleared from the synapse primarily by releasable nucleotidases (rNTPase) and by cell-fixed ectonucleotidases.

available at the inner surface of the membrane for the outward transport of NE ("facilitated exchange diffusion"). In addition, these indirect-acting sympathomimetic drugs mobilize NE stored in the vesicles by competing for the vesicular uptake process. By contrast, reserpine, which depletes vesicular stores of NE, inhibits VMAT-2, but enters the adrenergic nerve ending by passive diffusion.

Three extraneuronal transporters handle a range of endogenous and exogenous substrates (see Table 6-4). ENT, the extraneuronal amine transporter (*uptake 2* or *OCT3*), is an organic cation transporter. Relative to NET, ENT exhibits lower affinity for catecholamines, favors Epi over NE or DA, and shows a higher maximal rate of catecholamine uptake. ENT is not Na^+ -dependent and

FIGURE 6-6 Metabolism of catecholamines. Norepinephrine and epinephrine are first oxidatively deaminated by monoamine oxidase (MAO) to 3,4-dihydroxyphenylglyoxyaldehyde (DOPGAL) and then either reduced to 3,4-dihydroxyphenylethylene glycol (DOPEG) or oxidized to 3,4-dihydroxymandelic acid (DOMA). Alternatively, they can be methylated initially by catechol-*O*-methyltransferase (COMT) to normetanephrine and metanephrine, respectively. Most of the products of either enzyme then are metabolized by the other enzyme to form the major excretory products in blood and urine, 3-methoxy-4-hydroxyphenylethylene glycol (MOPEG or MHPG) and 3-methoxy-4-hydroxymandelic acid (vanillylmandelic acid, VMA). Free MOPEG is largely converted to VMA. The glycol and, to some extent, the *O*-methylated amines and the catecholamines may be conjugated to the corresponding sulfates or glucuronides.

displays a completely different profile of pharmacological inhibition. Other members of this family are OCT1 and OCT2 (*see* Chapter 2). In addition to catecholamines, OCT1-3 can transport other organic cations, including 5-HT, histamine, choline, spermine, guanidine, and creatinine.

RELEASE OF CATECHOLAMINES Details of excitation-secretion coupling in sympathetic neurons and the adrenal medulla are not completely known. The triggering event is the entry of Ca^{2+} , which results in the exocytosis of the granular contents, including NE or Epi, ATP, some neuroactive peptides or their precursors, chromogranins, and D β H. Ca^{2+} -triggered secretion involves interaction of molecular scaffolding proteins and fusion proteins, leading to docking of granules at the plasma membrane and thence to secretion (*see* Figure 6-5).

Prejunctional Regulation of Norepinephrine Release

The release of the three sympathetic cotransmitters (catecholamine, ATP, NPY; *see* Figure 6-5) can be modulated by prejunctional autoreceptors and heteroreceptors. Following their release from sympathetic terminals, all three cotransmitters—NE, NPY, and ATP—can feedback on prejunctional receptors to inhibit the subsequent exocytosis. The α_{2A} and α_{2C} adrenergic receptors are the principal prejunctional receptors that inhibit sympathetic neurotransmitter release; the α_{2B} adrenergic receptors also may inhibit transmitter release at selected sites. Antagonists of this receptor, in turn, can enhance the electrically-evoked release of sympathetic neurotransmitter. NPY, acting on Y_2 receptors, and ATP-derived adenosine, acting on P1 receptors, also can inhibit sympathetic

neurotransmitter release. Numerous heteroreceptors on sympathetic nerve varicosities also inhibit the release of sympathetic neurotransmitters; these include: M_2 and M_4 muscarinic, 5-HT, PGE_2 , histamine, enkephalin, and DA receptors. Enhancement of sympathetic neurotransmitter release can be produced by activation of β_2 adrenergic receptors, angiotensin II receptors, and nACh receptors. All these receptors are targets for agonists and antagonists.

TERMINATION OF THE ACTIONS OF CATECHOLAMINES The actions of NE and Epi are terminated by (1) reuptake into nerve terminals by NET; (2) dilution by diffusion out of the junctional cleft and uptake at end organs and extraneuronal sites by ENT, OCT1, and OCT2. Subsequent to uptake, the catecholamines are subject to metabolic transformation by MAO and catechol-*O*-methyltransferase (COMT). In addition, catecholamines are metabolized by sulfotransferases (*see* Chapter 3). Termination of action by a powerful degradative enzymatic pathway, such as that provided by AChE in cholinergic transmission, is absent from the adrenergic system. Inhibitors of neuronal reuptake of catecholamines (*e.g.*, cocaine, imipramine) potentiate the effects of the

neurotransmitter, whereas inhibitors of MAO and COMT have relatively little effect, demonstrating the predominant role of uptake in termination of effect. However, MAO metabolizes transmitter that is released within the nerve terminal cytosol. COMT, particularly in the liver, plays a major role in the metabolism of endogenous circulating and administered catecholamines.

Both MAO and COMT are distributed widely throughout the body, including the brain; the highest concentrations of each are in the liver and the kidney. However, little or no COMT is found in sympathetic neurons. In the brain, there is also no significant COMT in presynaptic terminals, but it is found in some postsynaptic neurons and glial cells. In the kidney, COMT is localized in proximal tubular epithelial cells, where DA is synthesized, and is thought to exert local diuretic and natriuretic effects. The physiological substrates for COMT include L-dopa, all three endogenous catecholamines (DA, NE, and Epi), their hydroxylated metabolites, catecholestrogens, ascorbate, and dihydroxyindolic intermediates of melanin. MAO and COMT are differentially localized: MAO associated chiefly with the outer surface of mitochondria, COMT largely cytosolic. These factors help to determine the primary metabolic pathways followed by catecholamines in various circumstances and to explain effects of certain drugs. Two different isozymes of MAO (MAO-A and MAO-B) are found in widely varying proportions in different cells in the CNS and in peripheral tissues. In the periphery, MAO-A is located in the syncytiotrophoblast layer of term placenta and liver, whereas MAO-B is located in platelets, lymphocytes, and liver. In the brain, MAO-A is located in all regions containing catecholamines, with the highest abundance in the locus ceruleus. MAO-B, on the other hand, is found primarily in regions that are known to synthesize and store serotonin. MAO-B is most prominent in the nucleus raphe dorsalis but also in the posterior hypothalamus and in glial cells in regions known to contain nerve terminals. MAO-B is also present in osteocytes around blood vessels.

Selective inhibitors of these two isozymes are available (see Chapter 17). Irreversible antagonists of MAO (e.g., phenelzine, tranylcypromine, and isocarboxazid) enhance the bioavailability of tyramine contained in many foods by inhibiting MAO-A; tyramine-induced NE release from sympathetic neurons may lead to markedly increased blood pressure (hypertensive crisis); selective MAO-B inhibitors (e.g., selegiline) or reversible MAO-A-selective inhibitors (e.g., moclobemide) are less likely to cause this potential interaction. MAO inhibitors are useful in the treatment of Parkinson's disease and mental depression (see Chapters 17 and 20).

Most of the Epi and NE that enters the circulation—from the adrenal medulla, sympathetic discharge or exogenous administration—is methylated by COMT to metanephrine or normetanephrine, respectively (Figure 6–6). NE that is released intraneuronally by drugs such as reserpine is deaminated initially by MAO and the aldehyde is reduced by aldehyde reductase or oxidized by aldehyde dehydrogenase. 3-Methoxy-4-hydroxymandelic acid [generally but incorrectly called vanillylmandelic acid (VMA)] is the major metabolite of catecholamines excreted in the urine. The corresponding product of the metabolic degradation of DA, which contains no hydroxyl group in the side chain, is homovanillic acid (HVA). Other metabolic reactions are described in Figure 6–6. Measurement of the concentrations of catecholamines and their metabolites in blood and urine is useful in the diagnosis of pheochromocytoma, a catecholamine-secreting tumor of the adrenal medulla/chromaffin tissue.

Inhibitors of MAO (e.g., pargyline and nialamide) can cause an increase in the concentration of NE, DA, and 5-HT in the brain and other tissues accompanied by a variety of pharmacological effects. No striking pharmacological action in the periphery can be attributed to the inhibition of COMT. However, the COMT inhibitors entacapone and tocaptopone are efficacious in the therapy of Parkinson's disease (see Chapter 20).

CLASSIFICATION OF ADRENERGIC RECEPTORS Understanding the diverse effects of the catecholamines and sympathomimetic agents requires understanding the properties of the different types of adrenergic receptors and their distribution on various tissues and organs (Tables 6–1, 6–5, 6–6, 6–7, and 10–6).

MOLECULAR BASIS OF ADRENERGIC RECEPTOR FUNCTION Adrenergic receptors are divided into two main classes, α and β , and thence into subclasses. All of the adrenergic receptors are GPCRs that link to heterotrimeric G proteins, each receptor showing a preference for a particular class of G proteins, that is, α_1 to G_{q_1} , α_2 to G_{i_1} , and all β to G_s (Table 6–6). The responses that follow activation of adrenergic receptors result from G protein-mediated effects on the generation of second messengers and on the activity of ion channels.

β ADRENERGIC RECEPTORS

β Receptors regulate numerous functional responses, including heart rate and contractility, smooth muscle relaxation, and multiple metabolic events (Table 6–1). All three of the β receptor

*This table provides examples of drugs that act on adrenergic receptors and of the location of subtypes of adrenergic receptors.

[†]At least three subtypes each of α_1 and α_2 adrenergic receptors are known, but distinctions in their mechanisms of action have not been clearly defined.

[‡]In some species (e.g., rat), metabolic responses in the liver are mediated by α_1 adrenergic receptors, whereas in others (e.g., dog) β_2 adrenergic receptors are predominantly involved. Both types of receptors appear to contribute to responses in human beings.

[§]Metabolic responses in adipocytes and certain other tissues with atypical pharmacological characteristics may be mediated by this subtype of receptor. Most β adrenergic receptor antagonists (including propranolol) do not block these responses.

subtypes (β_1 , β_2 , and β_3) couple to G_s and activate adenylyl cyclase (Table 6–6). Thus, stimulation of β adrenergic receptors leads to the accumulation of cyclic AMP, activation of PKA, and altered function of numerous cellular proteins as a result of their phosphorylation (see Chapter 1). In addition, G_s can enhance directly the activation of voltage-sensitive Ca^{2+} channels in the plasma membrane of skeletal and cardiac muscle. Catecholamines promote β receptor feedback regulation, i.e., desensitization and receptor down-regulation, and β receptors differ in the extent to which they undergo such regulation, with the β_2 receptor being the most susceptible. β_1 , β_2 , and β_3 receptors may differ in their signaling pathways and subcellular location in experimental systems, and coupling to G_i is possible, probably due to subtype-selective association with intracellular scaffolding and signaling proteins. The activation of PKA by cyclic AMP and the importance of compartmentation of components of the cyclic AMP pathway are discussed in Chapter 1.

α ADRENERGIC RECEPTORS

The α_1 receptors (α_{1A} , α_{1B} , and α_{1D}) and α_2 receptors (α_{2A} , α_{2B} , and α_{2C}) are GPCRs. α_2 receptors couple to a variety of effectors (Table 6–6), generally inhibiting adenylyl cyclase and activating G protein-gated K^+ channels, resulting in membrane hyperpolarization (possibly via Ca^{2+} -dependent processes or from direct interaction of liberated $\beta\gamma$ subunits with K^+ channels). α_2 receptors also can inhibit voltage-gated Ca^{2+} channels, an effect mediated by G_o . Other second-messenger systems linked to α_2 -receptor activation include acceleration of Na^+/H^+ exchange, stimulation of phospholipase C_{β_2} activity and arachidonic acid mobilization, increased phosphoinositide hydrolysis, and increased intracellular availability of Ca^{2+} . The latter is involved in the smooth muscle-contracting effect of α_2 adrenergic receptor agonists. The α_{2A} receptor plays a major role in inhibiting NE release from sympathetic nerve endings and suppressing sympathetic outflow from the brain, leading to hypotension. In the CNS, α_{2A} receptors, the most dominant adrenergic receptor, probably produce the antinociceptive effects, sedation, hypothermia, hypotension, and behavioral actions of α_2 agonists. The α_{2B} receptor is the main receptor mediating α_2 -induced vasoconstriction, whereas the α_{2C} receptor is the predominant receptor inhibiting the release of catecholamines from the adrenal medulla and modulating DA neurotransmission in the brain.

Stimulation of α_1 receptors results in the regulation of multiple effector systems, primarily activation of the G_q -PLC β -IP $_3$ - Ca^{2+} pathway and the activation of other Ca^{2+} - and calmodulin-sensitive pathways and the activation of PKC. PKC phosphorylates many substrates, including membrane proteins such as channels, pumps, and ion-exchange proteins (e.g., Ca^{2+} -transport ATPase). These effects presumably lead to regulation of various ion conductances. α_1 -receptor stimulation of phospholipase A_2 leads to the release of free arachidonate, which is then metabolized via the cyclooxygenase and lipoxygenase pathways to the bioactive prostaglandins and leukotrienes, respectively (see Chapter 25). Stimulation of phospholipase A_2 activity by various agonists (including Epi acting at α_1 receptors) is found in many tissues, suggesting that this effector is physiologically important. Phospholipase D hydrolyzes phosphatidylcholine to yield phosphatidic acid (PA). Although PA itself may act as a second messenger by releasing Ca^{2+} from intracellular stores, it also is metabolized to the second messenger DAG. Phospholipase D is an effector for ADP-ribosylating factor (ARF), suggesting that phospholipase D may play a role in membrane trafficking. Finally, some evidence in vascular smooth muscle suggests that α_1 receptors are capable of regulating a Ca^{2+} channel via a G protein.

In most smooth muscles, the increased concentration of intracellular Ca^{2+} ultimately causes contraction as a result of activation of Ca^{2+} -sensitive protein kinases such as the calmodulin-dependent myosin light-chain kinase; phosphorylation of the light chain of myosin is associated with the development of tension. In contrast, the increased concentration of intracellular Ca^{2+} that results from stimulation of α_1 receptors in GI smooth muscle causes hyperpolarization and relaxation by activation of Ca^{2+} -dependent K^+ channels. The α_{1A} receptor is the predominant receptor causing vasoconstriction in many vascular beds, including the mammary, mesenteric, splenic, hepatic, omental, renal, pulmonary, and epicardial coronary arteries. It is also the predominant subtype in the vena cava and the saphenous and pulmonary veins. Together with the α_{1B} receptor subtype, its activation promotes cardiac growth. The α_{1B} receptor subtype is the most abundant subtype in the heart, whereas the α_{1D} receptor subtype is the predominant receptor causing vasoconstriction in the aorta. Some evidence suggests that α_{1B} receptors mediate behaviors such as reaction to novelty and exploration and are involved in behavioral sensitizations and in the vulnerability to addiction (see Chapter 23).

Localization of Adrenergic Receptors—Presynaptically located α_2 and β_2 receptors fulfill important roles in the regulation of neurotransmitter release from sympathetic nerve endings (see above). Presynaptic α_2 receptors also may mediate inhibition of release of neurotransmitters other than NE in the central and peripheral nervous systems. Both α_2 and β_2 receptors are located

on many types of neurons in the brain. In peripheral tissues, postsynaptic α_2 receptors are found in vascular and other smooth muscle cells (where they mediate contraction), adipocytes, and many types of secretory epithelial cells (intestinal, renal, endocrine). Postsynaptic β_2 receptors are found in the myocardium (where they mediate contraction) as well as on vascular and other smooth muscle cells (where they mediate relaxation). Both α_2 and β_2 receptors may be situated at sites that are relatively remote from nerve terminals releasing NE. Such extrajunctional receptors typically are found on vascular smooth muscle cells and blood elements (platelets and leukocytes) and may be activated preferentially by circulating catecholamines, particularly Epi. In contrast, α_1 and β_1 receptors appear to be located mainly in the immediate vicinity of sympathetic adrenergic nerve terminals in peripheral target organs, strategically placed to be activated during stimulation of these nerves. These receptors also are distributed widely in the mammalian brain.

The cellular distributions of the three α_1 and three α_2 receptor subtypes still are incompletely understood. Recent findings indicate that α_{2A} subtype functions as a presynaptic autoreceptor in central noradrenergic neurons.

REFRACTORINESS TO CATECHOLAMINES Exposure of catecholamine-sensitive cells and tissues to adrenergic agonists causes a progressive diminution in their capacity to respond to such agents. This phenomenon, variously termed *refractoriness*, *desensitization*, *downregulation*, or *tachyphylaxis*, can limit the therapeutic efficacy and duration of action of catecholamines and other agents (see Chapter 1).

PHARMACOLOGICAL CONSIDERATIONS

Each step in neurotransmission (Figures 6–2, 6–3, and 6–5) represents a potential point of therapeutic intervention. This is depicted in the diagrams of the cholinergic and adrenergic terminals and their postjunctional sites (Figures 6–3 and 6–5). Drugs that affect processes involved in each step of transmission at both cholinergic and adrenergic junctions are summarized in Table 6–7.

OTHER AUTONOMIC NEUROTRANSMITTERS

Both central and peripheral neurons generally contain more than one transmitter substance (see Chapter 12). The anatomical separation of the parasympathetic and sympathetic components of the ANS and the actions of ACh and NE provide the essential framework for studying autonomic function, but a host of other chemical messengers (e.g., purines, eicosanoids, NO, peptides) also modulate or mediate responses in the ANS. ATP and ACh can coexist in cholinergic vesicles; ATP, NPY, and catecholamines are found within storage granules of sympathetic nerves and the adrenal medulla. Many peptides are found in the adrenal medulla, nerve fibers, or ganglia of the ANS or in the structures that are innervated by the ANS, including the enkephalins, substance P and other tachykinins, somatostatin, gonadotropin-releasing hormone, cholecystokinin, calcitonin gene-related peptide, galanin, pituitary adenylyl cyclase-activating peptide, VIP, chromogranins, and NPY. Some of the orphan GPCRs discovered in the course of genome-sequencing projects may represent receptors for undiscovered peptides or other cotransmitters. The evidence for widespread transmitter function in the ANS is substantial for VIP and NPY. ATP and its metabolites may act postsynaptically and exert presynaptic modulatory effects on transmitter release via P2 receptors and receptors for adenosine. In addition to acting as a cotransmitter with NE, ATP may be a cotransmitter with ACh in certain postganglionic parasympathetic nerves, for example, in the urinary bladder. NPY is colocalized and coreleased with NE and ATP in most peripheral sympathetic nerves, especially those innervating blood vessels. Thus, NPY, together with NE and ATP, may be the third sympathetic cotransmitter. The functions of NPY include (1) direct postjunctional contractile effects; (2) potentiation of the contractile effects of the other sympathetic cotransmitters; and (3) inhibitory modulation of the nerve stimulation-induced release of all three sympathetic cotransmitters.

VIP and ACh coexist in peripheral autonomic neurons, and it seems likely that VIP is a parasympathetic cotransmitter in certain locations, such as the nerves regulating GI sphincters.

NANC TRANSMISSION BY PURINES Autonomic neurotransmission may be nonadrenergic and noncholinergic (NANC). The existence of purinergic neurotransmission in the GI tract, genitourinary tract, and certain blood vessels is compelling; ATP fulfills the criteria for a neurotransmitter. Adenosine, generated from the released ATP by ectoenzymes and releasable nucleotidases, acts as a modulator, causing feedback inhibition of release of the transmitter. Purinergic receptors may be divided into the adenosine (P1) receptors and ATP receptors (P2X and P2Y receptors); both P1 and P2 receptors have various subtypes. Methylxanthines such as caffeine and

theophylline preferentially block adenosine receptors (see Chapter 27). The P1 and P2Y receptors mediate their responses *via* G proteins; P2X receptors are a subfamily of ligand-gated ion channels.

ENDOTHELIUM-DERIVED FACTORS AND NITRIC OXIDE Intact endothelium is necessary to achieve vascular relaxation in response to ACh. This inner cellular layer of the blood vessel now is known to modulate autonomic and hormonal effects on the contractility of blood vessels. In response to a variety of vasoactive agents and even physical stimuli, the endothelial cells release a short-lived vasodilator called *endothelium-derived relaxing factor* (EDRF), now known to be NO. Products of inflammation and platelet aggregation (*e.g.*, 5-HT, histamine, bradykinin, purines, thrombin) exert all or part of their actions by stimulating NO production. Endothelium-dependent relaxation is important in a variety of vascular beds, including the coronary circulation. Activation of receptors linked to the G_q -PLC-IP₃ pathway on endothelial cells mobilizes stored Ca²⁺, activates endothelial NO synthase, and promotes NO production. NO diffuses to the underlying smooth muscle and induces relaxation of vascular smooth muscle by activating the soluble guanylyl cyclase, which increases cyclic GMP concentrations. Nitrate vasodilators used to lower blood pressure or to treat ischemic heart disease act as NO donors (*see* Chapter 31). NO also is released from certain nerves (*nitroergic*) innervating blood vessels and smooth muscles of the GI tract. NO has a negative inotropic action on the heart. Alterations in the production or action of NO may affect a number of conditions such as atherosclerosis and septic shock.

NO is synthesized from L-arginine and molecular oxygen by Ca²⁺-calmodulin-sensitive *nitric oxide synthase* (NOS). There are three known forms of this enzyme. One form (eNOS) is constitutive, residing in the endothelial cell and synthesizing NO over short periods in response to receptor-mediated increases in cellular Ca²⁺. A second form (nNOS) is responsible for the Ca²⁺-dependent NO synthesis in neurons. The third form of NOS (iNOS) is induced after activation of cells by cytokines and bacterial endotoxins. Once expressed, iNOS binds Ca²⁺ tightly, is independent of fluctuations in [Ca²⁺]_i, and synthesizes NO for long periods of time. This inducible, high-output form is responsible for the toxic manifestations of NO. Glucocorticoids inhibit the expression of inducible, but not constitutive, forms of NOS in vascular endothelial cells. However, other endothelium-derived factors also may be involved in vasodilation and hyperpolarization of the smooth muscle cell. NOS inhibitors might have therapeutic benefit in septic shock and neurodegenerative diseases. Conversely, diminished production of NO by the endothelial cell layer in atherosclerotic coronary arteries may contribute to the risk of myocardial infarction.

MUSCARINIC RECEPTOR AGONISTS AND ANTAGONISTS

MUSCARINIC RECEPTORS AND MUSCARINIC AGONISTS

Actions of acetylcholine (ACh) are referred to as *muscarinic* based on the observation that muscarine acts selectively at certain sites and, qualitatively, produces the same effects as ACh. Peripheral muscarinic acetylcholine receptors are found primarily on autonomic effector cells innervated by postganglionic parasympathetic nerves and on some cells that receive little or no cholinergic innervation but express muscarinic receptors (e.g., vascular endothelial cells). There are also muscarinic receptors in ganglia and the adrenal medulla, where muscarinic stimulation seems to modulate the effects of nicotinic stimulation. Within the central nervous system (CNS), the hippocampus, cortex, and thalamus have high densities of muscarinic receptors.

Muscarinic agonists mimic the muscarinic effects of ACh and typically are longer-acting congeners of ACh or natural alkaloids that display little selectivity for the various subtypes of muscarinic receptors. The muscarinic, or parasympathomimetic, actions of the drugs considered in this chapter are practically equivalent to the effects of postganglionic parasympathetic nerve impulses listed in Table 6-1. All of the actions of ACh and its congeners at muscarinic receptors can be blocked by *atropine*.

Subtypes of Muscarinic Receptors

The cloning of complementary DNAs (cDNAs) encoding muscarinic receptors has identified five distinct gene products, designated as M_1 through M_5 (see Table 6-3). All of the muscarinic receptor subtypes are G protein-coupled receptors (GPCRs). Although selectivity is not absolute, stimulation of M_1 and M_3 receptors generally activates the G_q -PLC-IP₃ pathway and mobilizes intracellular Ca^{2+} , resulting in a variety of Ca^{2+} -mediated events, either directly or as a consequence of the phosphorylation of target proteins. In contrast, M_2 and M_4 muscarinic receptors couple to G_i to inhibit adenylyl cyclase and to G_i and G_o to regulate specific ion channels (e.g., enhancement of K^+ conductance in cardiac sinoatrial [SA] nodal cells) through β subunits of the G proteins.

Pharmacological Effects of Muscarinic Stimulation

CARDIOVASCULAR SYSTEM ACh has four primary effects on the cardiovascular system: vasodilation, a decrease in cardiac rate (the negative chronotropic effect), a decrease in the rate of conduction in the specialized tissues of the SA and atrioventricular (AV) nodes (the negative dromotropic effect), and a decrease in the force of cardiac contraction (the negative inotropic effect). The last effect is of lesser significance in ventricular than in atrial muscle. Certain of the above responses can be obscured by baroreceptor and other reflexes that dampen or counteract the direct responses to ACh.

Although ACh rarely is given systemically, its cardiac actions are important because of the involvement of cholinergic vagal impulses in the baroreceptor reflex and in the actions of the cardiac glycosides, antiarrhythmic agents, and many other drugs; afferent stimulation of the viscera during surgical interventions also stimulates vagal release of ACh.

The intravenous injection of a small dose of ACh produces a transient fall in blood pressure owing to generalized vasodilation, usually accompanied by reflex tachycardia. A considerably larger dose is required to elicit bradycardia or block of AV nodal conduction from a direct action of ACh on the heart. If large doses of ACh are injected after the administration of atropine, an increase in blood pressure is observed due to stimulation of nicotinic receptors on the adrenal medulla and sympathetic ganglia resulting in the release of catecholamines into the circulation and at postganglionic sympathetic nerve endings.

ACh produces dilation of essentially all vascular beds, including those of the pulmonary and coronary vasculature; the effect is mediated by stimulation of endothelial NO production. Vasodilation of coronary beds may be elicited by baroreceptor or chemoreceptor reflexes or by direct electrical stimulation of the vagus; however, neither parasympathetic vasodilator nor sympathetic vasoconstrictor tone plays a major role in the regulation of coronary blood flow relative to the effects of local oxygen tension and autoregulatory metabolic factors such as adenosine.

Dilation of vascular beds by exogenous ACh is due primarily to M_3 receptors on endothelial cells. Most vessels lack cholinergic innervation, but their endothelial and smooth muscle cells express muscarinic receptors. In each cell type, stimulation of the muscarinic receptors activates the G_q -PLC-IP₃ pathway and mobilizes cell Ca^{2+} . In endothelial cells, this leads to Ca^{2+} -calmodulin-dependent

activation of endothelial NO synthase (eNOS, NOS-3) and production of NO which diffuses to adjacent smooth muscle cells, where it stimulates the soluble guanylyl cyclase and causes relaxation (see Chapters 1 and 6). Vasodilation also may arise indirectly due to inhibition of norepinephrine (NE) release from adrenergic nerve endings by ACh. If the endothelium is damaged, as occurs under various pathophysiological conditions, the direct effect of ACh on the muscarinic receptors on vascular smooth muscle cells predominates, and the resultant mobilization of cell Ca^{2+} causes vasoconstriction. There is also evidence of NO-based (nitric) neurotransmission in peripheral blood vessels.

Cholinergic stimulation affects cardiac function both directly and by inhibiting the effects of adrenergic activation. The latter depends on the level of sympathetic drive to the heart and results in part from inhibition of cyclic AMP formation and reduction in L-type Ca^{2+} channel activity, mediated through M_2 receptors. Inhibition of adrenergic stimulation of the heart also results from the capacity of M_2 receptors to inhibit the release of NE from sympathetic nerve endings. Cholinergic innervation of the ventricular myocardium is less dense, and the parasympathetic fibers terminate largely on specialized conduction tissue such as the Purkinje fibers but also on some ventricular myocytes, which express M_2 receptors.

In the SA node, each normal cardiac impulse is initiated by the spontaneous depolarization of the pacemaker cells (see Chapter 34). When a threshold is reached, an action potential is initiated and conducted through the atrial muscle fibers to the AV node and thence through the Purkinje system to the ventricular muscle. ACh slows the heart rate by decreasing the rate of spontaneous diastolic depolarization (the pacemaker current) and by increasing the repolarizing K^+ current at the SA node (a direct effect of $\beta\gamma$ subunits of G_i/G_o); in sum, the membrane potential is more negative and attainment of the threshold potential and the succeeding events in the cardiac cycle are delayed.

In atrial muscle, ACh decreases the strength of contraction. This occurs largely indirectly, as a result of decreasing cyclic AMP and Ca^{2+} channel activity. Direct inhibitory effects are seen at higher ACh concentrations and result from M_2 receptor-mediated activation of G protein-regulated K^+ channels. The rate of impulse conduction in the normal atrium is either unaffected or may increase in response to ACh, due to the activation of additional Na^+ channels, possibly in response to the ACh-induced hyperpolarization. The combination of these factors is the basis for the perpetuation or exacerbation by vagal impulses of atrial flutter or fibrillation arising at an ectopic focus. In contrast, primarily in the AV node and to a much lesser extent in the Purkinje conducting system, ACh slows conduction and increases the refractory period. The decrease in AV nodal conduction usually is responsible for the complete heart block that may be observed when large quantities of cholinergic agonists are administered systemically. With an increase in vagal tone, such as is produced by *digoxin*, the increased refractory period can contribute to the reduction in the frequency with which aberrant atrial impulses are transmitted to the ventricle, and thus protect the ventricle during atrial flutter or fibrillation.

Although the effect is smaller than that observed in the atrium, ACh produces a negative inotropic effect in the ventricle. This inhibition is most apparent when there is concomitant adrenergic stimulation or underlying sympathetic tone. ACh suppresses automaticity of Purkinje fibers and increases the threshold for ventricular fibrillation. To the extent that the ventricle receives cholinergic innervation, sympathetic and vagal nerve terminals lie in close proximity, and muscarinic receptors are believed to exist at presynaptic as well as postsynaptic sites.

GASTROINTESTINAL AND URINARY TRACTS Although stimulation of vagal input to the gastrointestinal (GI) tract increases tone, amplitude of contraction, and secretory activity of the stomach and intestine, such responses are inconsistently seen with administered ACh. Poor perfusion of visceral organs and rapid hydrolysis by plasma butyrylcholinesterase limit access of systemically administered ACh to visceral muscarinic receptors. Parasympathetic sacral innervation causes detrusor muscle contraction, increased voiding pressure, and ureter peristalsis, but for similar reasons these responses are not evident with administered ACh.

MISCELLANEOUS EFFECTS

The influence of ACh and parasympathetic innervation on various organs and tissues is discussed in detail in Chapter 6. ACh and its analogs stimulate secretion by all glands that receive parasympathetic innervation, including the lacrimal, tracheobronchial, salivary, and digestive glands. The effects on the respiratory system, in addition to increased tracheobronchial secretion, include bronchoconstriction and stimulation of the chemoreceptors of the carotid and aortic bodies. When instilled into the eye, muscarinic agonists produce miosis (see Chapter 63).

CHOLINOMIMETIC CHOLINE ESTERS AND NATURAL ALKALOIDS

Muscarinic cholinergic receptor agonists can be divided into two groups: (1) ACh and several synthetic choline esters, and (2) the naturally occurring cholinomimetic alkaloids (particularly pilocarpine, *muscarine*, and *arecoline*) and their synthetic congeners. The structures and pharmacologic properties of a congeneric series are summarized by Table 7-1 and Figure 7-1.

Methacholine (acetyl- β -methylcholine) differs from ACh chiefly in its greater duration and selectivity of action. Its action is more prolonged because the added methyl group increases its resistance to hydrolysis by cholinesterases. Carbachol and bethanechol, unsubstituted carbamoyl esters, are completely resistant to hydrolysis by cholinesterases and thus survive long enough to be distributed to areas of low blood flow. Carbachol retains substantial nicotinic activity, particularly on autonomic ganglia; both its peripheral and its ganglionic actions are probably due, in part, to the release of endogenous ACh from the terminals of cholinergic fibers.

Of the three major natural plant alkaloids, muscarine acts almost exclusively at muscarinic receptor sites, arecoline also acts at nicotinic receptors, and pilocarpine has a dominant muscarinic action but causes anomalous cardiovascular responses (the sweat glands are particularly sensitive to this drug). Although these naturally occurring alkaloids are valuable as pharmacological tools, present clinical use is restricted largely to pilocarpine as a sialagogue and mitotic agent (see Chapter 63).

Pharmacological Properties**GASTROINTESTINAL TRACT**

All muscarinic agonists can stimulate GI smooth muscle, increasing tone and motility; large doses will cause spasm and tenesmus. Unlike methacholine, carbachol, bethanechol, and pilocarpine stimulate the GI tract without significant cardiovascular effects.

URINARY TRACT

Choline esters and pilocarpine contract the detrusor muscle of the bladder, increase voiding pressure, decrease bladder capacity, and increase ureteral peristalsis. In addition, the trigone and external sphincter muscles relax. Bethanechol shows some selectivity for bladder stimulation relative to cardiovascular activity (see Table 7-1).

EXOCRINE GLANDS

Choline esters and muscarinic alkaloids stimulate secretion of glands that receive parasympathetic or sympathetic cholinergic innervation, including the lacrimal, salivary, digestive, tracheo-bronchial, and sweat glands. Pilocarpine in particular causes marked diaphoresis (2-3 L of sweat may be secreted) and markedly increases salivation. Muscarine and arecoline also are potent diaphoretic agents. Accompanying side effects may include hiccough, salivation, nausea, vomiting, weakness, and occasionally collapse. These alkaloids also stimulate the lacrimal, gastric, pancreatic, and intestinal glands, and the mucous cells of the respiratory tract.

RESPIRATORY SYSTEM

In addition to tracheobronchial secretions, bronchial smooth muscle is stimulated by the muscarinic agonists. Asthmatic patients respond with intense bronchoconstriction, secretions, and a reduction in vital capacity. These actions form the basis of the methacholine challenge test used to diagnose airway hyperreactivity.

FIGURE 7-1 Acetylcholine and choline esters.

CARDIOVASCULAR SYSTEM

Continuous intravenous infusion of methacholine elicits hypotension and bradycardia, just as ACh does but at 1/200 the dose. Muscarine, at small doses, leads to a marked fall in blood pressure and a slowing or temporary cessation of the heartbeat. In contrast, carbachol and bethanechol generally cause only a transient fall in blood pressure at doses that affect the GI and urinary tracts.

EYE

Muscarinic agonists stimulate the pupillary constrictor and ciliary muscles when applied locally to the eye, causing pupil constriction and a loss of ability to accommodate to far vision.

CENTRAL NERVOUS SYSTEM

Quaternary choline esters do not cross the blood–brain barrier.

Therapeutic Uses

Acetylcholine (MIOCHOL-E) is available as an ophthalmic surgical aid for rapid production of miosis. Bethanechol chloride (URECHOLINE, others) is available in tablets and as an injection for use as a stimulant of GI smooth muscle, especially the urinary bladder. Pilocarpine hydrochloride (SALAGEN) is available as 5- or 7.5-mg oral doses for treatment of xerostomia or as ophthalmic solutions (PILOCAR, others) of varying strength. Methacholine chloride (PROVOCHOLINE) may be administered for diagnosis of bronchial hyperreactivity. The unpredictability of absorption and intensity of response has precluded its use as a vasodilator or cardiac vagomimetic agent. Cevimeline (EVOXAC) is a newer muscarinic agonist available orally for use in treatment of xerostomia.

GASTROINTESTINAL DISORDERS

Bethanechol can be of value in certain cases of postoperative abdominal distention and in gastric atony or gastroparesis. Oral administration is preferred; the usual dosage is 10–20 mg, three or four times daily. Bethanechol is given by mouth before each main meal in cases without complete retention; when gastric retention is complete and nothing passes into the duodenum, the subcutaneous route is necessary because of poor stomach absorption. Bethanechol has been used to advantage in certain patients with congenital megacolon and with adynamic ileus secondary to toxic states. Prokinetic agents with combined cholinergic-agonist and dopamine-antagonist activity (e.g., metoclopramide) or serotonin-antagonist activity (see Chapter 37) have largely replaced bethanechol in gastroparesis and esophageal reflux disorders.

URINARY BLADDER DISORDERS

Bethanechol may be useful in treating urinary retention and inadequate emptying of the bladder when organic obstruction is absent, as in postoperative and postpartum urinary retention and in certain cases of chronic hypotonic, myogenic, or neurogenic bladder. α Adrenergic antagonists are useful adjuncts in reducing outlet resistance of the internal sphincter (see Chapter 10). Bethanechol may enhance contractions of the detrusor muscle after spinal injury if the vesical reflex is intact, and some benefit has been noted in partial sensory or motor paralysis of the bladder. Catheterization thus can be avoided. For acute retention, multiple subcutaneous doses of 2.5 mg of bethanechol may be administered. The stomach should be empty when the drug is injected. In chronic cases, 10–50 mg of the drug may be given orally two to four times daily with meals to avoid nausea and vomiting. When voluntary or spontaneous voiding begins, bethanechol is then slowly withdrawn.

XEROSTOMIA

Pilocarpine is administered orally in 5–10-mg doses given three times daily for the treatment of xerostomia that follows head and neck radiation treatments or that is associated with Sjögren's syndrome, an autoimmune disorder occurring primarily in women in whom secretions, particularly salivary and lacrimal, are compromised. Side effects typify cholinergic stimulation, with sweating being the most common complaint. Bethanechol is an oral alternative that produces less diaphoresis. Cevimeline (EVOXAC) has activity at M_3 muscarinic receptors, such as those on lacrimal and salivary

gland epithelia. Cevimeline has a long-lasting sialogogic action and may have fewer side effects than pilocarpine. Cevimeline also enhances lacrimal secretions in Sjögren's syndrome.

OPHTHALMOLOGICAL

Pilocarpine is used in the treatment of glaucoma, where it is instilled into the eye usually as a 0.5–4% solution. An ocular insert (OCUSERT PILO-20) that releases 20 µg of pilocarpine per hour over 7 days also is marketed for the control of elevated intraocular pressure. Pilocarpine usually is better tolerated than are the anticholinesterases and is the standard cholinergic agent for the treatment of open-angle glaucoma. Reduction of intraocular pressure occurs within a few minutes and lasts 4–8 hours. The ophthalmic use of pilocarpine alone and in combination with other agents is discussed in Chapter 63. The miotic action of pilocarpine is useful in reversing a narrow-angle glaucoma attack and overcoming the mydriasis produced by atropine; alternated with mydriatics, pilocarpine is employed to break adhesions between the iris and the lens.

CENTRAL NERVOUS SYSTEM

Agonists that selectively stimulate postsynaptic M_1 receptors in the CNS without concomitantly stimulating the presynaptic M_2 receptors (that inhibit release of endogenous ACh) have been in clinical trial for treating the cognitive impairment associated with Alzheimer's disease. However, lack of efficacy in improvement of cognitive function has diminished enthusiasm for this approach.

Precautions, Toxicity, and Contraindications

Muscarinic agonists are administered subcutaneously to achieve an acute response and orally to treat more chronic conditions. Should serious toxic reactions to these drugs arise, atropine sulfate (0.5–1 mg in adults) should be given subcutaneously or intravenously. Epinephrine (0.3–1 mg, subcutaneously or intramuscularly) also is of value in overcoming severe cardiovascular or bronchoconstrictor responses.

Major contraindications to the use of the muscarinic agonists are asthma, hyperthyroidism, coronary insufficiency, and acid-peptic disease. Their bronchoconstrictor action is liable to precipitate an asthma attack; hyperthyroid patients may develop atrial fibrillation. Hypotension induced by these agents can severely reduce coronary blood flow, especially if it is already compromised. Other possible undesirable effects of the cholinergic agents are flushing, sweating, abdominal cramps, belching, a sensation of tightness in the urinary bladder, difficulty in visual accommodation, headache, and salivation.

Toxicology

Poisoning from pilocarpine, muscarine, or arecoline is characterized chiefly by exaggeration of their parasympathomimetic effects. Treatment consists of the parenteral administration of atropine in doses sufficient to cross the blood–brain barrier and measures to support the respiratory and cardiovascular systems and to counteract pulmonary edema.

MUSHROOM POISONING (MYCETISM)

Mushrooms are a rich source of toxins; mushroom poisoning has increased as the result of the popularity of hunting wild mushrooms. High concentrations of muscarine are present in various species of *Inocybe* and *Clitocybe*. The symptoms of muscarine intoxication (salivation, lacrimation, nausea, vomiting, headache, visual disturbances, abdominal colic, diarrhea, bronchospasm, bradycardia, hypotension, shock) develop within 30–60 minutes of ingestion. Treatment with atropine (1–2 mg intramuscularly every 30 minutes) effectively blocks these effects.

Intoxication produced by *Amanita muscaria* and related *Amanita* species arises from the neurologic and hallucinogenic properties of muscimol, ibotenic acid, and other isoxazole derivatives that stimulate excitatory and inhibitory amino acid receptors. Symptoms range from irritability, restlessness, ataxia, hallucinations, and delirium to drowsiness and sedation. Treatment is mainly supportive; benzodiazepines are indicated when excitation predominates; atropine often exacerbates the delirium.

Mushrooms from *Psilocybe* and *Panaeolus* species contain psilocybin and related derivatives of tryptamine that cause short-lasting hallucinations. *Gyromitra* species (false morels) produce GI disorders and a delayed hepatotoxicity. The toxic substance, acetaldehyde methylformylhydrazine, is converted in the body to reactive hydrazines. Although fatalities from liver and kidney failure have been reported, they are far less frequent than with amatoxin-containing mushrooms.

The most serious form of mycetism is produced by *Amanita phalloides*, other *Amanita* species, *Lepiota*, and *Galerina* species. These species account for >90% of fatal cases. Ingestion of as little as 50 g of *A. phalloides* (deadly nightcap) can be fatal. The principal toxins are the amatoxins (α - and β -amanitin), a group of cyclic octapeptides that inhibit RNA polymerase II and hence

block messenger RNA (mRNA) synthesis. This causes cell death, particularly in the GI mucosa, liver, and kidneys. Initial symptoms include diarrhea and abdominal cramps. A symptom-free period lasting up to 24 hours is followed by hepatic and renal malfunction. Death occurs in 4–7 days from renal and hepatic failure. Treatment is largely supportive; penicillin, thioctic acid, and silibinin may be effective antidotes, but the evidence is anecdotal.

Because the toxicity and treatment strategies for mushroom poisoning depend on the species ingested, their identification is key. Regional poison control centers in the U.S. maintain up-to-date information on the incidence of poisoning in the region and treatment procedures.

MUSCARINIC RECEPTOR ANTAGONISTS

General comments—Muscarinic receptor antagonists reduce the effects of ACh by competitively inhibiting its binding to muscarinic cholinergic receptors. In general, muscarinic antagonists cause little blockade at nicotinic receptors; however, the quaternary ammonium derivatives of atropine are generally more potent at muscarinic receptors and exhibit a greater degree of nicotinic blocking activity, and consequently are more likely to interfere with ganglionic or neuromuscular transmission. At high or toxic doses, central effects of atropine and related drugs are observed, generally CNS stimulation followed by depression; since quaternary compounds penetrate the blood–brain barrier poorly, they have little or no effect on the CNS.

Parasympathetic neuroeffector junctions in different organs vary in their sensitivity to muscarinic receptor antagonists (Table 7–2). Effects such as reduction of gastric secretions occur only at doses that produce severe undesirable effects. This hierarchy of relative sensitivities is not a consequence of differences in the affinity of atropine for the muscarinic receptors at these sites; atropine lacks receptor subtype selectivity. More likely determinants include the degree to which the functions of various end organs are regulated by parasympathetic tone and the involvement of intramural neurons and reflexes. Actions of most clinically available muscarinic receptor antagonists differ only quantitatively from those of atropine. No antagonist in the receptor-selective category, including pirenzepine, is completely selective; in fact, clinical efficacy may arise from a balance of antagonistic actions on two or more receptor subtypes.

Pharmacological Properties: The Prototypical Alkaloids Atropine and Scopolamine

Atropine and scopolamine differ quantitatively in antimuscarinic actions, particularly in their ability to affect the CNS. Atropine has almost no detectable effect on the CNS at doses that are used clinically. In contrast, scopolamine has prominent central effects at low therapeutic doses. The basis for this difference is probably the greater permeation of scopolamine across the blood–brain barrier. Because atropine has limited CNS effects, it is preferred to scopolamine for most purposes.

CENTRAL NERVOUS SYSTEM Atropine in therapeutic doses (0.5–1 mg) causes only mild vagal excitation as a result of stimulation of the medulla and higher cerebral centers. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability,

Table 7–2

Effects of Atropine in Relation to Dose

Dose	Effects
0.5 mg	Slight cardiac slowing; some dryness of mouth; inhibition of sweating
1 mg	Definite dryness of mouth; thirst; acceleration of heart, sometimes preceded by slowing; mild dilation of pupils
2 mg	Rapid heart rate; palpitation; marked dryness of mouth; dilated pupils; some blurring of near vision
5 mg	All the above symptoms marked; difficulty in speaking and swallowing; restlessness and fatigue; headache; dry, hot skin; difficulty in micturition; reduced intestinal peristalsis
10 mg and more	Above symptoms more marked; pulse rapid and weak; iris practically obliterated; vision very blurred; skin flushed, hot, dry, and scarlet; ataxia, restlessness, and excitement; hallucinations and delirium; coma

disorientation, hallucinations, or delirium (*see* discussion of atropine poisoning, below). With still larger doses, stimulation is followed by depression, leading to circulatory collapse and respiratory failure after a period of paralysis and coma.

Scopolamine in therapeutic doses normally causes CNS depression manifested as drowsiness, amnesia, fatigue, and dreamless sleep, with a reduction in rapid eye movement (REM) sleep. Scopolamine also causes euphoria and is therefore subject to some abuse. Scopolamine is effective in preventing motion sickness.

The belladonna alkaloids and related muscarinic receptor antagonists have long been used in parkinsonism. These agents can be effective adjuncts to treatment with *levodopa* (*see* Chapter 20). Muscarinic receptor antagonists also are used to treat the extrapyramidal symptoms that commonly occur as side effects of conventional antipsychotic drug therapy (*see* Chapter 18). Certain antipsychotic drugs are relatively potent muscarinic receptor antagonists, and these cause fewer extrapyramidal side effects.

GANGLIA AND AUTONOMIC NERVES Cholinergic neurotransmission in autonomic ganglia is mediated primarily by activation of nicotinic ACh receptors (*see* Chapters 6 and 9). ACh and other cholinergic agonists also cause the generation of slow excitatory postsynaptic potentials (EPSPs) that are mediated by ganglionic M_1 receptors. This response is particularly sensitive to blockade by pirenzepine. The extent to which the slow EPSPs can alter impulse transmission through the different sympathetic and parasympathetic ganglia is difficult to assess, but the effects of pirenzepine on responses of end organs suggest a physiological modulatory function for the ganglionic M_1 receptor.

Pirenzepine inhibits gastric acid secretion at doses that have little effect on salivation or heart rate. Since the muscarinic receptors on the parietal cells do not appear to have a high affinity for pirenzepine, the M_1 receptor responsible for alterations in gastric acid secretion may be localized in intramural ganglia. Blockade of ganglionic muscarinic receptors (rather than those at the neuroeffector junction) apparently underlies the capacity of pirenzepine to inhibit relaxation of the lower esophageal sphincter. Likewise, blockade of parasympathetic ganglia may contribute to the response to muscarinic antagonists in lung and heart.

Presynaptic muscarinic receptors on terminals of sympathetic and parasympathetic neurons generally inhibit transmitter release; thus, blockade of these presynaptic receptors will augment transmitter release. Nonselective muscarinic blocking agents may thus augment ACh release, partially counteracting their effective postsynaptic receptor blockade. Since muscarinic receptor antagonists can alter autonomic activity at the ganglion and postganglionic neuron, the ultimate response of end organs to blockade of muscarinic receptors is difficult to predict. Thus, while direct blockade at neuroeffector sites predictably reverses the usual effects of the parasympathetic nervous system, concomitant inhibition of ganglionic or presynaptic receptors may produce paradoxical responses.

EYE

*Muscarinic receptor antagonists block the cholinergic responses of the pupillary sphincter muscle of the iris and the ciliary muscle controlling lens curvature (*see* Chapter 63). Thus, they dilate the pupil (mydriasis) and paralyze accommodation (cycloplegia). Locally applied atropine and scopolamine produce ocular effects of considerable duration; accommodation and pupillary reflexes may not fully recover for 7–12 days; thus, other muscarinic antagonists with shorter durations of action are preferred as mydriatics (*see* Chapter 63). Muscarinic receptor antagonists administered systemically have little effect on intraocular pressure except in patients predisposed to narrow-angle glaucoma, in whom the pressure may occasionally rise dangerously.*

CARDIOVASCULAR SYSTEM

Heart Although the dominant response to atropine is tachycardia, the heart rate often decreases slightly (4–8 beats/min) transiently with average clinical doses (0.4–0.6 mg). The slowing is usually absent after rapid intravenous injection. Larger doses of atropine cause progressively increasing tachycardia by blocking vagal effects on M_2 receptors on the SA node. Resting heart rate increased by 35–40 beats/min in young men given 2 mg of atropine intramuscularly. The maximal heart rate (*e.g.*, in response to exercise) is not altered by atropine. The influence of atropine is most noticeable in healthy young adults, in whom vagal tone is considerable. In infancy and old age, even large doses of atropine may fail to accelerate the heart. Atropine often produces cardiac arrhythmias, but without significant cardiovascular symptoms.

With low doses of scopolamine (0.1–0.2 mg), the cardiac slowing is greater than with atropine. With higher doses, a transient cardioacceleration may be observed.

Adequate doses of atropine can abolish many types of reflex vagal cardiac slowing or asystole—for example, from inhalation of irritant vapors, stimulation of the carotid sinus, pressure on the eyeballs, peritoneal stimulation, or injection of contrast dye during cardiac catheterization. Atropine also prevents or abruptly abolishes bradycardia or asystole caused by choline esters, acetylcholinesterase inhibitors, or other parasympathomimetic drugs, as well as cardiac arrest from electrical stimulation of the vagus. The removal of vagal influence on the heart by atropine also may facilitate AV conduction.

Circulation Atropine, alone, has little effect on blood pressure, an expected result since most vessels lack cholinergic innervation. However, in clinical doses, atropine completely counteracts the peripheral vasodilation and sharp fall in blood pressure caused by choline esters. Atropine in toxic, and occasionally therapeutic, doses can dilate cutaneous blood vessels, especially those in the blush area (atropine flush).

RESPIRATORY TRACT Belladonna alkaloids inhibit secretions of the nose, mouth, pharynx, and bronchi, and thus dry the mucous membranes of the respiratory tract. Reduction of mucous secretion and mucociliary clearance resulting in mucus plugs are undesirable side effects of atropine in patients with airway disease. Inhibition by atropine of bronchoconstriction caused by histamine, bradykinin, and the eicosanoids presumably reflects the participation of parasympathetic efferents in the bronchial reflexes elicited by these agents. The ability to block the indirect bronchoconstrictive effects of these mediators that are released during attacks of asthma forms the basis for the use of anticholinergic agents, along with β -adrenergic receptor agonists, in the treatment of asthma (see Chapter 27).

GASTROINTESTINAL TRACT Atropine can completely abolish the effects of ACh (and other parasympathomimetic drugs) on the motility and secretions of the GI tract, but can only incompletely inhibit the effects of vagal impulses. This difference is particularly striking in the effects of atropine on gut motility. Preganglionic vagal fibers that innervate the GI tract synapse not only with postganglionic cholinergic fibers, but also with a network of noncholinergic intramural neurons. These neurons of the enteric plexus release numerous neurotransmitters and neuromodulators (e.g., 5-HT, DA, myriad peptides) whose actions atropine does not block and which can effect changes in motility. Similarly, while vagal activity modulates gastrin-elicited histamine release and gastric acid secretion, the actions of gastrin can occur independently of vagal tone. Histamine H_2 receptor antagonists and proton pump inhibitors have replaced nonselective muscarinic antagonists as inhibitors of acid secretion (see Chapter 36).

Secretions

Salivary secretion, mediated through M_3 receptors, is particularly sensitive to inhibition by muscarinic receptor antagonists, which can completely abolish the copious, watery, parasympathetically induced secretion. The mouth becomes dry, and swallowing and talking may become difficult. Gastric secretions during the cephalic and fasting phases are reduced markedly by muscarinic antagonists; the intestinal phase of gastric secretion is only partially inhibited. Atropine also reduces the cytoprotective secretions (HCO_3^- , mucus) of the superficial epithelial cells (see Figure 36–1).

Motility

The parasympathetic nerves enhance both tone and motility and relax sphincters, thereby favoring intestinal transit. Muscarinic antagonists produce prolonged inhibitory effects on the motor activity of the GI tract; relatively large doses are needed to produce such inhibition. The complex myenteric nervous system can regulate motility independently of parasympathetic control, however (see Chapter 6).

OTHER SMOOTH MUSCLES

Urinary Tract

Muscarinic antagonists decrease the normal tone and amplitude of contractions of the ureter and bladder, and often eliminate drug-induced enhancement of ureteral tone, but at doses of atropine that inhibit salivation and lacrimation and cause blurring of vision (Table 7–2). Control of bladder contraction is complex, involving mainly M_2 receptors at multiple sites and also M_3 receptors that can mediate detrusor muscle contraction.

Biliary Tract

Atropine exerts a mild antispasmodic action on the gallbladder and bile ducts, an effect that usually is insufficient to overcome or prevent the marked spasm and increase in biliary duct pressure induced by opioids, for which nitrites (see Chapter 31) are more effective.

SWEAT GLANDS AND TEMPERATURE

Small doses of atropine or scopolamine inhibit the activity of sweat glands innervated by sympathetic cholinergic fibers, making the skin hot and dry. After large doses or at high environmental temperatures, sweating may be sufficiently depressed to raise the body temperature.

Pharmacologic Properties: The Quaternary Derivatives Ipratropium and Tiotropium

Ipratropium bromide (ATROVENT, others) is a quaternary ammonium derivative of atropine. *Oxitropium bromide* is a quaternary derivative of scopolamine. Ipratropium blocks all subtypes of muscarinic receptors and thus blocks presynaptic muscarinic inhibition of ACh release. The most recently developed and bronchoselective member of this family, tiotropium bromide (SPIRIVA), has a longer duration of action and shows some selectivity for M_1 and M_3 receptors, with lower affinity for M_2 receptors, and thus less presynaptic effect on ACh release.

Ipratropium and tiotropium can produce bronchodilation, tachycardia, and inhibition of secretion similar to that of atropine but with less inhibitory effect on mucociliary clearance relative to atropine. Hence, inhaled ipratropium and tiotropium provide useful anticholinergic therapy of chronic obstructive pulmonary disease and asthma while minimizing the increased accumulation of lower airway secretions encountered with atropine.

Actions of inhaled ipratropium or tiotropium are confined almost exclusively to the mouth and airways. Dry mouth is the only side effect reported frequently. Selectivity results from the very inefficient absorption of the quaternary drug from the lungs or the GI tract. These drugs cause a marked reduction in sensitivity to methacholine in asthmatic subjects, but only modest inhibition of responses to histamine, bradykinin, or $PGF_{2\alpha}$, and little protection against bronchoconstriction induced by 5-HT or leukotrienes. The therapeutic uses of ipratropium and tiotropium are discussed further in Chapter 27.

ABSORPTION, FATE, AND EXCRETION OF MUSCARINIC ANTAGONISTS The belladonna alkaloids and the tertiary synthetic and semisynthetic derivatives are absorbed rapidly from the GI tract and mucosal surfaces; absorption from intact skin is limited, although efficient absorption does occur in the postauricular region for some agents, allowing delivery *via* transdermal patch. Systemic absorption of inhaled or orally ingested quaternary muscarinic antagonists is minimal, even from the conjunctiva of the eye; the quaternary agents do not cross the blood-brain barrier.

Atropine has a $t_{1/2}$ of ~4 hours; hepatic metabolism accounts for the elimination of about half of a dose; the remainder is excreted unchanged in the urine. Ipratropium is administered as an aerosol or solution for inhalation; tiotropium is administered as a dry powder. As with most drugs administered by inhalation, ~90% of the dose is swallowed and appears in the feces. After inhalation, maximal responses usually develop over 30–90 minutes, with tiotropium having the slower onset. The effects of ipratropium last for 4–6 hours; tiotropium's effects persist for 24 hours, and the drug is amenable to once-daily dosing.

THERAPEUTIC USES OF MUSCARINIC RECEPTOR ANTAGONISTS

The major limitation in the use of the nonselective muscarinic antagonists is the failure to obtain desired therapeutic responses without concomitant side effects. Some selectivity and reduction in side effects have been achieved by local administration and by the use of minimally absorbed quaternary compounds. Subtype-selective muscarinic receptor antagonists hold the most promise for treating specific clinical symptoms, but few show absolute selectivity.

RESPIRATORY TRACT These drugs reduce secretion in both the upper and lower respiratory tracts. This effect in the nasopharynx may provide symptomatic relief of acute rhinitis associated with coryza or hay fever. The contribution of antihistamines employed in “cold” mixtures is likely due to their antimuscarinic properties, except in conditions with an allergic basis.

Systemic administration of belladonna alkaloids or their derivatives for bronchial asthma or COPD carries the disadvantage of reducing bronchial secretions and inspissation of the residual secretions. This viscid material is difficult to remove from the respiratory tree, and its presence can dangerously obstruct airflow and predispose to infection. By contrast, ipratropium and tiotropium, administered by inhalation, do not produce adverse effects on mucociliary clearance, and can be used safely in the treatment of airway disease (*see* Chapter 27).

GENITOURINARY TRACT

Overactive urinary bladder disease can be successfully treated with muscarinic antagonists, primarily tolterodine and trospium chloride, which lower intravesicular pressure, increase capacity, and reduce the frequency of contractions by antagonizing parasympathetic control of the bladder. Oxybutynin is used as a transdermal system (OXYTROL) that delivers 3.9 mg/day and is associated with a lower incidence of side effects than the oral immediate- or extended-release formulations. Tolterodine is metabolized by CYP2D6 to a 5-hydroxymethyl metabolite; since this metabolite possesses similar activity to the parent drug, variations in CYP2D6 levels do not affect the duration of drug action. Trospium is as effective as oxybutynin, with better tolerability. Solifenacin is newly approved for overactive bladder with a favorable efficacy: side effect ratio. Stress urinary incontinence has been treated with some success with duloxetine (YENTREVE), which acts centrally to influence 5-HT and NE levels.

GASTROINTESTINAL TRACT In the management of acid-peptic disease, antisecretory doses of muscarinic antagonists produce limiting side effects (Table 7–2) and, consequently, poor patient compliance. Pirenzepine has selectivity for M_1 over M_2 and M_3 receptors. However, pirenzepine's affinities for M_1 and M_3 receptors are comparable, so it does not possess total M_1 selectivity.

*Telenzepine is an analog of pirenzepine that has higher potency and similar selectivity for M_1 muscarinic receptors. Both drugs are used in the treatment of acid-peptic disease in Europe, Japan, and Canada, but not currently in the U.S. At therapeutic doses of pirenzepine, the incidence of dry mouth, blurred vision, and central muscarinic disturbances are relatively low. Central effects are not seen because of the drug's limited penetration into the CNS. Pirenzepine's relative selectivity for M_1 receptors is a marked improvement over atropine. Pirenzepine (100–150 mg/day) produces about the same rate of healing of duodenal and gastric ulcers as the H_2 antagonists *cimetidine* or *ranitidine*. Side effects necessitate drug withdrawal in <1% of patients. H_2 -receptor antagonists and proton pump inhibitors generally are drugs of choice to reduce gastric acid secretion (see Chapter 36). The belladonna alkaloids and synthetic substitutes are very effective in reducing excessive salivation, such as drug-induced salivation and that associated with heavy-metal poisoning and parkinsonism.*

The belladonna alkaloids (atropine, *belladonna tincture*, 1-hyoscyamine sulfate [ANASPAZ, LEVSIN, others], and scopolamine), and combinations with sedatives (e.g., *phenobarbital* [DONNATAL, others] or *butabarbital* [BUTIBEL]), anti-anxiety agents (e.g., *chlordiazepoxide* [LIBRAX, others], or *ergotamine* [BELLAMINE]) also have been used in a wide variety of conditions of irritable bowel and increased tone (spasticity) or motility of the GI tract. Pharmacotherapy of inflammatory bowel disease is discussed in Chapter 38. Therapy of disorders of bowel motility and water flux are discussed in Chapter 37.

USES IN OPHTHALMOLOGY

Effects limited to the eye are obtained by local administration of muscarinic receptor antagonists to produce mydriasis and cycloplegia. Cycloplegia is not attainable without mydriasis and requires higher concentrations or more prolonged application of a given agent. In instances in which complete cycloplegia is required, more effective agents such as atropine or scopolamine are preferred to drugs such as cyclopentolate and tropicamide. Homatropine hydrobromide (ISOPTO HOMATROPINE, others), a semisynthetic derivative of atropine (Figure 7–2) cyclopentolate hydrochloride (CYCLOGYL, others), and tropicamide (MYDRIACYL, others) are preferred to topical atropine or scopolamine because of their shorter duration of action (see Chapter 63).

CARDIOVASCULAR SYSTEM

The cardiovascular effects of muscarinic receptor antagonists are of limited clinical application. Atropine may be considered in the initial treatment of patients with acute myocardial infarction in whom excessive vagal tone causes sinus or nodal bradycardia. Dosing must be judicious; doses that are too low can cause a paradoxical bradycardia; excessive doses will cause tachycardia that may extend the infarct by increasing O_2 demand. Atropine occasionally is useful in reducing the severe bradycardia and syncope associated with a hyperactive carotid sinus reflex. Atropine will protect the SA and AV nodes from the effects of excessive ACh in instances of poisoning with anticholinesterase pesticides.

CENTRAL NERVOUS SYSTEM

Certain muscarinic antagonists are effective against motion sickness. They should be given prophylactically; they are much less effective after severe nausea or vomiting has developed. Scopolamine is the most effective prophylactic agent for short (4–6 hours) exposures to severe motion, and probably for exposures of up to several days. A transdermal preparation of scopolamine (TRANSDERM SCOP) is highly effective when used prophylactically. Scopolamine, incorporated into a multilayered adhesive unit, is applied to the postauricular mastoid region, where transdermal

absorption is especially efficient, and over a period of about 72 hours, ~0.5 mg of scopolamine is delivered. Dry mouth is common, drowsiness is not infrequent, and blurred vision occurs in some individuals. Mydriasis and cycloplegia can occur by inadvertent transfer of the drug to the eye from the fingers after handling the patch. Rare but severe psychotic episodes have been reported.

Benztropine mesylate (*COGENTIN*, others), biperiden (*AKINETON*), procyclidine (*KEMADRIN*), and trihexyphenidyl hydrochloride (*ARTANE*, others) are tertiary-amine muscarinic receptor antagonists (together with the ethanolamine antihistamine diphenhydramine [*BENADRYL*, others]) that gain access to the CNS and can therefore be used when anticholinergics are indicated to treat parkinsonism and the extrapyramidal side effects of antipsychotic drugs (see Chapter 20).

USES IN ANESTHESIA

Atropine commonly is given to block responses to vagal reflexes induced by surgical manipulation of visceral organs. Atropine or glycopyrrolate is used with neostigmine to block its parasympathomimetic effects when the latter agent is used to reverse skeletal muscle relaxation after surgery (see Chapter 9).

ANTICHOLINESTERASE POISONING

The use of atropine in large doses for the treatment of poisoning by anticholinesterase organophosphorus insecticides is discussed in Chapter 8. Atropine also may be used to antagonize the parasympathomimetic effects of pyridostigmine or other anticholinesterase agents administered in the treatment of myasthenia gravis.

OTHER MUSCARINIC ANTAGONISTS

METHSCOPOLAMINE

Methscopolamine bromide (*PAMINE*), a quaternary ammonium derivative of scopolamine, lacks the central actions of scopolamine and is used chiefly in GI diseases. It is less potent than atropine and is poorly absorbed; however, its action is more prolonged, the usual oral dose (2.5 mg) acting for 6–8 hours.

HOMATROPINE METHYLBROMIDE

Homatropine methylbromide is the quaternary derivative of homatropine. It is less potent than atropine in antimuscarinic activity, but it is four times more potent as a ganglionic blocking agent. It is available in combination with hydrocodone as an antitussive combination (*HYCODAN*) and has been used for relief of GI spasms and as an adjunct in peptic ulcer disease.

GLYCOPYRROLATE

Glycopyrrolate (*ROBINUL*, others) is employed orally to inhibit GI motility and is used parenterally to block the effects of vagal stimulation during anesthesia and surgery.

MISCELLANEOUS ANTISPASMODICS

Dicyclomine hydrochloride (*BENTYL, others*), flavoxate hydrochloride (*URISPAS, others*), oxybutynin chloride (*DITROPAN, others*), and tolterodine tartrate (*DETROL*) are tertiary amines; trospium chloride (*SANCTURA*) is a quaternary amine; in therapeutic doses they decrease spasm of the GI tract, biliary tract, ureter, and uterus.

MEPENZOLATE BROMIDE

Mepenzolate bromide (*CENTIL*), a quaternary amine, has peripheral actions similar to those of atropine. It is indicated for adjunctive therapy of peptic ulcer disease and has been used as a GI antispasmodic.

PROPANTHELINE

Propantheline bromide (*PRO-BANTHINE*) is a widely used synthetic nonselective muscarinic receptor antagonist. High doses produce the symptoms of ganglionic blockade; toxic doses block the skeletal neuromuscular junction. Its duration of action is comparable to that of atropine.

POISONING BY MUSCARINIC RECEPTOR ANTAGONISTS AND OTHER DRUGS WITH ANTICHOLINERGIC PROPERTIES

The deliberate or accidental ingestion of natural belladonna alkaloids is a major cause of poisonings. Many histamine H₁-receptor antagonists, phenothiazines, and tricyclic antidepressants also block muscarinic receptors, and in sufficient dosage, produce syndromes that include features of atropine intoxication.

Among the tricyclic antidepressants, *protriptyline* and *amitriptyline* are potent muscarinic receptor antagonists, with an affinity for the receptor that is approximately one-tenth that reported for atropine. Since these drugs are administered in therapeutic doses considerably higher than the effective dose of atropine, antimuscarinic effects often are observed clinically (see Chapter 17), and overdose with suicidal intent is a danger in the population using antidepressants. Fortunately, most of the newer antidepressants and SSRIs are far less anticholinergic. In contrast, the newer antipsychotic drugs (“atypical”, characterized by their low propensity for inducing extrapyramidal side effects) include agents that are potent muscarinic receptor antagonists (e.g., *clozapine, olanzapine*). Accordingly, dry mouth is a prominent side effect of these drugs (a paradoxical side effect of clozapine is increased salivation and drooling, possibly the result of its partial agonist properties).

Infants and young children are especially susceptible to the toxic effects of muscarinic antagonists. Indeed, cases of intoxication in children have resulted from conjunctival instillation for ophthalmic purposes. Systemic absorption occurs either from the nasal mucosa after the drug has traversed the nasolacrimal duct or from the GI tract if the drug is swallowed. Poisoning with *diphenoxylate-atropine* (*LOMOTIL, others*), used to treat diarrhea, has been extensively reported in the pediatric literature. Transdermal preparations of scopolamine used for motion sickness may cause toxic psychoses, especially in children and in the elderly. Serious intoxication may occur in children who ingest berries or seeds containing belladonna alkaloids. Poisoning from ingestion and smoking of jimson weed, or thorn apple, is seen with some frequency.

Table 7–2 shows the oral doses of atropine causing undesirable responses or symptoms of overdose. Measures to limit intestinal absorption should be initiated without delay if the poison has been taken orally (see Chapter 64). For symptomatic treatment, intravenous physostigmine rapidly abolishes the delirium and coma caused by large doses of atropine, but carries some risk of overdose in mild atropine intoxication. Since physostigmine is metabolized rapidly, the patient may again lapse into coma within 1–2 hours, and repeated doses may be needed (see Chapter 8). If marked excitement is present and more specific treatment is not available, a benzodiazepine is the most suitable agent for sedation and for control of convulsions. Phenothiazines or agents with antimuscarinic activity should not be used, because their antimuscarinic action is likely to intensify toxicity. Support of respiration and control of hyperthermia may be necessary.

ACETYLCHOLINESTERASE INHIBITORS

Acetylcholinesterase (AChE) terminates the action of acetylcholine (ACh) at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites. Inhibitors of AChE, or *anticholinesterase* (anti-ChE) *agents*, cause ACh to accumulate in the vicinity of cholinergic nerve terminals and thus can produce effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems; such is the basis of their clinical use and their adverse effects. Since cholinergic neurotransmission is widely distributed across animal species, anti-ChE agents are also effective toxins (e.g., agricultural insecticides, pesticides, and, regrettably, chemical warfare “nerve gases”).

MECHANISM OF ACTION OF AChE INHIBITORS

AChE inhibitors may be divided into three groups: noncovalent or “reversible” inhibitors, carbamoylating inhibitors, and organophosphorus compounds. The mechanisms of the action of compounds that typify these three classes of anti-ChE agents are shown in Figure 8–1. Three distinct domains on AChE constitute binding sites for inhibitory ligands and form the basis for specificity differences between AChE and butyrylcholinesterase: the acyl pocket of the active center, the choline subsite of the active center, and the peripheral anionic site. Reversible inhibitors (e.g., edrophonium, tacrine) bind to the choline subsite. Edrophonium has a brief duration of action because it binds reversibly and its quaternary structure facilitates renal elimination. Additional reversible inhibitors, such as donepezil, bind with higher affinity to the active center. Other reversible inhibitors (e.g., propidium and the snake peptidic toxin fasciculon) bind to the peripheral anionic site on AChE.

Drugs that have a carbamoyl ester linkage (e.g., physostigmine and neostigmine) are hydrolyzed by AChE (much more slowly than is ACh), generating a carbamoylated enzyme (Figure 8–1C). In contrast to the acetyl enzyme, methylcarbamoyl AChE and dimethylcarbamoyl AChE are far more stable (the $t_{1/2}$ for hydrolysis of the dimethylcarbamoyl enzyme is 15–30 minutes), precluding enzyme-catalyzed hydrolysis of ACh for extended periods of time. In vivo, the duration of inhibition by the carbamoylating agents is 3–4 hours.

The organophosphorus inhibitors (e.g., DFP), form stable conjugates with AChE, with the active center serine phosphorylated or phosphonylated (Figure 8–1D). If the alkyl groups in the phosphorylated enzyme are ethyl or methyl, spontaneous regeneration of active enzyme requires several hours. Secondary (as in DFP) or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and significant regeneration of active enzyme usually does not occur. Hence, the return of AChE activity depends on synthesis of a new enzyme. The stability of the phosphorylated enzyme is enhanced through “aging,” which results from the loss of one of the alkyl groups.

Thus, the terms *reversible* and *irreversible* as applied to the carbamoyl ester and organophosphate anti-ChE agents, respectively, reflect only quantitative differences in rates of decarbamoylation or dephosphorylation of the conjugated enzyme. Both chemical classes react covalently with the enzyme serine in essentially the same manner as does ACh.

Action at Effector Organs The characteristic pharmacological effects of the anti-ChE agents are due primarily to the accumulation of ACh at sites of cholinergic transmission. Virtually all acute effects of moderate doses of organophosphates are attributable to this action. The consequences of enhanced concentrations of ACh at motor endplates are unique to these sites and are discussed below. The tertiary amine and particularly the quaternary ammonium anti-ChE compounds may have additional direct actions at certain cholinergic receptor sites (e.g., effects of neostigmine on the spinal cord and neuromuscular junction reflect anti-ChE activity and direct cholinergic stimulation).

CHEMISTRY AND STRUCTURE–ACTIVITY RELATIONSHIPS

Noncovalent Inhibitors

These agents share mechanism (above and Figure 8–1) but differ in their disposition in the body and their affinity for the enzyme. Edrophonium, a quaternary drug whose activity is limited to peripheral nervous system synapses, has a moderate affinity for AChE. Its volume of distribution is limited and renal elimination is rapid, accounting for its short duration of action. By contrast, tacrine and donepezil (Figure 8–2) have higher affinities for AChE and are more hydrophobic, contributing to their longer durations of action; they readily cross the blood–brain barrier to inhibit AChE in the central nervous system (CNS).

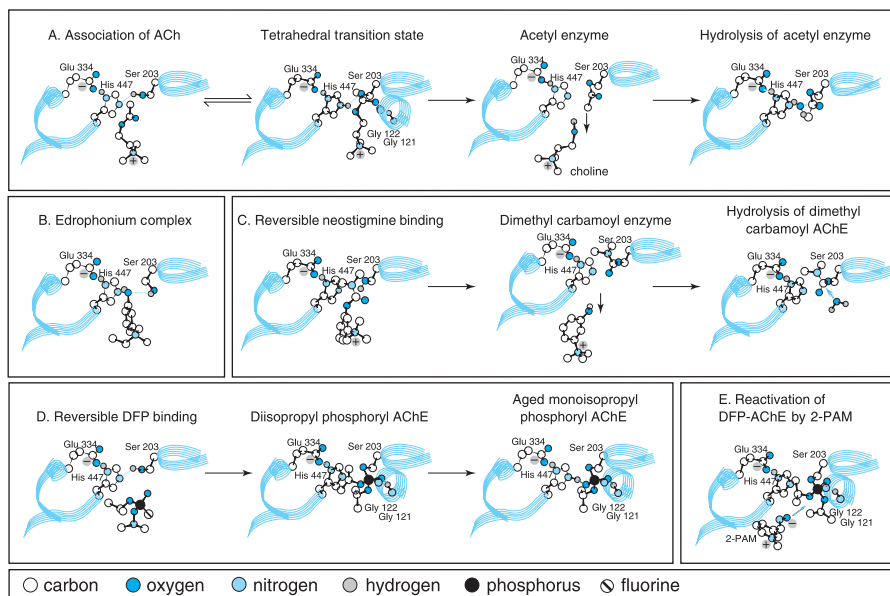

FIGURE 8-1 Steps in the hydrolysis of acetylcholine by acetylcholinesterase and in the inhibition and reactivation of AChE. Only the three residues of the catalytic triad are depicted. The associations and reactions shown are: **A.** Acetylcholine (ACh) catalysis: binding of ACh, formation of a tetrahedral transition state, formation of the acetyl enzyme with liberation of choline, rapid hydrolysis of the acetyl enzyme with return to the original state. **B.** Reversible binding and inhibition by edrophonium. **C.** Neostigmine reaction with and inhibition of acetylcholinesterase (AChE): reversible binding of neostigmine, formation of the dimethyl carbamoyl enzyme, slow hydrolysis of the dimethyl carbamoyl enzyme. **D.** Diisopropyl fluorophosphate (DFP) reaction and inhibition of AChE: reversible binding of DFP, formation of the diisopropyl phosphoryl enzyme, formation of the aged monoisopropyl phosphoryl enzyme. Hydrolysis of the diisopropyl enzyme is very slow and is not shown. The aged monoisopropyl phosphoryl enzyme is virtually resistant to hydrolysis and reactivation. The tetrahedral transition state of ACh hydrolysis resembles the conjugates formed by the tetrahedral phosphate inhibitors and accounts for their potency. Amide bond hydrogens from Gly 121 and 122 stabilize the carbonyl and phosphoryl oxygens. **E.** Reactivation of the diisopropyl phosphoryl enzyme by pralidoxime (2-PAM). 2-PAM attack of the phosphorus on the phosphorylated enzyme will form a phospho-oxime with regeneration of active enzyme.

“Reversible” Carbamate Inhibitors

Therapeutically useful drugs of this class of interest are shown in Figure 8-2; the essential moiety of physostigmine is a methylcarbamate of an amine-substituted phenol. An increase in anti-ChE potency and duration of action results from the linking of two quaternary ammonium moieties. One such example is the miotic agent demecarium (2 neostigmine molecules connected by a series of 10 methylene groups). The second quaternary group confers additional stability to the drug-AChE interaction. Carbamoylating inhibitors with high lipid solubilities (e.g., rivastigmine), which readily cross the blood-brain barrier and have longer durations of action, are approved or in clinical trial for the treatment of Alzheimer's disease (see Chapter 20).

The carbamate insecticides carbaryl (SEVIN), propoxur (BAYGON), and aldicarb (TEMIK), which are used extensively as garden insecticides, inhibit ChE in a fashion identical with other carbamoylating inhibitors.

Organophosphorus Compounds

The prototypic compound is DFP, which produces virtually irreversible inactivation of AChE and other esterases by alkylphosphorylation. Its high lipid solubility, low molecular weight, and volatility facilitate inhalation, transdermal absorption, and penetration into the CNS. After desulfuration, the insecticides in current use form the dimethoxy or diethoxyphosphoryl enzyme.

Malathion, parathion, and methylparathion have been popular insecticides. Acute and chronic toxicity has limited the use of parathion and methylparathion, and potentially less hazardous compounds have replaced them. The parent compounds are inactive in inhibiting AChE in vitro; they must be activated in vivo via a phosphoryl oxygen for sulfur substitution (phosphothioate to

FIGURE 8-2 Representative “reversible” anticholinesterase agents employed clinically.

phosphate), a conversion carried out predominantly by hepatic CYPs. This reaction also occurs in the insect, typically with more efficiency. Other insecticides possessing the phosphorothioate structure have been widely employed, including diazinon (SPECTRACIDE, others) and chlorpyrifos (DURSBAN, LORSBAN). Chlorpyrifos recently has been placed under restricted use because of evidence of chronic toxicity in the newborn animal. For the same reason, diazinon has been banned in the U.S.

Malathion (CHEMATHION, MALA-SPRAY) requires conversion to malaoxon (replacement of a sulfur atom with oxygen in vivo, conferring resistance to mammalian species). Malathion can be detoxified by hydrolysis of the carboxyl ester linkage by plasma carboxylesterases, and plasma carboxylesterase activity dictates species resistance to malathion. The detoxification reaction is much more rapid in mammals and birds than in insects. Malathion has been employed in aerial spraying of relatively populous areas for control of Mediterranean fruit flies and mosquitoes that harbor and transmit viruses harmful to human beings (e.g., West Nile encephalitis virus). Evidence of acute toxicity from malathion arises only with suicide attempts or deliberate poisoning.

The lethal dose in mammals is ~1 g/kg. Exposure to the skin results in a small fraction (<10%) of systemic absorption. Malathion is used topically in the treatment of pediculosis (lice) infestations.

Among the quaternary ammonium organophosphorus compounds, only echothiophate is useful clinically (limited to ophthalmic administration). It is not volatile and does not readily penetrate the skin.

PHARMACOLOGICAL PROPERTIES

The pharmacological properties of anti-ChE agents can be predicted by knowing where ACh is released physiologically by nerve impulses, the degree of nerve impulse activity, and the responses of the corresponding effector organs to ACh (*see* Chapter 6). The anti-ChE agents potentially can produce all the following effects: (1) stimulation of muscarinic receptor responses at autonomic effector organs; (2) stimulation, followed by depression or paralysis, of all autonomic ganglia and skeletal muscle (nicotinic actions); and (3) stimulation, with occasional subsequent depression, of cholinergic receptor sites in the CNS.

In general, compounds containing a quaternary ammonium group do not penetrate cell membranes readily; hence, anti-ChE agents in this category are absorbed poorly from the gastrointestinal (GI) tract or across the skin and are excluded from the CNS by the blood-brain barrier after moderate doses. On the other hand, such compounds act preferentially at the neuromuscular junctions of skeletal muscle, exerting their action both as anti-ChE agents and as direct agonists. They have comparatively less effect at autonomic effector sites and ganglia.

The more lipid-soluble agents are well absorbed after oral administration, have ubiquitous effects at both peripheral and central cholinergic sites, and may be sequestered in lipids for long periods of time. Lipid-soluble organophosphorus agents also are well absorbed through the skin, and the volatile agents are transferred readily across the alveolar membrane.

The therapeutically important sites of action of anti-ChE agents are the CNS, eye, intestine, and the neuromuscular junction of skeletal muscle; other actions are of toxicological consequence.

EYE When applied locally to the conjunctiva, anti-ChE agents cause conjunctival hyperemia and constriction of the pupillary sphincter muscle around the pupillary margin of the iris (miosis) and the ciliary muscle (block of accommodation reflex with resultant focusing to near vision). Miosis is apparent in a few minutes and can last several hours to days. The block of accommodation generally disappears before termination of miosis. Intraocular pressure, when elevated, usually falls as the result of facilitation of outflow of the aqueous humor (*see* Chapter 63).

GASTROINTESTINAL TRACT Neostigmine enhances gastric contractions, increases the secretion of gastric acid, and stimulates the lower portion of the esophagus. In patients with marked achalasia and dilation of the esophagus, the drug can cause a salutary increase in tone and peristalsis.

Neostigmine augments GI motor activity; the colon is particularly stimulated. Propulsive waves are increased in amplitude and frequency, and movement of intestinal contents is thus promoted. The effect of anti-ChE agents on intestinal motility probably represents a combination of actions at the ganglion cells of Auerbach's plexus and at the smooth muscle fibers (*see* Chapter 37).

NEUROMUSCULAR JUNCTION Most of the effects of potent anti-ChE drugs on skeletal muscle can be explained by their inhibition of AChE at neuromuscular junctions. However, there is good evidence for an accessory direct action of neostigmine and other quaternary ammonium anti-ChE agents on skeletal muscle.

The lifetime of free ACh in the nerve-muscle synapse (~200 μ sec) is normally shorter than the decay of the end-plate potential or the refractory period of the muscle. After inhibition of AChE, the residence time of ACh in the synapse increases, allowing for lateral diffusion and rebinding of the transmitter to multiple receptors and a prolongation of the decay time of the endplate potential. Asynchronous excitation and fasciculations of muscle fibers occur. With sufficient inhibition of AChE, depolarization of the endplate predominates, and blockade owing to depolarization ensues (*see* Chapter 9). The anti-ChE agents will reverse the antagonism caused by competitive neuromuscular blocking agents but not that caused by depolarizing agents (*e.g.*, *succinylcholine*), whose depolarization will be further enhanced by AChE inhibition (*see* Chapter 9).

ACTIONS AT OTHER SITES Secretory glands that are innervated by postganglionic cholinergic fibers include the bronchial, lacrimal, sweat, salivary, gastric (antral G cells and parietal cells), intestinal, and pancreatic acinar glands. Low doses of anti-ChE agents augment secretory responses to nerve stimulation; higher doses actually produce an increase in the resting rate of secretion.

Anti-ChE agents increase contraction of smooth muscle fibers of the bronchioles and ureters. The cardiovascular actions of anti-ChE agents are complex, since they reflect both ganglionic and postganglionic effects of accumulated ACh on the heart and blood vessels and actions in the CNS. The predominant effect on the heart from the peripheral action of accumulated ACh is bradycardia, resulting in a fall in cardiac output. Higher doses usually cause a fall in blood pressure, often due to effects of anti-ChE agents on medullary vasomotor centers of the CNS. Anti-ChE agents augment vagal influences on the heart. At the ganglia, accumulating ACh initially is excitatory on nicotinic receptors, but at higher concentrations, ganglionic blockade ensues as a result of persistent depolarization. Excitation of parasympathetic ganglion cells reinforces diminished cardiac function, whereas enhanced function results from the action of ACh on sympathetic ganglion cells. Excitation followed by inhibition also is elicited by ACh at the central medullary vasomotor and cardiac centers. These effects are complicated further by the hypoxemia resulting from the bronchoconstrictor and secretory actions of increased ACh on the respiratory system; hypoxemia, in turn, can reinforce both sympathetic tone and ACh-induced discharge of epinephrine from the adrenal medulla. Hence, it is not surprising that an increase in heart rate is seen with severe ChE inhibitor poisoning. Hypoxemia probably is a major factor in the CNS depression that appears after large doses of anti-ChE agents. Atropine antagonizes CNS-stimulant effects, although not as completely as muscarinic effects at peripheral autonomic effector sites.

ABSORPTION, FATE, AND EXCRETION Physostigmine is absorbed readily from the GI tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures (e.g., pressure on the inner canthus) are not taken to prevent absorption from the nasal mucosa. Parenterally administered physostigmine is largely destroyed within 2 hours, mainly by hydrolytic cleavage by plasma esterases; renal excretion plays only a minor role in its elimination.

Neostigmine and pyridostigmine are absorbed poorly after oral administration, such that much larger doses are needed than by the parenteral route (effective parenteral dose of neostigmine, 0.5–2 mg; equivalent oral dose, 15–30 mg or more). Neostigmine and pyridostigmine are destroyed by plasma esterases, with half-lives of 1–2 hours.

Organophosphorus anti-ChE agents with the highest risk of toxicity are highly lipid-soluble liquids; many have high vapor pressures. Agents used as agricultural insecticides (e.g., diazinon, malathion) generally are dispersed as aerosols or dusts that are absorbed rapidly through the skin and mucous membranes following contact with moisture, by the lungs after inhalation, and by the GI tract after ingestion. Absorbed organophosphorus compounds are hydrolyzed by plasma and liver esterases to the corresponding phosphoric and phosphonic acids, which are excreted in the urine. Young animals are deficient in these esterases (carboxylesterases and paraoxonases), which could contribute to toxicity in neonates and children.

TOXICOLOGY

ACUTE INTOXICATION

Acute intoxication by anti-ChE agents causes muscarinic and nicotinic signs and symptoms, and, except for compounds of extremely low lipid solubility, affects the CNS. Systemic effects appear within minutes after inhalation of vapors or aerosols. The onset of symptoms is delayed after GI and percutaneous absorption. Duration of effects is determined largely by the properties of the compound: lipid solubility, whether it must be activated to the oxon, stability of the organophosphorus-AChE bond, and whether “aging” of phosphorylated enzyme has occurred.

After local exposure to vapors or aerosols or after their inhalation, ocular and respiratory effects generally appear first. Ocular manifestations include marked miosis, ocular pain, conjunctival congestion, diminished vision, ciliary spasm, and brow ache. With acute systemic absorption, miosis may not be evident due to sympathetic discharge in response to hypotension. In addition to rhinorrhea and hyperemia of the upper respiratory tract, respiratory effects include tightness in the chest and wheezing due to bronchoconstriction and increased bronchial secretion. GI symptoms occur earliest after ingestion and include anorexia, nausea and vomiting, abdominal cramps, and diarrhea. With percutaneous absorption of liquid, localized sweating and muscle fasciculations in the immediate vicinity are generally the earliest symptoms. Severe intoxication is manifested by extreme salivation, involuntary defecation and urination, sweating, lacrimation, penile erection, bradycardia, and hypotension.

Nicotinic actions at the neuromuscular junctions of skeletal muscle usually consist of fatigability and generalized weakness, involuntary twitchings, scattered fasciculations, and eventually severe weakness and paralysis. The most serious consequence is paralysis of the respiratory muscles.

The broad spectrum of effects of acute AChE inhibition on the CNS includes confusion, ataxia, slurred speech, loss of reflexes, Cheyne-Stokes respiration, generalized convulsions, coma, and central respiratory paralysis. Actions on the vasomotor and other cardiovascular centers in the medulla oblongata lead to hypotension.

The time of death after a single acute exposure may range from <5 minutes to nearly 24 hours, depending on the dose, route, agent, and other factors. The cause of death primarily is respiratory failure, usually accompanied by a secondary cardiovascular component. Peripheral muscarinic and nicotinic as well as central actions all contribute to respiratory compromise; effects include laryngospasm, bronchoconstriction, increased tracheobronchial and salivary secretions, compromised voluntary control of the diaphragm and intercostal muscles, and central respiratory depression. Blood pressure may fall to alarmingly low levels and cardiac arrhythmias intervene. These effects usually result from hypoxemia and often are reversed by assisted pulmonary ventilation.

Delayed symptoms appearing after 1–4 days and marked by persistent low blood ChE and severe muscle weakness are termed the intermediate syndrome. A delayed neurotoxicity also may be evident after severe intoxication (see below).

Diagnosis and Treatment

The diagnosis of severe, acute anti-ChE intoxication is made readily from the history of exposure and the characteristic signs and symptoms. In suspected cases of milder, acute, or chronic intoxication, determination of the ChE activities in erythrocytes and plasma generally will establish the diagnosis. Although these values vary considerably in the normal population, they usually are depressed well below the normal range before symptoms are evident.

Atropine in sufficient dosage effectively antagonizes the actions at muscarinic receptor sites, and to a moderate extent, at peripheral ganglionic and central sites. Atropine should be given in doses sufficient to cross the blood–brain barrier: Following an initial injection of 2–4 mg (intravenously if possible, otherwise intramuscularly), 2 mg should be given every 5–10 minutes until muscarinic symptoms disappear, if they reappear, or until signs of atropine toxicity appear. More than 200 mg may be required on the first day. A mild degree of atropine block should then be maintained for as long as symptoms are evident. Atropine is virtually without effect against the peripheral neuromuscular compromise, which may be reversed by pralidoxime (2-PAM), a cholinesterase reactivator. AChE reactivators are beneficial in the therapy of organophosphorus anti-ChE intoxication, but their use is supplemental to the administration of atropine.

In moderate or severe intoxication with an organophosphorus anti-ChE agent, the recommended adult dose of pralidoxime is 1–2 g, infused intravenously over not less than 5 minutes. If weakness is not relieved or if it recurs after 20–60 minutes, the dose should be repeated. Early treatment is very important to assure that the oxime reaches the phosphorylated AChE while the latter still can be reactivated. Many of the alkylphosphates are extremely lipid soluble, and if extensive partitioning into body fat has occurred and desulfuration is required for inhibition of AChE, toxicity will persist and symptoms may recur after initial treatment. With severe toxicities from the lipid-soluble agents, it is necessary to continue treatment with atropine and pralidoxime for a week or longer.

General supportive measures are important, including: (1) termination of exposure, by removal of the patient or application of a gas mask if the atmosphere remains contaminated, removal and destruction of contaminated clothing, copious washing of contaminated skin or mucous membranes with water, or gastric lavage; (2) maintenance of a patent airway; (3) artificial respiration, if required; (4) administration of oxygen; (5) alleviation of persistent convulsions with diazepam (5–10 mg, intravenously); and (6) treatment of shock.

CHOLINESTERASE REACTIVATORS Although the phosphorylated esteratic site of AChE undergoes hydrolytic regeneration at a slow or negligible rate, nucleophilic agents, such as hydroxylamine (NH_2OH), hydroxamic acids (RCONH-OH), and oximes (RCH=NOH), reactivate the enzyme more rapidly than does spontaneous hydrolysis. Reactivation with pralidoxime (Figure 8–1E) occurs at a million times the rate of that with hydroxylamine. Several bis-quaternary oximes are even more potent as reactivators for insecticide and nerve gas poisoning (e.g., HI-6, used in Europe as an antidote).

PHARMACOLOGY, TOXICOLOGY, AND DISPOSITION The reactivating action of oximes *in vivo* is most marked at the skeletal neuromuscular junction. Following a dose of an organophosphorus compound that produces total blockade of transmission, the intravenous injection of an oxime restores responsiveness of the motor nerve to stimulation within minutes. Antidotal effects are less striking at autonomic effector sites, and the quaternary ammonium group restricts entry into the CNS.

Although high doses or accumulation of oximes can inhibit AChE and cause neuromuscular blockade, they should be given until one can be assured of clearance of the offending organophosphate. Many organophosphates partition into lipid and are released slowly as the active entity.

Current antidotal therapy for organophosphate exposure resulting from warfare or terrorism includes parenteral atropine, an oxime (2-PAM or HI-6), and a benzodiazepine as an anticonvulsant. Oximes and their metabolites are readily eliminated by the kidney.

THERAPEUTIC USES

AVAILABLE THERAPEUTIC AGENTS

The compounds described here are those commonly used as anti-ChE drugs and ChE reactivators in the U.S. Ophthalmic preparations are described in Chapter 63. Conventional dosages and routes of administration are given in the discussion of therapeutic applications.

Physostigmine salicylate (*ANTILIRIUM*), for injection. Physostigmine sulfate ophthalmic ointment; physostigmine salicylate ophthalmic solution. Pyridostigmine bromide, for oral (*MESTINON*) or parenteral (*REGONOL*, *MESTINON*) use. Neostigmine bromide (*PROSTIGMIN*), for oral use. Neostigmine methylsulfate (*PROSTIGMIN*), for parenteral use. Ambenonium chloride (*MYTELASE*), for oral use. Tacrine (*COGNEX*), donepezil (*ARICEPT*), rivastigmine (*EXELON*), and galantamine (*REMINYL*), approved for the treatment of Alzheimer's disease.

Pralidoxime chloride (*PROTOPAM CHLORIDE*), the only AChE reactivator currently available in the U.S., available in a parenteral formulation. The AChE reactivator HI-6 is available in several European and Near Eastern countries.

PARALYTIC ILEUS AND ATONY OF THE URINARY BLADDER

In the treatment of both these conditions, neostigmine generally is preferred among the anti-ChE agents. The direct parasympathomimetic agents (Chapter 7) are employed for the same purposes. The usual subcutaneous dose of neostigmine methylsulfate for postoperative paralytic ileus is 0.5 mg, given as needed. Peristaltic activity commences 10–30 minutes after parenteral administration, whereas 2–4 hours are required after oral administration of neostigmine bromide (15–30 mg). It may be necessary to assist evacuation with a small low enema or gas with a rectal tube.

A similar dose of neostigmine is used for the treatment of atony of the detrusor muscle of the urinary bladder.

Neostigmine should not be used when the intestine or urinary bladder is obstructed, when peritonitis is present, when the viability of the bowel is doubtful, or when bowel dysfunction results from inflammatory bowel disease.

GLAUCOMA AND OTHER OPHTHALMOLOGIC INDICATIONS

For a complete account of the pharmacotherapy of glaucoma and the roles of anti-ChE agents in ocular therapy, see Chapter 63.

MYASTHENIA GRAVIS

Myasthenia gravis is a neuromuscular disease characterized by weakness and marked fatigability of skeletal muscle; exacerbations and partial remissions occur frequently. The defect in myasthenia gravis is in synaptic transmission at the neuromuscular junction, such that mechanical responses to nerve stimulation are not well sustained. Myasthenia gravis is caused by an autoimmune response primarily to the ACh receptor at the postjunctional endplate. These antibodies reduce the number of receptors detectable by receptor-binding assays and electrophysiological measurements of ACh sensitivity. The similarity of the symptoms of myasthenia gravis and curare poisoning suggested that physostigmine might be of therapeutic value; 40 years elapsed before this suggestion was tried, successfully.

In a subset of ~10% of patients with myasthenic syndrome, muscle weakness has a congenital rather than an autoimmune basis, with mutations in the ACh receptor that affect ligand-binding and channel-opening kinetics, or in a form of AChE tethered by a collagen-like tail. Administration of anti-ChE agents does not result in subjective improvement in most congenital myasthenic patients.

Diagnosis

Although the diagnosis of autoimmune myasthenia gravis usually can be made from the history, signs, and symptoms, its differentiation from certain neurasthenic, infectious, endocrine, congenital, neoplastic, and degenerative neuromuscular diseases can be challenging. Myasthenia gravis is the only condition in which the muscular weakness can be improved dramatically by anti-ChE medication. The edrophonium test for evaluation of possible myasthenia gravis is performed by rapid intravenous injection of 2 mg of edrophonium chloride, followed 45 seconds later by an

additional 8 mg if the first dose is without effect; a positive response consists of brief improvement in strength, unaccompanied by lingual fasciculation (which generally occurs in nonmyasthenic patients). An excessive dose of an anti-ChE drug results in a cholinergic crisis, characterized by skeletal muscle weakness (due to depolarization blockade of nicotinic receptors at the neuromuscular junction) and other features (see above) from excess ACh at muscarinic receptors. The distinction between the weakness of cholinergic crisis/anti-AChE overdose and myasthenic weakness is of practical importance: the former is treated by withholding, and the latter by administering, the anti-ChE agent. When the edrophonium test is performed cautiously (limiting the dose to 2 mg and with facilities for respiratory resuscitation available) a further decrease in strength indicates cholinergic crisis, while improvement signifies myasthenic weakness. Atropine sulfate, 0.4–0.6 mg or more intravenously, should be given immediately if a severe muscarinic reaction ensues. Detection of antireceptor antibodies in muscle biopsies or plasma is now widely employed to establish the diagnosis.

Treatment

Pyridostigmine, neostigmine, and ambenonium are the standard anti-ChE drugs used in the symptomatic treatment of myasthenia gravis. All can increase the response of myasthenic muscle to repetitive nerve impulses, primarily by the preservation of endogenous ACh. The optimal single oral dose of an anti-ChE agent is determined empirically. Baseline recordings are made for grip strength, vital capacity, and a number of signs and symptoms that reflect the strength of various muscle groups. The patient then is given an oral dose of pyridostigmine (30–60 mg), neostigmine (7.5–15 mg), or ambenonium (2.5–5 mg). The improvement in muscle strength and changes in other signs and symptoms are noted at frequent intervals until there is a return to the basal state. After an hour or longer in the basal state, the drug is readministered at 1.5 times the initial amount, and the functional observations are repeated. This sequence is continued, with increasing increments of one-half the initial dose, until an optimal response is obtained.

The interval between oral doses required to maintain a reasonably even level of strength usually is 2–4 hours for neostigmine, 3–6 hours for pyridostigmine, and 3–8 hours for ambenonium. However, the required dose may vary from day to day; physical and emotional stress, infections, and menstruation usually necessitate an increase in the frequency or size of the dose. In addition, unpredictable exacerbations and remissions of the myasthenic state may require adjustment of dosage. Patients can be taught to modify their dosage regimens according to their changing requirements.

Pyridostigmine is available in sustained-release tablets containing a total of 180 mg, of which 60 mg is released immediately and 120 mg over several hours; this preparation is of value in maintaining patients for 6–8-hour periods but should be limited to use at bedtime. Muscarinic cardiovascular and GI side effects of anti-ChE agents generally can be controlled by atropine or other anticholinergic drugs (see Chapter 7), remembering that anticholinergic drugs mask many side effects of an excessive dose of an anti-ChE agent. In most patients, tolerance develops eventually to the muscarinic effects, so that anticholinergic medication is not necessary.

A number of drugs, including curariform agents and certain antibiotics and general anesthetics, interfere with neuromuscular transmission (see Chapter 9); their administration to patients with myasthenia gravis is hazardous without proper adjustment of anti-ChE dosage and other appropriate precautions. Glucocorticoids and immunosuppressant therapies are also used in the treatment of myasthenia gravis.

INTOXICATION BY ANTICHOLINERGIC DRUGS

In addition to atropine and other muscarinic agents, phenothiazines, antihistamines, and tricyclic antidepressants have central and peripheral anticholinergic activity. The effectiveness of physostigmine in reversing the anticholinergic effects of these agents has been documented. However, other toxic effects of the tricyclic antidepressants and phenothiazines (see Chapters 17 and 18), such as intraventricular conduction deficits and ventricular arrhythmias, are not reversed by physostigmine. In addition, physostigmine may precipitate seizures; hence, its usually small potential benefit must be weighed against this risk. The initial intravenous or intramuscular dose of physostigmine is 2 mg, with additional doses given as necessary. Physostigmine, a tertiary amine, crosses the blood–brain barrier; in contrast to the quaternary anti-AChE drugs.

ALZHEIMER'S DISEASE

A deficiency of intact cholinergic neurons, particularly those extending from subcortical areas such as the nucleus basalis of Meynert, has been observed in patients with progressive dementia of the Alzheimer type. Using a rationale similar to that in other CNS degenerative diseases, therapy for enhancing concentrations of cholinergic neurotransmitters in the CNS has been used in

mild-to-moderate Alzheimer's disease. Therapeutic strategies are directed at maximizing the ratio of central to peripheral ChE inhibition and using ChE inhibitors in conjunction with selective cholinergic agonists and antagonists.

Donepezil, 5 and 10 mg/day oral doses, may improve cognition and global clinical function and delay symptomatic progression of the disease. The drug is well tolerated in single daily doses; side effects are largely attributable to excessive cholinergic stimulation (nausea, diarrhea, and vomiting). Usually, 5 mg doses are administered at night for 4–6 weeks; if this dose is well tolerated, the dose can be increased to 10 mg daily. Rivastigmine, a long-acting carbamoylating inhibitor, has efficacy, tolerability, and side effects similar to those of donepezil. Galantamine, a recently approved AChE inhibitor, has a side-effect profile similar to those of donepezil and rivastigmine. Tacrine is approved for mild-to-moderate Alzheimer's disease, but a high incidence of hepatotoxicity limits this drug's utility. See Chapter 20 for further discussion of therapies for this disease.

AGENTS ACTING AT THE NEUROMUSCULAR JUNCTION AND AUTONOMIC GANGLIA

The nicotinic acetylcholine (ACh) receptor mediates neurotransmission postsynaptically at the neuromuscular junction and peripheral autonomic ganglia; in the central nervous system (CNS), it largely controls release of neurotransmitters from presynaptic sites. The receptor is called the *nicotinic acetylcholine* receptor because it is stimulated by both the neurotransmitter ACh and the alkaloid *nicotine*.

THE NICOTINIC ACETYLCHOLINE RECEPTOR

ACh interacts with the nicotinic ACh receptor to initiate an end-plate potential (EPP) in muscle or an excitatory postsynaptic potential (EPSP) in peripheral ganglia (Chapter 6). The nicotinic receptor of vertebrate skeletal muscle is a pentamer composed of 4 distinct subunits (α , β , γ , and δ) in the stoichiometric ratio of 2:1:1:1, respectively. In mature, innervated muscle end plates, the γ subunit is replaced by the closely related ϵ subunit. The nicotinic receptor is prototypical of other pentameric ligand-gated ion channels, which include the receptors for the inhibitory amino acids (γ -aminobutyric acid [GABA] and glycine) and 5-HT₃ serotonin receptors (Figure 9-1).

NEUROMUSCULAR BLOCKING AGENTS

Classification and Overview of Chemical Properties of Neuromuscular Blocking Agents

A single depolarizing agent, succinylcholine, is in general clinical use; multiple competitive or nondepolarizing agents are available (Figure 9-2). Therapeutic selection should be based on achieving a pharmacokinetic profile consistent with the duration of the interventional procedure and minimizing cardiovascular compromise or other adverse effects (Table 9-1). Two general classifications are useful in distinguishing side effects and pharmacokinetic behavior. The first relates to the duration of drug action; these agents are categorized as long-, intermediate-, and short-acting. The persistent blockade and difficulty in complete reversal after surgery with D-tubocurarine, metocurine, *pancuronium*, and *doxacurium* led to the development of *vecuronium* and *atracurium*, agents of intermediate duration, followed by development of a short-acting agent, *mivacurium*. Often, the long-acting agents are the more potent, requiring the use of low concentrations. The necessity of administering potent agents in low concentrations delays their onset. Rocuronium is an agent of intermediate duration but of rapid onset and lower potency. Its rapid onset allows it to be used as an alternative to succinylcholine in rapid-induction anesthesia and in relaxing the laryngeal and jaw muscles to facilitate tracheal intubation.

The second useful designation is the chemical class of the agents (Table 9-1). The natural alkaloid D-tubocurarine and the semisynthetic alkaloid alcuronium seldom are used. Apart from a shorter duration of action, the newer agents exhibit greatly diminished frequency of side effects, chief of which are ganglionic blockade, block of vagal responses, and histamine release. The prototype ammonio steroid, pancuronium, induces virtually no histamine release; however, it blocks muscarinic receptors, and this antagonism is manifested primarily in vagal blockade and tachycardia. Tachycardia is eliminated in the newer ammonio steroids, vecuronium and rocuronium. The benzyloisoquinolines lack vagolytic and ganglionic blocking actions but show a slight propensity for histamine release. Mivacurium is extremely sensitive to catalysis by cholinesterase or other plasma hydrolases, therein accounting for its short duration of action.

Pharmacological Properties

Table 9-1 summarizes the pharmacological properties of various neuromuscular blocking agents. The anatomy, physiology, and pharmacology of the motor end plate are shown in Figure 9-3.

SKELETAL MUSCLE Competitive antagonists competitively block the binding of ACh to the nicotinic ACh receptor at the end plate. The depolarizing agents, such as succinylcholine, act by a different mechanism: initially, they depolarize the membrane by opening channels in the same manner as ACh. However, they persist for longer durations at the neuromuscular junction because of their resistance to AChE. The depolarization is thus longer-lasting, resulting in a brief period of repetitive excitation (fasciculations), followed by block of neuromuscular transmission (and flaccid paralysis). Paralysis occurs because released ACh binds to receptors on an already depolarized end

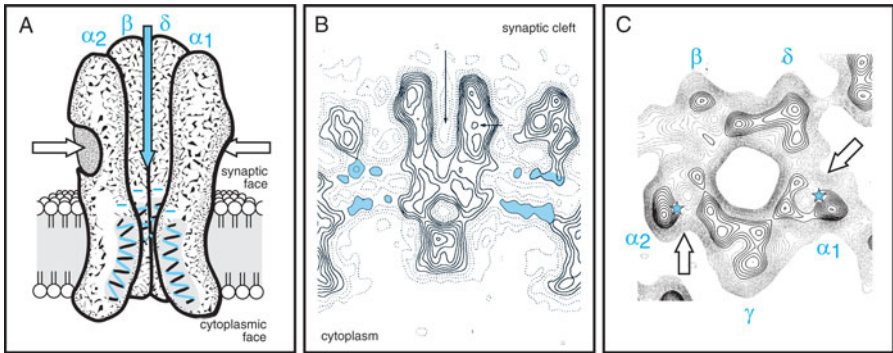

FIGURE 9-1 Subunit organization of the nicotinic ACh receptor and related pentameric ligand-gated ion channels. For each subunit (MW ~40–60 kDa), the amino terminal region (~210 amino acids) is at the extracellular surface, followed by 4 transmembrane domains (TM₁–TM₄), with a small carboxyl terminus at the extracellular surface. Five subunits aggregate to form the receptor/pore/ion channel; the α -helical TM₁ regions from each subunit of the pentameric receptor line the internal pore of the receptor. One disulfide motif is conserved throughout the family of receptors.

plate (an end plate depolarized from -80 to -55 mV by a depolarizing blocking agent is resistant to further depolarization by ACh). The exact sequence from fasciculations to paralysis is influenced by such factors as the anesthetic agent used concurrently, the type of muscle, and the rate of drug administration. The characteristics of depolarization and competitive blockade are contrasted in Table 9-2.

SEQUENCE AND CHARACTERISTICS OF PARALYSIS Following intravenous administration of an appropriate dose of a competitive antagonist, motor weakness progresses to a total flaccid paralysis. Small, rapidly moving muscles (*e.g.*, those of the eyes, jaw, and larynx) relax before those of the limbs and trunk. Ultimately, intercostal muscles and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order to that of their paralysis, and thus the diaphragm ordinarily is the first muscle to regain function.

After a single intravenous dose of 10–30 mg of a depolarizing agent such as succinylcholine, muscle fasciculations, particularly over the chest and abdomen, occur briefly; relaxation occurs within 1 minute, becomes maximal within 2 minutes, and generally disappears within 5 minutes. Transient apnea usually occurs at the time of maximal effect. Muscle relaxation of longer duration is achieved by continuous intravenous infusion. After infusion is discontinued, the effects of the drug usually disappear rapidly because of its rapid hydrolysis by plasma and hepatic butyrylcholinesterase. Muscle soreness may follow the administration of succinylcholine. Small prior doses of competitive blocking agents have been employed to minimize fasciculations and muscle pain caused by succinylcholine, but this procedure is controversial because it increases the requirement for the depolarizing drug.

During prolonged depolarization, muscle cells may lose significant quantities of K^+ and gain Na^+ , Cl^- , and Ca^{2+} . In patients in whom there has been extensive injury to soft tissues, the efflux of K^+ following continued administration of succinylcholine can be life-threatening. Thus, there are many conditions for which succinylcholine administration is contraindicated or should be undertaken with great caution. Under clinical conditions, with increasing concentrations of succinylcholine and over time, the block may convert slowly from a depolarizing to a nondepolarizing type (termed *phase I* and *phase II* blocks). This change in the nature of the blockade produced by succinylcholine (from phase I to phase II) presents an additional complication with long-term infusions (*see* Table 9-3).

Central Nervous System

Tubocurarine and other quaternary neuromuscular blocking agents are virtually devoid of central effects following ordinary clinical doses because of their inability to penetrate the blood-brain barrier.

AUTONOMIC GANGLIA AND MUSCARINIC SITES Neuromuscular blocking agents show variable potencies in producing ganglionic blockade. Clinical doses of tubocurarine produce partial blockade both at autonomic ganglia and at the adrenal medulla, resulting in a fall in blood pressure and tachycardia. Pancuronium shows less ganglionic blockade at standard clinical doses.

The modification of excitation-ACh secretion and nicotinic receptor activation-contraction coupling by various agents is shown on the right; an arrow marked with an X indicates inhibition or block; a plain arrow indicates enhancement or activation.

Atracurium, vecuronium, doxacurium, *pipecuronium* (no longer marketed in the U.S.), mivacurium, and rocuronium are even more selective. The maintenance of cardiovascular reflex responses usually is desired during anesthesia.

Pancuronium has a vagolytic action, presumably from blockade of muscarinic receptors, that leads to tachycardia. Of the depolarizing agents, succinylcholine, at doses producing skeletal muscle relaxation, rarely causes effects attributable to ganglionic blockade. However, cardiovascular effects are sometimes observed, probably owing to the successive stimulation of vagal ganglia (manifested by bradycardia) and sympathetic ganglia (resulting in hypertension and tachycardia).

HISTAMINE RELEASE Tubocurarine produces typical histamine-like wheals when injected intracutaneously or intra-arterially in humans; some clinical responses to neuromuscular

blocking agents (e.g., bronchospasm, hypotension, excessive bronchial and salivary secretion) appear to be caused by the release of histamine. Succinylcholine, mivacurium, doxacurium, and atracurium also cause histamine release, but to a lesser extent unless administered rapidly. The ammonio steroids, pancuronium, vecuronium, pipecuronium, and rocuronium, have even less tendency to release histamine after intradermal or systemic injection. Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than IgE-mediated anaphylaxis.

ACTIONS OF NEUROMUSCULAR BLOCKING AGENTS WITH LIFE-THREATENING IMPLICATIONS Depolarizing agents can release K^+ rapidly from intracellular sites; this may be a causative factor in production of the prolonged apnea in patients who receive these drugs while in electrolyte imbalance.

Succinylcholine-induced hyperkalemia is a life-threatening complication of that drug (e.g., in patients with congestive heart failure who are receiving digoxin or diuretics). Likewise, caution should be used or depolarizing blocking agents should be avoided in patients with extensive soft tissue trauma or burns. A higher dose of a competitive blocking agent often is indicated in these patients. In addition, succinylcholine administration is contraindicated or should be given with great caution in patients with nontraumatic rhabdomyolysis, ocular lacerations, spinal cord injuries with paraplegia or quadriplegia, or muscular dystrophies. Succinylcholine no longer is indicated for children ≤ 8 years of age unless emergency intubation or securing an airway is necessary. Hyperkalemia, rhabdomyolysis, and cardiac arrest have been reported; a subclinical dystrophy frequently is associated with these adverse responses. Neonates also may have an enhanced sensitivity to competitive neuromuscular blocking agents.

DRUG INTERACTIONS From a clinical viewpoint, important pharmacological interactions of these drugs occur with certain general anesthetics, certain antibiotics, Ca^{2+} channel blockers, and anti-ChE compounds. Since the anti-ChE agents *neostigmine*, *pyridostigmine*, and *edrophonium* preserve endogenous ACh and also act directly on the neuromuscular junction, they can be used in the treatment of overdose with competitive blocking agents. Similarly, on completion of the surgical procedure, many anesthesiologists employ *neostigmine* or *edrophonium* to reverse and decrease the duration of competitive neuromuscular blockade. Succinylcholine should never be administered after reversal of competitive blockade with *neostigmine*; in this circumstance, a prolonged and intense blockade often results (see Table 9-2). A muscarinic antagonist (atropine or glycopyrrolate) is used concomitantly to prevent stimulation of muscarinic receptors and thereby to avoid slowing of the heart rate. Many inhalational anesthetics (e.g., halothane, isoflurane, enflurane) "stabilize" the postjunctional membrane and act synergistically with the competitive blocking agents; this requires a reduction in the dose of the nicotinic receptor blocking drugs.

Aminoglycoside antibiotics produce neuromuscular blockade by inhibiting ACh release from the preganglionic terminal (through competition with Ca^{2+}) and to a lesser extent by noncompetitively blocking the receptor. Tetracyclines also can produce neuromuscular blockade, possibly by chelation of Ca^{2+} . Additional antibiotics that have neuromuscular blocking action, through both presynaptic

and postsynaptic actions, include polymyxin B, colistin, clindamycin, and lincomycin. Ca^{2+} channel blockers enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. When neuromuscular blocking agents are administered to patients receiving these agents, dose adjustments should be considered; if recovery of spontaneous respiration is delayed, Ca^{2+} salts may facilitate recovery.

Miscellaneous drugs that may have significant interactions with either competitive or depolarizing neuromuscular blocking agents include trimethaphan (no longer marketed in the U.S.), opioid analgesics, procaine, lidocaine, quinidine, phenelzine, phenytoin, propranolol, magnesium salts, corticosteroids, digitalis glycosides, chloroquine, catecholamines, and diuretics.

TOXICOLOGY The important untoward responses of the neuromuscular blocking agents include prolonged apnea, cardiovascular collapse, those resulting from histamine release, and, rarely, anaphylaxis. Related factors may include alterations in body temperature; electrolyte imbalance, particularly of K^+ (discussed earlier); low plasma butyrylcholinesterase levels, resulting in a reduction in the rate of destruction of succinylcholine; the presence of latent myasthenia gravis or of malignant disease such as small cell carcinoma of the lung (Eaton-Lambert myasthenic syndrome); reduced blood flow to skeletal muscles, causing delayed removal of the blocking drugs; and decreased elimination of the muscle relaxants secondary to reduced renal function. Great care should be taken when administering these agents to dehydrated or severely ill patients.

MALIGNANT HYPERTHERMIA Malignant hyperthermia is a potentially life-threatening event triggered by certain anesthetics and neuromuscular blocking agents. Clinical features include contracture, rigidity, and heat production from skeletal muscle resulting in severe hyperthermia, accelerated muscle metabolism, metabolic acidosis, and tachycardia. Uncontrolled release of Ca^{2+} from the sarcoplasmic reticulum of skeletal muscle is the initiating event. Although the halogenated hydrocarbon anesthetics (e.g., halothane, isoflurane, and *sevoflurane*) and succinylcholine alone reportedly precipitate the response, most incidents arise from the combination of depolarizing blocking agent and anesthetic.

Susceptibility to malignant hyperthermia, an autosomal dominant trait, is associated with certain congenital myopathies such as central core disease. In the majority of cases, however, no clinical signs are visible in the absence of anesthetic intervention.

Susceptibility relates to a mutation in RyR-1, the gene encoding the skeletal muscle ryanodine receptor (RYR-1); other loci have been identified on the L-type Ca^{2+} channel and on associated proteins.

Treatment entails intravenous administration of *dantrolene* (DANTRIUM), which blocks Ca^{2+} release and its sequelae in skeletal muscle. Rapid cooling, inhalation of 100% oxygen, and control of acidosis should be considered adjunct therapy in malignant hyperthermia.

Central core disease has five allelic variants of RyR-1; patients with central core disease are highly susceptible to malignant hyperthermia with the combination of an anesthetic and a depolarizing neuromuscular blocker. Patients with other muscle syndromes or dystonias also have an increased frequency of contracture and hyperthermia in the anesthesia setting.

RESPIRATORY PARALYSIS Treatment of respiratory paralysis arising from an adverse reaction or overdose of a neuromuscular blocking agent includes positive-pressure artificial respiration with oxygen and maintenance of a patent airway until recovery of normal respiration is ensured. With the competitive blocking agents, this may be hastened by the administration of neostigmine methylsulfate (0.5–2 mg intravenously) or edrophonium (10 mg intravenously, repeated as required).

INTERVENTIONAL STRATEGIES FOR OTHER TOXIC EFFECTS Neostigmine effectively antagonizes only the skeletal muscular blocking action of the competitive blocking agents and may aggravate side effects (e.g., hypotension) or induce bronchospasm. In such circumstances, sympathomimetic amines may be given to support the blood pressure. Atropine or glycopyrrolate is administered to counteract muscarinic stimulation. *Antihistamines* will counteract the responses that follow the release of histamine, particularly when administered before the neuromuscular blocking agent.

ABSORPTION, FATE, AND EXCRETION Quaternary ammonium neuromuscular blocking agents are poorly and irregularly absorbed from the gastrointestinal (GI) tract. Absorption is adequate from intramuscular sites. Rapid onset is achieved with intravenous administration. The more potent agents must be given in lower concentrations, and diffusional requirements slow their rate of onset.

With long-acting competitive blocking agents (*e.g.*, D-tubocurarine, pancuronium), blockade may diminish after 30 minutes owing to redistribution of the drug, yet residual blockade and plasma levels of the drug persist. Subsequent doses show diminished redistribution. Long-acting agents may accumulate with multiple doses.

The ammonio steroids contain ester groups that are hydrolyzed in the liver. Typically, the metabolites have about half the activity of the parent compound and contribute to the total relaxation profile. Ammonio steroids of intermediate duration of action (*e.g.*, vecuronium, rocuronium; *see* Table 9–1) are cleared more rapidly by the liver than is pancuronium. The more rapid decay of neuromuscular blockade with compounds of intermediate duration argues for sequential dosing of these agents rather than administering a single dose of a long duration neuromuscular blocking agent.

Atracurium is converted to less active metabolites by plasma esterases and spontaneous degradation. Because of these alternative routes of metabolism, atracurium does not exhibit an increased $t_{1/2}$ in patients with impaired renal function and therefore is the agent of choice in this setting. Mivacurium shows an even greater susceptibility to butyrylcholinesterases, and thus has the shortest duration among nondepolarizing blockers. The extremely brief duration of action of succinylcholine also is due largely to its rapid hydrolysis by the butyrylcholinesterase of liver and plasma. Among the occasional patients who exhibit prolonged apnea following the administration of succinylcholine or mivacurium, most (but not all) have atypical or deficient plasma cholinesterase, hepatic or renal disease, or a nutritional disturbance.

Therapeutic Uses

Neuromuscular blocking agents are used mainly as adjuvants in surgical anesthesia to relax skeletal muscle, particularly of the abdominal wall, to facilitate operative manipulations; with muscle relaxation not dependent on the depth of general anesthesia, a much lighter level of anesthesia suffices, minimizing risk of respiratory and cardiovascular depression and shortening postanesthetic recovery. Neuromuscular blocking agents will not substitute for inadequate depth of anesthesia.

Muscle relaxation is useful in orthopedic procedures (*e.g.*, correction of dislocations, alignment of fractures). Neuromuscular blocking agents of short duration often are used to facilitate endotracheal intubation and have been used to facilitate laryngoscopy, bronchoscopy, and esophagoscopy in combination with a general anesthetic agent.

Neuromuscular blocking agents are administered parenterally, generally intravenously. These drugs are hazardous and should be administered to patients only by clinicians who have had extensive training in their use and in a setting where facilities for respiratory and cardiovascular resuscitation are immediately at hand.

MEASUREMENT OF NEUROMUSCULAR BLOCKADE IN HUMANS

Assessment of neuromuscular block usually is performed by stimulation of the ulnar nerve. Responses are monitored from compound action potentials or muscle tension developed in the adductor pollicis (thumb) muscle. Responses to repetitive or tetanic stimuli are most useful for evaluation of blockade of transmission. Thus, stimulus schedules such as the “train of four” and the “double burst” or responses to tetanic stimulation are preferred procedures. Rates of onset of blockade and recovery are more rapid in the airway musculature (jaw, larynx, and diaphragm) than in the thumb. Hence, tracheal intubation can be performed before onset of complete block at the adductor pollicis, whereas partial recovery of function of this muscle allows sufficient recovery of respiration for extubation.

PREVENTING TRAUMA DURING ELECTROSHOCK THERAPY

Electroconvulsive therapy (ECT) of psychiatric disorders occasionally is complicated by trauma to the patient; the seizures induced may cause dislocations or fractures. Inasmuch as the muscular component of the convulsion is not essential for benefit from the procedure, neuromuscular blocking agents and thiopental are employed. Succinylcholine or mivacurium is used most often because of the brevity of relaxation.

CONTROL OF MUSCLE SPASMS Agents that act in the CNS to block spasms are considered in Chapter 20. Two peripherally-acting agents are used, *botulinum toxin* (*see* Chapter 6) and dantrolene. Botulinum toxin A (BOTOX), by blocking ACh release, produces flaccid paralysis of skeletal muscle and diminished activity of parasympathetic and sympathetic cholinergic synapses. Inhibition lasts from several weeks to 3–4 months, and restoration of function requires nerve sprouting. Uses of BOTOX in dermatology and ophthalmology are described in Chapters 62 and 63.

In addition to its use in managing an acute attack of malignant hyperthermia (*see above*), dantrolene has been used in the treatment of spasticity and hyperreflexia. Dantrolene causes a generalized weakness; thus, its use should be restricted to nonambulatory patients with severe spasticity. Hepatotoxicity has been reported with continued use, requiring liver function tests.

GANGLIONIC NEUROTRANSMISSION

Neurotransmission in autonomic ganglia is a more complex process than that described by a single neurotransmitter–receptor system, with at least 4 distinct changes in membrane potential elicited by stimulation of the preganglionic nerve. The primary event involves a rapid depolarization of postsynaptic sites by ACh. An action potential is generated in the postganglionic neuron when the initial EPSP attains sufficient amplitude; in mammalian sympathetic ganglia *in vivo*, effective transmission likely requires activation at multiple synapses. The EPSP is followed by a slow inhibitory postsynaptic potential (IPSP), a slow EPSP, and a late, slow EPSP; slow IPSP and slow EPSP are not seen in all ganglia. The initial EPSP is mediated through nicotinic (N) receptors, the slow IPSP and EPSP through M_2 and M_1 muscarinic receptors, and the late, slow EPSP through various peptidergic receptors in response to peptides released from presynaptic nerve endings or interneurons in specific ganglia (*see Chapter 7*). The slow EPSPs result from decreased K^+ conductance (the M current, which regulates the sensitivity of the cell to repetitive fast-depolarizing events). The IPSP is unaffected by nicotinic receptor antagonists but is generally sensitive to blockade by both atropine and α adrenergic receptor antagonists; apparently, ACh released at the preganglionic terminal acts on catecholamine-containing interneurons to stimulate the release of dopamine (DA) or norepinephrine (NE); the catecholamine, in turn, produces hyperpolarization (an IPSP) of ganglion cells. Small, intensely fluorescent (SIF) cells containing DA and NE and adrenergic nerve terminals are present in ganglia and presumably participate in IPSP generation (*see Figure 9–5 in the 11th edition of the parent text*).

The relative importance of secondary pathways and the identity of modulating transmitters differ amongst individual ganglia and between parasympathetic and sympathetic ganglia. Myriad peptides (gonadotropin-releasing hormone, substance P, angiotensin, calcitonin gene-related peptide [CGRP], vasoactive intestinal polypeptide, neuropeptide Y, and enkephalins), are present in ganglia and are presumed to mediate the late slow EPSP. Other neurotransmitters, such as 5-HT and GABA, are known to modify ganglionic transmission. Precise details of their modulatory actions are not understood; they are most closely associated with the late slow EPSP and inhibition of the M current. Secondary transmitters (and their antagonists) only modulate the initial EPSP. By contrast, conventional ganglionic blocking agents can inhibit ganglionic transmission completely.

Drugs that stimulate cholinergic receptor sites on autonomic ganglia can be grouped into two categories. The first group consists of drugs with nicotinic specificity, including nicotine itself. Their excitatory effects on ganglia are rapid in onset, are blocked by ganglionic nicotinic receptor antagonists, and mimic the initial EPSP. The second group is composed of agents such as *muscarine*, *McN-A-343*, and *methacholine*. Their excitatory effects on ganglia are delayed in onset, blocked by atropine-like drugs, and mimic the slow EPSP.

Ganglionic blocking agents acting on the nicotinic receptor may be classified into two groups. The first group includes drugs that initially stimulate the ganglia by an ACh-like action and then block them because of a persistent depolarization (*e.g.*, nicotine); prolonged application of nicotine results in desensitization of the cholinergic receptor site and continued blockade. Drugs in the second group of blockers, of which hexamethonium and trimethaphan are prototypes, impair transmission either by competing with ACh for ganglionic nicotinic receptor sites (trimethaphan) or by blocking the channel after it opens (hexamethonium). Regardless of the mechanism, the initial EPSP is blocked, and ganglionic transmission is inhibited.

GANGLIONIC STIMULATING DRUGS

Nicotine and several other compounds stimulate ganglionic nicotinic receptors (Figure 9–4).

Nicotine

Nicotine is medically and socially significant because of its presence in tobacco, its toxicity, and its propensity to cause dependence in its users. The chronic effects of nicotine and the untoward effects of the chronic use of tobacco are considered in Chapter 23. Nicotine is one of the few natural liquid alkaloids. It is a colorless, volatile base ($pK_a = 8.5$) that turns brown and acquires the odor of tobacco on exposure to air.

FIGURE 9-4 Ganglionic stimulants.

PHARMACOLOGICAL ACTIONS

The complex and often unpredictable changes that occur in the body after administration of nicotine are due not only to its actions on a variety of neuroeffector and chemosensitive sites but also to the fact that the alkaloid can stimulate and desensitize receptors. The ultimate response of any one system represents the summation of stimulatory and inhibitory effects of nicotine. For example, the drug can increase heart rate by excitation of sympathetic or paralysis of parasympathetic cardiac ganglia, or it can slow heart rate by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. In addition, the effects of the drug on the chemoreceptors of the carotid and aortic bodies and on brain centers influence heart rate, as do the cardiovascular compensatory reflexes resulting from changes in blood pressure caused by nicotine. Finally, nicotine elicits a discharge of epinephrine from the adrenal medulla, which accelerates heart rate and raises blood pressure.

Peripheral Nervous System

The major action of nicotine consists initially of transient stimulation followed by a more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and may facilitate impulse transmission. When larger doses of the drug are applied, the initial stimulation is followed very quickly by a blockade of transmission. Nicotine also possesses a biphasic action on the adrenal medulla; small doses evoke the discharge of catecholamines, and larger doses prevent their release in response to splanchnic nerve stimulation.

The effects of nicotine on the neuromuscular junction are similar to those on ganglia. However, the stimulant phase is obscured largely by the rapidly developing paralysis. In the latter stage, nicotine also produces neuromuscular blockade by receptor desensitization.

Nicotine, like ACh, will stimulate a number of sensory receptors. These include mechanoreceptors that respond to stretch or pressure of the skin, mesentery, tongue, lung, and stomach; chemoreceptors of the carotid body; thermal receptors of the skin and tongue; and pain receptors. Prior administration of hexamethonium prevents stimulation of the sensory receptors by nicotine but has little, if any, effect on the activation of sensory receptors by physiological stimuli.

Central Nervous System

Nicotine markedly stimulates the CNS. Low doses produce weak analgesia; with higher doses, tremors leading to convulsions at toxic doses are evident. The excitation of respiration is a prominent action of nicotine; although large doses act directly on the medulla oblongata, smaller doses augment respiration reflexly by excitation of the chemoreceptors of the carotid and aortic bodies.

Stimulation of the CNS with large doses is followed by depression, and death results from failure of respiration owing to both central paralysis and peripheral blockade of muscles of respiration.

Nicotine induces vomiting by both central and peripheral actions. The primary sites of action of nicotine in the CNS are prejunctional, causing the release of other transmitters. Accordingly, the stimulatory and pleasure-reward actions of nicotine appear to result from release of excitatory amino acids, DA, and other biogenic amines from various CNS centers. Release of excitatory amino acids may account for much of nicotine's stimulatory action. Chronic exposure to nicotine increases the density or number of nicotinic receptors.

Cardiovascular System

In general, the cardiovascular responses to nicotine are due to stimulation of sympathetic ganglia and the adrenal medulla, together with the discharge of catecholamines from sympathetic nerve endings. Also contributing to the sympathomimetic response to nicotine is the activation of chemoreceptors of the aortic and carotid bodies, which reflexly results in vasoconstriction, tachycardia, and elevated blood pressure.

Gastrointestinal Tract

The combined activation of parasympathetic ganglia and cholinergic nerve endings by nicotine results in increased tone and motor activity of the bowel. Nausea, vomiting, and occasionally diarrhea are observed following systemic absorption of nicotine in an individual who has not been exposed to nicotine previously.

Exocrine Glands

Nicotine causes an initial stimulation of salivary and bronchial secretions that is followed by inhibition.

ABSORPTION, FATE, AND EXCRETION

Nicotine is readily absorbed from the respiratory tract, buccal membranes, and skin. Severe poisoning has resulted from percutaneous absorption. Being a relatively strong base, its absorption from the stomach is limited. Intestinal absorption is far more efficient. Nicotine in chewing tobacco, because it is absorbed more slowly than inhaled nicotine, has a longer duration of effect. The average cigarette contains 6–11 mg nicotine and delivers about 1–3 mg nicotine systemically to the smoker; bioavailability can increase as much as threefold with intensity of puffing and technique of the smoker.

Nicotine is available in several dosage forms to help achieve abstinence from tobacco use. Efficacy results primarily from preventing a withdrawal or abstinence syndrome. Nicotine may be administered orally as a gum (nicotine polacrilex, NICORETTE), transdermal patch (NICODERM, HABITROL, others), a nasal spray (NICOTROL NS), and a vapor inhaler (NICOTROL INHALER). The first two are used most widely, and the objective is to obtain a sustained plasma nicotine concentration lower than venous blood concentrations after smoking (arterial blood concentrations immediately following inhalation can be as much as tenfold higher than venous concentrations). The efficacy of these dosage forms in producing abstinence from smoking is enhanced when linked to counseling and motivational therapy (see Chapter 23).

Approximately 80–90% of nicotine is altered in the body, mainly in the liver but also in the kidney and lung; cotinine is the major metabolite. The profile of metabolites and the rate of metabolism appear to be similar in smokers and nonsmokers. The $t_{1/2}$ of nicotine following inhalation or parenteral administration is ~2 hours. Nicotine and its metabolites are eliminated rapidly by the kidney. The rate of urinary excretion of nicotine diminishes when the urine is alkaline. Nicotine also is excreted in the milk of lactating women who smoke; the milk of heavy smokers may contain 0.5 mg/L.

ACUTE NICOTINE POISONING

Poisoning from nicotine may occur from accidental ingestion of nicotine-containing insecticide sprays or in children from ingestion of tobacco products. The acutely fatal dose of nicotine for an adult is probably ~60 mg of the base. Smoking tobacco usually contains 1–2% nicotine. Apparently, the gastric absorption of nicotine from tobacco taken by mouth is delayed because of slowed gastric emptying, so vomiting caused by the central effect of the initially absorbed fraction may remove much of the tobacco remaining in the GI tract.

The onset of symptoms of acute, severe nicotine poisoning is rapid: nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and marked weakness. Faintness and prostration ensue; the blood pressure falls; breathing is difficult; the pulse is weak, rapid, and irregular; and collapse may be followed by terminal convulsions. Death may result within a few minutes from respiratory failure.

Therapy

Vomiting may be induced, or gastric lavage should be performed. Alkaline solutions should be avoided. A slurry of activated charcoal is then passed through the tube and left in the stomach. Respiratory assistance and treatment of shock may be necessary.

Other Ganglionic Stimulants

Stimulation of ganglia by tetramethylammonium (TMA) or 1,1-dimethyl-4-phenylpiperazinium iodide (DMPP) differs from that produced by nicotine in that the initial stimulation is not followed by a dominant blocking action. DMPP is about three times more potent and slightly more ganglion-selective than nicotine. Although parasympathomimetic drugs stimulate ganglia, their effects usually are obscured by stimulation of other neuroeffector sites. McN-A-343 is an exception; it can stimulate muscarinic M_1 receptors in ganglia.

GANGLIONIC BLOCKING DRUGS

A chemically diverse group of compounds blocks autonomic ganglia without causing prior stimulation (Figure 9–5).

PHARMACOLOGICAL PROPERTIES

Most of the physiological alterations observed after the administration of ganglionic blocking agents can be anticipated by a careful inspection of Figure 6–1 and by knowing which division of the autonomic nervous system exercises dominant control of various organs (Table 9–4). For example, blockade of sympathetic ganglia interrupts adrenergic control of arterioles and results in vasodilation, improved peripheral blood flow in some vascular beds, and a fall in blood pressure.

Generalized ganglionic blockade also may result in atony of the bladder and GI tract, cycloplegia, xerostomia, diminished perspiration, and postural hypotension (via abolition of circulatory reflex pathways); these changes are the generally undesirable effects that limit the therapeutic efficacy of ganglionic blocking agents.

Cardiovascular System

Existing sympathetic tone is critical in determining the degree to which blood pressure is lowered by ganglionic blockade; thus, blood pressure may be decreased only minimally in recumbent normotensive subjects but may fall markedly in sitting or standing subjects. Postural hypotension limits use of ganglionic blockers in ambulatory patients.

Changes in heart rate following ganglionic blockade depend largely on existing vagal tone. Mild tachycardia usually accompanies the hypotension, a sign that indicates fairly complete

ganglionic blockade. However, a decrease may occur if the heart rate is high initially. In patients with normal cardiac function, these drugs may reduce cardiac output as a consequence of diminished venous return resulting from venous dilation and peripheral pooling of blood. In patients with cardiac failure, ganglionic blockade frequently results in increased cardiac output owing to a reduction in peripheral resistance. In hypertensive subjects, cardiac output, stroke volume, and left ventricular work are diminished.

Although ganglionic blockade decreases total systemic vascular resistance, changes in blood flow and vascular resistance of individual vascular beds vary: reduction of cerebral blood flow is small unless mean systemic blood pressure falls below 50–60 mm Hg; skeletal muscle blood flow is unaltered; splanchnic and renal blood flow decrease.

ABSORPTION, FATE, AND EXCRETION

Absorption of quaternary ammonium and sulfonium compounds from the GI tract is incomplete and unpredictable, due to the limited ability of these ionized substances to penetrate cell membranes and depression of propulsive movements of the small intestine and gastric emptying.

Absorption of mecamylamine is less erratic, but reduced bowel activity and paralytic ileus are a danger. After absorption, the quaternary ammonium- and sulfonium-blocking agents are confined primarily to the extracellular space and are excreted mostly unchanged by the kidney. Mecamylamine concentrates in the liver and kidney and is excreted slowly in an unchanged form.

UNTOWARD RESPONSES AND SEVERE REACTIONS

Milder untoward responses are: visual disturbances, dry mouth, conjunctival suffusion, urinary hesitancy, decreased potency, subjective chilliness, moderate constipation, occasional diarrhea, abdominal discomfort, anorexia, heartburn, nausea, eructation, and bitter taste and the signs and symptoms of syncope caused by postural hypotension. More severe reactions include marked hypotension, constipation, syncope, paralytic ileus, urinary retention, and cycloplegia.

FORMULATIONS AND THERAPEUTIC USES

Only mecamylamine (INVERSINE) is currently available in the U.S. Ganglionic blocking agents have been supplanted by superior agents for the treatment of chronic hypertension (see Chapter 32), acute hypertensive crises and the production of controlled hypotension (e.g., reduction in blood pressure during surgery to minimize hemorrhage in the operative field).

ADRENERGIC AGONISTS AND ANTAGONISTS

I. CATECHOLAMINES AND SYMPATHOMIMETIC DRUGS

Actions of catecholamines and sympathomimetic agents can be classified into seven broad types: (1) peripheral excitatory actions on smooth muscles (*e.g.*, in blood vessels supplying skin, kidney, and mucous membranes) and on gland cells (*e.g.*, in salivary and sweat glands); (2) peripheral inhibitory action on certain other types of smooth muscle (*e.g.*, in the wall of the gut, bronchial tree, and blood vessels supplying skeletal muscle); (3) cardiac excitatory action (increased rate and force of contraction); (4) metabolic actions (*e.g.*, enhanced glycogenolysis in liver and muscle, accelerated liberation of free fatty acids from adipose tissue); (5) endocrine actions (*e.g.*, modulation of secretion of insulin, renin, and pituitary hormones); (6) actions in the central nervous system (CNS) (*e.g.*, respiratory stimulation, increased wakefulness and psychomotor activity, reduced appetite); and (7) prejunctional actions (inhibition or facilitation of neurotransmitter release, inhibition being physiologically more important). Not all sympathomimetic drugs show each of the above types of action to the same degree; however, many of their differences are only quantitative.

Understanding the pharmacological properties of sympathomimetics and their antagonists depends on knowledge of the classification, distribution, and mechanism of action of α and β adrenergic receptors (*see* Tables 6–1, 6–6, 6–7, Figure 10–1, and Table 10–6).

CLASSIFICATION OF SYMPATHOMIMETIC DRUGS

Catecholamines and sympathomimetic drugs are classified as direct, indirect, or mixed acting. Direct-acting agents act directly on one or more of the adrenergic receptors. Indirect-acting drugs increase the availability of norepinephrine (NE) or epinephrine (Epi) to stimulate adrenergic receptors (by releasing or displacing NE from sympathetic nerve varicosities [*e.g.*, amphetamine]; by blocking the transport of NE into sympathetic neurons [*e.g.*, cocaine]; or by blocking the metabolizing enzymes, MAO [*e.g.*, *pargyline*] or COMT [*e.g.*, *entacapone*]). Drugs that indirectly release NE and also directly activate receptors are referred to as mixed-acting sympathomimetic drugs (*e.g.*, *ephedrine*). The classification is not absolute and activities may overlap; prototypical drugs are listed in Figure 10–1.

*β -phenylethylamine, a benzene ring with an ethylamine side chain, may be viewed as a parent structure for sympathomimetic amines (Table 10–1). NE, Epi, dopamine (DA), isoproterenol, and a few other agents have hydroxyl groups substituted at positions 3 and 4 of the benzene ring. Since *o*-dihydroxybenzene is also known as catechol, sympathomimetic amines with these hydroxyl substitutions in the aromatic ring are termed catecholamines. Many directly acting sympathomimetic drugs influence both α and β receptors, but the ratio of activities varies among drugs in a continuous spectrum from predominantly α activity (phenylephrine) to predominantly β activity (isoproterenol). Maximal α and β activity depends on the presence of hydroxyl groups on positions 3 and 4. The response to noncatecholamines is partly determined by their capacity to release NE from storage sites. Phenylethylamines that lack hydroxyl groups on the ring and the β -hydroxyl group on the side chain act almost exclusively by causing the release of NE from sympathetic nerve terminals. Unsubstituted or alkyl-substituted compounds cross the blood–brain barrier more readily and have more central activity. Thus, ephedrine, amphetamine, and methamphetamine exhibit considerable CNS activity, and the absence of polar hydroxyl groups results in a loss of direct sympathomimetic activity.*

Catecholamines have only a brief duration of action and are ineffective when administered orally because they are rapidly inactivated in the intestinal mucosa and the liver (see Chapter 6). Compounds without one or both hydroxyl substituents are not substrates for COMT, and their oral effectiveness and duration of action are enhanced. Substitution on the α -carbon blocks oxidative deamination by MAO, prolonging the duration of action of noncatecholamines. Thus, the duration of action of ephedrine and amphetamine is measured in hours rather than minutes. Substitution of an $-OH$ on the β carbon generally decreases actions within the CNS (largely by reducing lipid solubility) but greatly enhances agonist activity at both α and β adrenergic receptors.

PHYSIOLOGICAL EFFECTS OF ADRENERGIC RECEPTOR STIMULATION In the response of any cell or organ to sympathomimetic amines, the density and proportion of α and β adrenergic receptors are key. For example, the receptors in bronchial smooth muscle are largely of the β_2 subtype; thus, NE (stimulating predominantly β_1 + α receptors) has relatively little capacity to increase bronchial airflow. In contrast, isoproterenol (a β agonist) and Epi (an α + β agonist)

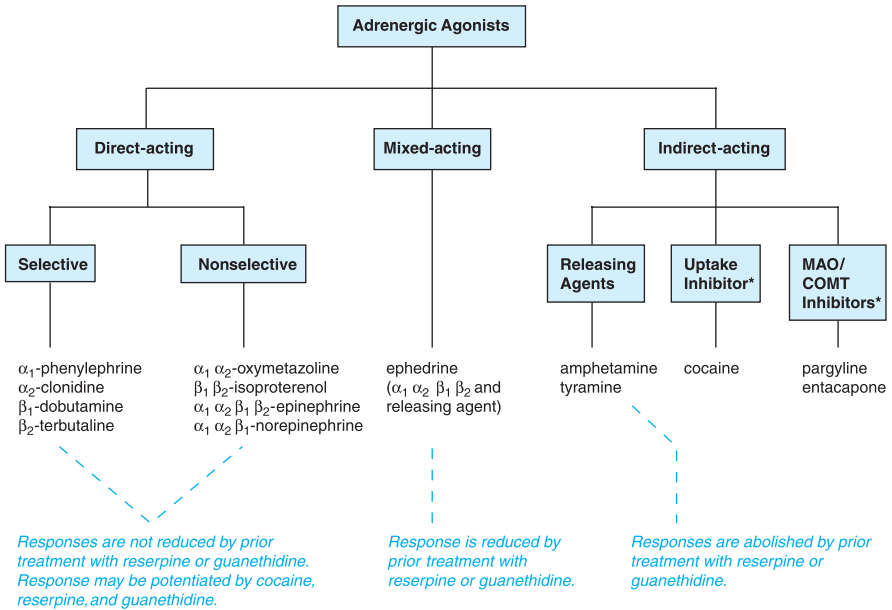

FIGURE 10–1 Classification of adrenergic receptor agonists and drugs that produce sympathomimetic effects. For each category, a prototypical drug is shown. *Not actually sympathetic drugs but produce sympathomimetic effects.

are potent bronchodilators. Cutaneous blood vessels physiologically express almost exclusively α receptors; thus, NE and Epi cause constriction of such vessels, whereas isoproterenol has little effect. The smooth muscle of blood vessels that supply skeletal muscles has both β_2 and α receptors; activation of β_2 receptors causes vasodilation, and stimulation of α receptors constricts these vessels. In such vessels, the threshold concentration for activation of β_2 receptors by Epi is lower than that for α receptors, but when both types of receptors are activated at high concentrations of Epi, the response to α receptors predominates; physiological concentrations of Epi primarily cause vasodilation.

The integrated response of an organ to sympathomimetic amines results not only from their direct effects, but also from reflex homeostatic adjustments. A striking effect of many sympathomimetic amines is a rise in arterial blood pressure caused by stimulation of vascular α adrenergic receptors. This stimulation elicits compensatory reflexes (mediated by the carotid–aortic baroreceptor system) that adjust CNS outflow to the cardiovascular system. As a result, sympathetic tone is diminished and vagal tone is enhanced; each of these responses leads to slowing of the heart rate. Conversely, when a drug (e.g., a β_2 agonist) lowers mean blood pressure at the mechanoreceptors of the carotid sinus and aortic arch, the baroreceptor reflex works to restore pressure by reducing parasympathetic (vagal) outflow from the CNS to the heart, and increasing sympathetic outflow to the heart and vessels. The baroreceptor reflex effect is of special importance for drugs that have little capacity to activate β receptors directly. With diseases (e.g., atherosclerosis) that may impair baroreceptor mechanisms, effects of sympathomimetic drugs may be magnified.

ENDOGENOUS CATECHOLAMINES

Epinephrine (Epi)

Epinephrine (adrenaline) is a potent stimulant of both α and β adrenergic receptors, and its effects on target organs are thus complex. Most of the responses listed in Table 6–1 are seen after injection of Epi (although sweating, piloerection, and mydriasis depend on the physiological state of the subject). Particularly prominent are the actions on the heart and on vascular and other smooth muscle. Effects of Epi reproduce those of adrenal medullary stimulation and are often described by the paradigm of “fight or flight.”

BLOOD PRESSURE Epi is a potent vasopressor. A pharmacological dose of Epi, given rapidly by an intravenous route, rapidly increases blood pressure to a peak that is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pressure, so that the pulse pressure increases. As the response wanes, the mean pressure may fall below normal before returning to control levels. The mechanism of the rise in blood pressure due to Epi is threefold: (1) a direct myocardial stimulation that increases the strength of ventricular contraction (positive inotropic action, via β_1 receptors); (2) an increased heart rate (positive chronotropic action, via β_1 receptors); and (3) vasoconstriction in many vascular beds (especially in the precapillary resistance vessels of skin, mucosa, and kidney) along with marked constriction of the veins (via α receptors). The pulse rate, at first accelerated by the direct positive chronotropic effect of Epi, may slow down markedly as blood pressure rises, due to the compensatory baroreceptor reflex (bradycardia due to vagal discharge). Small doses of Epi ($0.1 \mu\text{g}/\text{kg}$) may cause the blood pressure to fall; the depressor effect of small doses and the biphasic response to larger doses are due to greater sensitivity to Epi of vasodilator β_2 receptors than of constrictor α receptors.

The effects are somewhat different when the drug is given by slow intravenous infusion or by subcutaneous injection. Absorption of Epi after subcutaneous injection is slow due to local vasoconstrictor action. There is a moderate increase in systolic pressure due to increased cardiac contractile force and a rise in cardiac output (Figure 10–2). Peripheral resistance decreases, owing to a dominant action on β_2 receptors of vessels in skeletal muscle, where blood flow is enhanced; as a consequence, diastolic pressure usually falls. Since the mean blood pressure usually is not greatly elevated, compensatory baroreceptor reflexes do not appreciably antagonize the direct cardiac actions. Heart rate, cardiac output, stroke volume, and left ventricular stroke work increase as a result of direct cardiac stimulation and increased venous returns to the heart, which is reflected by an increase in right atrial pressure. At slightly higher rates of infusion, there may be no change or a slight rise in peripheral resistance and diastolic pressure, depending on the dose and the resultant ratio of α to β responses in the various vascular beds; compensatory reflexes also may come into play. The effects of intravenous infusion of Epi, NE, and isoproterenol are compared in Table 10–2 and Figure 10–2.

VASCULAR EFFECTS The chief vascular action of Epi is on the smaller arterioles and precapillary sphincters, although veins and large arteries also respond. Various vascular beds react differently, resulting in substantial redistribution of blood flow. Injected Epi markedly decreases cutaneous blood flow, constricting precapillary vessels and small venules. Cutaneous vasoconstriction accounts for a marked decrease in blood flow in the hands and feet. The “after congestion” of mucosa following the vasoconstriction from locally applied Epi probably is due to changes in

vascular reactivity as a result of tissue hypoxia rather than to β agonist activity of the drug on mucosal vessels.

Blood flow to skeletal muscles is increased by therapeutic doses, due in part to powerful β_2 -mediated vasodilation that is only partially counterbalanced by vasoconstrictor via the α receptors that also are present. If an α receptor antagonist is given, vasodilation in muscle is more pronounced, total peripheral resistance is decreased, and mean blood pressure falls (*Epi reversal*). After the administration of a nonselective β receptor antagonist, Epi produces only vasoconstriction and a considerable pressor effect.

In usual therapeutic doses, Epi has little constrictor action on cerebral arterioles. The cerebral circulation does not constrict in response to activation of the sympathetic nervous system by stressful stimuli; indeed, autoregulatory mechanisms tend to limit the increase in cerebral blood flow caused by increased blood pressure.

Doses of Epi that have little effect on mean arterial pressure consistently increase renal vascular resistance and reduce renal blood flow. All segments of the renal vascular bed contribute to the increased resistance. Since the glomerular filtration rate is only slightly and variably altered, the filtration fraction is consistently increased. Excretion of Na^+ , K^+ , and Cl^- is decreased. Maximal tubular reabsorptive and excretory capacities are unchanged. The secretion of renin is increased as a consequence of the stimulation of β_1 receptors on the juxtaglomerular cells (see Figure 30-2).

Epi increases arterial and venous pulmonary pressures. Although direct pulmonary vasoconstriction occurs, redistribution of blood from the systemic to the pulmonary circulation, due to

constriction of the more powerful musculature in the systemic great veins, contributes to an increase in pulmonary pressure. Very high concentrations of Epi may cause pulmonary edema precipitated by elevated pulmonary capillary filtration pressure and possibly by "leaky" capillaries.

Coronary blood flow is enhanced by Epi or by cardiac sympathetic stimulation under physiological conditions. The increased flow, which occurs even with doses that do not increase the aortic blood pressure, is the result of two factors. The first is the increased relative duration of diastole at higher heart rates (see below); this is partially offset by decreased blood flow during systole because of more forceful contraction of the surrounding myocardium and an increase in mechanical compression of the coronary vessels. The increased flow during diastole is further enhanced if aortic blood pressure is elevated by Epi; as a consequence, total coronary flow may be increased. The second factor is a metabolic dilator effect that results from the increased strength of contraction and myocardial O_2 consumption due to direct effects of Epi on cardiac myocytes. This vasodilation is mediated in part by adenosine released from cardiac myocytes, which tends to override a direct vasoconstrictor effect of Epi that results from activation of α receptors in coronary vessels.

CARDIAC EFFECTS Epi is a powerful cardiac stimulant. Direct responses to Epi include increase in the rate of tension development, peak contractile force, and rate of relaxation; decreased time to peak tension; increased excitability, acceleration of the rate of spontaneous beating, and induction of automaticity in specialized regions of the heart. Epi acts directly on the predominant β_1 receptors of the myocytes and of the cells of the pacemaker and conducting tissues. The heart rate increases, and the rhythm often is altered. Cardiac systole is shorter and more powerful, cardiac output is enhanced, and the work of the heart and its O_2 consumption are markedly increased. Cardiac efficiency (work done relative to O_2 consumption) is lessened.

By increasing the rates of ventricular contraction and relaxation, Epi preferentially shortens systole and usually does not reduce the duration of diastole. Epi speeds the heart by accelerating the slow depolarization of sinoatrial (SA) nodal cells that takes place during phase 4 of the action potential (see Chapter 34). The amplitude of the AP and the maximal rate of depolarization (phase 0) also are increased. A shift in the location of the pacemaker within the SA node often occurs, owing to activation of latent pacemaker cells. In Purkinje fibers, Epi accelerates diastolic depolarization and may activate latent pacemakers. If large doses of Epi are given, premature ventricular contractions occur and may herald more serious ventricular arrhythmias. Conduction through the Purkinje system depends on the level of membrane potential at the time of excitation. Epi often increases the membrane potential and improves conduction in Purkinje fibers that have been excessively depolarized.

Epi normally shortens the refractory period of the atrioventricular (AV) node by direct effects on the heart, although doses of Epi that elicit a vagal reflex may indirectly slow the heart and prolong the AV node's refractory period. Epi decreases the grade of AV block that occurs as a result of disease, drugs, or vagal stimulation. Supraventricular arrhythmias may occur from the combination of Epi and cholinergic stimulation. Depression of sinus rate and AV conduction by vagal discharge probably plays a part in Epi-induced ventricular arrhythmias, since various drugs that block the vagal effect confer some protection. The actions of Epi in enhancing cardiac automaticity and in causing arrhythmias are effectively antagonized by β receptor antagonists. However, activation of cardiac α_1 receptors prolongs the refractory period and strengthens myocardial contractions. Cardiac arrhythmias have been seen in patients after inadvertent intravenous administration of conventional subcutaneous doses of Epi.

Epi and other catecholamines may cause myocardial cell death, particularly after intravenous infusions. Acute toxicity is associated with contraction band necrosis and other pathological changes; prolonged sympathetic stimulation of the heart, such as in congestive cardiomyopathy, may promote apoptosis of cardiomyocytes.

NONVASCULAR SMOOTH MUSCLES The effects of Epi on smooth muscle depend on the types and densities of adrenergic receptors expressed by the muscle (see Table 6-1). In general, Epi relaxes GI smooth muscle, due to activation of both α and β receptors. Intestinal tone and the frequency and amplitude of spontaneous contractions are reduced. The stomach usually is relaxed. By contrast, the pyloric and ileocecal sphincters are contracted (but these effects depend on the pre-existing tone of the muscle; if tone already is high, Epi causes relaxation; if low, contraction).

The responses of uterine muscle to Epi vary with phase of the sexual cycle, state of gestation, and dose. During the last month of pregnancy and at parturition, Epi inhibits uterine tone and contractions. β_2 -Selective agonists (e.g., ritodrine or terbutaline) can delay premature labor, although

their efficacy is limited (see below). Epi relaxes the detrusor muscle of the bladder (via activation of β receptors) and contracts the trigone and sphincter muscles (via α agonist activity). This can result in hesitancy in urination and may contribute to retention of urine in the bladder. Activation of smooth muscle contraction in the prostate promotes urinary retention.

RESPIRATORY EFFECTS

Acting at β_2 receptors on bronchial smooth muscle, Epi is a powerful bronchodilator, especially when bronchial muscle is contracted because of disease or in response to drugs or various autacoids. Beneficial effects of Epi in asthma also may arise from β_2 -mediated inhibition of antigen-induced release of inflammatory mediators from mast cells, and to a lesser extent from an α adrenergic effect to diminish bronchial secretions and congestion within the mucosa. Other drugs, such as glucocorticoids and leukotriene-receptor antagonists, have more profound anti-inflammatory effects in asthma (see Chapter 27).

EFFECTS ON THE CNS

Epi, a polar compound, penetrates poorly into the CNS and, at conventional therapeutic doses, is not a powerful CNS stimulant. While Epi may cause restlessness, apprehension, headache, and tremor, these effects in part may be secondary to the effects of Epi on the cardiovascular system, skeletal muscles, and intermediary metabolism (i.e., the result of somatic manifestations of anxiety).

METABOLIC EFFECTS Epi elevates the concentrations of glucose and lactate in blood (see Chapter 6), and can inhibit (α_2 effect) or stimulate (β_2 effect) insulin secretion; inhibition is the predominant effect. Glucagon secretion is enhanced via activation of β receptors of the α cells of pancreatic islets. Epi also decreases the uptake of glucose by peripheral tissues, in part because of its effects on the secretion of insulin, but also possibly due to direct effects on skeletal muscle. Glycosuria rarely occurs. The effect of Epi to stimulate glycogenolysis in most tissues and in most species involves β receptors.

Epi raises the plasma concentration of free fatty acids by stimulating β receptors in adipocytes, activating triglyceride lipase and accelerating triglyceride breakdown to free fatty acids and glycerol. The calorogenic action of Epi (increase in metabolism) is reflected by an increase of 20–30% in O_2 consumption, mainly due to enhanced breakdown of triglycerides in brown adipose tissue, providing an increase in oxidizable substrate.

MISCELLANEOUS EFFECTS

Epi rapidly increases the number of circulating polymorphonuclear leukocytes, likely due to β receptor-mediated demargination of these cells. Epi accelerates blood coagulation and promotes fibrinolysis. The effects of Epi on secretory glands are not marked; in most glands, secretion is inhibited, partly owing to the reduced blood flow caused by vasoconstriction. Epi stimulates lacrimation and a scanty mucus secretion from salivary glands. Sweating and pilomotor activity are minimal after systemic administration of Epi, but occur after intradermal injection of dilute solutions of either Epi or NE; such effects are inhibited by α receptor antagonists.

Mydriasis is readily seen during physiological sympathetic stimulation but not when Epi is instilled into the conjunctival sac of normal eyes. Epi usually lowers intraocular pressure (see Chapter 63).

Epi facilitates neuromuscular transmission, particularly that following prolonged rapid stimulation of motor nerves; stimulation of α receptors promotes transmitter release from the somatic motor neuron, perhaps as a result of enhanced influx of Ca^{2+} . These responses likely are mediated by α_1 receptors and may explain in part the ability of intra-arterial Epi to briefly increase strength in patients with myasthenia gravis. Epi also acts directly on white, fast-twitch muscle fibers to prolong the active state, thereby increasing peak tension. Of greater physiological and clinical importance is the capacity of Epi and selective β_2 agonists to increase physiological tremor, at least in part due to β receptor-mediated enhancement of discharge of muscle spindles.

Via activation of β_2 receptors, Epi promotes a fall in plasma K^+ , largely due to stimulation of K^+ uptake into cells, particularly skeletal muscle. This is associated with decreased renal K^+ excretion.

ABSORPTION, FATE, AND EXCRETION Epi is ineffective after oral administration because it is rapidly metabolized in the GI mucosa and liver. Absorption from subcutaneous tissues occurs relatively slowly because of local vasoconstriction, and the rate may be further decreased by systemic hypotension (e.g., in shock). Absorption is more rapid after intramuscular injection. In emergencies, it may be necessary to administer Epi intravenously. When relatively concentrated solutions (1%) are nebulized and inhaled, the actions of the drug largely are restricted to the respiratory tract; however, systemic reactions such as arrhythmias may occur, particularly if larger amounts are used.

Epi is rapidly inactivated, especially by the liver, which is rich in COMT and MAO (see Figure 6–6 and Table 6–5).

FORMULATIONS

Epi injection is available in 1 mg/mL (1:1000), 0.1 mg/mL (1:10,000), and 0.5 mg/mL (1:2000) solutions. The usual adult dose given subcutaneously ranges from 0.3 to 0.5 mg. The intravenous route is used cautiously if an immediate and reliable effect is mandatory. If the solution is given by vein, it must be adequately diluted and injected very slowly. The dose is seldom as much as 0.25 mg, except for cardiac arrest, when larger doses may be required. Epi suspensions are used to slow subcutaneous absorption and must never be injected intravenously. Also, a 1% (10 mg/mL; 1:100) formulation is available for administration via inhalation; every precaution must be taken not to confuse this 1:100 solution with the 1:1000 solution designed for parenteral administration; inadvertent injection of the 1:100 solution can be fatal. Epi is unstable in alkaline solution; when exposed to air or light, it turns pink from oxidation to adrenochrome and then brown from polymer formation; thus, an antioxidant or acid must be included.

TOXICITY, ADVERSE EFFECTS, AND CONTRAINDICATIONS

Epi may cause restlessness, throbbing headache, tremor, and palpitations; these effects rapidly subside with rest, quiet, recumbency, and reassurance. More serious reactions include cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental, rapid intravenous injection of Epi may result in cerebral hemorrhage from the sharp rise in blood pressure. Ventricular arrhythmias may follow the drug's administration. Epi may induce angina in patients with coronary artery disease. Use of Epi generally is contraindicated in patients receiving nonselective β receptor–blocking drugs, since its unopposed actions on vascular α_1 receptors may lead to severe hypertension and cerebral hemorrhage.

THERAPEUTIC USES

Clinical uses of Epi are based on its actions on blood vessels, heart, and bronchial muscle. A major use is to provide rapid relief of hypersensitivity reactions, including anaphylaxis, to drugs and other allergens. Epi is used to prolong the action of local anesthetics, presumably by vasoconstriction and a consequent reduction in absorption (see Chapter 14). It may restore cardiac rhythm in patients with cardiac arrest. Epi also is used as a topical hemostatic agent on bleeding surfaces such as in the mouth or in bleeding peptic ulcers during endoscopy of the stomach and duodenum. Systemic absorption of the drug can occur with dental application. In addition, inhalation of Epi may be useful in the treatment of postintubation and infectious croup. The therapeutic uses of Epi, in relation to other sympathomimetic drugs, are discussed later in this chapter.

Norepinephrine

NE (LEVARTERENOL, *l*-noradrenaline) is released by mammalian postganglionic sympathetic nerves (Table 10–1). NE constitutes 10–20% of the catecholamine content of human adrenal medulla and as much as 97% in some pheochromocytomas, which may not express phenylethanolamine-*N*-methyltransferase.

PHARMACOLOGICAL PROPERTIES The pharmacological actions of NE and Epi have been extensively compared *in vivo* and *in vitro* (Table 10–2). They are approximately equipotent in stimulating β_1 receptors; they differ mainly in their effectiveness in stimulating α and β_2 receptors. NE is a potent α agonist and has relatively little action on β_2 receptors; however, it is somewhat less potent than Epi on the α receptors of most organs. Isoproterenol stimulates all β receptors but not α receptors. Figure 10–2 compares the cardiovascular effects of infusions of NE, Epi, and isoproterenol.

Cardiovascular Effects In response to infused NE, systolic and diastolic pressures, and usually pulse pressure, increase (see Figure 10–2). Cardiac output is unchanged or decreased, and total peripheral resistance is raised. Compensatory vagal reflex activity slows the heart, overcoming direct cardioaccelerator action; stroke volume increases. Peripheral vascular resistance increases in most vascular beds, and renal blood flow is reduced. NE constricts mesenteric vessels and reduces splanchnic and hepatic blood flow. Coronary flow usually is increased, probably owing both to indirectly induced coronary dilation, as with Epi, and to elevated blood pressure. Although generally a poor β_2 agonist, NE may increase coronary blood flow directly by stimulating β_2 receptors on coronary vessels. Patients with Prinzmetal's variant angina may be supersensitive to the α constrictor effects of NE.

ABSORPTION, FATE, AND EXCRETION

NE, like Epi, is ineffective when given orally and is absorbed poorly from sites of subcutaneous injection. It is rapidly inactivated in the body by uptake and the actions of COMT and MAO. Small amounts normally are found in the urine. The excretion rate may be greatly increased in patients with pheochromocytoma.

ADVERSE EFFECTS; PRECAUTIONS

The untoward effects of NE resemble those of Epi, although there typically is greater elevation of blood pressure with NE. Excessive doses cause severe hypertension. Care must be taken that necrosis and sloughing do not occur at the site of intravenous injection owing to extravasation of the drug. The infusion should be made high in the limb, preferably through a long plastic cannula extending centrally. Impaired circulation at injection sites, with or without extravasation of NE, may be relieved by infiltrating the area with phentolamine, an α receptor antagonist. Blood pressure must be determined frequently. Reduced blood flow to organs such as kidney and intestines is a constant danger with the use of NE.

THERAPEUTIC USES

NE (LEVOPHED, others) has limited therapeutic value. Its use in shock is discussed below. In the treatment of low blood pressure, the dose is titrated to the desired pressor response.

Dopamine

DA (3,4-dihydroxyphenylethylamine; Table 10–1) is the metabolic precursor of NE and Epi; it is a central neurotransmitter particularly important in the regulation of movement (*see* Chapters 12, 18, and 20). In the periphery, DA is synthesized in epithelial cells of the proximal tubule and is thought to exert local diuretic and natriuretic effects. DA is a substrate for both MAO and COMT and thus is ineffective when administered orally. Classification of DA receptors is described in Chapters 12 and 20.

PHARMACOLOGICAL PROPERTIES

Cardiovascular Effects The cardiovascular effects of DA are mediated by several distinct types of receptors that vary in their affinity for DA. At low concentrations, the primary interaction of DA is with vascular D_1 receptors, especially in the renal, mesenteric, and coronary beds; this interaction leads to smooth muscle vasodilation (via the G_s -adenylyl cyclase-cAMP pathway). Infusion of low doses of DA causes an increase in glomerular filtration rate, renal blood flow, and Na^+ excretion. Activation of D_1 receptors on renal tubular cells decreases sodium transport by cAMP-dependent and cAMP-independent mechanisms. Increasing cAMP production in the proximal tubular cells and the medullary part of the thick ascending limb of the loop of Henle inhibits the Na^+ - H^+ exchanger and the Na^+ , K^+ -ATPase. Renal tubular actions of DA that cause natriuresis may be augmented by the increase in renal blood flow and in glomerular filtration rate that follow its administration. The resulting increase in hydrostatic pressure in the peritubular capillaries and reduction in oncotic pressure may contribute to diminished Na^+ reabsorption by the proximal tubular cells. Thus, DA has pharmacologically appropriate effects in the management of states of low cardiac output associated with compromised renal function, such as severe congestive heart failure.

At higher concentrations, DA acts on cardiac β_1 receptors to produce a positive inotropic effect. DA also causes the release of NE from nerve terminals, which contributes to its effects on the heart. DA usually increases systolic blood pressure and pulse pressure and either has no effect on diastolic blood pressure or increases it slightly. Total peripheral resistance usually is unchanged when low or intermediate doses of DA are given, probably because of reduced regional arterial resistance in some vascular beds (e.g., mesenteric and renal) with minor increases in others. At high concentrations, DA activates vascular α_1 receptors, leading to more general vasoconstriction.

CNS

Although there are specific DA receptors in the CNS, injected DA usually has no central effects because it does not readily cross the blood–brain barrier.

THERAPEUTIC USES Dopamine (INTROPIN, others) is used in the treatment of severe congestive failure, particularly in patients with oliguria and low or normal peripheral vascular resistance. The drug also may improve physiological parameters in the treatment of cardiogenic and septic shock. While DA may acutely improve cardiac and renal function in severely ill patients with

chronic heart disease or renal failure, there is little evidence supporting long-term benefit in clinical outcome. The management of shock is discussed below.

Dopamine hydrochloride is used only intravenously, initially at a rate of 2–5 $\mu\text{g}/\text{kg}/\text{min}$, increasing gradually to 20–50 $\mu\text{g}/\text{kg}/\text{min}$ if necessary. During the infusion, patients require clinical assessment of myocardial function, perfusion of vital organs such as the brain, and the production of urine. Reduction in urine flow, tachycardia, or the development of arrhythmias may be indications to slow or terminate the infusion. The duration of action of DA is brief; thus, the rate of administration can be used to control the intensity of effect.

Related drugs include fenoldopam and dopexamine. Fenoldopam (CORLOPAM), a benzazepine derivative, is a rapidly acting vasodilator used for control of severe hypertension (e.g., malignant hypertension with end-organ damage) in hospitalized patients for not more than 48 hours. Fenoldopam is an agonist for peripheral D_1 receptors and binds with moderate affinity to α_2 adrenergic receptors; it has no significant affinity for D_2 receptors or α_1 or β adrenergic receptors. Fenoldopam is a racemate; the R-isomer is the active component. It dilates a variety of blood vessels, including coronary arteries, afferent and efferent arterioles in the kidney, and mesenteric arteries. Of an orally administered dose, <6% is absorbed because of extensive first-pass metabolism. The elimination $t_{1/2}$ of intravenously infused fenoldopam is ~10 minutes. Adverse effects are related to vasodilation and include headache, flushing, dizziness, and tachycardia or bradycardia.

Dopexamine (DOPACARD) is a synthetic analog with intrinsic activity at D_1 , D_2 , and β_2 receptors; it may also inhibit catecholamine uptake. Dopexamine has favorable hemodynamic actions in patients with severe congestive heart failure, sepsis, and shock. In patients with low cardiac output, dopexamine infusion significantly increases stroke volume and decreases systemic vascular resistance. Tachycardia and hypotension can occur, but usually only at high infusion rates. Dopexamine is not available in the U.S.

PRECAUTIONS, ADVERSE REACTIONS, AND CONTRAINDICATIONS Before DA is administered to patients in shock, hypovolemia should be corrected. Untoward effects due to overdosage generally are attributable to excessive sympathomimetic activity (although this also may be the response to worsening shock). Nausea, vomiting, tachycardia, anginal pain, arrhythmias, headache, hypertension, and peripheral vasoconstriction may be encountered during DA infusion. Extravasation of large amounts of DA during infusion may cause ischemic necrosis and sloughing. Rarely, gangrene of the fingers or toes has followed prolonged infusion of the drug. DA should be avoided or used at reduced dosage (one-tenth or less) if the patient has received an MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

β ADRENERGIC RECEPTOR AGONISTS

β Adrenergic receptor agonists play a major role only in the treatment of bronchoconstriction in patients with asthma (reversible airway obstruction) or chronic obstructive pulmonary disease (COPD). Minor uses include management of preterm labor; treatment of complete heart block in shock, and short-term treatment of cardiac decompensation after surgery or in patients with congestive heart failure or myocardial infarction. The chronotropic effect of β agonists is useful in the emergency treatment of arrhythmias such as torsades de pointes, bradycardia, or heart block (see Chapter 34).

Isoproterenol

Isoproterenol (isopropylarterenol, isopropyl NE, isoprenaline; see Table 10–1) is a potent, nonselective β receptor agonist with very low affinity for α receptors. Consequently, isoproterenol has powerful effects on all β receptors and almost no action at α receptors.

PHARMACOLOGICAL ACTIONS The major cardiovascular effects of isoproterenol (compared with Epi and NE) are illustrated in Figure 10–2. Intravenous infusion of isoproterenol lowers peripheral vascular resistance, primarily in skeletal muscle but also in renal and mesenteric vascular beds. Diastolic pressure falls. Systolic blood pressure may remain unchanged or rise; mean arterial pressure typically falls. Cardiac output increases due to the positive inotropic and chronotropic effects of the drug in the face of diminished peripheral vascular resistance. The cardiac effects of isoproterenol may lead to palpitations, sinus tachycardia, and more serious arrhythmias.

Isoproterenol relaxes almost all varieties of smooth muscle when the tone is high, an action that is most pronounced on bronchial and GI smooth muscle. Isoproterenol's effect in asthma may be

due in part to inhibition of antigen-induced release of histamine and other mediators of inflammation, an action shared by β_2 -selective agonists.

ABSORPTION, FATE, AND EXCRETION

Isoproterenol is readily absorbed when given parenterally or as an aerosol. It is metabolized in the liver and other tissues by COMT. Isoproterenol is a relatively poor substrate for MAO and is not taken up by sympathetic neurons via NET to the same extent as Epi and NE. Isoproterenol's duration of action exceeds that of Epi but still is brief.

TOXICITY AND ADVERSE EFFECTS

Palpitations, tachycardia, headache, and flushing are common. Cardiac ischemia and arrhythmias may occur, particularly in patients with underlying coronary artery disease.

THERAPEUTIC USES

Isoproterenol (ISUPREL, others) may be used in emergencies to stimulate heart rate in patients with bradycardia or heart block, particularly in anticipation of inserting an artificial cardiac pacemaker or in patients with the ventricular arrhythmia torsades de pointes. In asthma and shock, isoproterenol largely has been replaced by other sympathomimetic drugs (see below and Chapter 27).

Dobutamine

The pharmacological effects of *dobutamine* (see Table 10–1 for structure) result from direct interactions with α and β receptors and are complex. The preparation of dobutamine used clinically is a racemate. The (–) isomer of dobutamine is a potent α_1 agonist and pressor; (+) dobutamine is a potent α_1 antagonist that can block the effects of (–) dobutamine. Both isomers are full agonists at β receptors, but the (+) isomer is more potent than the (–) isomer by ~tenfold.

CARDIOVASCULAR EFFECTS

The cardiovascular effects of racemic dobutamine are a composite of the pharmacological properties of the (–) and (+) stereoisomers. Dobutamine has relatively more prominent inotropic than chronotropic effects, compared to isoproterenol. This useful selectivity may arise because peripheral resistance is relatively unchanged due to a counterbalancing of α_1 receptor–mediated vasoconstriction and β_2 receptor–mediated vasodilation. Alternatively, cardiac α_1 receptors may contribute to the inotropic effect. At equivalent inotropic doses, dobutamine enhances automaticity of the sinus node to a lesser extent than does isoproterenol; however, enhancement of AV and intraventricular conduction is similar for both drugs.

ADVERSE EFFECTS

Blood pressure and heart rate may increase significantly during dobutamine administration, requiring reduction of infusion rate; hypertensive patients may exhibit such an exaggerated pressor response more frequently. Since dobutamine facilitates AV conduction, patients with atrial fibrillation are at risk of marked increases in ventricular response rates; digoxin or other measures may be required to prevent this from occurring. Some patients may develop ventricular ectopic activity. As with any inotropic agent, dobutamine may increase the size of an infarct by increasing myocardial O_2 demand. The efficacy of dobutamine for more than a few days is uncertain; there is evidence of the development of tolerance.

THERAPEUTIC USES; PHARMACOKINETICS

Dobutamine (DOBUTREX, others) is indicated for the short-term treatment of cardiac decompensation post cardiac surgery or in patients with congestive heart failure or acute myocardial infarction. An infusion of dobutamine in combination with echocardiography is useful in the noninvasive assessment of patients with coronary artery disease; stressing the heart with dobutamine may reveal cardiac abnormalities in selected patients.

A loading dose is not required, and steady-state concentrations generally are achieved within 10 minutes of initiation of the infusion. The rate of infusion required to increase cardiac output typically is 2.5–10 $\mu\text{g}/\text{kg}/\text{min}$; higher infusion rates occasionally are required. The rate and duration of the infusion are determined by the clinical and hemodynamic responses of the patient. The onset of effect is rapid. Dobutamine has a $t_{1/2}$ of ~2 minutes; the major metabolites are conjugates of dobutamine and 3-O-methyldobutamine.

β_2 -Selective Adrenergic Receptor Agonists

In treating asthma, preferential activation of β_2 receptors without stimulation of β_1 receptors in the heart is desirable. Drugs with preferential affinity for β_2 receptors over β_1 receptors have been

developed, but selectivity is not absolute and is lost at high concentrations. Administration by inhalation of small doses of a β_2 agonist in aerosol form leads to effective activation of β_2 receptors in the bronchi but very low systemic drug concentrations. Consequently, there is less potential to activate cardiac β_1 receptors or to stimulate β_2 receptors in skeletal muscle (which can cause tremor). The use of β agonists for the treatment of asthma is discussed in Chapter 27.

METAPROTERENOL *Metaproterenol* (called *orciprenaline* in Europe), *terbutaline*, and *fenoterol* belong to the structural class of resorcinol bronchodilators that have hydroxyl groups at positions 3 and 5 of the phenyl ring (rather than at positions 3 and 4 as in catechols; see Table 10–1). Consequently, these agents are resistant to methylation by COMT, and a substantial fraction (40%) is absorbed in active form after oral administration. Metaproterenol is excreted primarily as glucuronic acid conjugates. Metaproterenol is β_2 selective, although probably less selective than albuterol or terbutaline; thus, metaproterenol is more prone to cause cardiac stimulation.

Effects occur within minutes of inhalation and persist for several hours. After oral administration, onset of action is slower, but effects last 3 to 4 hours. Metaproterenol (ALUPENT, others) is used for the long-term treatment of obstructive airway diseases, asthma, and for treatment of acute bronchospasm (see Chapter 27). Side effects are similar to the short- and intermediate-acting sympathomimetic bronchodilators.

TERBUTALINE

Terbutaline is a β_2 -selective bronchodilator that contains a resorcinol ring and thus is not a substrate for COMT. It is effective when taken orally, subcutaneously, or by inhalation. Effects are observed rapidly after inhalation or parenteral administration; after inhalation, its action may persist for 3–6 hours. With oral administration, the onset of effect may be delayed for 1–2 hours. Terbutaline (BRETHINE, others) is used for the long-term treatment of obstructive airway diseases and acute bronchospasm; a parenteral formulation is used for the emergency treatment of status asthmaticus (see Chapter 27).

ALBUTEROL

Albuterol (VENTOLIN, PROVENTIL, others) is a selective β_2 agonist with pharmacological properties and therapeutic indications similar to those of terbutaline. It is administered by inhalation or orally for the symptomatic relief of bronchospasm. When administered by inhalation, terbutaline produces significant bronchodilation within 15 minutes; effects persist for 3–4 hours. Cardiovascular effects of albuterol are considerably weaker than those of isoproterenol that produce comparable bronchodilation when administered by inhalation. Oral albuterol may delay preterm labor. Rare CNS and respiratory side effects are sometimes observed.

ISOETHARINE

The selectivity of isoetharine for β_2 receptors may not approach that of other agents. Although resistant to metabolism by MAO, it is a catecholamine and thus is a good substrate for COMT (Table 10–1). It is used only by inhalation for acute episodes of bronchoconstriction.

PIRBUTEROL

Pirbuterol is a relatively selective β_2 agonist structurally related to albuterol. Pirbuterol acetate (MAXAIR) is available for inhalation therapy; dosing is typically every 4–6 hours.

BITOLTEROL

Bitolterol (TORNALATE) is a novel β_2 agonist prodrug in which the OH groups in the catechol moiety are protected by esterification. Esterase activities thought to be higher in lung than heart hydrolyze the prodrug to the active form, colterol, or terbutylne (Table 10–1). The duration of bitolterol's effect after inhalation is 3–6 hours.

FENOTEROL

Fenoterol (BEROTEC) is a β_2 -selective agonist administered by inhalation. Fenoterol has a prompt onset of action, and a sustained effect (4–6 hours). Possible association of fenoterol use with increased deaths from asthma in New Zealand is controversial. Fenoterol is under investigation for use in the U.S.

FORMOTEROL

Formoterol (FORADIL) is a long-acting, lipophilic, high-affinity β_2 -selective agonist. Significant bronchodilation occurs within minutes of inhalation and may persist for up to 12 hours, an advantage over many β_2 -selective agonists in settings such as nocturnal asthma. Formoterol is

FDA-approved for treatment of asthma, bronchospasm, prophylaxis of exercise-induced bronchospasm, and COPD.

PROCATEROL

Procaterol (MASCACIN, others; not available in U.S.), a β_2 -selective agonist, is administered by inhalation and has a prompt onset of action that is sustained for ~5 hours.

SALMETEROL

Salmeterol (SEREVENT) is a lipophilic β_2 -selective receptor agonist with prolonged action (>12 hours) and relatively high selectivity (50 \times that of albuterol) for β_2 receptors. Since the onset of action of inhaled salmeterol is relatively slow, it is not suitable monotherapy for acute breakthrough attacks of bronchospasm. Salmeterol or formoterol are the agents of choice for nocturnal asthma in patients who remain symptomatic despite anti-inflammatory agents and other standard management. Salmeterol provides symptomatic relief and improved lung function in patients with COPD. Salmeterol should not be used more than twice daily (morning and evening) and should not be used to treat acute asthma symptoms, which should be treated with a short-acting β_2 agonist when breakthrough symptoms occur. Salmeterol is metabolized by CYP3A4 to α -hydroxy-salmeterol, which is eliminated primarily in the feces.

RITODRINE

Ritodrine is a selective β_2 agonist originally developed as a uterine relaxant. Ritodrine is rapidly but incompletely (30%) absorbed following oral administration; 90% of the drug is excreted in the urine as inactive conjugates; ~50% of ritodrine is excreted unchanged after intravenous administration. The pharmacokinetic properties of ritodrine are complex and incompletely defined, especially in pregnant women. Administered intravenously to selected patients, ritodrine can arrest premature labor and prolong pregnancy; however, β_2 -selective agonists may not have clinically significant benefits on perinatal mortality and may actually increase maternal morbidity. In one trial comparing nifedipine with ritodrine in managing preterm labor, nifedipine was associated with a longer postponement of delivery, fewer maternal side effects, and fewer admissions to the neonatal intensive care unit.

ADVERSE EFFECTS OF β_2 -SELECTIVE AGONISTS

The major adverse effects of β -receptor agonists occur as a result of excessive activation of β receptors: tremor, to which tolerance develops and which can be minimized by starting oral therapy with a low dose of drug and progressively increasing the dose as tolerance to the tremor develops; feelings of restlessness, apprehension, and anxiety, which may limit therapy; and tachycardia, primarily via β_1 receptors but also possibly via cardiac β_2 receptors, or to reflex effects that stem from β_2 receptor-mediated peripheral vasodilation. During a severe asthma attack, heart rate actually may decrease during therapy with a β agonist, presumably because of improvement in pulmonary function with consequent reduction in endogenous cardiac sympathetic stimulation. In patients without cardiac disease, β agonists rarely cause significant arrhythmias or myocardial ischemia; however, patients with underlying coronary artery disease or preexisting arrhythmias are at greater risk. The risk of adverse cardiovascular effects is increased in patients receiving MAO inhibitors; 2 weeks should elapse between use of MAO inhibitors and administration of β_2 agonists or other sympathomimetics. Severe pulmonary edema has been reported in women receiving ritodrine or terbutaline for premature labor.

Epidemiologic studies suggest a connection between prolonged use of β receptor agonists and death or near-death from asthma, raising questions about the role of β agonists in the treatment of chronic asthma. Tolerance to the pulmonary effects of these drugs is not a major clinical problem for the majority of asthmatics. Regular use of β_2 -selective agonists may cause increased bronchial hyperreactivity and deterioration in disease control; whether this potential adverse association may be more unfavorable for long-acting β agonists or excess doses is not yet known. For patients requiring regular use of β agonists over prolonged periods, strong consideration should be given to additional or alternative therapy (e.g., inhaled glucocorticoids). In some diabetic patients, β agonists may worsen hyperglycemia, and higher doses of insulin may be required. All these adverse effects are far less likely with inhalation therapy than with parenteral or oral therapy.

α_1 -SELECTIVE ADRENERGIC RECEPTOR AGONISTS

Activation of α adrenergic receptors in vascular smooth muscle results in contraction, causing increases in peripheral vascular resistance and blood pressure. Although the clinical utility of α agonists is limited, they may be useful in the treatment of hypotension and shock. Some of the properties of the drugs listed below may be inferred from their structures (Table 10–1).

Phenylephrine

Phenylephrine (NEO-SYNEPHRINE, others) is a selective α_1 receptor agonist; it activates β receptors only at much higher concentrations. The drug causes marked arterial vasoconstriction during intravenous infusion. Phenylephrine also is used as a nasal decongestant and as a mydriatic in various nasal and ophthalmic formulations (see Chapter 63 for ophthalmic uses).

Mephentermine

Mephentermine (WYAMINE SULFATE) acts both directly and indirectly. After an intramuscular injection, the onset of action is prompt (within 5–15 minutes), and effects may last for several hours. Since the drug releases NE, cardiac contraction is enhanced, and cardiac output and systolic and diastolic pressures usually are increased. The change in heart rate is variable, depending on the degree of vagal tone. Adverse effects are related to CNS stimulation, excessive rises in blood pressure, and arrhythmias. Mephentermine is used to prevent hypotension, which frequently accompanies spinal anesthesia.

Metaraminol

Metaraminol (ARAMINE) is a mixed-acting agent: an agonist at vascular α adrenergic receptors and an indirectly acting agent that stimulates the release of NE. The drug has been used in the treatment of hypotensive states or off-label to relieve attacks of paroxysmal atrial tachycardia, particularly those associated with hypotension (see Chapter 34 for preferable treatments of this arrhythmia).

Midodrine

Midodrine (PROAMATINE) is an orally effective α_1 receptor agonist. It is a prodrug; its activity is due to its conversion to an active metabolite, desglymidodrine, which achieves peak concentrations ~1 hour after a dose of midodrine. The $t_{1/2}$ of desglymidodrine is ~3 hours; its duration of action is 4–6 hours. Midodrine stimulates contraction of both arterial and venous smooth muscle, and has useful effects in treating autonomic insufficiency and postural hypotension. A frequent complication in these patients is supine hypertension, which can be minimized by avoiding dosing prior to bedtime and by elevating the head of the bed. Typical dosing, achieved by careful titration of blood pressure responses, is 2.5–10 mg 3 times daily.

α_2 -SELECTIVE ADRENERGIC RECEPTOR AGONISTS

α_2 -selective adrenergic agonists are used primarily for the treatment of systemic hypertension, a surprising use since many blood vessels contain postsynaptic α_2 adrenergic receptors that promote vasoconstriction; indeed, increased blood pressure is a transient immediate response to these agents. Thus, all α_2 agonists must be used with caution in patients with cardiovascular disease. Some α_2 agonists usefully decrease intraocular pressure.

Clonidine

Intravenous infusion of clonidine causes an acute rise in blood pressure due to activation of postsynaptic α_2 receptors in vascular smooth muscle. The affinity of clonidine for these receptors is high, although the drug is a partial agonist with relatively low efficacy at these sites. The hypertensive response that follows parenteral administration of clonidine generally is not seen when the drug is given orally. After either oral or parenteral administration, the transient vasoconstriction is followed by a more prolonged hypotensive response that results from decreased sympathetic outflow from the CNS, apparently from activation of α_2 receptors in the lower brainstem region. Clonidine also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate. In addition, some of the antihypertensive effects of clonidine may be mediated by activation of presynaptic α_2 receptors that suppress the release of NE, ATP, and NPY from postganglionic sympathetic nerves. Clonidine decreases the plasma concentration of NE and reduces its excretion in the urine.

ABSORPTION, FATE, AND EXCRETION

Clonidine is well absorbed after oral administration, with bioavailability ~100%. The peak concentration in plasma and the maximal hypotensive effect are observed 1–3 hours after an oral dose; plasma concentrations of clonidine and its pharmacological effects correlate well. The elimination $t_{1/2}$ of the drug ranges from 6–24 hours (mean ~12 hours). About half of an administered dose appears unchanged in the urine; the $t_{1/2}$ of the drug may increase with renal failure. A transdermal delivery patch permits continuous administration of clonidine at a relatively constant rate for a week; 3–4 days are required to reach steady-state concentrations in plasma. When the patch

is removed, plasma concentrations remain stable for ~8 hours and then decline gradually over a period of several days; this decrease is associated with a rise in blood pressure.

ADVERSE EFFECTS

The major adverse effects of clonidine are dry mouth and sedation, which may diminish in intensity after several weeks of therapy. Sexual dysfunction and marked bradycardia may occur. These effects of clonidine frequently are dose-related; their incidence may be lower with transdermal administration of clonidine, which avoids the relatively high peak concentrations that occur after oral administration. About 15–20% of patients develop contact dermatitis when using clonidine in the transdermal system. Withdrawal reactions follow abrupt discontinuation of long-term therapy with clonidine in some hypertensive patients.

THERAPEUTIC USES

The major therapeutic use of clonidine (CATAPRES, others) is in the treatment of hypertension (see Chapter 32). Clonidine also has apparent efficacy in the off-label treatment of a range of other disorders: reducing diarrhea in some diabetic patients with autonomic neuropathy; treating and preparing addicted subjects for withdrawal (see Chapter 23); ameliorating some of the adverse sympathetic nervous activity associated with withdrawal, and decreasing craving for the drug. Transdermal administration of clonidine (CATAPRES-TTS) may be useful in reducing the incidence of menopausal hot flashes.

The capacity of clonidine to activate postsynaptic α_2 receptors in vascular smooth muscle has been exploited in a limited number of patients whose autonomic failure is so severe that reflex sympathetic responses on standing are absent; postural hypotension is thus marked. Since the central effect of clonidine on blood pressure is unimportant in these patients, the drug can elevate blood pressure and improve the symptoms of postural hypotension. Among the other off-label uses of clonidine are atrial fibrillation, attention-deficit/hyperactivity disorder (ADHD), constitutional growth delay in children, cyclosporine-associated nephrotoxicity, Tourette's syndrome, hyperhidrosis, mania, posthepatic neuralgia, psychosis, restless leg syndrome, ulcerative colitis, and allergy-induced inflammatory reactions in patients with extrinsic asthma.

Apraclonidine

Apraclonidine (IOPIDINE) is a relatively selective α_2 agonist that is used topically to reduce intraocular pressure with minimal systemic effects; apraclonidine seems not to cross the blood–brain barrier and is more useful than clonidine for ophthalmic therapy. The drug is useful as short-term adjunctive therapy in glaucoma patients whose intraocular pressure is not well controlled by other pharmacological agents and to control or prevent elevations in intraocular pressure that occur in patients after laser trabeculoplasty or iridotomy (see Chapter 63).

Brimonidine

Brimonidine (ALPHAGAN), a clonidine derivative and α_2 agonist, is administered topically to lower intraocular pressure in patients with ocular hypertension or open-angle glaucoma; brimonidine both decreases aqueous humor production and increases outflow (see Chapter 63). Unlike apraclonidine, brimonidine crosses the blood–brain barrier and can produce hypotension and sedation, although these effects are slight compared to those of clonidine.

Dexmedetomidine (PRECEDEX), a relatively selective α_2 agonist with sedative properties, produces preoperative sedation and anxiolysis, drying of secretions, and analgesia; the drug is used as an anesthetic adjunct.

Guanfacine

Guanfacine (TENEX), an α_2 agonist, is more selective for α_2 receptors than is clonidine. Guanfacine lowers blood pressure by activation of brainstem receptors with resultant suppression of sympathetic activity. The drug is well absorbed after oral administration. About 50% of guanfacine appears unchanged in the urine; the rest is metabolized. The $t_{1/2}$ for elimination ranges from 12–24 hours. Guanfacine and clonidine appear to have similar efficacy for the treatment of hypertension and a similar pattern of adverse effects. A withdrawal syndrome may occur after abrupt discontinuation, but it is less frequent and milder than the syndrome that follows clonidine withdrawal, perhaps reflecting the longer $t_{1/2}$ of guanfacine.

Guanabenz

Guanabenz (WYTENSIN, others) and guanfacine are closely related chemically and pharmacologically. Guanabenz is a centrally acting α_2 agonist that decreases blood pressure. Guanabenz has a $t_{1/2}$ of 4–6 hours and is extensively metabolized by the liver. Dosage adjustment may be necessary

in patients with hepatic cirrhosis. The adverse effects of guanabenz (e.g., dry mouth and sedation) are similar to those of clonidine.

Methyl dopa

In the brain, methyl dopa (α -methyl-3,4-dihydroxyphenylalanine) is metabolized to α -methylNE, and this compound is thought to activate central α_2 receptors and lower blood pressure in a manner similar to that of clonidine (see Chapter 32).

Tizanidine

Tizanidine (ZANAFLEX, others) is an α_2 agonist with some properties similar to those of clonidine. The drug is also a muscle relaxant used for the treatment of spasticity associated with cerebral and spinal disorders.

MISCELLANEOUS SYMPATHOMIMETIC AGONISTS

Amphetamine

Amphetamine (racemic β -phenylisopropylamine; see Table 10–1) acts indirectly to produce powerful stimulant actions in the CNS and α and β receptor stimulation in the periphery. Unlike Epi, amphetamine is effective after oral administration, and its effects last for several hours.

CARDIOVASCULAR RESPONSES

Amphetamine given orally raises systolic and diastolic blood pressure. Heart rate often is reflexly slowed; with large doses, cardiac arrhythmias may occur.

OTHER SMOOTH MUSCLES

In general, smooth muscles respond to amphetamine as they do to other sympathomimetic amines. The contractile effect on the sphincter of the urinary bladder is particularly marked, and for this reason amphetamine has been used in treating enuresis and incontinence. Pain and difficulty in micturition occasionally occur. GI effects are unpredictable: relaxation if enteric activity is pronounced, stimulation if the gut already is relaxed. The response of the human uterus varies, but there usually is an increase in tone.

CNS

Amphetamine is one of the most potent sympathomimetic amines in stimulating the CNS. It stimulates the medullary respiratory center; lessens the degree of central depression caused by various drugs, and produces other signs of CNS stimulation; the *d*-isomer (dextroamphetamine) is three to four times more potent than the *l*-isomer. Psychic effects depend on the dose and the mental state and personality of the individual. The main results of an oral dose of 10–30 mg include wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often, elation and euphoria; and increase in motor and speech activities. Performance of simple mental tasks is improved; although more work may be accomplished, the number of errors may increase. Physical performance—in athletes, for example—is often improved, and the drug often is abused for this purpose. Prolonged use or large doses are nearly always followed by depression and fatigue. Many individuals given amphetamine experience headache, palpitation, dizziness, vasomotor disturbances, agitation, confusion, dysphoria, apprehension, delirium, or fatigue (see Chapter 23).

FATIGUE AND SLEEP

In general, amphetamine prolongs the duration of adequate performance before fatigue appears, and partly reverses the effects of fatigue, most noticeably when performance has been reduced by fatigue and lack of sleep. The need for sleep may be postponed, but it cannot be avoided indefinitely. When the drug is discontinued after long use, the pattern of sleep may take as long as 2 months to return to normal.

Analgesia

Amphetamine and some other sympathomimetic amines have a small analgesic effect that is not sufficiently pronounced to be therapeutically useful. Amphetamine can enhance the analgesia produced by opiates.

Respiration

Amphetamine stimulates the respiratory center, increasing the rate and depth of respiration. In normal individuals, usual doses of the drug do not appreciably increase respiratory rate or minute volume. Nevertheless, when respiration is depressed by centrally acting drugs, amphetamine may stimulate respiration.

Appetite

Weight loss in obese humans treated with amphetamine is almost entirely due to reduced food intake and only in small measure to increased metabolism. In humans, tolerance to the appetite suppression develops rapidly.

Mechanisms of Action in the CNS

Amphetamine appears to exert most or all of its CNS effects indirectly by releasing biogenic amines from storage sites in nerve terminals. The alerting effect of amphetamine, its anorectic effect, and at least a component of its locomotor-stimulating action presumably are mediated by release of NE from central noradrenergic neurons. Some aspects of locomotor activity and the stereotyped behavior induced by amphetamine probably result from the release of DA from dopaminergic nerve terminals in the neostriatum. Higher doses are required to produce these behavioral effects. With still higher doses of amphetamine, disturbances of perception and overt psychosis occur, possibly due to release of 5-HT from serotonergic neurons and of DA in the mesolimbic system.

TOXICITY AND ADVERSE EFFECTS The acute toxic effects of amphetamine usually are extensions of its therapeutic actions and as a rule result from overdosage. CNS effects commonly include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggressiveness, changes in libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. However, these psychotic effects can be elicited in any individual if sufficient quantities of amphetamine are ingested for a prolonged period. Fatigue and depression usually follow central stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing, palpitation, cardiac arrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating occurs. GI symptoms include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning usually terminates in convulsions and coma; cerebral hemorrhages are the main pathological findings.

Toxicity shows great biological variability, occasionally occurring after as little as 2 mg, but rare with <15 mg. Severe reactions have occurred with 30 mg, yet doses of 400–500 mg are not uniformly fatal. Larger doses can be tolerated after chronic use of the drug. Treatment of acute amphetamine intoxication may include acidification of the urine with ammonium chloride to enhance the rate of elimination. Sedatives may be required for the CNS symptoms. Severe hypertension may require administration of sodium nitroprusside or an α adrenergic receptor antagonist. Chronic amphetamine intoxication causes symptoms similar to those of acute overdosage, but abnormal mental conditions are more common. Weight loss may be marked. A psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia, is the most common serious effect. Recovery usually is rapid after withdrawal of the drug, but the condition can become chronic, with amphetamine hastening the onset of incipient schizophrenia.

Amphetamines are schedule II drugs and should be used only under medical supervision. Amphetamine use is inadvisable in patients with anorexia, insomnia, asthenia, psychopathic personality, or a history of homicidal or suicidal tendencies.

DEPENDENCE AND TOLERANCE

Psychological dependence often occurs when amphetamine or dextroamphetamine is used chronically, as discussed in Chapter 23. Tolerance almost invariably develops to the anorexigenic effect of amphetamines, and often is seen also in the need for increasing doses to maintain improvement of mood in psychiatric patients, yet cases of narcolepsy have been treated for years without requiring an increase in the initially effective dose.

THERAPEUTIC USES

Dextroamphetamine (DEXEDRINE, others), with greater CNS action and less peripheral action, is FDA approved for the treatment of narcolepsy and attention-deficit/hyperactivity disorder (see below).

Methamphetamine

Methamphetamine (DESOXYN) acts centrally to release DA and other biogenic amines and to inhibit neuronal and vesicular monoamine transporters and MAO. Small doses have prominent central stimulant effects without significant peripheral actions; somewhat larger doses produce a sustained rise in systolic and diastolic blood pressures, due mainly to cardiac stimulation and an increase in cardiac output secondary to vasoconstriction. Methamphetamine is a schedule II drug and is widely abused (see Chapter 23).

Methylphenidate

Methylphenidate (*RITALIN*, others), structurally related to amphetamine, is a mild CNS stimulant with more prominent effects on mental than on motor activities. However, large doses produce signs of generalized CNS stimulation and convulsions. Its pharmacological properties are essentially the same as those of the amphetamines, including the potential for abuse. Methylphenidate is a schedule II-controlled substance in the U.S. Methylphenidate is effective in the treatment of narcolepsy and attention-deficit/hyperactivity disorder (see below). Racemic methylphenidate is readily absorbed after oral administration and reaches peak concentrations in plasma in ~2 hours. The more potent (+) enantiomer has a $t_{1/2}$ of ~6 hours. Concentrations in the brain exceed those in plasma. The main urinary metabolite is a deesterified product, ritalinic acid, which accounts for 80% of the dose. Methylphenidate is contraindicated in patients with glaucoma.

Dexmethylphenidate

Dexmethylphenidate (*FOCALIN*) is the *d*-threo enantiomer of racemic methylphenidate. It is FDA approved for the treatment of attention-deficit/hyperactivity disorder and is a schedule II-controlled substance in the U.S.

Pemoline

Pemoline (*CYLERT*, others), structurally dissimilar to methylphenidate, elicits similar changes in CNS function with minimal effects on the cardiovascular system. It is a schedule IV-controlled substance in the U.S. and is used in treating attention-deficit/hyperactivity disorder. It can be given once daily because of its long $t_{1/2}$. Clinical improvement may require treatment for 3–4 weeks. Pemoline has been associated with severe hepatic failure.

Ephedrine

Ephedrine is an agonist at both α and β receptors and also enhances release of NE from sympathetic neurons; thus, it is a mixed-acting sympathomimetic. Ephedrine does not contain a catechol moiety and is effective after oral administration. The drug stimulates heart rate and cardiac output and variably increases peripheral resistance; as a result, it usually increases blood pressure. Activation of β receptors in the lungs promotes bronchodilation. Ephedrine is a potent CNS stimulant. After oral administration, effects of the drug may persist for several hours. Ephedrine is eliminated in the urine largely as unchanged drug, with a $t_{1/2}$ of ~3–6 hours. A stereoisomer of ephedrine, pseudoephedrine, is used as a nasal mucosal vasoconstrictor and decongestant (see below)

TOXICITY

Untoward effects of ephedrine include hypertension and insomnia. Tachyphylaxis may occur with repetitive dosing. Usual or higher-than-recommended doses may cause adverse cardiovascular effects in individuals with underlying cardiovascular disease. Herbal preparations containing ephedrine (*ma huang*, *ephedra*) are widely utilized; these preparations vary in their content of ephedrine; thus, their use may lead to inadvertent consumption of dangerously high doses of ephedrine and its isomers. Because of this, the FDA has banned the sale of dietary supplements containing *ephedra* in the U.S.

Other Sympathomimetics

Several sympathomimetic drugs are used primarily as vasoconstrictors for local application to the nasal mucous membrane or the eye: propylhexedrine (*BENZEDREX*, others), naphazoline (*PRIVINE*, *NAPHCON*, others), oxymetazoline (*AFRIN*, *OCUCLEAR*, others), and xylometazoline (*OTRIVIN*, others) [see Table 10–1]. Ethylnorepinephrine (*BRONKEPHRINE*) is a β agonist that is used as a bronchodilator; the drug also has α agonist activity, which may cause local vasoconstriction and thereby reduce bronchial congestion. Phenylephrine (see above), pseudoephedrine (*SUDAFED*, others) (a stereoisomer of ephedrine), and phenylpropanolamine are sympathomimetics used most commonly in oral preparations for the relief of nasal congestion. Pseudoephedrine is available without a prescription in a variety of solid and liquid dosage forms. Phenylpropanolamine shares the pharmacological properties of ephedrine and is approximately equal in potency except that it causes less CNS stimulation. The drug has been available over-the-counter (OTC), and numerous proprietary mixtures marketed for the oral treatment of nasal and sinus congestion contain one of these sympathomimetic amines, usually in combination with an H_1 histamine antagonist. Because phenylpropanolamine increases the risk of hemorrhagic stroke, most manufacturers have voluntarily stopped marketing products containing phenylpropanolamine in the U.S. and the FDA is withdrawing approval for the drug.

THERAPEUTIC USES OF SYMPATHOMIMETIC DRUGS

SHOCK

Shock is a life-threatening condition characterized by inadequate perfusion of tissues, hypotension, and, ultimately, failure of organ systems. Treatment of shock consists of specific efforts to reverse the underlying pathogenesis as well as nonspecific measures aimed at correcting hemodynamic abnormalities. Regardless of etiology, the accompanying fall in blood pressure generally leads to marked activation of the sympathetic nervous system. This, in turn, causes peripheral vasoconstriction and an increase in the rate and force of cardiac contraction. In the initial stages of shock, these mechanisms may maintain blood pressure and cerebral blood flow, although blood flow to the kidneys, skin, and other organs may be decreased, leading to impaired production of urine and metabolic acidosis.

The initial therapy of shock involves basic life-support measures (maintenance of blood volume, etc.). Specific therapy (e.g., antibiotics for patients in septic shock) should be initiated immediately. If these measures do not lead to an adequate therapeutic response, it may be necessary to use vasoactive drugs in an effort to improve abnormalities in blood pressure and flow. This therapy generally is empirically based on response to hemodynamic measurements. Many of these pharmacological approaches, while reasonable, are of uncertain efficacy. Adrenergic receptor agonists may be used in an attempt to increase myocardial contractility or to modify peripheral vascular resistance. In general terms, β receptor agonists increase heart rate and force of contraction, α receptor agonists increase peripheral vascular resistance, and DA promotes dilation of renal and splanchnic vascular beds, in addition to activating β and α receptors.

Cardiogenic shock due to myocardial infarction has a poor prognosis; therapy is aimed at improving peripheral blood flow. Medical intervention is designed to optimize cardiac filling pressure (preload), myocardial contractility, and peripheral resistance (afterload). Preload may be increased by administration of intravenous fluids or reduced with drugs such as diuretics and nitrates. Sympathomimetic amines have been used to increase the force of contraction of the heart. Some of these drugs have disadvantages: isoproterenol is a powerful chronotropic agent and can greatly increase myocardial O_2 demand; NE intensifies peripheral vasoconstriction; Epi increases heart rate and may predispose the heart to dangerous arrhythmias. DA is an effective inotropic agent that causes less increase in heart rate than does isoproterenol and also promotes renal arterial dilation (possibly useful in preserving renal function). When given in high doses (>10 – 20 $\mu\text{g}/\text{kg}/\text{min}$), DA activates α receptors, causing peripheral and renal vasoconstriction. Dobutamine has complex pharmacological actions that are mediated by its stereoisomers; it increases myocardial contractility with little increase in heart rate or peripheral resistance.

In some patients, hypotension is so severe that vasoconstrictors are required to maintain a blood pressure sufficient for CNS perfusion. Alpha agonists (e.g., NE, phenylephrine, metaraminol, mephentermine, midodrine, ephedrine, Epi, DA, and methoxamine) have been used. This approach may be advantageous in patients with hypotension due to failure of the sympathetic nervous system (e.g., after spinal anesthesia or injury). In patients with other forms of shock, such as cardiogenic shock, reflex vasoconstriction generally is intense, and α receptor agonists may further compromise blood flow to organs such as the kidneys and gut and adversely increase the work of the heart. Indeed, vasodilating drugs such as nitroprusside are more likely to improve blood flow and decrease cardiac work in such patients by decreasing afterload if a minimally adequate blood pressure can be maintained.

The hemodynamic abnormalities in septic shock are complex and poorly understood. Most patients with septic shock initially have low or marginal peripheral vascular resistance, possibly reflecting excessive nitric oxide (NO) production. If the syndrome progresses, myocardial depression, increased peripheral resistance, and impaired tissue oxygenation occur. The primary treatment of septic shock is antibiotics. Therapy with vasoactive drugs must be individualized according to hemodynamic monitoring.

HYPOTENSION

Drugs with predominantly α agonist activity can be used to raise blood pressure in patients with decreased peripheral resistance in conditions such as spinal anesthesia or intoxication with anti-hypertensive medications. However, hypotension per se is not an indication for treatment with these agents unless there is inadequate perfusion of organs such as the brain, heart, or kidneys. Furthermore, adequate replacement of fluid or blood may be more appropriate than drug therapy for many patients with hypotension.

Patients with orthostatic hypotension (excessive fall in blood pressure with standing) often represent a pharmacological challenge. There are diverse causes for this disorder, including the Shy-Drager syndrome and idiopathic autonomic failure. Therapeutic approaches include physical

maneuvers and a variety of drugs (fludrocortisone, prostaglandin synthesis inhibitors, somatostatin analogs, caffeine, vasopressin analogs, and DA antagonists). The ideal agent would enhance venous constriction prominently and produce relatively little arterial constriction so as to avoid supine hypertension. No such agent currently is available. Drugs used include α_1 agonists and indirect-acting agents. Midodrine shows promise in treating orthostatic hypotension.

HYPERTENSION

Centrally acting α_2 receptor agonists such as clonidine are useful in the treatment of hypertension. Drug therapy of hypertension is discussed in Chapter 32.

CARDIAC ARRHYTHMIAS

During cardiopulmonary resuscitation, Epi and other α agonists increase diastolic pressure and improve coronary blood flow. α agonists also help to preserve cerebral blood flow. Thus, during external cardiac massage, Epi facilitates distribution of the limited cardiac output to the cerebral and coronary circulations. The optimal dose of epinephrine in patients with cardiac arrest is unclear. Once a cardiac rhythm has been restored, it may be necessary to treat arrhythmias, hypotension, or shock. Treatment of cardiac arrhythmias is detailed in Chapter 34.

HEART FAILURE

Use of β agonists and β antagonists in the treatment of heart failure is described in Chapter 33.

LOCAL VASCULAR EFFECTS OF α ADRENERGIC RECEPTOR AGONISTS

Epi is used in many surgical procedures in the nose, throat, and larynx to shrink the mucosa and improve visualization by limiting hemorrhage. Simultaneous injection of Epi with local anesthetics retards the absorption of the anesthetic and increases the duration of anesthesia (see Chapter 14). Injection of α agonists into the penis may be useful in reversing priapism, a complication of the use of α receptor antagonists or PDE5 inhibitors (e.g., sildenafil) in the treatment of erectile dysfunction. Both phenylephrine and oxymetazoline are efficacious vasoconstrictors when applied locally during sinus surgery.

NASAL DECONGESTION

α Receptor agonists are used extensively as nasal decongestants, as discussed above. Sympathomimetic decongestants should be used with great caution in patients with hypertension and in men with prostatic enlargement and not used by patients who are taking MAO inhibitors. Oral decongestants are much less likely to cause rebound congestion but carry a greater risk of inducing adverse systemic effects. Indeed, patients with uncontrolled hypertension or ischemic heart disease generally should avoid the oral consumption of OTC products or herbal preparations containing sympathomimetics.

ASTHMA

Use of β adrenergic agonists in the treatment of asthma is discussed in Chapter 27.

ALLERGIC REACTIONS

Epi is the drug of choice to reverse the manifestations of serious acute hypersensitivity reactions (e.g., from food, bee sting, or drug allergy). A subcutaneous injection of Epi rapidly relieves itching, hives, and swelling of lips, eyelids, and tongue. In some patients, careful intravenous infusion of Epi may be required to ensure prompt pharmacological effects. This treatment may be life saving when edema of the glottis threatens airway patency or when there is hypotension or shock in patients with anaphylaxis. In addition to its cardiovascular effects, Epi activates β receptors that suppress the release from mast cells of mediators such as histamine and leukotrienes. Although glucocorticoids and antihistamines frequently are administered to patients with severe hypersensitivity reactions, Epi remains the mainstay.

OPHTHALMIC USES

Ophthalmic uses are discussed in Chapter 63.

NARCOLEPSY

Narcolepsy is characterized by hypersomnia. Some patients respond to treatment with tricyclic antidepressants or MAO inhibitors. Alternatively, CNS stimulants such as amphetamines may be useful. Therapy with amphetamines is complicated by the risk of abuse and the likelihood of the development of tolerance and a variety of behavioral changes (see above). Amphetamines may

disturb nocturnal sleep, which increases the difficulty of avoiding daytime attacks of sleep in these patients. Modafinil (PROVIGIL), a CNS stimulant, may be beneficial via an unknown mechanism. In the U.S., modafinil is a schedule IV-controlled substance.

Occasionally, narcolepsy results from mutations in orexin neuropeptides (also called hypocretins), which are expressed in the lateral hypothalamus, or in their G protein-coupled receptors. Although such mutations are not present in most subjects with narcolepsy, the levels of orexins in the CSF are diminished, suggesting that deficient orexin signaling may play a pathogenic role. The association of these neuropeptides and their cognate GPCRs with narcolepsy provides an attractive target for the development of novel pharmacotherapies for this disorder.

WEIGHT REDUCTION

Optimally, weight loss is achieved by a gradual increase in energy expenditure from exercise combined with dieting to decrease the caloric intake. Amphetamine promotes weight loss by suppressing appetite rather than by increasing energy expenditure. Other anorexic drugs include methamphetamine, dextroamphetamine, phentermine, benzphetamine, phendimetrazine, phenmetrazine, diethylpropion, mazindol, phenylpropranolamine, and sibutramine (a mixed adrenergic/serotonergic drug). These agents may be effective adjuncts in the treatment of obesity but they all present significant risk of adverse effects (see above). Available evidence does not support the isolated use of these drugs in the absence of a more comprehensive program that stresses exercise and diet modification.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

ADHD, usually first evident in childhood, is characterized by excessive motor activity, difficulty in sustaining attention, and impulsiveness. A variety of stimulant drugs have been utilized in the treatment of ADHD, and they are particularly indicated in moderate-to-severe cases. Methylphenidate is effective in children with ADHD and is the most common intervention; treatment may start with a dose of 5 mg in the morning and at lunch, increasing gradually over a period of weeks depending on the response as judged by parents, teachers, and the clinician. The total daily dose generally should not exceed 60 mg. Methylphenidate has a short duration of action; thus, most children require 2–3 doses/day, with the timing individualized for effect. Methylphenidate, dextroamphetamine, and amphetamine probably have similar efficacy in ADHD. Pemoline appears to be less effective, although like sustained release preparations of methylphenidate (RITALIN SR, CONCERTA, METADATE) and amphetamine (ADDERAL XR), pemoline may be used once daily in children and adults. Potential adverse effects of these medications include insomnia, abdominal pain, anorexia, and weight loss that may be associated with suppression of growth in children. Minor symptoms may be transient or may respond to adjustment of dosage or administration of the drug with meals.

II. ADRENERGIC RECEPTOR ANTAGONISTS

Adrenergic receptor antagonists inhibit the interaction of NE, Epi, and other sympathomimetic drugs with α and β receptors (see Figure 10–3). Detailed knowledge of the localization of adrenergic receptors and of effector-response coupling is essential for understanding the pharmacological properties and therapeutic uses of this important class of drugs (see Tables 6–1, 6–6, 6–7, 6–8, 10–2 and 10–6).

α ADRENERGIC RECEPTOR ANTAGONISTS

Effects of α adrenergic antagonists may be predicted from the consequences of α receptor stimulation. The α_1 adrenergic receptors mediate contraction of arterial and venous smooth muscle. The α_2 receptors are involved in suppressing sympathetic outflow from the CNS, increasing vagal tone, facilitating platelet aggregation, inhibiting the release of NE and ACh from nerve endings, and regulating metabolic effects (e.g., suppression of insulin secretion and inhibition of lipolysis) and contraction of some arteries and veins.

α receptor antagonists are chemically heterogeneous and have a wide spectrum of pharmacological specificities (Figure 10–3, Table 10–3). Prazosin is much more potent in blocking α_1 than α_2 receptors (i.e., α_1 selective), whereas yohimbine is α_2 selective; phentolamine has similar affinities for both of these receptor subtypes. Newer agents discriminate amongst the subtypes of a particular receptor (e.g., tamsulosin has higher potency at α_{1A} than at α_{1B} receptors). Table 10–3 summarizes the properties of three chemically distinct groups of α blockers.

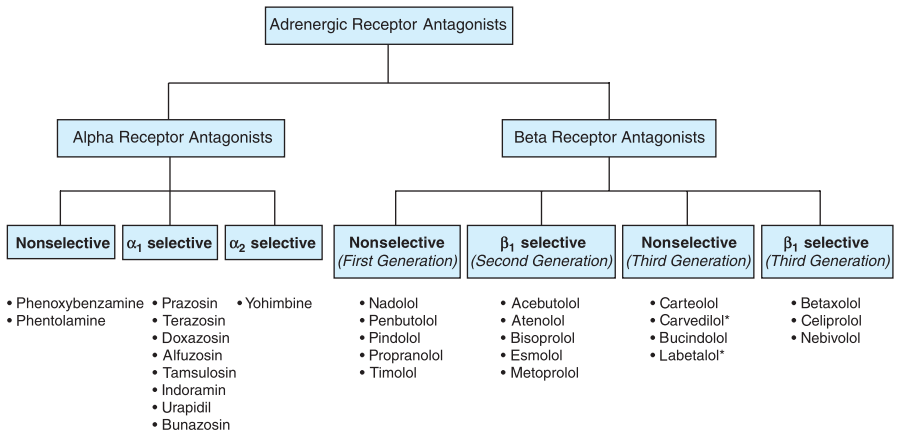

FIGURE 10–3 Classification of adrenergic receptor antagonists. Drugs marked by an asterisk (*) also block α₁ receptors.

Pharmacological Properties

CARDIOVASCULAR SYSTEM

α₁ Receptor Antagonists Blockade of α₁ adrenergic receptors inhibits vasoconstriction induced by endogenous catecholamines; vasodilation may occur in both arteriolar resistance vessels and veins. The result is a fall in blood pressure due to decreased peripheral resistance; the magnitude of such effects depends on the activity of the sympathetic nervous system, is less in supine than in upright subjects, and is enhanced by hypovolemia. For most α receptor antagonists, the fall in blood pressure is opposed by baroreceptor reflexes that cause increases in heart rate and cardiac output, as well as fluid retention. These compensatory reflexes are exaggerated if the antagonist also blocks α₂ receptors on peripheral sympathetic nerve endings, leading to enhanced release of NE and increased stimulation of postsynaptic β₁ receptors in the heart and on juxtaglomerular cells. Since blockade of α₁ receptors inhibits vasoconstriction, pressor responses to Epi may be transformed to vasodepressor effects (“epinephrine reversal”) due to unopposed stimulation of β₂ receptors in the vasculature with resultant vasodilation.

α₂ Adrenergic Receptor Antagonists Activation of α₂ receptors in the pontomedullary region of the CNS inhibits sympathetic nervous system activity and leads to a fall in blood pressure; these receptors are a site of action for drugs such as clonidine. Activation of presynaptic α₂ receptors inhibits the release of NE and cotransmitters from peripheral sympathetic nerve endings. Thus, blockade of peripheral α₂ receptors with selective antagonists such as yohimbine increases sympathetic outflow and potentiates the NE release, leading to activation of α₁ and β₁ receptors in the heart and peripheral vasculature with a consequent rise in blood pressure. Antagonists that simultaneously block α₁ and α₂ receptors cause similar effects on sympathetic outflow and NE release, but the net increase in blood pressure is prevented by inhibition of vasoconstriction (α₁ blockade).

The physiological role of vascular α₂ receptors in the regulation of blood flow within various vascular beds is uncertain. Vascular α₂ receptors probably are preferentially stimulated by circulating catecholamines, whereas α₁ receptors are activated by NE released from sympathetic nerves.

OTHER ACTIONS

Catecholamines increase the output of glucose from the liver, predominantly via β receptors, although α receptors may contribute, and thus, α receptor antagonists may reduce glucose release. α_{2A} Receptors facilitate platelet aggregation; the effect of blockade of platelet α₂ receptors in vivo is not clear. Activation of α₂ receptors in the pancreatic islets suppresses insulin secretion; conversely, their blockade may facilitate insulin release (see Chapter 60). Alpha receptor antagonists reduce smooth muscle tone in the prostate and neck of the bladder, thereby decreasing resistance to urine outflow in benign prostatic hypertrophy (see below).

Table 10–3

Comparative Information About α Adrenergic Receptor Antagonists

	Haloalkylamines	Imidazolines	Quinazolines
Prototype	Phenoxybenzamine (PBZ)	Phentolamine	Prazosin
Others		Tolazoline	Terazosin Doxazosin Trimazosin Alfuzosin
Antagonism Selectivity	Irreversible α_1 with some α_2	Competitive Nonselective between α_1 and α_2	Competitive Selective for α_1 ; does not distinguish among α_1 subtypes
Hemodynamic effects	Decreased PVR and blood pressure Venodilation is prominent Cardiac stimulation (cardiovascular reflexes and enhanced NE release due to α_2 antagonism)	Similar to PBZ	Decreased PVR and blood pressure Veins less susceptible than arteries; thus, postural hypotension less of a problem Cardiac stimulation is less (NE release is not enhanced due to α_1 selectivity)
Actions other than α blockade	Some antagonism of ACh, 5-HT, and histamine Blockade of neuronal and extraneuronal uptake	Cholinomimetic; adrenomimetic; histamine-like actions Antagonism of 5-HT	At high doses some direct vasodilator action, probably due to PDE inhibition
Routes of administration	Intravenous and oral; oral absorption incomplete and erratic	Similar to PBZ	Oral
Adverse reactions	Postural hypotension, tachycardia, miosis, nasal stuffiness, failure of ejaculation	Same as PBZ, plus GI disturbances due to cholinomimetic and histamine-like actions	Some postural hypotension, especially with the first dose; less of a problem overall than with PBZ or phentolamine
Therapeutic uses	Conditions of catecholamine excess (e.g., pheochromocytoma) Peripheral vascular disease	Same as PBZ	Primary hypertension Benign prostatic hypertrophy

ABBREVIATIONS: ACh, acetylcholine; 5-HT, 5-hydroxytryptamine; PBZ, phenoxybenzamine; NE, norepinephrine; PVR, peripheral vascular resistance.

Phenoxybenzamine

Phenoxybenzamine (PBZ), a haloalkylamine that blocks α_1 and α_2 receptors, is covalently conjugated with α receptors. Consequently, receptor blockade is irreversible and restoration of cellular responsiveness to α receptor agonists probably requires the synthesis of new receptors. Table 10–3 summarizes salient properties of PBZ, the major physiological effects of which result from blockade of α receptors in smooth muscle.

PBZ causes a progressive decrease in peripheral resistance, an increase in cardiac output (due, in part, to reflex sympathetic nerve stimulation), tachycardia accentuated by enhanced release of NE (due to α_2 blockade), and decreased clearance of NE (due to inhibition of NET and ENT by the drug). PBZ impairs pressor responses to exogenously administered catecholamines and

causes “epinephrine reversal” (β_2 predominance in the vasculature). PBZ has little effect on supine blood pressure in normotensive subjects but causes a marked fall in blood pressure on standing (antagonism of compensatory vasoconstriction). The drug impairs the ability to respond to hypovolemia and anesthetic-induced vasodilation. At higher doses, PBZ also irreversibly inhibits responses to 5-HT, histamine, and ACh.

THERAPEUTIC USES

A major use of PBZ (DIBENZYLIN) is in the treatment of pheochromocytoma, tumors of the adrenal medulla and sympathetic neurons that secrete enormous quantities of catecholamines. The usual result is hypertension, which may be episodic and severe. PBZ is almost always used to treat the patient in preparation for surgical removal of the tumor. The standard therapy is to initiate PBZ (at a dosage of 10 mg twice daily) 1–3 weeks before the operation, increasing the dose every other day until the desired effect on blood pressure is achieved. Therapy may be limited by postural hypotension; nasal stuffiness is another frequent adverse effect. Prolonged treatment with PBZ may be necessary in patients with inoperable or malignant pheochromocytoma; the usual daily dose is 40–120 mg given in 2–3 divided portions. Metyrosine, a competitive inhibitor of tyrosine hydroxylase, may be a useful adjuvant. Beta receptor antagonists also are used to treat pheochromocytoma, but only after the administration of an α receptor antagonist (see below).

PBZ has been used off-label to control the manifestations of autonomic hyperreflexia in patients with spinal cord transection.

TOXICITY AND ADVERSE EFFECTS

The major adverse effect of PBZ is postural hypotension, often accompanied by reflex tachycardia and other arrhythmias. Hypotension can be particularly severe in hypovolemic patients or under conditions that promote vasodilation (administration of vasodilator drugs, exercise, ingestion of alcohol or large quantities of food). Reversible inhibition of ejaculation may occur because of impaired smooth muscle contraction in the vas deferens and ejaculatory ducts. PBZ is mutagenic in the Ames test; the clinical significance of this finding is unknown.

Phentolamine and Tolazoline

Phentolamine, an imidazoline, is a competitive α receptor antagonist that has similar affinities for α_1 and α_2 receptors. Its effects on the cardiovascular system are very similar to those of PBZ (see Table 10–3).

THERAPEUTIC USES

Phentolamine (REGITINE) can be used in short-term control of hypertension in patients with pheochromocytoma. Rapid infusions of phentolamine may cause severe hypotension, so the drug should be administered cautiously. Phentolamine also may be useful to relieve pseudo-obstruction of the bowel in patients with pheochromocytoma; this condition may result from the inhibitory effects of catecholamines on intestinal smooth muscle. Phentolamine has been used locally to prevent dermal necrosis after the inadvertent extravasation of an α receptor agonist. The drug also may be useful for the treatment of hypertensive crises that follow the abrupt withdrawal of clonidine or that may result from the ingestion of tyramine-containing foods during the use of nonselective MAO inhibitors. Phentolamine administered buccally, orally, or by intracavernous injection into the penis may have efficacy in some men with sexual dysfunction.

TOXICITY AND ADVERSE EFFECTS

Hypotension is the major adverse effect of phentolamine; reflex cardiac stimulation may cause tachycardia, arrhythmias, and ischemic cardiac events. GI stimulation may result in abdominal pain, nausea, and exacerbation of peptic ulcer. Phentolamine should be used with particular caution in patients with coronary artery disease or a history of peptic ulcer.

Quinazoline α Antagonists

Prazosin

Prazosin, the prototypic quinazoline α blocker, is a potent and selective α_1 receptor antagonist. The quinazoline class of α receptor antagonists has largely replaced the nonselective haloalkylamine (e.g., PBZ) and imidazoline (e.g., phentolamine) α receptor antagonists. The affinity of prazosin for α_1 adrenergic receptors is $\sim 1000\times$ that for α_2 adrenergic receptors; prazosin has similar potencies at α_{1A} , α_{1B} , and α_{1D} subtypes. Interestingly, the drug also is a relatively potent inhibitor of cyclic nucleotide PDEs. Prazosin frequently is used for the treatment of hypertension (see Chapter 32). The major effects of prazosin result from its blockade of α_1 receptors in arterioles and veins, leading

to a fall in peripheral vascular resistance and in venous return to the heart. With little or no α_2 receptor–blocking effect at concentrations achieved clinically, prazosin probably does not promote the release of NE from sympathetic nerve endings in the heart. In addition, prazosin decreases cardiac preload and thus has little tendency to increase cardiac output and rate, in contrast to vasodilators such as hydralazine that have minimal dilatory effects on veins. Prazosin also may act in the CNS to suppress sympathetic outflow. Prazosin appears to depress baroreflex function in hypertensive patients. Prazosin and related drugs in this class tend to have favorable effects on serum lipids in humans, decreasing low-density lipoproteins (LDL) and triglycerides while increasing concentrations of high-density lipoproteins (HDL).

Prazosin (MINIPRESS, others) is well absorbed after oral administration, with a bioavailability of 50–70% and peak plasma concentrations 1–3 hours after an oral dose. Because prazosin binds avidly α_1 -acid glycoprotein (only 5% of the drug is free), diseases that modify the concentration of this protein (e.g., inflammatory processes) may change the free fraction. Prazosin is extensively metabolized in the liver; the plasma $t_{1/2}$, 2–3 hours, may be prolonged to 6–8 hours in congestive heart failure). In the treatment of hypertension, the duration of action of the drug is 7–10 hours. Therapy is begun with 1 mg given 2–3 times daily, and the dose is increased to achieve target blood pressure. The initial dose should be 1 mg, usually given at bedtime (recumbency reduces the risk of syncopal reactions that may follow the first dose of prazosin). A maximal antihypertensive effect generally is observed with a total daily dose of 20 mg. In treating benign prostatic hyperplasia (BPH), doses from 1 to 5 mg twice daily typically are used. The twice-daily dosing requirement for prazosin is a disadvantage compared with newer α_1 receptor antagonists.

Terazosin

Terazosin (HYTRIN, others), a prazosin congener, is less potent than prazosin but retains high specificity for α_1 receptors; terazosin does not discriminate among α_{1A} , α_{1B} , and α_{1D} receptors. The major distinction between the two drugs is in their pharmacokinetic properties: terazosin is more water soluble, has a higher bioavailability (>90%), a longer $t_{1/2}$ (~12 hours), and a longer duration of action at typical doses (>18 hours). Consequently, the drug may be taken once daily to treat hypertension and BPH in most patients. Terazosin and doxazosin induce apoptosis in prostate smooth muscle cells, an action that may lessen the symptoms associated with chronic BPH. This apoptotic effect apparently relates to the quinazoline moiety rather than α_1 receptor antagonism. An initial dose of 1 mg is recommended. Doses are titrated upward depending on the therapeutic response; 10 mg/day may be required for maximal effect in BPH.

Doxazosin

Doxazosin (CARDURA, others), a structural analog of prazosin, is a highly selective α_1 antagonist, although nonselective among α_1 receptor subtypes. Doxasin has effects similar to those of prazosin but differs pharmacokinetically: long $t_{1/2}$ (~20 hours) and long duration of action (36 hours). Bioavailability and extent of metabolism of doxazosin and prazosin are similar; most doxazosin metabolites are eliminated in the feces. Doxazosin is given initially as a 1-mg dose in the treatment of hypertension or BPH. Similarly to terazosin, doxazosin may have beneficial actions related to apoptosis in the long-term management of BPH.

ALFUZOSIN

Alfuzosin (UROXATRAL), a quinazoline-based, non-subtype-selective α_1 antagonist, has been used extensively in treating BPH (recommended dosage, one 10-mg extended-release tablet daily, after the same meal each day).

TAMSULOSIN

Tamsulosin (FLOMAX), a benzenesulfonamide, is an α_1 receptor antagonist with some selectivity for α_{1A} and α_{1D} subtypes, favoring α_{1A} blockade in prostate. Tamsulosin is efficacious in the treatment of BPH with little effect on blood pressure. The drug is well absorbed, has a $t_{1/2}$ of 5–10 hours, and is extensively metabolized by CYPs. Tamsulosin may be administered at a 0.4-mg starting dose. Abnormal ejaculation is an adverse effect of tamsulosin.

ADVERSE EFFECTS

An adverse effect of prazosin and its congeners is the first-dose effect; marked postural hypotension and syncope may occur 30–90 minutes after the initial dose. The mechanisms responsible for exaggerated hypotensive response and the subsequent development of tolerance to the effect are not clear; an action in the CNS to reduce sympathetic outflow may contribute. Risk of the first-dose phenomenon is minimized by limiting the initial dose (e.g., 1 mg at bedtime), by increasing the dosage slowly, and by introducing additional antihypertensive drugs cautiously. Since orthostatic

hypotension may be a problem during long-term use, standing and recumbent blood pressures should be checked. Nonspecific adverse effects (e.g., headache, dizziness, and asthenia) rarely limit treatment with prazosin. The adverse effects of structural analogs of prazosin are similar to those of prazosin.

THERAPEUTIC USES *Hypertension* Prazosin and its congeners are used in the treatment of hypertension (see Chapter 32).

Congestive Heart Failure

Prazosin provides short-term symptomatic relief in heart failure but is not a drug of choice (see Chapter 33).

Benign Prostatic Hyperplasia (BPH)

The symptoms of BPH (e.g., urethral obstruction leading to weak stream, urinary frequency, and nocturia) result from mechanical pressure on the urethra (due to an increase in smooth muscle mass) and an α_1 -mediated increase in smooth muscle tone in the prostate and neck of the bladder. α_1 receptors in the trigone muscle of the bladder and urethra contribute to the resistance to outflow of urine; prazosin reduces this. The efficacy and importance of α receptor antagonists in the medical treatment of BPH have been demonstrated in multiple controlled clinical trials. Finasteride (PROPECIA) and dutasteride (AVODART), which inhibit conversion of testosterone to dihydrotestosterone (see Chapter 58), can reduce prostate volume in some patients; however, their overall efficacy appears less than that of α_1 receptor antagonists. Selective α_1 receptor antagonists have efficacy in BPH owing to relaxation of smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. Recent studies show that combination therapy with doxazosin and finasteride reduces the risk of overall clinical progression of BPH significantly more than treatment with either drug alone. Prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin have been studied extensively and used widely in patients with BPH. With the exception of tamsulosin, the comparative efficacies of each of these drugs appear similar. Tamsulosin at the recommended dose of 0.4 mg daily is less likely to cause orthostatic hypotension than are the other drugs. The predominant α_1 receptor subtype in the human prostate appears to be α_{1A} .

Other Disorders

Prazosin can decrease the incidence of digital vasospasm in patients with Raynaud's disease; however, its efficacy relative to Ca^{2+} channel blockers is not known. Prazosin may be useful in treating vasospastic disorders, and in patients with mitral or aortic valvular insufficiency (presumably because of afterload reduction).

Additional α Adrenergic Receptor Antagonists

ERGOT ALKALOIDS

For information on ergot alkaloids, see Chapter 11.

INDORAMIN

Indoramin is a competitive α_1 antagonist that also antagonizes agonist effects at H_1 and 5-HT receptors. Via α_1 antagonism, indoramin lowers blood pressure with minimal tachycardia and decreases the incidence of attacks of Raynaud's phenomenon. Indoramin has modest bioavailability (<30%, with considerable variability), with extensive first-pass metabolism and an elimination $t_{1/2}$ ~5 hours; some metabolites may be biologically active. Adverse effects include sedation, dry mouth, and failure of ejaculation. Indoramin is an effective antihypertensive, but has complex pharmacokinetics and lacks a well-defined therapeutic niche. Indoramin is not available in the U.S.

KETANSERIN

Ketanserin, a 5-HT receptor/ α_1 receptor antagonist, is discussed in Chapter 11.

URAPIDIL

Urapidil is a selective α_1 receptor antagonist whose role in the treatment of hypertension remains to be determined. Urapidil is not available in the U.S.

BUNAZOSIN

Bunazosin, a quinazoline α_1 -selective antagonist, lowers blood pressure in patients with hypertension. Bunazosin is not available in the U.S.

YOHIMBINE

Yohimbine (YOCON), a competitive α_2 antagonist, is an indolealkylamine alkaloid found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root; structurally, yohimbine resembles reserpine.

Yohimbine readily enters the CNS, where it acts to increase blood pressure and heart rate; it also enhances motor activity and produces tremors. Yohimbine also is an antagonist of 5-HT. In the past, yohimbine was used to treat male sexual dysfunction, although efficacy never was clearly demonstrated; yohimbine also may be useful for diabetic neuropathy and in the treatment of postural hypotension.

NEUROLEPTIC AGENTS

Chlorpromazine, haloperidol, and other phenothiazine and butyrophenone neuroleptics produce significant blockade of both α and D_2 receptors (see Chapter 18).

β ADRENERGIC RECEPTOR ANTAGONISTS

β Adrenergic receptor *antagonists* inhibit the interaction of NE, Epi, and sympathomimetic drugs with β receptors. Detailed knowledge of autonomic tone, localization of β receptor subtypes, effector-response coupling, and the multiplicity of possible actions of these drugs is essential for understanding their pharmacological effects and therapeutic uses (see Tables 6–1, 6–6, 6–7, 6–8, 10–2, 10–6, and Figure 10–3). Effects of β adrenergic antagonists may be predicted from the consequences of β receptor stimulation (generally equivalent to the effects of elevated cyclic AMP). Effects of β antagonists at a particular site depend on the level of receptor stimulation, or tone, at that site. Effects of antagonists are more prominent when receptor stimulation by agonist is high.

β antagonists can be distinguished by: relative specificity for β_1 over β_2 receptors, intrinsic sympathomimetic activity, capacity to block β receptors, differences in lipid solubility, capacity to induce vasodilation, and pharmacokinetic properties. β Adrenergic antagonists may be classified as Non-Subtype Selective (First Generation), β_1 -Selective (Second Generation), and Antagonists with Additional Cardiovascular Actions (Third Generation). Table 10–4 summarizes pharmacological and pharmacokinetic properties of β receptor antagonists.

Table 10–4

CARDIOVASCULAR SYSTEM The major therapeutic effects of β receptor antagonists are on the cardiovascular system. It is important to distinguish these effects in normal subjects from those in subjects with cardiovascular disease such as hypertension or myocardial ischemia.

Since catecholamines have positive chronotropic and inotropic actions, β antagonists slow the heart rate and decrease myocardial contractility. When tonic stimulation of β receptors is low, this effect is correspondingly modest. However, when the sympathetic nervous system is activated, as during exercise or stress, β receptor antagonists attenuate the expected rise in heart rate. Short-term administration of β receptor antagonists decreases cardiac output; peripheral resistance increases in proportion to maintain blood pressure as a result of blockade of vascular β_2 receptors and compensatory reflexes, such as increased sympathetic nervous system activity, leading to activation of vascular β receptors. With long-term use of β receptor antagonists, total peripheral resistance returns to initial values or decreases in patients with hypertension. With β antagonists that also are β_1 receptor antagonists (e.g., labetalol, carvedilol, bucindolol) or direct vasodilators (celiprolol, nebivolol, nipradilol, carteolol, betaxolol, bopindolol, bevantolol), cardiac output is maintained with a greater fall in peripheral resistance.

β Receptor antagonists have significant effects on cardiac rhythm and automaticity, to which blockade of both β_1 and β_2 receptors likely contributes. β_3 receptors occur in normal myocardial tissue, where they can couple to G_i and inhibit cardiac contraction and relaxation. The physiological role of cardiac β_3 receptors remains to be established. β antagonists reduce sinus rate, decrease the spontaneous rate of depolarization of ectopic pacemakers, slow conduction in the atria and in the AV node, and increase the functional refractory period of the AV node.

ACTIVITY AS ANTIHYPERTENSIVE AGENTS β Receptor antagonists generally do not reduce blood pressure in patients with normal blood pressure but will lower blood pressure in patients with hypertension. Reduction of β_1 -stimulated renin release from the juxtaglomerular cells is a putative contributing mechanism (see Chapter 30).

Since presynaptic β receptors enhance the release of NE from sympathetic neurons, diminished release of NE resulting from β blockade is a possible response, but its relationship to the antihypertensive effects of β antagonists is unclear. Although β blockade would not be expected to decrease the contractility of vascular smooth muscle, long-term administration of these drugs to hypertensive patients ultimately decreases peripheral vascular resistance. The mechanism of this effect is unknown, but the delayed fall in peripheral vascular resistance in the face of a persistently reduced cardiac output appears to account for much of the antihypertensive effect of these drugs. There is relatively little evidence to support a postulated CNS effect of β blockers that contributes to their antihypertensive effects. Indeed, drugs that poorly penetrate the blood-brain barrier are effective antihypertensive agents.

Some β receptor antagonists produce peripheral vasodilation; at least six properties may contribute to this effect, including production of nitric oxide, activation of β_2 receptors, blockade of α_1 receptors, blockade of Ca^{2+} entry, opening of K^+ channels, and antioxidant activity (see Table 10-5 and Figure 10-4). These mechanisms appear to contribute to the antihypertensive effects by enhancing hypotension, increasing peripheral blood flow, and decreasing afterload. Two of these agents (e.g., celiprolol and nebivolol) may produce vasodilation and thereby reduce preload. Nebivolol reportedly activates endothelial β_3 receptors, leading to NO production and dilation of human coronary microvessels.

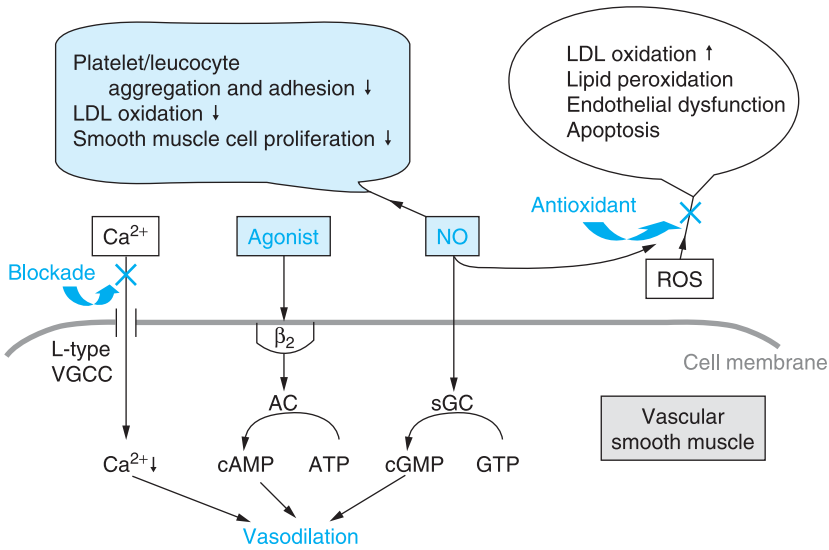

FIGURE 10-4 Mechanisms underlying actions of vasodilating β blockers in blood vessels. ROS, reactive oxygen species; sGC, soluble guanylyl cyclase; AC, adenylyl cyclase; L-type VGCC, L-type voltage-gated Ca^{2+} channel.

Propranolol and other nonselective β receptor antagonists inhibit the vasodilation caused by isoproterenol and augment the pressor response to Epi. This action is significant in patients with pheochromocytoma, in whom β receptor antagonists should be used only after adequate α receptor blockade has been established. This sequence avoids uncompensated α receptor-mediated vasoconstriction caused by catecholamines secreted by the tumor.

PULMONARY SYSTEM Nonselective β receptor antagonists such as propranolol block β_2 receptors in bronchial smooth muscle, with little effect on pulmonary function in normal individuals. In patients with COPD, such blockade can lead to life-threatening bronchoconstriction. Although β_1 -selective antagonists or antagonists with intrinsic sympathomimetic activity are less likely than propranolol to increase airway resistance, these drugs should be used only with great caution, if at all, in patients with bronchospastic diseases. Drugs with β_1 selectivity and β_2 receptor partial agonism (e.g., celiprolol) have potential here, although clinical experience is limited.

METABOLIC EFFECTS Catecholamines promote glycogenolysis and mobilize glucose in response to hypoglycemia. Nonselective β blockers blunt these responses and may delay recovery from hypoglycemia in type 1 (insulin-dependent) diabetes mellitus, but infrequently in type 2 diabetes mellitus. β receptor antagonists can interfere with the counterregulatory effects of catecholamines secreted during hypoglycemia by blunting the perception of symptoms such as tremor, tachycardia, and nervousness. Thus, β adrenergic receptor antagonists should be used with great caution in patients with labile diabetes and frequent hypoglycemic reactions; if a β antagonist must be used, a β_1 -selective antagonist is preferred. In contrast to classical β blockers, which decrease insulin sensitivity, the vasodilating β receptor antagonists increase insulin sensitivity in patients with insulin resistance.

β Receptor antagonists can reduce activation of hormone-sensitive lipase and attenuate the release of free fatty acids from adipose tissue. Nonselective β receptor antagonists consistently reduce HDL cholesterol, increase LDL cholesterol, and increase triglycerides. In contrast, β_1 -selective antagonists improve the serum lipid profile of dyslipidemic patients. Propranolol and atenolol increase triglycerides, whereas chronic celiprolol, carvedilol, and carteolol reduce plasma triglycerides.

OTHER EFFECTS

β Receptor antagonists block catecholamine-induced tremor and inhibit mast-cell degranulation by catecholamines.

NON-SUBTYPE-SELECTIVE β RECEPTOR ANTAGONISTS**Propranolol**

Propranolol interacts with β_1 and β_2 receptors with equal affinity, lacks intrinsic sympathomimetic activity, and does not block α receptors.

ABSORPTION, FATE, AND EXCRETION

Propranolol is highly lipophilic, almost completely absorbed after oral administration, and subject to a prominent first-pass effect (hepatic metabolism during the drug's first passage through the portal circulation), such that only ~25% reaches the systemic circulation. Individual variation in hepatic clearance of propranolol contributes to variability in plasma concentrations (~20 \times) after oral administration. Hepatic extraction of propranolol is saturable, thus the extracted fraction declines as the dose is increased; one hepatic metabolite, 4-hydroxypropranolol, has some β antagonist activity. The bioavailability of propranolol may be increased by the concomitant ingestion of food and during long-term administration of the drug. Propranolol readily enters the CNS. A sustained-release formulation of propranolol (INDERAL LA) maintains therapeutic plasma concentrations over a 24-hour period.

THERAPEUTIC USES

For the treatment of hypertension and angina, the initial oral dose generally is 40–80 mg/day, titrated upward until the desired response is obtained, typically at <320 mg/day. In hypertension, the full antihypertensive effect may not develop for several weeks. If propranolol is taken twice daily for hypertension, blood pressure should be measured just prior to a dose to ensure that the duration of effect is sufficiently prolonged. Adequacy of β adrenergic blockade can be assessed by measuring suppression of exercise-induced tachycardia.

Propranolol also is used to treat various arrhythmias (Chapter 34), myocardial infarction (Chapter 31), congestive heart failure (Chapter 33), pheochromocytoma, and migraine (prophylactically). Propranolol also has been used for several off-label indications including parkinsonian tremors (sustained-release only), akathisia induced by antipsychotic drugs, variceal bleeding in portal hypertension, and generalized anxiety disorder.

Nadolol

Nadolol (CORGARD, others) is a long-acting antagonist with equal affinity for β_1 and β_2 receptors. Its pharmacological and pharmacokinetic properties are summarized in Table 10–4. Nadolol is used in hypertension and angina pectoris. Unlabeled uses have included migraine prophylaxis, parkinsonian tremors, and variceal bleeding in portal hypertension. Nadolol is water soluble and incompletely absorbed from the gut. The drug is largely excreted intact in the urine; thus, nadolol may accumulate in patients with renal failure, in whom dosage should be reduced. With its long $t_{1/2}$, nadolol may be administered once daily.

Timolol

Timolol (BLOCADREN, others) is a potent, non-subtype-selective β receptor antagonist, with properties summarized in Table 10–4. It is used for hypertension, congestive heart failure, migraine prophylaxis, open-angle glaucoma, and intraocular hypertension. Timolol is well absorbed from the GI tract. The drug is subject to first-pass metabolism and is metabolized extensively by hepatic CYP2D6 in the liver. The ophthalmic formulation of timolol (TIMOPTIC, others), used for the treatment of glaucoma, may be extensively absorbed systemically (see Chapter 63), causing adverse effects in susceptible patients (e.g., those with asthma or congestive heart failure).

Pindolol

Pindolol (VISKEN, others) is a non-subtype-selective β receptor antagonist, as described in Table 10–4. Notably, pindolol is a weak partial β agonist; such drugs may be preferred as antihypertensive agents in individuals with diminished cardiac reserve or a propensity for bradycardia.

 β_1 -SELECTIVE ADRENERGIC ANTAGONISTS**Metoprolol**

Metoprolol (LOPRESSOR, others) is a β_1 -selective antagonist lacking intrinsic sympathomimetic activity and membrane-stabilizing activity (see Table 10–4). Despite almost complete GI absorption, metoprolol's bioavailability is relatively low because of first-pass metabolism. Plasma concentrations vary widely, which may relate to genetically determined differences in hepatic CYP2D6 activity. The $t_{1/2}$ of metoprolol (3–4 hours) can double in CYP2D6 poor metabolizers, who have

a 5× higher risk for developing adverse effects compared to normal metabolizers. An extended-release formulation (TOPROL XL) is available for once-daily administration.

For hypertension, the usual initial dose is 100 mg/day, increasing at weekly intervals until optimal reduction of blood pressure is achieved. If the drug is taken only once daily, confirm that blood pressure is controlled for the entire 24-hour period. Metoprolol generally is used in two divided doses for the treatment of stable angina. For the initial treatment of patients with acute myocardial infarction, an intravenous formulation of metoprolol tartrate is available; initiate oral dosing as soon as the clinical situation permits. Metoprolol generally is contraindicated for the treatment of acute MI in patients with heart rates <45 beats/min, heart block greater than first-degree (PR interval ≥ 0.24 second), systolic blood pressure <100 mm Hg, or moderate-to-severe heart failure. Metoprolol is also effective in chronic heart failure (see Chapter 33).

Atenolol

Atenolol (TENORMIN, others) is a β_1 -selective antagonist (see Table 10–4). The drug is excreted largely unchanged in the urine; thus, atenolol accumulates in patients with renal failure, and dosage should be reduced when creatinine clearance is <35 ml/min. The initial dose of atenolol for the treatment of hypertension usually is 50 mg/day, given once daily. The daily dose may be increased to 100 mg; higher doses are unlikely to provide any greater antihypertensive effect. Atenolol has been shown to be efficacious, in combination with a diuretic, in elderly patients with isolated systolic hypertension.

Esmolol

Esmolol (BREVIBLOC, others) is a β_1 -selective antagonist that is administered intravenously when β blockade of short duration is desired or in critically ill patients in whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. The duration of action of esmolol is brief because esterases in erythrocytes rapidly degrade the drug. Onset and cessation of esmolol's β blockade are rapid; peak effects occur within 6–10 minutes of administration of a loading dose, and there is substantial attenuation of β blockade within 20 minutes of stopping an infusion. Because esmolol is used in urgent settings where immediate onset of β blockade is warranted, a partial loading dose typically is administered, followed by a continuous infusion of the drug. If an adequate therapeutic effect is not observed within 5 minutes, the same loading dose is repeated, followed by a maintenance infusion at a higher rate. This process may be repeated until the desired endpoint (e.g., lowered heart rate or blood pressure) is reached.

Acebutolol

Acebutolol (SECTRAL, others) is a selective β_1 adrenergic receptor antagonist. The drug undergoes significant first-pass metabolism to an active metabolite, diacetolol, which accounts for most of the drug's activity. The elimination $t_{1/2}$ of acebutolol is ~3 hours, that of diacetolol, 8–12 hours. The initial dose of acebutolol in hypertension usually is 400 mg/day, given as a single dose or as two divided doses, as required to control blood pressure. Optimal responses usually occur with doses of 400–800 mg/day. For treatment of ventricular arrhythmias, acebutolol should be given twice daily.

Bisoprolol

Bisoprolol (ZEBETA) is a highly selective β_1 receptor antagonist that is approved for the treatment of hypertension. Bisoprolol can be considered a standard treatment option when selecting a β blocker for use in combination with ACE inhibitors and diuretics in patients with stable, moderate-to-severe chronic heart failure (in whom it lowers all-case mortality; see Chapter 33) and in treating hypertension. Bisoprolol generally is well-tolerated; side effects include dizziness, bradycardia, hypotension, and fatigue.

β Antagonists with Additional Cardiovascular Effects (Third Generation β Blockers)

Some β adrenergic antagonists have additional vasodilating actions that are produced through a variety of mechanisms summarized in Table 10–5 and Figure 10–4.

Labetalol

Labetalol (NORMODYNE, TRANDATE, others) is a competitive antagonist at both α_1 and β receptors. The pharmacological properties of labetalol are complex, because each of four isomers displays

different relative activities. The properties of the racemic mixture include selective blockade of α_1 receptors (as compared with the α_2 subtype), blockade of β_1 and β_2 receptors, partial agonist activity at β_2 receptors, and inhibition of neuronal uptake of NE (cocaine-like effect). The potency of the mixture for β receptor blockade is 5–10 \times that for α_1 receptor blockade. Actions of labetalol on both α_1 and β -receptors contribute to the fall in blood pressure observed in patients with hypertension. β_1 receptor blockade leads to relaxation of arterial smooth muscle and vasodilation, particularly in the upright position. β_1 Blockade contributes to a fall in blood pressure, in part by blocking reflex sympathetic stimulation of the heart. In addition, intrinsic sympathomimetic activity of labetalol at β_2 receptors may contribute to vasodilation.

Although labetalol is completely absorbed from the gut, there is extensive first-pass clearance; bioavailability may be increased by food intake. The rate of hepatic metabolism of labetalol is sensitive to changes in hepatic blood flow. The various isomers have different elimination kinetics.

Two forms are available, an oral form for therapy of chronic hypertension, and an intravenous formulation for hypertensive emergencies. Labetalol has been associated with hepatic injury in a limited number of patients.

Carvedilol

Carvedilol (COREG) blocks β_1 , β_2 , and α_1 receptors and also has myriad additional cardiovascular effects (see Tables 10–4 and 10–5). Carvedilol produces vasodilation; its antioxidant and antiproliferative effects may be beneficial in treating congestive heart failure. Carvedilol improves ventricular function and reduces mortality and morbidity in patients with mild-to-severe congestive heart failure. Combined with conventional therapy, carvedilol reduces mortality in myocardial infarction. There are no significant changes in the pharmacokinetics of carvedilol in elderly hypertensives. Since the drug is metabolized by hepatic CYPs, no change in dosage is needed in patients with moderate-to-severe renal insufficiency.

Bucindolol

Bucindolol (SANDONORM) is a third-generation non-selective β antagonist with some α_1 receptor blocking as well as β_2 and β_3 agonistic properties. Bucindolol reduces afterload and increases plasma HDL cholesterol, but does not affect plasma triglycerides. In contrast to other β receptor antagonists studied in multicenter trials, bucindolol was not associated with improved survival. Bucindolol is not available in the U.S.

Celiprolol

Celiprolol (SELECTOR) is a third-generation cardioselective, β receptor antagonist with weak vasodilating and bronchodilating effects attributed to partial β_2 agonist activity. It may block peripheral α_2 -adrenergic receptors and promote NO production (see Tables 10–4 and 10–5). Celiprolol is safe and effective for hypertension and angina.

Nebivolol

Nebivolol is a racemate: the *d*-isomer is a highly selective β_1 antagonist; the *l*-isomer enhances NO production, possibly via activation of endothelial β_3 receptors. Nebivolol has a distinct hemodynamic profile: it acutely lowers arterial blood pressure without depressing left ventricular function, and reduces systemic vascular resistance. Nebivolol is devoid of intrinsic sympathomimetic activity, inverse agonistic activity, and α_1 receptor-blocking properties. It is effective in treating hypertension and diastolic heart failure. A New Drug Application has been submitted to the FDA for neбиволol's use in hypertension.

Other β Receptor Antagonists

Other β antagonists have been evaluated to varying extents. Oxprenolol (no longer marketed in the U.S.) and penbutolol (LEVATOL) are non-subtype-selective β blockers with intrinsic sympathomimetic activity. Medroxalol is a nonselective β blocker with α_1 receptor-blocking activity. Levobunolol (BETAGAN LIQUIFILM, others) is a non-subtype-selective β antagonist used topically in the treatment of glaucoma. Betaxolol (BETOPTIC), a β_1 -selective antagonist, is available as an ophthalmic preparation for glaucoma and an oral formulation for systemic hypertension. Betaxolol may be less likely to induce bronchospasm than are the ophthalmic preparations of the nonselective β blockers timolol and levobunolol. Similarly, ocular administration of carteolol (OCUPRESS) may be less likely than timolol to have systemic effects. Sotalol (BETAPACE, BETAPACE AF, others) is a nonselective β antagonist that has antiarrhythmic actions independent of its ability to block β adrenergic receptors (see Chapter 34).

Propafenone (*RHYTHMOL*), a Na^+ -channel blocking drug, is also a β receptor antagonist (see Chapter 34).

ADVERSE EFFECTS AND PRECAUTIONS

The most common adverse effects of β receptor antagonists arise as pharmacological consequences of blockade of β receptors; serious adverse effects unrelated to β receptor blockade are rare.

CARDIOVASCULAR SYSTEM β receptor blockade may cause or exacerbate heart failure in patients with compensated heart failure, acute myocardial infarction, or cardiomegaly. Nonetheless, chronic administration of β receptor antagonists is efficacious in prolonging life in the therapy of heart failure in selected patients (see below and Chapter 33). The bradycardia caused by β antagonists may cause life-threatening bradyarrhythmias in patients with partial or complete AV conduction defects. Particular caution is indicated in patients who are taking other drugs, such as *verapamil* or various antiarrhythmic agents, which may impair sinus-node function or AV conduction.

Some patients complain of cold extremities while taking β blockers. Symptoms of peripheral vascular disease may worsen (this is uncommon), or Raynaud's phenomenon may develop.

After prolonged β blockade, there is enhanced sensitivity to β adrenergic stimulation when the β blocker is withdrawn abruptly, possibly related to upregulation of β receptors during β blockade. Thus, abrupt discontinuation of β receptor antagonists after long-term treatment can exacerbate angina and may increase the risk of sudden death. Optimal strategies for discontinuation of β blockers are not known, but it is prudent to decrease the dose gradually (over several weeks) and to restrict exercise during this period.

PULMONARY FUNCTION A major adverse effect of β receptor antagonists is the bronchoconstriction resulting from blockade of β_2 receptors in bronchial smooth muscle. β Blockers may cause a life-threatening increase in airway resistance in patients with bronchospastic disease. β_1 -selective antagonists or those with intrinsic sympathomimetic activity at β_2 adrenergic receptors may be somewhat less likely to induce bronchospasm; however, the selectivity of current β_1 blockers is modest, and these drugs should be avoided if possible in patients with asthma.

CNS CNS-related adverse effects may include fatigue, sleep disturbances (including insomnia and nightmares), and depression. There is no clear correlation between the incidence of the adverse effects of β receptor antagonists and their lipophilicity.

METABOLISM β adrenergic blockade may blunt recognition of hypoglycemia and may delay recovery from insulin-induced hypoglycemia. β receptor antagonists should be used with caution in diabetic patients who are prone to hypoglycemic reactions; β_1 -selective agents may be preferable.

MISCELLANEOUS

Despite anecdotal evidence, the incidence of sexual dysfunction in hypertensive males treated with β receptor antagonists is not clearly defined. Information about the safety of β antagonists during pregnancy still is limited.

OVERDOSAGE

Manifestations of poisoning with β receptor antagonists depend on the pharmacological properties of the ingested drug. Hypotension, bradycardia, prolonged AV conduction times, and widened QRS complexes are common manifestations. Seizures and depression may occur. Hypoglycemia is rare, and bronchospasm is uncommon in the absence of pulmonary disease. Significant bradycardia should be treated with atropine, but a cardiac pacemaker often is required. Large doses of isoproterenol or an α receptor agonist may be necessary to treat hypotension.

DRUG INTERACTIONS

Aluminum salts, cholestyramine, and colestipol may decrease absorption of β blockers. Phenytoin, rifampin, and phenobarbital, as well as smoking, induce hepatic biotransformation enzymes and may decrease plasma concentrations of β receptor antagonists that are metabolized extensively (e.g., propranolol). Cimetidine and hydralazine may increase bioavailability of propranolol and metoprolol by affecting hepatic blood flow. β Receptor antagonists can impair the clearance of lidocaine.

Other drug interactions have pharmacodynamic explanations. For example, β antagonists and Ca^{2+} channel blockers have additive effects on the cardiac conducting system. Additive effects on blood pressure between β blockers and other antihypertensive agents often are employed to

clinical advantage. The antihypertensive effects of β receptor antagonists can be opposed by indomethacin and other NSAIDs (see Chapter 26).

THERAPEUTIC USES

Cardiovascular Diseases

β Receptor antagonists are used extensively in the treatment of hypertension (see Chapter 32), angina and acute coronary syndromes (see Chapter 31), and congestive heart failure (see Chapter 33). These drugs also are used frequently in the treatment of supraventricular and ventricular arrhythmias (see Chapter 34).

MYOCARDIAL INFARCTION

β Receptor antagonists lacking intrinsic sympathomimetic activity, administered during the early phases of acute myocardial infarction and continued long-term, may decrease mortality by ~25%.

CONGESTIVE HEART FAILURE The reflex sympathetic responses to heart failure may stress the failing heart and exacerbate the progression of the disease, and blocking those responses is beneficial (see Chapter 33). β Receptor antagonists are highly effective treatment for all grades of heart failure secondary to left ventricular systolic dysfunction. The drugs improve myocardial function and the quality of life, and prolong life. Thus, β blockers have moved from being contraindicated to being the standard of care in many settings of heart failure.

USE OF β ANTAGONISTS IN OTHER CARDIOVASCULAR DISEASES

β Receptor antagonists, particularly propranolol, are used in the treatment of hypertrophic obstructive cardiomyopathy, for relieving angina, palpitations, and syncope. β Blockers also may attenuate catecholamine-induced cardiomyopathy in pheochromocytoma.

β Blockers are used frequently in the medical management of acute dissecting aortic aneurysm; their usefulness comes from reduction in the force of myocardial contraction and in dP/dt . Patients with Marfan's syndrome may develop progressive dilation of the aorta, which may lead to aortic dissection and regurgitation, a major cause of death in these patients; chronic treatment with propranolol may slow the progression of aortic dilation and its complications.

Glaucoma

β Receptor antagonists are very useful in the treatment of chronic open-angle glaucoma. Six drugs currently are available: carteolol (OCUPRESS, others), betaxolol (BETAOPTIC, others), levobunolol (BETAGAN, others), *metipranolol* (OPTIPRANOLOL, others), timolol (TIMOPTIC, others), and *levobetaxolol* (BETAXON). Timolol, levobunolol, carteolol, and metipranolol are nonselective; betaxolol and levobetaxolol are β_1 selective; none has significant membrane-stabilizing or intrinsic sympathomimetic activity. Topically administered β blockers have little or no effect on pupil size or accommodation and are devoid of blurred vision and night blindness often seen with miotics. These agents decrease the production of aqueous humor, which appears to be the mechanism for their clinical effectiveness. For details of the treatment of glaucoma, see Chapter 63.

Other Uses

β Receptor antagonists control many of the cardiovascular signs and symptoms of hyperthyroidism and are useful adjuvants to more definitive therapy. Propranolol, timolol, and metoprolol are effective for the prophylaxis of migraine; the mechanism of this effect is not known; these drugs are not useful for treating acute migraine attacks. By reducing signs of increased sympathetic activity (tachycardia, muscle tremors, etc.), propranolol and other β blockers are effective in controlling acute panic symptoms in individuals who are required to perform in public or in other anxiety-provoking situations. Propranolol also may be useful in the treatment of essential tremor.

β Blockers may be of some value in the treatment of patients undergoing withdrawal from alcohol or those with akathisia. Propranolol and nadolol are efficacious in the primary prevention of variceal bleeding in patients with portal hypertension caused by hepatic cirrhosis.

5-HYDROXYTRYPTAMINE (SEROTONIN)

5-Hydroxytryptamine (5-HT, serotonin, 3-[β -aminoethyl]-5-hydroxyindole) is widely distributed, occurring in vertebrates, tunicates, mollusks, arthropods, coelenterates, fruits, and nuts. In humans, 5-HT is found in enterochromaffin cells throughout the gastrointestinal (GI) tract, in storage granules in platelets, and broadly throughout the central nervous system (CNS). 5-HT is also present in venoms (e.g., those of the common stinging nettle, wasps, and scorpions).

SYNTHESIS AND METABOLISM

5-HT is synthesized by a two-step pathway from tryptophan (Figure 11-1), which is actively transported into the brain by a carrier protein that also transports other large neutral and branched-chain amino acids. Tryptophan hydroxylase, a mixed-function oxidase that requires O_2 and a reduced pteridine cofactor, is the rate-limiting enzyme in the synthetic pathway. Unlike tyrosine hydroxylase, tryptophan hydroxylase is not regulated by end-product inhibition, although regulation by phosphorylation is common to both enzymes. Brain tryptophan hydroxylase is not generally saturated with substrate; consequently the concentration of tryptophan in the brain influences the synthesis of 5-HT.

The enzyme that converts L-5-hydroxytryptophan to 5-HT, aromatic L-amino acid decarboxylase, is the same enzyme that decarboxylates L-dopa in catecholamine synthesis (see Chapter 6). 5-HT is stored in secretory granules by a vesicular transporter and released by exocytosis. The action of released 5-HT is terminated by neuronal uptake mediated by a specific 5-HT transporter localized in the membrane of serotonergic axon terminals (where it terminates the action of 5-HT in the synapse) and in the membrane of platelets (where it takes up 5-HT from the blood). This uptake system is the only way that platelets acquire 5-HT (they lack the enzymes required to synthesize 5-HT). The 5-HT transporter, SERT, has been cloned (see Chapters 2 and 12).

The principal route of metabolism of 5-HT involves oxidative deamination by MAO, with subsequent conversion of the aldehyde to 5-hydroxyindole acetic acid (5-HIAA) by an aldehyde dehydrogenase (Figure 11-1). Reduction of the acetaldehyde to an alcohol, 5-hydroxytryptophol, is normally insignificant. 5-HIAA is actively transported out of the brain by a process that is sensitive to probenecid. Since 5-HIAA formation accounts for nearly 100% of the metabolism of 5-HT in brain, the turnover rate of brain 5-HT is estimated by measuring the rate of rise of 5-HIAA after administration of probenecid. 5-HIAA from brain and peripheral sites of 5-HT storage and metabolism is excreted in the urine (range of urinary excretion of 5-HIAA by a normal adult, 2–10 mg/day). Larger amounts are excreted by patients with carcinoid syndrome, providing a reliable diagnostic test for the disease. Ingestion of ethyl alcohol results in elevated amounts of nicotinamide adenine dinucleotide (NADH), which diverts 5-hydroxyindole acetaldehyde from the oxidative route to the reductive pathway, increasing excretion of 5-hydroxytryptophol and reducing excretion of 5-HIAA. MAO-A preferentially metabolizes 5-HT and NE. Neurons contain both isoforms of monoamine oxidase (MAO-A and MAO-B); MAO-B is the principal isoform in platelets.

A close relative of 5-HT, melatonin (5-methoxy-N-acetyltryptamine), is formed by sequential N-acetylation and O-methylation (Figure 11-1). Melatonin is the principal indoleamine in the pineal gland, where it may be said to constitute a pigment of the imagination. External factors including environmental light control melatonin synthesis. Melatonin induces pigment lightening in skin cells and suppresses ovarian functions; it also serves a role in regulating biological rhythms and shows promise in the treatment of jet lag and other sleep disturbances.

PHYSIOLOGICAL FUNCTIONS OF SEROTONIN

Multiple 5-HT Receptors

The multiple 5-HT receptor subtypes comprise the largest known neurotransmitter-receptor family. 5-HT receptor subtypes are expressed in distinct but often overlapping patterns and couple to different transmembrane-signaling mechanisms (Table 11-1). Four 5-HT receptor families are recognized: 5-HT₁ through 5-HT₄. The 5-HT₁, 5-HT₂, and 5-HT₄₋₇ receptor families are members of the superfamily of GPCRs (see Chapter 1). The 5-HT₃ receptor, on the other hand, is a ligand-gated ion channel that gates Na^+ and K^+ and has a predicted membrane topology akin to that of the nicotinic cholinergic receptor (see Chapter 9).

5-HT₁ RECEPTORS All 5 members of the 5-HT₁ receptor subfamily inhibit adenylyl cyclase. At least one 5-HT₁ receptor subtype, the 5-HT_{1A} receptor, also activates a receptor-operated K^+ channel and inhibits a voltage-gated Ca^{2+} channel, a common property of receptors coupled to

the pertussis toxin-sensitive G_i/G_o family of G proteins. The 5-HT_{1A} receptor is found in the raphe nuclei of the brainstem, where it functions as an inhibitory, somatodendritic autoreceptor on cell bodies of serotonergic neurons (Figure 11-2). Another subtype, the 5-HT_{1D} receptor, functions as an autoreceptor on axon terminals, inhibiting 5-HT release. 5-HT_{1D} receptors, abundantly expressed in the substantia nigra and basal ganglia, may regulate the firing rate of dopamine (DA)-containing cells and the release of DA at axonal terminals.

5-HT₂ RECEPTORS The three subtypes of 5-HT₂ receptors couple to pertussis toxin-insensitive G proteins (*e.g.*, G_q and G₁₁) and thence to PLC to generate *diacylglycerol* (a cofactor in the activation of PKC) and *inositol trisphosphate* (which mobilizes intracellular stores of Ca²⁺). 5-HT_{2A} receptors are broadly distributed in the CNS, primarily in serotonergic terminal areas. High densities of 5-HT_{2A} receptors are found in prefrontal, parietal, and somatosensory cortex, claustrum, and in platelets. 5-HT_{2A} receptors in the GI tract are thought to correspond to the D subtype of 5-HT receptor. 5-HT_{2B} receptors originally were described in stomach fundus. The expression of 5-HT_{2B} receptor messenger RNA (mRNA) is highly restricted in the CNS. 5-HT_{2C} receptors have a very high density in the choroid plexus, an epithelial tissue that is the primary site of cerebrospinal fluid production. The 5-HT_{2C} receptor has been implicated in feeding behavior and susceptibility to seizure.

5-HT₃ RECEPTORS The 5-HT₃ receptor is the only monoamine neurotransmitter receptor that is known to function as a ligand-operated ion channel. The 5-HT₃ receptor corresponds to the originally described M receptor. Activation of 5-HT₃ receptors elicits a rapidly desensitizing depolarization, mediated by the gating of cations. These receptors are located on parasympathetic terminals in the GI tract, including vagal and splanchnic afferents. In the CNS, a high density of 5-HT₃ receptors is found in the solitary tract nucleus and the area postrema. 5-HT₃ receptors in both the GI tract and the CNS participate in the emetic response, providing an anatomical basis for the antiemetic property of 5-HT₃ receptor antagonists.

5-HT₄ RECEPTORS 5-HT₄ receptors are widely distributed throughout the body. In the CNS, the receptors are found on neurons of the superior and inferior colliculi and in the hippocampus. In the GI tract, 5-HT₄ receptors are located on neurons of the myenteric plexus and on smooth muscle and secretory cells. The 5-HT₄ receptor is thought to evoke secretion in the alimentary tract and to facilitate the peristaltic reflex. 5-HT₄ receptors couple to G_s to activate adenylyl cyclase, leading to a rise in intracellular levels of cyclic AMP, possibly accounting for the utility of prokinetic benzamides in GI disorders (*see* Chapter 37).

ADDITIONAL CLONED 5-HT RECEPTORS

Two other cloned receptors, 5-HT₆ and 5-HT₇, are linked to activation of adenylyl cyclase. Multiple splice variants of the 5-HT₇ receptor have been found, although functional distinctions are not clear. Circumstantial evidence suggests that 5-HT₇ receptors play a role in smooth-muscle relaxation in the GI tract and the vasculature. The atypical antipsychotic drug clozapine has a high

affinity for 5-HT₆ and 5-HT₇ receptors, but whether this relates to the broader effectiveness of clozapine as an antipsychotic is not known (see Chapter 18). Two subtypes of the 5-HT₃ receptor have been cloned; the 5-HT_{3A} receptor couples to inhibit adenylyl cyclase; functional coupling of the cloned 5-HT_{3B} receptor has not been described.

Sites of 5-HT Action

ENTEROCHROMAFFIN CELLS AND GASTROINTESTINAL TRACT

Enterochromaffin cells of the GI mucosa (highest density in the duodenum) synthesize and store 5-HT and other autacoids. Basal release of enteric 5-HT is augmented by mechanical stretching and efferent vagal stimulation. 5-HT probably has an additional role in stimulating motility via the myenteric network of neurons (see Chapters 6 and 37). 5-HT released from enterochromaffin cells enters the portal vein and is subsequently metabolized by MAO-A in the liver. 5-HT that survives hepatic oxidation is rapidly removed by the endothelium of lung capillaries and then inactivated by MAO. 5-HT released by mechanical or vagal stimulation also acts locally to regulate GI function. Motility of gastric and intestinal smooth muscle may be either enhanced or inhibited via at least six subtypes of 5-HT receptors (Table 11–2). Abundant 5-HT₃ receptors on vagal and other afferent neurons and on enterochromaffin cells play a pivotal role in emesis (see Chapter 37). Enteric 5-HT is released in response to ACh, sympathetic nerve stimulation, increases in intraluminal pressure, and lowered pH, triggering peristaltic contraction.

PLATELETS

Platelets differ from other formed elements of blood in expressing mechanisms for uptake, storage, and endocytotic release of 5-HT. 5-HT is not synthesized in platelets, but is taken up from the circulation and stored in secretory granules by active transport, similar to the uptake and storage of NE by sympathetic nerve terminals (see Chapters 6 and 12). Measuring the rate of Na⁺-dependent 5-HT uptake by platelets provides a sensitive assay for 5-HT-uptake inhibitors.

A complex local interplay of multiple factors, including 5-HT, regulates thrombosis and hemostasis (see Chapters 25 and 54). When platelets contact injured endothelium, they release substances that promote platelet aggregation, and secondarily, they release 5-HT (Figure 11–3). 5-HT binds to platelet 5-HT_{2A} receptors and elicits a weak aggregation response that is markedly augmented by the presence of collagen. If the damaged blood vessel is injured to a depth where vascular smooth muscle is exposed, 5-HT exerts a direct vasoconstrictor effect, thereby contributing to hemostasis, which is enhanced by locally released autacoids (thromboxane A₂, kinins, and vasoactive peptides). Conversely, 5-HT may stimulate production of NO and antagonize its own vasoconstrictor action, as well as the vasoconstriction produced by other locally released agents.

CARDIOVASCULAR SYSTEM

The classical response of blood vessels to 5-HT is contraction, particularly in the splanchnic, renal, pulmonary, and cerebral vasculatures. This response also occurs in bronchial smooth muscle. 5-HT induces a variety of cardiac responses that result from activation of multiple 5-HT receptor subtypes, stimulation or inhibition of autonomic nerve activity, and reflex responses to 5-HT. Thus, 5-HT has positive inotropic and chronotropic actions on the heart that may be blunted by simultaneous stimulation of afferent nerves from baroreceptors and chemoreceptors. An effect

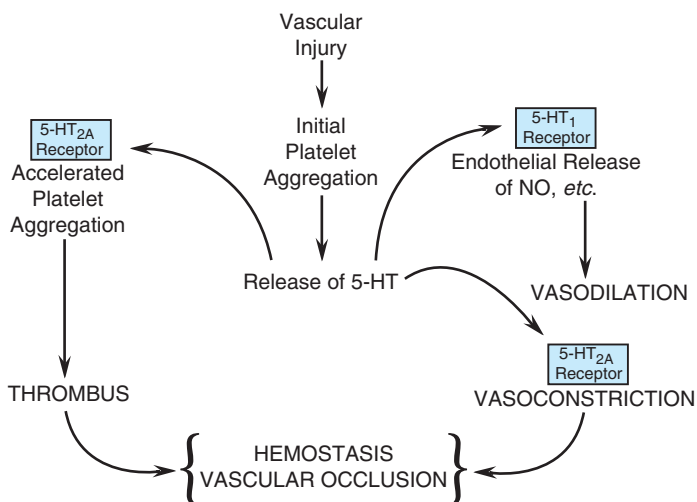

FIGURE 11-3 Local influences of platelet 5-HT. Aggregation triggers the release of 5-HT stored in platelets. Local actions of 5-HT include feedback actions on platelets (shape change and accelerated aggregation) mediated by 5-HT_{2A} receptors, stimulation of NO production mediated by 5-HT₁-like receptors on vascular endothelium, and contraction of vascular smooth muscle mediated by 5-HT_{2A} receptors. These influences act in concert with many other mediators (not shown) to promote thrombus formation and hemostasis. See Chapter 54 for details of adhesion and aggregation of platelets and factors contributing to thrombus formation and blood clotting.

on vagus nerve endings elicits the Bezold-Jarisch reflex, causing bradycardia and hypotension. The local response of arterial blood vessels to 5-HT also may be inhibitory, the result of stimulated NO and prostaglandin synthesis and blockade of NE release from sympathetic nerves. On the other hand, 5-HT amplifies the local constrictor actions of NE, AngII, and histamine, which reinforce the hemostatic response to 5-HT.

CENTRAL NERVOUS SYSTEM

A multitude of brain functions are influenced by 5-HT, including sleep, cognition, sensory perception, motor activity, temperature regulation, nociception, mood, appetite, sexual behavior, and hormone secretion. All of the cloned 5-HT receptors are expressed in the brain, often in overlapping domains. The principal cell bodies of 5-HT neurons are located in raphe nuclei of the brainstem and project throughout the brain and spinal cord. In addition to being released at discrete synapses, release of serotonin also seems to occur at sites of axonal swelling, termed varicosities, which do not form distinct synaptic contacts. 5-HT released at nonsynaptic varicosities is thought to diffuse to outlying targets, rather than acting on discrete synaptic targets, perhaps acting as a neuromodulator as well as a neurotransmitter (see Chapter 12). Serotonergic nerve terminals contain all of the proteins needed to synthesize 5-HT from L-tryptophan (Figure 11-1). Newly formed 5-HT is rapidly accumulated in synaptic vesicles, where it is protected from MAO. 5-HT released by nerve-impulse flow is reaccumulated into the presynaptic terminal by the 5-HT transporter, SERT (see Chapter 2); thus, reuptake terminates the neurotransmitter action of 5-HT. 5-HT taken up by nonneuronal cells is destroyed by MAO. 5-HT has direct excitatory and inhibitory actions (Table 11-3), which may occur in the same preparation, but with distinct temporal patterns.

Behavior

Sleep-Wake Cycle

5-HT plays a role in control of the sleep-wake cycle. Depletion of 5-HT elicits insomnia that is reversed by the 5-HT precursor, 5-hydroxytryptophan; treatment with L-tryptophan or nonselective 5-HT agonists accelerates sleep onset and prolongs total sleep time. 5-HT antagonists reportedly can increase and decrease slow-wave sleep, probably reflecting interacting or opposing roles for subtypes of 5-HT receptors. One relatively consistent finding in humans and in laboratory animals is an increase in slow-wave sleep following administration of a selective 5-HT_{2A/2C} receptor antagonist such as ritanserin.

Table 11-3

Electrophysiological Effects of 5-HT Receptors

Subtype	Response
5-HT _{1A,B}	Increase K ⁺ conductance; hyperpolarization
5-HT _{2A}	Decrease K ⁺ conductance; slow depolarization
5-HT ₃	Gating of Na ⁺ , K ⁺ ; fast depolarization
5-HT ₄	Decrease K ⁺ conductance; slow depolarization

Aggression and Impulsivity

Studies in laboratory animals and in human beings suggest that 5-HT serves a critical role in aggression and impulsivity. Low 5-HIAA is associated with violent suicidal acts, but not with suicidal ideation per se. Knockout mice lacking the 5-HT_{1B} receptor exhibit extreme aggression, suggesting either a role for 5-HT_{1B} receptors in the development of neuronal pathways important in aggression or a direct role in the mediation of aggressive behavior. A human genetic study identified a point mutation in the gene encoding MAO-A, which was associated with extreme aggressiveness and mental retardation. Laboratory genetic studies add credence to the proposition that abnormalities in 5-HT are related to aggressive behaviors.

Anxiety and Depression

A mechanism for altering synaptic availability of 5-HT is inhibition of presynaptic reaccumulation of neuronally released 5-HT. Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine [PROZAC]) potentiate and prolong the action of 5-HT released by neuronal activity. Effects of 5-HT-active drugs, like the SSRIs, in anxiety and depressive disorders strongly suggest an effect of 5-HT in the neurochemical mediation of these disorders. SSRIs are the most widely used treatment for endogenous depression (see Chapter 17).

Appetite

Two halogenated amphetamines, fenfluramine and dexfenfluramine, have been used to reduce appetite; these drugs were withdrawn from the U.S. market after reports of cardiac toxicity associated with their use. The mechanism of action of this class of drugs is controversial. A profound reduction in levels of 5-HT in the brain lasts for weeks and is accompanied by a loss of proteins (5-HT transporter and tryptophan hydroxylase) selectively localized in 5-HT neurons, suggesting that the halogenated amphetamines have a neurotoxic action, although neuroanatomical signs of neuronal death are not readily apparent.

Sibutramine (MERIDIA), an inhibitor of the reuptake of 5-HT, NE, and DA, is used as an appetite suppressant in the management of obesity; two active metabolites probably account for sibutramine's therapeutic effects. Whether effects on a single neurotransmitter system are primarily responsible for sibutramine's effects in obese patients is unclear.

5-HT RECEPTOR AGONISTS AND ANTAGONISTS**5-HT Receptor Agonists**

Direct-acting 5-HT receptor agonists have diverse chemical structures and diverse pharmacological properties (Table 11-4), not surprising considering the plethora of 5-HT receptor subtypes. 5-HT_{1A} receptor-selective agonists have helped elucidate the functions of this receptor in the brain and have resulted in a new class of antianxiety drugs including buspirone, gepirone, and ipsapirone (see Chapter 17). 5-HT_{1D} receptor-selective agonists (e.g., sumatriptan) cause constriction of intracranial blood vessels and are used for treatment of acute migraine attacks (see below). A number of 5-HT₄ receptor-selective agonists have been developed or are being developed for the treatment of disorders of the GI tract (see Chapter 37).

5-HT RECEPTOR AGONISTS AND MIGRAINE Migraine headaches afflict 10–20% of the population in the U.S., producing a morbidity estimated at 64 million missed workdays/year. Although migraine is a specific neurological syndrome, manifestations vary widely: migraine without aura (common migraine); migraine with aura (classic migraine), which includes subclasses of migraine with typical aura, migraine with prolonged aura, migraine without headache, and migraine

Table 11–4

Serotonergic Drugs: Primary Actions and Clinical Uses

Receptor	Action	Drug Examples	Clinical Disorder

5-HT _{1D}	Agonist	Sumatriptan	Migraine
5-HT _{2A/2C}	Antagonist	Methysergide, trazodone, risperidone, ketanserin	Migraine, depression, schizophrenia
5-HT ₃	Antagonist	Ondansetron	Chemotherapy-induced emesis
5-HT ₄	Agonist	Cisapride, mosapride, renzapride	GI disorders
5-HT transporter	Inhibitor	Fluoxetine, sertraline	Depression; panic, obsessive-compulsive, and posttraumatic stress disorders; social phobia

with acute-onset aura; and several other rarer types. Auroras also may appear without a subsequent headache. Premonitory aura may begin as long as 24 hours before the onset of pain and often is accompanied by photophobia, hyperacusis, polyuria, and diarrhea, and by disturbances of mood and appetite. A migraine attack may last for hours or days and be followed by prolonged pain-free intervals. The frequency of migraine attacks is extremely variable, but usually ranges from 1–2/year to 1–4/month.

Therapy of migraine headaches is complicated by the variable responses among and within individual patients and by the lack of a firm understanding of the pathophysiology of the syndrome. The efficacy of antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and as yet undefined environmental and genetic factors. A rather vague and inconsistent pathophysiological characteristic of migraine is the spreading depression of neural impulses from a focal point of vasoconstriction followed by vasodilation. However, it is unlikely that vasoconstriction followed by vasodilation (spreading depression) or vasodilation alone accounts for the local edema and focal tenderness often observed in migraine patients.

Consistent with the hypothesis that 5-HT is a key mediator in the pathogenesis of migraine, 5-HT receptor agonists have become the mainstay for acute treatment of migraine headaches. New treatments for the prevention of migraines, such as botulinum toxin and newer antiepileptic drugs, have unique mechanisms of action, presumably unrelated to 5-HT.

5-HT₁ Receptor Agonists: The Triptans

The triptans are indole derivatives, with substituents on the 3 and 5 positions (Figure 11–4). The selective pharmacological effects of the triptans (sumatriptan [IMITREX], zolmitriptan [ZOMIG], naratriptan [AMERGE], and rizatriptan [MAXALT and MAXALT-MLT]) at 5-HT₁ receptors have provided

FIGURE 11–4 Structures of the triptans (selective 5-HT₁ receptor agonists).

insights into the pathophysiology of migraine. Clinically, the drugs are effective, acute antimigraine agents. Their capacity to decrease the nausea and vomiting of migraine is an important advance in the treatment of the condition.

Pharmacological Properties In contrast to ergot alkaloids (*see below*), the pharmacological effects of the triptans appear to be limited to the 5-HT₁ family of receptors, providing evidence that this receptor subclass plays an important role in the acute relief of a migraine attack. The triptans are much more selective agents than are ergot alkaloids, interacting potently with 5-HT_{1B} and 5-HT_{1D} receptors, with low or no affinity for other subtypes of 5-HT receptors or for α_1 and α_2 adrenergic, β adrenergic, dopaminergic, muscarinic cholinergic, and GABA_A receptors. Clinically effective doses of the triptans correlate well with their affinities for 5-HT_{1B} and 5-HT_{1D} receptors. Current data are thus consistent with the hypothesis that 5-HT_{1B} and/or 5-HT_{1D} receptors are the most likely 5-HT receptors involved in the mechanism of action of acute antimigraine drugs.

Mechanism of Action

Two hypotheses have been proposed to explain the efficacy of 5-HT_{1B/1D} receptor agonists in migraine. According to one pathophysiological model of migraine, unknown events lead to the abnormal dilation of carotid arteriovenous anastomoses in the head, diverting blood from the capillary beds and thereby producing cerebral ischemia and hypoxia. In this model, an effective antimigraine agent constricts intracranial blood vessels, including arteriovenous anastomoses, and restores blood flow to the brain. Indeed, ergotamine, dihydroergotamine, and sumatriptan share the capacity to produce this vascular effect with a pharmacological specificity that mirrors the effects of these agents on 5-HT_{1B} and 5-HT_{1D} receptor subtypes.

An alternative hypothesis relates to the observation that both 5-HT_{1B} and 5-HT_{1D} receptors serve as presynaptic autoreceptors, modulating neurotransmitter release from neuronal terminals (Figure 11–2). 5-HT₁ agonists may block the release of proinflammatory neuropeptides at the level of the nerve terminal in the perivascular space. Ergotamine, dihydroergotamine, and sumatriptan can block the development of neurogenic plasma extravasation in dura mater associated with depolarization of perivascular axons following capsaicin injection or unilateral electrical stimulation of the trigeminal nerve. The capacity of potent 5-HT₁ receptor agonists to inhibit endogenous neurotransmitter release in the perivascular space could account for their efficacy in the acute treatment of migraine.

Absorption, Fate, and Excretion When given subcutaneously, sumatriptan reaches its peak plasma concentration in ~12 minutes. Following oral administration, peak plasma concentrations occur within 1–2 hours. Bioavailability following subcutaneous administration is ~97%; after oral administration or nasal spray, bioavailability is 14–17%. The elimination $t_{1/2}$ is ~1–2 hours. Sumatriptan is metabolized predominantly by MAO-A, and its metabolites are excreted in the urine.

Zolmitriptan reaches its peak plasma concentration 1.5–2 hours after oral administration. Its bioavailability is ~40% following oral ingestion. Zolmitriptan is converted to an active *N*-desmethyl metabolite, which has severalfold higher affinity for 5-HT_{1B} and 5-HT_{1D} receptors than does the parent drug. Both the metabolite and the parent drug have half-lives of 2–3 hours.

Naratriptan, administered orally, reaches its peak plasma concentration in 2–3 hours and has an absolute bioavailability of ~70%. It is the longest acting of the triptans, having a $t_{1/2}$ of ~6 hours. Fifty percent of a dose of naratriptan is excreted unchanged in the urine; ~30% is excreted as products of oxidation by CYPs.

Rizatriptan has an oral bioavailability of ~45% and reaches peak plasma levels within 1–1.5 hours after oral ingestion of tablets of the drug. An orally disintegrating dosage form has a somewhat slower rate of absorption, yielding peak plasma levels of the drug 1.6–2.5 hours after administration. Rizatriptan is principally metabolized *via* oxidative deamination by MAO-A.

Adverse Effects and Contraindications Rare but serious cardiac events have been associated with the administration of 5-HT₁ agonists, including coronary artery vasospasm, transient myocardial ischemia, atrial and ventricular arrhythmias, and myocardial infarction, predominantly in patients with risk factors for coronary artery disease. Generally, only minor side effects are seen with the triptans in the acute treatment of migraine. Up to 83% of patients experience at least one side effect after subcutaneous injection of sumatriptan; most report transient mild pain, stinging, or burning sensations at the site of injection. The most common side effect of sumatriptan nasal spray is a bitter taste. Orally administered triptans can cause paresthesias; asthenia and fatigue; flushing; feelings of pressure, tightness, or pain in the chest, neck, and jaw; drowsiness; dizziness; nausea; and sweating. Triptans are contraindicated in patients with a history of significant cardiovascular

disease. Because triptans may cause an acute, usually small, increase in blood pressure, they also are contraindicated in patients with uncontrolled hypertension. Naratriptan is contraindicated in patients with severe renal or hepatic impairment. Rizatriptan should be used with caution in patients with renal or hepatic disease but is not contraindicated in such patients. Sumatriptan, rizatriptan, and zolmitriptan are contraindicated in patients who are taking MAO inhibitors.

Use in Treatment of Migraine Triptans are effective in the acute treatment of migraine (with or without aura), but are not intended for use in prophylaxis of migraine. Treatment should begin as soon as possible after onset of a migraine attack. Oral dosage forms of the triptans are the most convenient but may not be practical in patients experiencing migraine-associated nausea and vomiting. Approximately 70% of individuals report significant headache relief from a 6-mg subcutaneous dose of sumatriptan. This dose may be repeated once within a 24-hour period if the first dose does not relieve the headache. An oral formulation and a nasal spray of sumatriptan also are available. The onset of action is as early as 15 minutes with the nasal spray. The recommended oral dose of sumatriptan is 25–100 mg, repeatable after 2 hours up to a total dose of 200 mg over a 24-hour period. When administered by nasal spray, from 5–20 mg of sumatriptan is recommended. The dose can be repeated after 2 hours up to a maximum dose of 40 mg over a 24-hour period. Zolmitriptan is given orally in a 1.25–2.5-mg dose, repeatable after 2 hours, up to a maximum dose of 10 mg over 24 hours, if the migraine attack persists. Naratriptan is given orally in a 1–2.5-mg dose, which should not be repeated until 4 hours after the previous dose; the maximum dose over a 24-hour period should not exceed 5 mg. The recommended oral dose of rizatriptan is 5–10 mg, repeatable after 2 hours up to a maximum dose of 30 mg over a 24-hour period. The safety of treating more than 3–4 headaches over a 30-day period with triptans has not been established. Triptans should not be used concurrently with (or within 24 hours of) an ergot derivative (*see below*), nor should one triptan be used concurrently or within 24 hours of another.

Ergot and the Ergot Alkaloids Ergot is the product of a fungus (*Claviceps purpurea*) that grows on rye and other grains. The contamination of an edible grain by a poisonous, parasitic fungus spread death (called “holy fire” or “St. Anthony’s fire”) for centuries, causing gangrene of the extremities and limbs, and abortion when ingested during pregnancy. Pharmacological effects of the ergot alkaloids are varied and complex; the complexity of their actions limits their therapeutic uses. In general, the effects result from their actions as partial agonists or antagonists at adrenergic, dopaminergic, and serotonergic receptors (*see also* Chapter 10). The spectrum of effects depends on the agent, dosage, species, tissue, physiological and endocrinological state, and experimental conditions.

For chemical structures of ergot alkaloids, see Table 11–6 in the 11th edition of the parent text. A synthetic ergot derivative, bromocriptine (2-bromo- α -ergocryptine), is used to control the secretion of prolactin (see Chapter 55), a property derived from its DA agonist effect. Other agents of this series include lysergic acid diethylamide (LSD), a potent hallucinogenic drug, and methysergide, a 5-HT antagonist.

Absorption, Fate, and Excretion

Oral administration of ergotamine generally results in low or undetectable systemic drug concentrations, because of extensive first-pass metabolism. Bioavailability after sublingual administration probably is <1% and is inadequate for therapeutic purposes. The bioavailability after administration of rectal suppositories is greater. Ergotamine is metabolized in the liver by largely undefined pathways; 90% of the metabolites are excreted in the bile; traces of unmetabolized drug are found in urine and feces. Despite a plasma $t_{1/2}$ of ~2 hours, ergotamine produces vasoconstriction that lasts for 24 hours or longer. Dihydroergotamine is eliminated more rapidly than ergotamine, presumably due to its rapid hepatic clearance.

Ergonovine and methylergonovine are rapidly absorbed after oral administration and reach peak concentrations in plasma within 60–90 minutes that are >10 times those achieved with an equivalent dose of ergotamine. A uterotonic effect in postpartum women can be observed within 10 minutes after oral administration of 0.2 mg of ergonovine. Judging from the relative durations of action, ergonovine is metabolized and/or eliminated more rapidly than is ergotamine. The $t_{1/2}$ of methylergonovine in plasma is 0.5–2 hours.

Use in the Treatment of Migraine

The multiple pharmacological effects of ergot alkaloids complicate determination of their precise mechanism of action in the acute treatment of migraine. Actions of ergot alkaloids at 5-HT_{1B/1D} receptors likely mediate their acute antimigraine effects. The ergot derivative methysergide,

a 5-HT receptor antagonist, has been used for the prophylactic treatment of migraine headaches and is discussed below (see 5-HT Receptor Antagonists).

The use of ergot alkaloids for migraine should be restricted to patients having frequent, moderate migraine or infrequent, severe migraine attacks. The patient should take ergot preparations as soon as possible after the onset of a headache. GI absorption of ergot alkaloids is erratic, perhaps contributing to the large variation in patient response. Available preparations in the U.S. include sublingual tablets of ergotamine tartrate (ERGOMAR) and a nasal spray and solution for injection of dihydroergotamine mesylate (MIGRANAL and D.H.E. 45, respectively). The recommended dose for ergotamine tartrate is 2 mg sublingually, which can be repeated at 30-minute intervals if necessary up to a total dose of 6 mg in a 24-hour period or 10 mg/week. Dihydroergotamine mesylate injections can be given intravenously, subcutaneously, or intramuscularly. The recommended dose is 1 mg, which can be repeated after 1 hour if necessary up to a total dose of 2 mg (intravenously) or 3 mg (subcutaneously or intramuscularly) in a 24-hour period or 6 mg in a week. The dose of dihydroergotamine mesylate administered as a nasal spray is 0.5 mg (one spray) in each nostril, repeated after 15 minutes for a total dose of 2 mg (4 sprays). The safety of more than 3 mg over 24 hours or 4 mg over 7 days has not been established.

Adverse Effects and Contraindications

Nausea and vomiting, due to a direct effect on CNS emetic centers, occur in ~10% of patients after oral administration of ergotamine, and in about twice that number after parenteral administration. Noticing this side effect may be difficult, since nausea and sometimes vomiting are part of the symptomatology of migraine. Leg weakness is common; muscle pains, occasionally severe, may occur in the extremities, as well as numbness and tingling of extremities. Precordial distress, angina-like pain, and transient tachycardia or bradycardia, also have been noted, presumably as a result of coronary vasospasm induced by ergotamine. Localized edema and itching may occur in an occasional hypersensitive patient, but usually do not necessitate interruption of ergotamine therapy. In the event of acute or chronic poisoning (ergotism), treatment consists of complete withdrawal of the offending drug and maintenance of adequate circulation. Dihydroergotamine has lower potency than does ergotamine as an emetic, vasoconstrictor, and oxytocic.

Ergot alkaloids are contraindicated in women who are or may become pregnant; the drugs may cause fetal distress and miscarriage. Ergot alkaloids also are contraindicated in patients with peripheral vascular disease, coronary artery disease, hypertension, impaired hepatic or renal function, and sepsis. Ergot alkaloids should not be taken within 24 hours of the use of the triptans, and should not be used concurrently with other drugs that can cause vasoconstriction.

Use of Ergot Alkaloids in Postpartum Hemorrhage

All natural ergot alkaloids markedly increase the motor activity of the uterus. As the dose is increased, contractions become more forceful and prolonged, resting tone is dramatically increased, and sustained contracture can result. Although this precludes their use for induction or facilitation of labor, it is compatible with their use postpartum or after abortion to control bleeding and maintain uterine contraction. The gravid uterus is very sensitive, and small doses of ergot alkaloids can be given immediately postpartum to obtain a marked uterine response, usually without significant side effects. Ergot alkaloids are used primarily to prevent postpartum hemorrhage. Although all natural ergot alkaloids have qualitatively the same effect on the uterus, ergonovine is the most active and also is less toxic than ergotamine. Thus, ergonovine and its semisynthetic derivative methylegonovine have replaced other ergot preparations as uterine-stimulating agents in obstetrics.

D-Lysergic Acid Diethylamide (LSD)

LSD (see Table 11-6 in the 11th edition of the parent text) is a nonselective 5-HT agonist. This ergot derivative profoundly alters human behavior; eliciting perception disturbances such as sensory distortion (especially visual and auditory) and hallucinations at doses as low as 1 µg/kg. The potent, mind-altering effects of LSD explain its abuse by human beings (see Chapter 23) and the fascination of scientists with the mechanism of action of LSD. LSD interacts with brain 5-HT receptors as an agonist/partial agonist. LSD mimics 5-HT at 5-HT_{1A} autoreceptors on raphe cell bodies, producing a marked slowing of the firing rate of serotonergic neurons. Current theories focus on the ability of hallucinogens such as LSD to promote glutamate release in thalamocortical terminals, thus causing a dissociation between sensory relay centers and cortical output. LSD and other hallucinogenic drugs act as partial or full agonists at 5-HT_{2A} and 5-HT_{2C} receptors. Whether the agonist property of hallucinogenic drugs at 5-HT_{2C} receptors contributes to the behavioral alterations is not known. The hallucinogenic phenethylamine derivatives such as 1-(4-bromo-2,5-dimethoxyphenyl)-2-aminopropane are selective 5-HT_{2A/2C} receptor agonists.

***m*-Chlorophenylpiperazine (mCPP)** The actions of mCPP *in vivo* primarily reflect activation of 5-HT_{1B} and/or 5-HT_{2A/2C} receptors, although this agent is not subtype-selective in radioligand-binding studies *in vitro*. mCPP is an active metabolite of the antidepressant drug *trazodone* (DESYREL).

mCPP has been employed to probe brain 5-HT function in human beings. The drug alters a number of neuroendocrine parameters and elicits profound behavioral effects, with anxiety as a prominent symptom. mCPP elevates corticotropin and prolactin secretion (probably *via* a combination of 5-HT₁ and 5-HT_{2A/2C} receptor activation) and increases growth hormone secretion (apparently by a 5-HT-independent mechanism). 5-HT_{2A/2C} receptors appear to mediate at least part of the anxiogenic effects of mCPP, since 5-HT_{2A/2C} receptor antagonists attenuate mCPP-induced anxiety.

5-HT Receptor Antagonists

Clinical effects of 5-HT-related drugs often exhibit a significant delay in onset, notable in drugs used to treat affective disorders such as anxiety and depression (*see* Chapter 17). This delayed onset may relate to adaptive changes in 5-HT receptor density and sensitivity after chronic drug treatments. Laboratory studies have documented agonist-promoted receptor subsensitivity and down-regulation of 5-HT receptor subtypes. However, an unusual adaptive process, *antagonist*-induced down-regulation of 5-HT_{2C} receptors, occurs in laboratory animals after chronic treatment with receptor antagonists. Many clinically effective drugs, including clozapine, ketanserin, and amitriptyline, exhibit this unusual property. These drugs, as well as several other 5-HT_{2A/2C} receptor antagonists, possess negative intrinsic activity or inverse agonism, reducing constitutive (spontaneous) receptor activity as well as blocking agonist occupancy (competitive antagonism). Other 5-HT_{2A/2C} receptor antagonists act in the classical manner, simply blocking receptor occupancy by agonists. Even though there is modest evidence for constitutive activity *in vivo*, drug development has been further refined by focusing on reduction of preexisting constitutive neuronal activity as opposed to blockade of excess neurotransmitter action.

Ketanserin

Ketanserin (*SUFREXAL*) potently blocks 5-HT_{2A} receptors, less potently blocks 5-HT_{2C} receptors, and has no significant effect on 5-HT₃ or 5-HT₄ receptors or any members of the 5-HT₁ receptor family. Ketanserin also has high affinity for α adrenergic and histamine H₁ receptors.

Ketanserin lowers blood pressure in patients with hypertension, causing a reduction comparable to that seen with β adrenergic-receptor antagonists or diuretics. The drug appears to reduce the tone of both capacitance and resistance vessels. This effect likely relates to its blockade of α_1 adrenergic receptors, not its blockade of 5-HT_{2A} receptors. Ketanserin inhibits 5-HT-induced platelet aggregation but does not greatly reduce the capacity of other agents to cause aggregation. Severe side effects after treatment with ketanserin have not been reported. Its oral bioavailability is ~50%; its plasma $t_{1/2}$ is 12–25 hours. The primary mechanism of inactivation is hepatic metabolism. Ketanserin is available in Europe but not in the U.S.

Chemical relatives of ketanserin such as ritanserin are more selective 5-HT_{2A} receptor antagonists with low affinity for α_1 adrenergic receptors. However, ritanserin, as well as most other 5-HT_{2A} receptor antagonists, also potently antagonize 5-HT_{2C} receptors. The physiological significance of 5-HT_{2C}-receptor blockade is unknown. MDL 100,907 is the prototype of a new series of potent 5-HT_{2A} receptor antagonists, with high selectivity for 5-HT_{2A} versus 5-HT_{2C} receptors.

Atypical Antipsychotic Drugs *Clozapine* (CLOZARIL), a 5-HT_{2A/2C} receptor antagonist, represents a class of atypical antipsychotic drugs with reduced incidence of extrapyramidal side effects compared to the classical neuroleptics, and possibly a greater efficacy for reducing negative symptoms of schizophrenia (see Chapter 18). Clozapine also has a high affinity for subtypes of DA receptors.

One of the newest strategies for the design of additional atypical antipsychotic drugs is to combine 5-HT_{2A/2C} and DA D₂-receptor blocking actions in the same molecule. *Risperidone* (RISPERDAL), for example, is a potent 5-HT_{2A} and D₂ receptor antagonist. Low doses of risperidone have been reported to attenuate negative symptoms of schizophrenia with a low incidence of extrapyramidal side effects. Extrapyramidal effects are commonly seen, however, with doses of risperidone in excess of 6 mg/day. Other atypical antipsychotic agents—*quetiapine* (SEROQUEL) and *olanzapine* (ZYPREXA)—act on multiple receptors, but their antipsychotic properties are thought to be due to antagonism of DA and 5-HT.

Methysergide *Methysergide* (SANSERT; 1-methyl-*d*-lysergic acid butanolamide) is a congener of methylergonovine (see Table 11–6 in the 11th edition of the parent text). Methysergide blocks 5-HT_{2A} and 5-HT_{2C} receptors but has partial agonist activity in some preparations. Methysergide inhibits the vasoconstrictor and pressor effects of 5-HT, as well as the actions of 5-HT on various types of extravascular smooth muscle. It can both block and mimic the central effects of 5-HT. Methysergide is not selective: it also interacts with 5-HT₁ receptors, but its therapeutic effects appear primarily to reflect blockade of 5-HT₂ receptors. Although methysergide is an ergot derivative, it has only weak vasoconstrictor and oxytocic activity.

Methysergide has been used for the prophylactic treatment of migraine and other vascular headaches, including Horton's syndrome. It is without benefit when given during an acute migraine attack. The protective effect takes 1–2 days to develop and disappears slowly when treatment is terminated, possibly due to the accumulation of an active metabolite of methysergide, methylergometrine, which is more potent than the parent drug. Methysergide also has been used to combat diarrhea and malabsorption in patients with carcinoid tumors, and in the postgastroectomy dumping syndrome; these conditions have a 5-HT-mediated component. However, methysergide is ineffective against other substances (e.g., kinins) released by carcinoid tumors. The preferred agent to treat malabsorption in carcinoid patients is a somatostatin analog, *octreotide acetate* (SANDOSTATIN), which inhibits the secretion of all mediators released by carcinoid tumors (see Chapter 55).

Side effects of methysergide are usually mild and transient, although drug withdrawal is infrequently required to reverse more severe reactions. Common side effects include GI disturbances (heartburn, diarrhea, cramps, nausea, and vomiting), and symptoms related to vasospasm-induced ischemia (numbness and tingling of extremities, pain in the extremities, and low back and abdominal pain). Effects attributable to central actions include unsteadiness, drowsiness, weakness, light-headedness, nervousness, insomnia, confusion, excitement, hallucinations, and even frank psychotic episodes. Reactions suggestive of vascular insufficiency and exacerbation of angina pectoris have been observed in a few patients. A potentially serious complication of prolonged treatment is inflammatory fibrosis, giving rise to various syndromes that include retroperitoneal fibrosis, pleuropulmonary fibrosis, and coronary and endocardial fibrosis. Usually the fibrosis regresses after drug withdrawal, although persistent cardiac valvular damage has been reported. Because of this danger, other drugs are preferred for the prophylactic treatment of migraine (see earlier discussion of migraine therapy). If methysergide is used chronically, treatment should be interrupted for 3 weeks or more every 6 months.

Cyproheptadine The structure of *cyproheptadine* (PERIACTIN; see below) resembles that of the phenothiazine histamine H₁ receptor antagonists; indeed, cyproheptadine is an effective H₁ receptor antagonist. The drug also has prominent 5-HT blocking activity on smooth muscle via its binding to 5-HT_{2A} receptors. In addition, it has weak anticholinergic activity and mild CNS depressant properties. Cyproheptadine shares the properties and uses of other H₁ receptor antagonists (see Chapter 24). It is effective in controlling skin allergies, particularly the accompanying pruritus. In allergic conditions, the action of cyproheptadine as a 5-HT receptor antagonist is irrelevant, since 5-HT_{2A} receptors are not involved in human allergic responses. Some physicians recommend cyproheptadine to counteract the sexual side effects of selective 5-HT reuptake inhibitors such as fluoxetine and sertraline (see Chapter 17). The 5-HT blocking actions of cyproheptadine explain its value in the postgastroectomy dumping syn-

CYPROHEPTADINE

drome, GI hypermotility of carcinoid syndrome, and migraine prophylaxis. Cyproheptadine is not, however, a preferred treatment for these conditions. Side effects of cyproheptadine include those common to other H_1 receptor antagonists, such as drowsiness. Weight gain and increased growth observed in children have been attributed to impaired regulation of growth hormone secretion.

DRUGS ACTING ON THE CENTRAL NERVOUS SYSTEM

NEUROTRANSMISSION AND THE CENTRAL NERVOUS SYSTEM

CELLULAR ORGANIZATION OF THE BRAIN: A PHARMACOLOGICAL VIEW OF NEURONS

Neurons are classified according to function (sensory, motor, or interneuron), location, and identity of the transmitter(s) that they synthesize and release. They exhibit the cytological characteristics of highly active secretory cells with large nuclei; large amounts of smooth and rough endoplasmic reticulum; and frequent clusters of specialized smooth endoplasmic reticulum (Golgi complex), in which secretory products of the cell are packaged into membrane-bound organelles for transport from the cell body proper to the axon or dendrites (Figure 12–1). Neurons are rich in microtubules, which support the complex cellular structure and assist in the reciprocal transport of essential macromolecules and organelles between the cell body and the distant axon or dendrites. The sites of interneuronal communication in the CNS are termed synapses. Although synapses are functionally analogous to “junctions” in the somatic motor and autonomic nervous systems, the central junctions contain an array of specific proteins presumed to be the active zone for transmitter release and response. Like peripheral “junctions,” central synapses also are denoted by accumulations of tiny (500–1500 Å) organelles, termed synaptic vesicles. The proteins of these vesicles have been shown to have specific roles in transmitter storage, vesicle docking onto presynaptic membranes, voltage- and Ca^{2+} -dependent secretion (see Chapter 6), and recycling and restoration of released transmitter.

SUPPORTIVE CELLS

According to most estimates, neurons are outnumbered, perhaps by an order of magnitude, by various supportive cells: the macroglia, the microglia, the cells of the vascular elements comprising the intracerebral vasculature and cerebrospinal fluid (CSF)–forming cells of the choroid plexus found within the intracerebral ventricular system, and the meninges, which cover the brain surface and comprise the CSF-containing envelope. Macroglia are the most abundant supportive cells; some are categorized as astrocytes (cells interposed between the vasculature and the neurons, often surrounding individual compartments of synaptic complexes), which play a variety of metabolic support roles including furnishing energy intermediates and supplementary removal of extracellular neurotransmitter secretions. The oligodendroglia, a second category of macroglia, are the myelin-producing cells. Myelin, made up of multiple layers of their compacted membranes, insulates segments of long axons bioelectrically and accelerates action potential conduction velocity. Microglia are derived from mesoderm and are related to the macrophage/monocyte lineage. Some microglia reside within the brain, while additional microglial cells may be recruited to the brain by inflammation following microbial infection or other brain injury (see Chapter 52).

BLOOD–BRAIN BARRIER

Apart from instances in which drugs are introduced directly into the CNS, the concentration of the agent in the blood after oral or parenteral administration differs substantially from its concentration in the brain. The blood–brain barrier (BBB) is a boundary between the periphery and the CNS that forms a permeability barrier to the passive diffusion of substances from the bloodstream into various regions of the CNS. Evidence of the barrier is provided by the greatly diminished rate of access of chemicals from plasma to the brain (see Chapters 1 and 2). This barrier is nonexistent in the peripheral nervous system, and is much less prominent in the hypothalamus and in several small, specialized organs (the circumventricular organs) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ. Selective barriers to permeation into and out of the brain also exist for small, charged molecules such as neurotransmitters, their precursors and metabolites, and some drugs. These diffusional barriers are viewed as a combination of the partition of solute across the vasculature (which governs passage by definable properties such as molecular weight, charge, and lipophilicity) and the presence or absence of energy-dependent transport systems (see Chapter 2).

FIGURE 12-1 Schematic view of the drug-sensitive sites in prototypical synaptic complexes. In the center, a post-synaptic neuron receives a somatic synapse (shown greatly oversized) from an axonic terminal; an axoaxonic terminal is shown in contact with this presynaptic nerve terminal. Drug-sensitive sites include: (1) microtubules and molecular motors responsible for bidirectional transport of macromolecules between the neuronal cell body and distal processes; (2) electrically conductive membranes; (3) sites for the synthesis and storage of transmitters; (4) sites for the active uptake of transmitters by nerve terminals or glia; (5) sites for the release of transmitter; (6) postsynaptic receptors, cytoplasmic organelles, and postsynaptic proteins for expression of synaptic activity and for long-term mediation of altered physiological states; (7) presynaptic receptors on adjacent presynaptic processes; and (8) on nerve terminals (autoreceptors). Around the central neuron are schematic illustrations of the more common synaptic relationships in the CNS.

The brain clears metabolites of transmitters into the CSF by excretion via the acid transport system of the choroid plexus. Substances that rarely gain access to the brain from the bloodstream often can reach the brain when injected directly into the CSF. Under certain conditions, it may be possible to open the BBB, at least transiently, to permit the entry of chemotherapeutic agents. Cerebral ischemia and inflammation also modify the BBB, increasing access to substances that ordinarily would not affect the brain.

INTEGRATIVE CHEMICAL COMMUNICATION IN THE CNS AND NEUROPHARMACOLOGY

A central underlying concept of neuropsychopharmacology is that drugs that influence behavior and improve the functional status of patients with neurological or psychiatric diseases act by enhancing or blunting the effectiveness of specific combinations of synaptic transmitter actions.

Four research strategies provide the neuroscientific substrates of neuropsychological phenomena: molecular (or biochemical), cellular, multicellular (or systems), and behavioral. Molecular mechanisms include: (1) ion channels, which provide for changes in excitability induced by neurotransmitters; (2) neurotransmitter receptors; (3) auxiliary intramembranous and cytoplasmic transductive molecules that couple these receptors to intracellular effectors for short-term changes in excitability and for longer-term regulation through alterations in gene expression; and (4) transporters for the conservation of released transmitter molecules by reaccumulation into nerve terminals, and then into synaptic vesicles (see Chapter 6). Vesicular transporters are distinct from the plasma membrane proteins involved in transmitter uptake into nerve terminals. Electrical excitability of neurons occurs through modifications of the transmembrane ion channels that all neurons express in abundance. Discriminative ion channels (Figures 12–2 and Chapter 9) regulate the flow of the three major cations, Na^+ , K^+ and Ca^{2+} , and Cl^- anions. Two other families of channels regulate ion fluxes: cyclic nucleotide–modulated channels, and transient receptor potential (TRP) channels.

FIGURE 12–2 The major molecular motifs of ion channels that establish and regulate neuronal excitability in the central nervous system. **A.** The α_1 subunits of the Ca^{2+} and Na^+ channels share a similar presumptive six-transmembrane structure, repeated four times, in which an intramembranous segment separates transmembrane segments 5 and 6. **B.** The Ca^{2+} channel also requires several auxiliary small proteins (α_2 , β , γ , and δ). The α_2 and δ subunits are linked by a disulfide bond (not shown). Regulatory subunits also exist for Na^+ channels. **C.** Voltage-sensitive K^+ channels (K_v) and the rapidly activating K^+ channel (K_a) share a similar presumptive six-transmembrane domain similar in overall configuration to one repeat unit within the Na^+ and Ca^{2+} channel structure, while the inwardly rectifying K^+ channel protein (K_i) retains the general configuration of just loops 5 and 6. Regulatory β subunits (cytosolic) can alter K_v channel functions. Channels of these two overall motifs can form heteromultimers.

FIGURE 12-3 Ionophore receptors for neurotransmitters are composed of subunits with four transmembrane domains and are assembled as tetramers or pentamers (at right). The predicted motif shown likely describes nicotinic cholinergic receptors for ACh, GABA_A receptors for gamma-aminobutyric acid, and receptors for glycine.

Voltage-dependent ion channels (Figure 12-2) provide for rapid changes in ion permeability along axons and within dendrites and for the excitation-secretion coupling that releases neurotransmitters from presynaptic sites. Ligand-gated ion channels, regulated by the binding of neurotransmitters, form a distinct group of ion channels (Figure 12-3). Within the CNS, variants of the K⁺ channels (the delayed rectifier, the Ca²⁺-activated K⁺ channel, and the after-hyperpolarizing K⁺ channel) regulated by intracellular second messengers repeatedly have been shown to underlie complex forms of synaptic modulation.

Cyclic nucleotide–modulated channels consist of two groups: the cyclic nucleotide–gated (CNG) channels, which play key roles in sensory transduction for olfactory and photoreceptors, and the hyperpolarization-activated, cyclic nucleotide–gated (HCN) channels. HCN channels are cation channels that open with hyperpolarization and close with depolarization; upon direct binding of cyclic AMP or cyclic GMP, the activation curves for the channels are shifted to more hyperpolarized potentials. These channels play essential roles in cardiac pacemaker cells and presumably in rhythmically discharging neurons.

TRP channels, named for their role in *Drosophila* phototransduction, are a family of hexaspanning receptors with a pore domain between the fifth and sixth transmembrane segments and a common 25-amino acid TRP “box” C-terminal of the sixth transmembrane domain; these channels are found across the phylogenetic scale from bacteria to mammals. Members of the TRPV subfamily serve as the receptors for endogenous cannabinoids, such as anandamide, and the hot pepper toxin, capsaicin.

Identification of Central Transmitters

The criteria for the identification of central transmitters require the same data used to establish the transmitters of the autonomic nervous system (see Chapter 6).

1. *The transmitter must be shown to be present in the presynaptic terminals of the synapse and in the neurons from which those presynaptic terminals arise.* Extensions of this criterion involve the demonstration that the presynaptic neuron synthesizes the transmitter substance, rather than simply storing it after accumulation from a nonneuronal source.
2. *The transmitter must be released from the presynaptic nerve concomitantly with presynaptic nerve activity.* This criterion is best satisfied by electrical stimulation of the nerve pathway *in vivo* and collection of the transmitter in an enriched extracellular fluid within the synaptic target area. The release of all known transmitter substances, including presumptive transmitter release from dendrites, is voltage-dependent and requires Ca²⁺ influx into the presynaptic terminal. However, transmitter release is relatively insensitive to extracellular Na⁺ or to tetrodotoxin, which blocks transmembrane movement of Na⁺.
3. *When applied experimentally to the target cells, the effects of the putative transmitter must be identical to the effects of stimulating the presynaptic pathway.* This criterion can be met loosely by qualitative comparisons (e.g., both the substance and the pathway inhibit or excite the target cell). More convincing is the demonstration that the ionic conductances activated by the pathway are the same as those activated by the candidate transmitter. The criterion can be satisfied less rigorously by demonstration of the pharmacological identity of receptors (order of potency of agonists and antagonists). Generally, pharmacological antagonism of the actions of the pathway

and those of the candidate transmitter should be achieved by similar concentrations of antagonist. To be convincing, the antagonistic drug should not affect responses of the target neurons to other unrelated pathways or to chemically distinct transmitter candidates. Actions that are qualitatively identical to those that follow stimulation of the pathway also should be observed with synthetic agonists that mimic the actions of the transmitter.

Many brain and spinal cord synapses, especially those involving peptide neurotransmitters, apparently contain more than one transmitter substance. Substances that coexist in a given synapse are presumed to be released together, but in a frequency-dependent fashion, with higher frequency bursts mediating peptide release. Coexisting substances may either act jointly on the postsynaptic membrane, or affect release of transmitter from the presynaptic terminal. Clearly, if more than one substance transmits information, no single agonist or antagonist would faithfully mimic or fully antagonize activation of a given presynaptic element. Costorage and corelease of ATP and NE are an example.

RECEPTOR PROPERTIES

Biochemical techniques and molecular cloning studies have revealed two major motifs and one minor motif of transmitter receptors. The first, oligomeric ion channel receptors, are composed of multiple subunits, usually with four transmembrane domains (Figure 12–3). The ion channel receptors (ionotropic receptors or IRs) for neurotransmitters contain sites for reversible phosphorylation by protein kinases and phosphoprotein phosphatases and for voltage gating. Receptors with this structure include nicotinic cholinergic receptors; the receptors for the amino acids GABA, glycine, glutamate, and aspartate; and the 5-HT₃ receptor.

The second major motif comprises the G protein-coupled receptors (GPCRs), a large family of heptahelical receptors (see Figures 1–7 and 10–1). Activated receptors (themselves subject to reversible phosphorylation at one or more functionally distinct sites) can interact with the heterotrimeric GTP-binding protein complex. Such protein-protein interactions can activate, inhibit, or otherwise regulate effector systems such as adenylyl cyclase or phospholipase C, and ion channels, such as voltage-gated Ca²⁺ channels or receptor-operated K⁺ channels (see Chapter 1). GPCRs are employed by muscarinic cholinergic receptors, one subtype each of GABA and glutamate receptors, and all other aminergic and peptidergic receptors.

A third receptor motif is the growth factor receptor (GFR), a monospanning membrane protein that has an extracellular binding domain that regulates an intracellular catalytic activity, such as the atrial natriuretic peptide-binding domain that regulates the activity of the membrane-bound guanylyl cyclase (see Figure 1–7). Dimerization of GPCRs and GFRs apparently contributes to their activities, as does localization within or outside of caveolae in the membrane.

Postsynaptic receptivity of CNS localization is regulated continuously in terms of the number of receptor sites and the threshold required to generate a response. Receptor number often depends on the concentration of agonist to which the target cell is exposed. Thus, chronic excess of agonist can lead to a reduced number of receptors (desensitization or down-regulation) and consequently to subsensitivity or tolerance to the transmitter. For many GPCRs, short-term down-regulation is achieved by the actions of G protein-linked receptor kinases (GRKs) and internalization of the receptors (see Chapter 1). Conversely, deficit of agonist or prolonged pharmacologic blockade of receptors can lead to increased numbers of receptors and supersensitivity of the system. These adaptive processes become especially important when drugs are used to treat chronic illness of the CNS. After prolonged exposure to drug, the actual mechanisms underlying the therapeutic effect may differ strikingly from those that operate when the agent is first introduced. Similar adaptive modifications of neuronal systems also can occur at presynaptic sites, such as those concerned with transmitter synthesis, storage, and release.

TRANSMITTERS, HORMONES, AND MODULATORS: CONTRASTING PRINCIPLES OF NEURONAL REGULATION

NEUROTRANSMITTERS Transmitters may produce minimal effects on bioelectric properties, yet activate or inactivate biochemical mechanisms necessary for responses to other circuits. Alternatively, the action of a transmitter may vary with the context of ongoing synaptic events—enhancing excitation or inhibition, rather than operating to impose direct excitation or inhibition. Each chemical substance that fits within the broad definition of a transmitter may therefore require operational definition within the spatial and temporal domains of a specific cell-cell circuit. Those same properties may not necessarily be generalized to other cells contacted by the same presynaptic neurons; differences in operation may relate to differences in postsynaptic receptors and the mechanisms by which an activated receptor produces its effects.

Classically, electrophysiological signs of the action of a *bona fide* transmitter fall into two major categories: (1) *excitation*, in which ion channels are opened to permit net influx of positively charged ions, leading to depolarization with a reduction in the electrical resistance of the membrane; and (2) *inhibition*, in which selective ion movements lead to hyperpolarization, also with decreased membrane resistance. There also may be many “nonclassical” transmitter mechanisms operating in the CNS. In some cases, either depolarization or hyperpolarization is accompanied by a *decreased* ionic conductance (increased membrane resistance) as actions of the transmitter lead to the closure of ion channels (so-called leak channels) that normally are open in some resting neurons. For transmitters such as monoamines and certain peptides, a “conditional” action may be involved, *i.e.*, a transmitter substance may enhance or suppress the response of the target neuron to classical excitatory or inhibitory transmitters while producing little or no change in membrane potential or ionic conductance when applied alone. Such conditional responses are termed *modulatory*. Regardless of the mechanisms that underlie such synaptic operations, their temporal and biophysical characteristics differ substantially from the rapid onset-offset effects previously thought to describe all synaptic events. These differences raise the issue of whether substances that produce slow synaptic effects should be described as neurotransmitters. Some of the alternative terms and the relevant molecules are described below.

NEUROHORMONES

Peptide-secreting cells of the hypothalamic-hypophyseal circuits originally were described as neurosecretory cells, receiving synaptic information from other central neurons, yet secreting transmitters in a hormone-like fashion into the circulation. The transmitter released from such neurons was termed a neurohormone, i.e., a substance secreted into the blood by a neuron. These hypothalamic neurons also may form traditional synapses with central neurons, and cytochemical evidence indicates that the same substances that are secreted as hormones from the posterior pituitary (oxytocin, arginine-vasopressin; see Chapters 29 and 55) mediate transmission at these sites. Thus, the designation hormone relates to the release at the posterior pituitary and does not necessarily describe all actions of the peptide.

NEUROMODULATORS

The distinctive feature of a modulator is that it originates from nonsynaptic sites, yet influences the excitability of nerve cells. Substances such as CO₂ and ammonia, arising from active neurons or glia, are potential modulators through nonsynaptic actions. Similarly, circulating steroid hormones, steroids produced in the nervous system (i.e., neurosteroids), locally released adenosine, other purines, eicosanoids, and NO are regarded as modulators (see below).

NEUROMEDIATORS

Substances that participate in eliciting the postsynaptic response to a transmitter fall under this heading. The clearest examples of such effects are provided by the involvement of cyclic AMP, cyclic GMP, and inositol phosphates as second messengers at specific sites of synaptic transmission (see Chapters 1, 6, 7, 10, and 11). Changes in the concentration of second messengers may enhance the generation of synaptic potentials, and second messenger-dependent protein phosphorylation can initiate a complex cascade of molecular events that regulate the properties of membrane and cytoplasmic proteins central to neuronal excitability. These possibilities are particularly pertinent to the action of drugs that augment or reduce transmitter effects (see below).

NEUROTROPHIC FACTORS

Neurotrophic factors are substances produced within the CNS by neurons, astrocytes, microglia, or transiently invading peripheral inflammatory or immune cells that assist neurons in their attempts to repair damage. Seven categories of neurotrophic peptides are recognized: (1) the classic neurotrophins (NGF, brain-derived neurotrophic factor, and the related neurotrophins); (2) the neuropoietic factors, which have effects both in brain and in myeloid cells (e.g., cholinergic differentiation factor [also called leukemia inhibitory factor], ciliary neurotrophic factor, and some interleukins); (3) growth factor peptides, such as EGF, TGF α and β , glial cell-derived neurotrophic factor, and activin A; (4) the fibroblast growth factors; (5) insulin-like growth factors; (6) platelet-derived growth factors; and (7) axon guidance molecules.

CENTRAL NEUROTRANSMITTERS

Table 12-1 summarizes the pharmacological properties of the transmitters in the CNS that have been studied extensively. Neurotransmitters are discussed below as groups of substances within given chemical categories: amino acids, amines, and neuropeptides.

Receptor-effector coupling consists of ion channel mechanisms for ionotropic receptors (IR) or coupling to G proteins for GPCRs. All GPCRs modulate neuronal activity by affecting second messenger production, protein phosphorylation, and ion channel function by mechanisms described in Chapter 1. In general, G_s couples to adenylyl cyclase to activate cyclic AMP production, while coupling to G_i inhibits adenylyl cyclase; coupling to G_q activates the PLC-IP₃-Ca²⁺ pathway; $\beta\gamma$ subunits of G proteins may modulate ion channels directly.

AMINO ACIDS The CNS contains high concentrations of certain amino acids, notably glutamate and gamma-aminobutyric acid (GABA). The dicarboxylic amino acids (*e.g.*, glutamate and aspartate) produce near universal excitation, while the monocarboxylic ω -amino acids (*e.g.*, GABA, glycine, β -alanine, and taurine) produce qualitatively similar, consistent inhibitions. The availability of selective antagonists has permitted identification of selective amino acid receptors and receptor subtypes. These data, together with the development of methods for mapping the ligands and their receptors, demonstrate that the amino acids GABA, glycine, and glutamate are central transmitters. The structures of glycine, glutamate, GABA, and some related compounds are shown in Figure 12–4.

FIGURE 12–4 Amino acid transmitters and congeners. Endogenous compounds are shown in blue.

GABA

GABA is the major inhibitory neurotransmitter in the mammalian CNS; it mediates the inhibitory actions of local interneurons in the brain and may also mediate presynaptic inhibition within the spinal cord. Presumptive GABA-containing inhibitory synapses have been demonstrated most clearly between cerebellar Purkinje neurons and their targets in Deiter's nucleus; between small interneurons and the major output cells of the cerebellar cortex, olfactory bulb, cuneate nucleus, hippocampus, and lateral septal nucleus; and between the vestibular nucleus and the trochlear motoneurons. GABA also mediates inhibition within the cerebral cortex and between the caudate nucleus and the substantia nigra. GABA-containing neurons and nerve terminals can be localized with immunocytochemical methods that visualize glutamic acid decarboxylase, the enzyme that catalyzes the synthesis of GABA from glutamic acid, or by *in situ* hybridization of the mRNA for this protein. GABA-containing neurons frequently coexpress one or more neuropeptides (see below). The most useful compounds for confirmation of GABA-mediated effects have been bicuculline and picrotoxin (Figure 12-4); however, many convulsants whose actions previously were unexplained (including penicillin and pentylenetetrazol) also may act as relatively selective antagonists of GABA action. Useful therapeutic effects have not yet been obtained through the use of agents that mimic GABA (e.g., muscimol), inhibit its active reuptake (e.g., 2,4-diaminobutyrate, nipecotic acid, and guvacine), or alter its turnover (e.g., aminooxyacetic acid).

GABA receptors have been divided into three main types: A, B, and C. The most prominent subtype, the GABA_A receptor, is a ligand-gated Cl⁻ ion channel, an "ionotropic receptor" that is opened after release of GABA from presynaptic neurons. The GABA_B receptor is a GPCR. The GABA_C receptor is a transmitter-gated Cl⁻ channel. The GABA_A receptor subunit proteins have been well characterized due to their abundance. The receptor also has been extensively characterized as the site of action of many neuroactive drugs (see Chapters 16 and 22), notably benzodiazepines, barbiturates, ethanol, anesthetic steroids, and volatile anesthetics. Based on sequence homology, more than 15 other subunits have been cloned and appear to be expressed in multiple multimeric, pharmacologically distinctive combinations. In addition to these subunits, which are products of separate genes, splice variants for several subunits have been described. The GABA_A receptor, by analogy with the nicotinic cholinergic receptor, may be either a pentameric or tetrameric protein in which the subunits assemble together around a central ion pore typical for all ionotropic receptors (see below). The major form of the GABA_A receptor contains at least three different subunits— α , β , and γ —but their stoichiometry is not known. All three subunits are required to interact with benzodiazepines with the profile expected of the native GABA_A receptor, and inclusion of variant α , β , or γ subunits alters the pharmacological profiles. The GABA_B or metabotropic GABA receptor interacts with G_i to inhibit adenylyl cyclase, activate K⁺ channels, and reduce Ca²⁺ conductance. Presynaptic GABA_B receptors function as autoreceptors, inhibiting GABA release, and may play the same role on neurons releasing other transmitters. There are two subtypes of GABA_B receptors, 1a and 1b. The GABA_C receptor is less widely distributed than the A and B subtypes and is pharmacologically distinct: GABA is more potent by an order of magnitude at GABA_C than at GABA_A receptors, and a number of GABA_A agonists (e.g., baclofen) and modulators (e.g., benzodiazepines and barbiturates) seem not to interact with GABA_C receptors. GABA_C receptors are found in the retina, spinal cord, superior colliculus, and pituitary.

Glycine

Many of the features described for the GABA_A receptor family apply to the inhibitory glycine receptor that is prominent in the brainstem and spinal cord. Multiple subunits assemble into a variety of glycine receptor subtypes, the complete functional significance of which is not known.

Glutamate and Aspartate

Glutamate and aspartate have powerful excitatory effects on neurons in virtually every region of the CNS. Glutamate and possibly aspartate are the principal fast ("classical") excitatory transmitters throughout the CNS. Glutamate receptors are classified functionally either as ligand-gated ion channel ("ionotropic") receptors or as "metabotropic" GPCRs. Neither the precise number of subunits that form a functional glutamate ionotropic receptor ion channel *in vivo* nor the intramembranous topography of the subunits has been established unequivocally. The ligand-gated ion channels are further classified according to the identity of agonists that selectively activate each receptor subtype and are broadly divided into N-methyl-D-aspartate (NMDA) receptors and "non-NMDA" receptors. The non-NMDA receptors include the α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainate receptors (Figure 12-4). Selective agonists and antagonists for NMDA receptors are available; the latter include open-channel blockers such as phencyclidine (PCP or "angel dust"), antagonists such as 5,7-dichlorokynurenic acid, which act

at an allosteric glycine-binding site, and the novel antagonist ifenprodil, which may act as a closed channel blocker. In addition, the activity of NMDA receptors can be modulated by pH and a variety of endogenous modulators including Zn^{2+} , some neurosteroids, arachidonic acid, redox reagents, and polyamines (e.g., spermine). Diversity of glutamate receptors arises by alternative splicing or by single-base editing of mRNAs encoding the receptors or receptor subunits. Alternative splicing has been described for metabotropic receptors and for subunits of NMDA, AMPA, and kainate receptors. AMPA and kainate receptors mediate fast depolarization at most glutamatergic synapses in the brain and spinal cord. NMDA receptors also are involved in normal synaptic transmission, but activation of NMDA receptors is associated more closely with the induction of various forms of synaptic plasticity rather than with fast point-to-point signaling in the brain. AMPA or kainate receptors and NMDA receptors may be co-localized at many glutamatergic synapses. A well-characterized phenomenon involving NMDA receptors is the induction of long-term potentiation (LTP). LTP refers to a prolonged (hours to days) increase in the size of a postsynaptic response to a presynaptic stimulus of given strength. Activation of NMDA receptors is obligatory for the induction of one type of LTP that occurs in the hippocampus. NMDA receptors normally are blocked by Mg^{2+} at resting membrane potentials. Thus, activation of NMDA receptors requires not only binding of synaptically released glutamate but also simultaneous depolarization of the postsynaptic membrane. This is achieved by activation of AMPA/kainate receptors at nearby synapses by inputs from different neurons. AMPA receptors also are dynamically regulated to affect their sensitivity to the synergism with NMDA. Thus, NMDA receptors may function as coincidence detectors, being activated only when there is simultaneous firing of two or more neurons. NMDA receptors also can induce long-term depression (LTD; the converse of LTP) at CNS synapses.

Glutamate Excitotoxicity

High concentrations of glutamate produce neuronal cell death. The cascade of events leading to neuronal death is thought to be triggered by excessive activation of NMDA or AMPA/kainate receptors, allowing significant influx of Ca^{2+} into the neurons. Following a period of ischemia or hypoglycemia in the brain, NMDA receptor antagonists can attenuate neuronal cell death induced by activation of these receptors but cannot prevent all such damage. Glutamate-induced depletion of Na^+ and K^+ and small elevations of extracellular Zn^{2+} can activate necrotic and proapoptotic cascades, leading to neuronal death. Glutamate receptors are targets for therapeutic interventions (e.g., in chronic neurodegenerative diseases and schizophrenia; see Chapters 18 and 20).

ACETYLCHOLINE In most regions of the CNS, the effects of ACh, assessed either by iontophoresis or by radioligand-binding assays, appear to be generated by interaction with a mixture of nicotinic and muscarinic receptors. Several presumptive cholinergic pathways have been proposed in addition to that of the motoneuron-Renshaw cell. Eight major clusters of ACh neurons and their pathways have been characterized.

CATECHOLAMINES The brain contains separate neuronal systems that utilize three different catecholamines—dopamine (DA), norepinephrine (NE), and epinephrine (Epi). Each system is anatomically distinct and serves separate, but similar, functional roles within its field of innervation.

Dopamine

The CNS distributions of DA and NE differ markedly. More than half the CNS content of catecholamine is DA, with large amounts in the basal ganglia (especially the caudate nucleus), the nucleus accumbens, the olfactory tubercle, the central nucleus of the amygdala, the median eminence, and restricted fields of the frontal cortex. Most attention has been directed to the long projections between the major DA-containing nuclei in the substantia nigra and ventral tegmentum and their targets in the striatum, in the limbic zones of the cerebral cortex, and in other major limbic regions (but generally not in the hippocampus).

Initial pharmacological studies distinguished two subtypes of DA receptors: D_1 (which couples to G_s and adenylyl cyclase) and D_2 (which couples to G_i to inhibit adenylyl cyclase). Subsequent cloning studies identified three additional genes encoding subtypes of DA receptors: one resembling the D_1 receptor, D_5 ; and two resembling the D_2 receptor, D_3 and D_4 , as well as two isoforms of the D_2 receptor that differ in the predicted length of their third intracellular loops, D_2 short and D_2 long. The D_1 and D_5 receptors activate adenylyl cyclase. The D_2 receptors couple to multiple effector systems, including the inhibition of adenylyl cyclase activity, suppression of Ca^{2+} currents, and activation of K^+ currents. The effector systems to which the D_3 and D_4 receptors

couple are not well defined. DA receptors have been implicated in the pathophysiology of schizophrenia and Parkinson's disease (see Chapters 18 and 20).

Norepinephrine

There are relatively large amounts of NE within the hypothalamus and in certain zones of the limbic system (e.g., the central nucleus of the amygdala, the dentate gyrus of the hippocampus). NE also is present in lower amounts in most brain regions. Mapping studies indicate that noradrenergic neurons of the locus ceruleus innervate specific target cells in a large number of cortical, subcortical, and spinomedullary fields.

Three types of adrenergic receptors (α_1 , α_2 , and β) and their subtypes occur in the CNS; all are GPCRs and can be distinguished in terms of their pharmacological properties and their distribution (see Chapter 10). The β adrenergic receptors are coupled to stimulation of adenylyl cyclase activity. The α_1 adrenergic receptors are associated predominantly with neurons, while α_2 adrenergic receptors are more characteristic of glial and vascular elements. The α_1 receptors couple to G_q to stimulate phospholipase C. The α_1 receptors on noradrenergic target neurons of the neocortex and thalamus respond to NE with prazosin-sensitive, depolarizing responses due to decreases in K^+ conductances (both voltage sensitive and voltage insensitive). Stimulation of α_1 receptors also can augment cyclic AMP accumulation in neocortical slices in response to vasoactive intestinal polypeptide, possibly an example of G_q - G_s cross-talk involving Ca^{2+} /calmodulin and/or PKC. α_2 Adrenergic receptors are prominent on noradrenergic neurons, where they presumably couple to G_p , inhibit adenylyl cyclase, and mediate a hyperpolarizing response due to enhancement of an inwardly rectifying K^+ channel.

Epinephrine

Epinephrine-containing neurons are found in the medullary reticular formation and make restricted connections to a few pontine and diencephalic nuclei, coursing as far rostrally as the paraventricular nucleus of the dorsal midline thalamus. Their physiological properties have not been identified.

5-HYDROXYTRYPTAMINE

In the mammalian CNS, neurons containing 5-hydroxytryptamine (5-HT) are found in nine nuclei lying in or adjacent to the midline (raphe) regions of the pons and upper brainstem. Cells receiving 5-HT input, such as the suprachiasmatic nucleus, ventrolateral geniculate body, amygdala, and hippocampus, exhibit a uniform and dense investment of reactive terminals.

There are 14 distinct mammalian 5-HT receptor subtypes (see Chapter 11) that exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, exhibit subtype-specific distributions within the CNS, and mediate distinct behavioral effects of 5-HT. The 5-HT receptors fall into four broad classes: the 5-HT₁ and 5-HT₂ classes both are GPCRs and include multiple isoforms within each class; the 5-HT₃ receptor is a ligand-gated ion channel with structural similarity to the α subunit of the nicotinic ACh receptor. Members of the 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇ classes all are GPCRs but have not been fully characterized in the CNS.

The 5-HT₁ receptor subset contains at least five receptor subtypes (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}) that are linked to inhibition of adenylyl cyclase activity or to regulation of K^+ or Ca^{2+} channels. The 5-HT_{1A} receptors are abundantly expressed on 5-HT neurons of the dorsal raphe nucleus, where they are thought to be involved in temperature regulation. They also are found in regions of the CNS associated with mood and anxiety such as the hippocampus and amygdala. Activation of 5-HT_{1A} receptors opens an inwardly rectifying K^+ conductance, which leads to hyperpolarization and neuronal inhibition. These receptors can be activated by the drugs buspirone and ipsapirone, which are used to treat anxiety and panic disorders (see Chapter 17). In contrast, 5-HT_{1D} receptors are activated by the drug sumatriptan (used for acute management of migraine headaches; see Chapters 11 and 21).

The 5-HT₂ receptor class has three subtypes: 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C}; all couple to pertussis toxin-insensitive G proteins (e.g., G_q and G_{11}) and link to activation of phospholipase C. 5-HT_{2A} receptors are enriched in forebrain regions such as the neocortex and olfactory tubercle, as well as in several nuclei arising from the brainstem. The 5-HT_{2C} receptor, similar in sequence and pharmacology to the 5-HT_{2A} receptor, is expressed abundantly in the choroid plexus, where it may modulate CSF production (see Chapter 11).

The 5-HT₃ receptors function as ligand-gated ion channels and are expressed in the area postrema and solitary tract nucleus, where they couple to potent depolarizing responses that show rapid desensitization to continued 5-HT exposure. Actions of 5-HT at central 5-HT₃ receptors can lead to emesis and antinociceptive actions, and 5-HT₃ antagonists are beneficial in the management of chemotherapy-induced emesis (see Chapter 37).

5-HT₄ receptors occur on neurons within the inferior and superior colliculi and in the hippocampus. Activation of 5-HT₄ receptors stimulates the G_s-adenylyl cyclase–cyclic AMP pathway. The 5-HT₆ and 5-HT₇ receptors also couple to G_s-adenylyl cyclase; their affinity for clozapine may relate to its antipsychotic efficacy (see Chapters 11 and 18). Of the two subtypes of 5-HT₅ receptors, the 5-HT_{5A} receptor seems to inhibit cyclic AMP synthesis, while 5-HT_{5B} receptor-effector coupling has not been described.

The hallucinogen lysergic acid diethylamide (LSD) interacts with 5-HT, primarily through 5-HT₂ receptors. When applied iontophoretically, LSD and 5-HT both potently inhibit the firing of raphe (5-HT) neurons, whereas LSD and other hallucinogens are far more potent excitants on facial motoneurons that receive innervation from the raphe. The inhibitory effect of LSD on raphe neurons offers a plausible explanation for its hallucinogenic effects, namely that these effects result from depression of activity in a system that tonically inhibits visual and other sensory inputs. However, typical LSD-induced behavior is still seen in animals with destroyed raphe nuclei or after blockade of the synthesis of 5-HT by *p*-chlorophenylalanine.

HISTAMINE Histaminergic neurons are located in the ventral posterior hypothalamus; they give rise to long ascending and descending tracts to the entire CNS. Based on the central effects of histamine antagonists, the histaminergic system is thought to regulate arousal, body temperature, and vascular dynamics.

There are four subtypes of histamine receptors; all are GPCRs. H₁ receptors, the most prominent, are located on glia, vessels, and neurons and act to mobilize Ca²⁺ in receptive cells through the G_q-PLC pathway. H₂ receptors couple via G_s to the activation of adenylyl cyclase, perhaps in concert with H₁ receptors in certain circumstances. H₃ receptors, which have the greatest sensitivity to histamine, are localized in basal ganglia and olfactory regions; consequences of H₃ receptor activation remain unresolved but may include reduced Ca²⁺ influx and feedback inhibition of transmitter synthesis and release (see Chapter 24). The expression of H₄ receptors is confined to cells of hematopoietic origin: eosinophils, T cells, mast cells, basophils, and dendritic cells. H₄ receptors appear to couple to G_{i/o} and G_q and are postulated to play a role in inflammation and chemotaxis.

PEPTIDES There are novel peptides in the CNS, each capable of regulating neural function, and peptides thought to be restricted to the gut or endocrine glands. While some CNS peptides may function individually, most appear to act in concert with coexisting transmitters (amines and amino acids). Some neurons may contain two or more transmitters, and their release can be independently regulated.

Since almost all peptides were identified initially on the basis of bioassays, their names reflect these biologically assayed functions (e.g., thyrotropin-releasing hormone and vasoactive intestinal polypeptide). A parsimonious view is that each peptide has unique messenger roles at the cellular level that are used repeatedly in functionally similar pathways within functionally distinct systems.

Peptides differ in several important respects from monoamine and amino acid transmitters. Peptide synthesis is performed in the rough endoplasmic reticulum. The propeptide is cleaved to the secreted form as secretory vesicles are transported from the perinuclear cytoplasm to the nerve terminals. Furthermore, no active recycling mechanisms for peptides have been described. This increases the dependency of peptidergic nerve terminals on distant sites of synthesis.

Since linear chains of amino acids can assume many conformations at their receptors, it is difficult to define the sequences and their steric relationships that are critical for activity. Thus, development of nonpeptidic synthetic agonists or antagonists that interact with specific peptide receptors has been difficult; similarly, morphine is only natural product that acts selectively at peptidergic synapses.

OTHER REGULATORY SUBSTANCES

Purines

Adenosine and uridine di- and triphosphates have roles as extracellular signaling molecules. ATP is a component of the adrenergic storage vesicle and is released with catecholamines. Intracellular nucleotides may also reach the cell surface by other means and extracellular adenosine can result from cellular release or extracellular production from adenine nucleotides. Extracellular nucleotides and adenosine act on a family of purinergic receptors that is divided into two classes, P1 and P2. The P1 receptors are GPCRs that interact with adenosine; two of these receptors (A₁ and A₃) couple to G_i and two (A_{2a} and A_{2b}) couple to G_s; methylxanthines antagonize A₁ and A₃ receptors (see Chapter 27). Activation of A₁ receptors is associated with inhibition of adenylyl

cyclase, activation of K^+ currents, and in some instances, with activation of PLC; stimulation of A_2 receptors activates adenylyl cyclase. The P2 class consists of a large number of P2X receptors that are ligand-gated ion channels, and of the P2Y receptors, a large subclass of GPCRs that couple to G_q or G_s and their associated effectors. P2Y₁₄ receptors are expressed in the CNS, interact with UDP-glucose, and may couple to G_q . The costorage of ATP and catecholamines in adrenergic storage vesicles and their co-release from adrenergic nerves suggests that P2Y receptors in the synaptic region will be stimulated whenever a nerve releases catecholamine. There is in vitro evidence for synergistic $G_q \rightarrow G_s$ cross talk (enhanced β adrenergic response) when β_2 receptors and G_q -linked P2Y receptors are activated simultaneously.

Much current interest stems from pharmacological rather than physiological observations. Adenosine can act presynaptically throughout the cortex and hippocampal formation to inhibit the release of amine and amino acid transmitters. ATP-regulated responses have been linked pharmacologically to a variety of supracellular functions, including anxiety, stroke, and epilepsy.

Diffusible Mediators

Arachidonic acid can be liberated during phospholipid hydrolysis (by pathways involving phospholipases A₂, C, and D; see Chapter 1) and converted to local regulatory molecules by cyclooxygenases (leading to prostaglandins and thromboxanes), lipoxygenases (leading to the leukotrienes and other transient catabolites of eicosatetraenoic acid), and CYPs (which are expressed at low levels in brain and are inducible) (see Chapter 25). Arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, particularly for LTP and other forms of plasticity.

In addition to its importance in the periphery as a regulator of vascular tone and inflammation, nitric oxide (NO) has roles in the CNS. Both constitutive and inducible forms of nitric oxide synthase (NOS) are expressed in the brain. Studies with potent inhibitors of NOS (e.g., methyl arginine and nitroarginine) and NO donors (e.g., nitroprusside) have implicated NO in a host of CNS phenomena, including LTP, activation of the soluble guanylyl cyclase, neurotransmitter release, and enhancement of glutamate (NMDA)-mediated neurotoxicity. Carbon monoxide (CO) may be a second gaseous, labile, diffusible intercellular regulator.

Cytokines

Cytokines are a family of polypeptide regulators produced throughout the body by cells of diverse embryological origin. Effects of cytokines are regulated by the conditions imposed by other cytokines, interacting as a network with variable effects leading to synergistic, additive, or opposing actions. Tissue-produced peptidic factors termed chemokines serve to attract cells of the immune and inflammatory lines into interstitial spaces. These special cytokines have received much attention as potential regulators in nervous system inflammation (as in early stages of dementia, following infection with human immunodeficiency virus, and during recovery from traumatic injury). Neurons and astrocytes may be induced under some pathophysiological conditions to express cytokines or other growth factors.

ACTIONS OF DRUGS IN THE CNS

SPECIFICITY AND NONSPECIFICITY OF CNS DRUG ACTIONS Specificity of CNS-active drugs often is a property of the dose–response relationship of the drug and the cell or mechanisms under scrutiny (see Chapters 1 and 5). Even a drug that is highly specific when tested at a low concentration may exhibit nonspecific actions at higher doses. Conversely, even generally acting drugs may not act equally on all levels of the CNS. For example, sedatives, hypnotics, and general anesthetics would have very limited utility if central neurons that control the respiratory and cardiovascular systems were especially sensitive to their actions. Drugs with specific actions may produce nonspecific effects if the dose and route of administration produce high tissue concentrations.

Drugs whose mechanisms currently appear to be primarily general or nonspecific are classed according to whether they produce behavioral depression or stimulation. Specifically acting CNS drugs can be classed more definitively according to their locus of action or specific therapeutic usefulness. The absence of overt behavioral effects does not rule out the existence of important central actions for a given drug. For example, the impact of muscarinic cholinergic antagonists on the behavior of normal animals may be subtle, but these agents are used extensively in the treatment of movement disorders and motion sickness (see Chapter 7).

The specificity of a drug's action frequently is overestimated, partly because the drug is identified with the effect that is implied by the class name. Although selectivity of action may be remarkable, a drug usually affects several CNS functions to varying degrees.

General (Nonspecific) CNS Depressants

This category includes the anesthetic gases and vapors, the aliphatic alcohols, and some hypnotic-sedative drugs. These agents can depress excitable tissue at all levels of the CNS, leading to a decrease in the amount of transmitter released by the nerve impulse, as well as to general depression of postsynaptic responsiveness and ion movement. At sub-anesthetic concentrations, these agents (e.g., ethanol) can exert relatively specific effects on certain groups of neurons, which may account for differences in their behavioral effects, especially the propensity to produce dependence (see Chapters 13, 16, and 22).

General (Nonspecific) CNS Stimulants

In this category are pentylene-tetrazol and related agents that are capable of powerful excitation of the CNS, and the methylxanthines, which have a much weaker stimulant action. Stimulation may be accomplished by one of two general mechanisms: (1) by blockade of inhibition or (2) by direct neuronal excitation (which may involve increased transmitter release, more prolonged transmitter action, labilization of the postsynaptic membrane, or decreased synaptic recovery time).

Drugs That Selectively Modify CNS Function

Modifiers may cause either depression or excitation, in some instances producing both effects simultaneously on different systems. Some modifiers have little effect on excitability in therapeutic doses. The principal classes of CNS modifiers are: anticonvulsants, drugs used in treating Parkinson's disease, opioid and nonopioid analgesics, appetite suppressants, antiemetics, analgesic-antipyretics, certain stimulants, neuroleptics (antidepressants and antimanic and antipsychotic agents), tranquilizers, sedatives, and hypnotics. Medications employed in the treatment of Alzheimer's disease (cholinesterase inhibitors and antiglutamate neuroprotectants) and compounds promising in the symptomatic treatment of Huntington's disease (tetraabenazine for the depletion of monoamines and reduction in tremor) may be included.

GENERAL CHARACTERISTICS OF CNS DRUGS Combinations of centrally acting drugs frequently are administered to therapeutic advantage (e.g., an anticholinergic drug and levodopa for Parkinson's disease). However, other combinations of drugs may be detrimental because of potentially dangerous additive or mutually antagonistic effects.

The effect of a CNS drug is additive with the physiological state and with the effects of other depressant and stimulant drugs. For example, anesthetics are less effective in a hyperexcitable subject than in a normal patient; the converse is true for stimulants. In general, the depressant effects of drugs from all categories are additive (e.g., the fatal combination of barbiturates or benzodiazepines with ethanol), as are the effects of stimulants. Therefore, respiration depressed by morphine is further impaired by depressant drugs, while stimulant drugs can augment the excitatory effects of morphine to produce vomiting and convulsions.

Antagonism between depressants and stimulants is variable. Some instances of true pharmacological antagonism among CNS drugs are known; for example, opioid antagonists selectively block the effects of opioid analgesics. However, the antagonism exhibited between two CNS drugs is usually physiological in nature. Thus, an individual whose CNS is depressed by an opiate cannot be returned entirely to normal by stimulation by caffeine.

The selective effects of drugs on specific neurotransmitter systems may be additive or competitive. This potential for drug interaction must be considered whenever such drugs are administered concurrently. To minimize such interactions, a drug-free period may be required when modifying therapy, and development of desensitized and supersensitive states with prolonged therapy may limit the speed with which one drug may be halted and another started. An excitatory effect is commonly observed with low concentrations of certain depressant drugs due either to depression of inhibitory systems or to a transient increase in the release of excitatory transmitters. Examples are the stage of excitement during induction of general anesthesia and the effects of alcohol to relieve inhibitions. The excitatory phase occurs only with low concentrations of the depressant; uniform depression ensues with increasing drug concentration. The excitatory effects can be minimized, when appropriate, by pretreatment with a depressant drug that is devoid of such effects (e.g., benzodiazepines in preanesthetic medication). Acute, excessive stimulation of the cerebrospinal axis normally is followed by depression, which is in part a consequence of neuronal fatigue and exhaustion of stores of transmitters. Postictal depression is additive with the effects of depressant drugs. Acute, drug-induced depression generally is not followed by stimulation. However, chronic drug-induced sedation or depression may be followed by prolonged hyperexcitability upon abrupt

withdrawal of the medication (barbiturates or alcohol). This type of hyperexcitability can be controlled effectively by the same or another depressant drug (*see* Chapters 16, 17, and 18).

Attempts to predict the behavioral or therapeutic consequences of drugs designed to elicit precise and restricted receptor actions in simple model systems may fail as a consequence of the complexity of the interactions possible, including differences between normal and diseased tissue.

GENERAL ANESTHETICS

General anesthetics depress the central nervous system (CNS) sufficiently to permit the performance of surgery and other noxious or unpleasant procedures. General anesthetics have low therapeutic indices and require great care in administration. While all general anesthetics produce a relatively similar anesthetic state, they differ in their secondary actions (side effects) on other organ systems. The selection of specific drugs and routes of administration to produce general anesthesia is based on their pharmacokinetic properties and on the secondary effects of the various drugs, in the context of the proposed diagnostic or surgical procedure and with the consideration of the individual patient's age, associated medical condition, and medication use. Anesthesiologists also employ sedatives (*see* Chapter 16), neuromuscular blocking agents (*see* Chapter 9), and local anesthetics (*see* Chapter 14)

GENERAL PRINCIPLES OF SURGICAL ANESTHESIA

The practice of anesthesia is usually neither therapeutic nor diagnostic, and the exceptions to this (*e.g.*, treatment of status asthmaticus with halothane and intractable angina with epidural local anesthetics) should not obscure this critical point. Hence, administration of general anesthesia and developments of new anesthetic agents and physiologic monitoring technology have been driven by three general objectives:

1. *Minimizing the potentially deleterious effects of anesthetic agents and techniques.*
2. *Sustaining physiologic homeostasis during surgical procedures* that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation.
3. *Improving postoperative outcomes* by choosing techniques that block or treat components of the *surgical stress response*, which may lead to short- or long-term sequelae.

Hemodynamic Effects of General Anesthesia The most prominent physiological effect of anesthesia induction is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, a blunting of baroreceptor control, and a generalized decrease in central sympathetic tone. The hypotensive response is enhanced by underlying volume depletion or preexisting myocardial dysfunction. Even anesthetics that show minimal hypotensive tendencies under normal conditions (*e.g.*, *etomidate* and *ketamine*) must be used with caution in trauma victims, in whom intravascular volume depletion is being compensated by intense sympathetic discharge. Smaller-than-normal anesthetic dosages are employed in patients presumed to be sensitive to hemodynamic effects of anesthetics.

Respiratory Effects of General Anesthesia Airway maintenance is essential following induction of anesthesia, as nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation is a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (*see* Chapter 9), reducing the risk of coughing or gagging during laryngoscopic-assisted instrumentation of the airway and of aspiration prior to secure placement of an endotracheal tube. Alternatives to an endotracheal tube include a facemask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis.

Hypothermia Prevention of hypothermia has emerged as a major goal of anesthetic care. Patients commonly develop hypothermia (body temperature $<36^{\circ}\text{C}$) during surgery. The reasons for hypothermia include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, reduced metabolic rate, and peripheral vasodilation produced by anesthetics that permits heat transfer from the core to peripheral body compartments. General anesthetics lower the core temperature set point at which thermoregulatory vasoconstriction is activated to defend against heat loss. Metabolic rate and total body oxygen consumption decrease with general anesthesia by $\sim 30\%$, reducing heat generation. Even small drops in body temperatures may increase perioperative morbidity, including cardiac complications, wound infections, and impaired coagulation.

Modalities to maintain normothermia include using warm intravenous fluids, heat exchangers in the anesthesia circuit, forced-warm-air covers, and new technology involving water-filled garments with microprocessor feedback control to a core temperature set point.

Nausea and Vomiting Nausea and vomiting in the postoperative period continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by serotonin (5-HT), histamine, acetylcholine, and dopamine. The 5-HT₃ receptor antagonist *ondansetron* (see Chapter 37) is very effective in suppressing nausea and vomiting. Common treatments also include *droperidol*, *metoclopramide*, *dexamethasone*, and avoidance of N₂O. The use of *propofol* as an induction agent and the nonsteroidal anti-inflammatory drug *ketorolac* as a substitute for opioids may decrease the incidence and severity of postoperative nausea and vomiting.

Other Emergence and Postoperative Phenomena Physiological changes accompanying emergence from general anesthesia can be profound. Hypertension and tachycardia are common as the sympathetic nervous system regains its tone, which is enhanced by pain. Myocardial ischemia can appear or markedly worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5–30% of patients and is characterized by tachycardia, restlessness, crying, moaning and thrashing, and various neurological signs. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of *meperidine* (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of these emergence phenomena is greatly reduced when opioids are employed as part of the intraoperative regimen.

Airway obstruction may occur during the postoperative period because residual anesthetic effects continue to partially obtund consciousness and reflexes (especially in patients who normally snore or who have sleep apnea). Strong inspiratory efforts against a closed glottis can lead to negative-pressure pulmonary edema. Pulmonary function is reduced postoperatively following all types of anesthesia and surgery, and hypoxemia may occur. Hypertension can be prodigious, often requiring aggressive treatment.

Pain control can be complicated in the immediate postoperative period. Respiratory suppression associated with opioids can be problematic among postoperative patients with a substantial residual anesthetic effect. Patients can alternate between screaming in apparent agony and being deeply somnolent with airway obstruction, all in a matter of moments. The nonsteroidal antiinflammatory agent *ketorolac* (30–60 mg intravenously) frequently is effective, and the development of injectable cyclooxygenase-2 inhibitors (see Chapter 26) holds promise for analgesia without respiratory depression. In addition, regional anesthetic techniques are an important part of a perioperative multimodal approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, α_2 adrenergic receptor agonists, and NMDA receptor antagonists. Patient-controlled administration of intravenous and epidural analgesics makes use of small, computerized pumps activated on demand but programmed with safety limits to prevent overdose. Agents used are intravenous opioids (frequently *morphine*), and opioid, local anesthetic, or both, by the epidural route. These techniques have revolutionized postoperative pain management, can be continued for hours or days, and promote ambulation and improved bowel function until oral pain medications are initiated.

ACTIONS AND MECHANISMS OF GENERAL ANESTHETICS

The Anesthetic State

General anesthetics produce a behavioral state referred to as *general anesthesia*, which can be defined as a global but reversible depression of CNS function resulting in the loss of response to and perception of all external stimuli. However, anesthesia is not simply a deafferented state (*e.g.*, amnesia is an important aspect of the anesthetic state), and not all general anesthetics produce identical patterns of deafferentation.

Components of the anesthetic state include *amnesia*, *immobility* in response to noxious stimulation, *attenuation of autonomic responses* to noxious stimulation, *analgesia*, and *unconsciousness*. General anesthesia is useful only insofar as it facilitates the performance of surgery or other noxious procedures. The performance of surgery usually requires an immobilized patient who does not have an excessive autonomic response to surgery (blood pressure and heart rate) and who has amnesia for the procedure. Thus, the essential components of the anesthetic state are immobilization, amnesia, and attenuation of autonomic responses to noxious stimulation. If an anesthetic produces profound amnesia, it can be difficult in principle to determine if it also produces either analgesia or unconsciousness.

Anesthetic Potency

The potency of general anesthetics usually is measured by determining the concentration of drug that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in MAC units, with 1 MAC defined as the *minimum alveolar concentration* that prevents movement in response to surgical stimulation in 50% of subjects. The strengths of MAC as a measurement are that (1) alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry; (2) it provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the CNS; (3) it is a simple-to-measure end point that reflects an important clinical goal. End points other than immobilization also can be used to measure anesthetic potency (e.g., the ability to respond to verbal commands [MAC_{awake}] or to form memories; both are suppressed at a fraction of MAC) (Table 13–1). Potency of intravenous anesthetic agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Sites and Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology.

SITES OF ACTION

In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Delimitation of the precise anatomic sites of action is difficult because many anesthetics diffusely inhibit electrical activity in the CNS. Anesthetics may produce specific components of the anesthetic state via actions at specific sites in the CNS. Inhalational anesthetics produce immobilization in response to a surgical incision (the end point used in determining MAC) by action on the spinal cord. Given that amnesia or unconsciousness cannot result from anesthetic actions in the spinal cord, different components of anesthesia must be produced at different sites in the CNS. Indeed, the sedative effects of pentobarbital and propofol (GABAergic anesthetics) are mediated by GABA_A receptors in the tuberomammillary nucleus, and the sedative effects of the intravenous anesthetic dexmedetomidine (an α_2 adrenergic receptor agonist) are produced via actions in the locus ceruleus, suggesting that the sedative actions of some anesthetics share the neuronal pathways involved in endogenous sleep. Inhalational anesthetics depress the excitability of thalamic neurons, pointing to the thalamus as a potential locus for the sedative effects of inhalational anesthetics, since blockade of thalamocortical communication would produce unconsciousness. Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission, a probable locus for their amnesic effects.

CELLULAR MECHANISMS

General anesthetics produce two important physiologic effects at the cellular level. First, inhalational anesthetics hyperpolarize neurons, possibly an important effect on neurons serving a pace-maker role and on pattern-generating circuits and in synaptic communication, since reduced excitability in a postsynaptic neuron diminishes the likelihood that an action potential will be initiated in response to neurotransmitter release. Second, at anesthetizing concentrations, both inhalational and intravenous anesthetics have substantial effects on synaptic transmission and much smaller effects on action-potential generation or propagation. Inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses via effects on pre- and postsynaptic sites. The inhalational anesthetic isoflurane clearly can inhibit neurotransmitter release and produce a small reduction in presynaptic action potential amplitude (3% reduction at MAC concentration) that inhibits neurotransmitter release, a significant effect because the reduced action potential is amplified into a larger reduction in presynaptic Ca²⁺ influx, and thence into an even greater reduction in transmitter release. Inhalational anesthetics also can act postsynaptically, to alter the response to released neurotransmitter, probably via actions at neurotransmitter receptors.

Intravenous anesthetics produce a narrower range of physiological effects, predominantly at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

MOLECULAR ACTIONS

There is strong evidence that ligand-gated ion channels are important targets for anesthetic action. Chloride channels gated by the inhibitory GABA_A receptors (see Chapters 12 and 16) are sensitive

to clinical concentrations of a wide variety of anesthetics, including the halogenated inhalational agents and many intravenous agents (propofol, barbiturates, etomidate, and neurosteroids). At clinical concentrations, general anesthetics increase the sensitivity of the GABA_A receptor to GABA, thus enhancing inhibitory neurotransmission and depressing nervous system activity. This effect probably is mediated by binding of the anesthetics to specific sites on the GABA_A receptor subunits, since point mutations of the receptor eliminate the effects. General anesthetics do not compete with GABA binding to the GABA_A receptor; however, there likely are specific binding sites for several classes of anesthetics, since mutations in various regions (and subunits) of the GABA_A receptor selectively affect the actions of various anesthetics. The capacity of propofol and etomidate to inhibit the response to noxious stimuli is mediated by a specific site on the β_3 subunit of the GABA_A receptor; the sedative effects of these anesthetics are mediated by the same site on the β_2 subunit. These results indicate that two components of anesthesia can be mediated by GABA_A receptors; for anesthetics other than propofol and etomidate, which components of anesthesia are produced by actions on GABA_A receptors remains a matter of conjecture.

Clinical concentrations of inhalational anesthetics enhance the capacity of glycine to activate glycine-gated chloride channels (glycine receptors), which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. Propofol, neurosteroids, and barbiturates also potentiate glycine-activated currents; etomidate and ketamine do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic ACh receptors; these actions do not appear to mediate anesthetic immobilization but could mediate other components of anesthesia such as analgesia or amnesia.

The only general anesthetics that do not have significant effects on GABA_A or glycine receptors are ketamine, nitrous oxide, cyclopropane, and xenon. These agents inhibit a different type of ligand-gated ion channel, the N-methyl-D-aspartate (NMDA) receptor (see Chapter 12). Ketamine inhibits NMDA receptors by binding to the phencyclidine site on the NMDA receptor protein. Nitrous oxide and xenon are potent and selective inhibitors of NMDA-activated currents; perhaps these agents produce unconsciousness via actions on NMDA receptors.

Inhalational anesthetics have two other known molecular targets that may mediate some of their actions. Halogenated inhalational anesthetics activate some members of a class of K⁺ channels known as two-pore domain channels; xenon, nitrous oxide, and cyclopropane activate other two-pore domain channel family members. These channels are important in setting the resting membrane potential of neurons and may be the molecular locus through which these agents hyperpolarize neurons. A second target is the molecular machinery involved in neurotransmitter release. In *Caenorhabditis elegans*, the action of inhalational anesthetics requires a protein complex (syntaxin, SNAP-25, synaptobrevin) involved in synaptic neurotransmitter release. These molecular interactions may explain in part the capacity of inhalational anesthetics to cause presynaptic inhibition in the hippocampus and could contribute to the amnesic effect of inhalational anesthetics.

PARENTERAL ANESTHETICS

Pharmacokinetic Principles

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 13–1). Hydrophobicity is the key factor governing their pharmacokinetics. After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord where they produce anesthesia within a single circulation time. Subsequently, blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less perfused tissues such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism. After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-lives are “context-sensitive,” and the degree to which a $t_{1/2}$ is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Table 13–2 and Figure 13–2). Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of and fraction of anesthetic dose delivered to the brain is higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of anesthetic. The elderly also typically require a smaller anesthetic dose, primarily because of a smaller initial volume of distribution.

FIGURE 13-1 Structures of parenteral anesthetics.

Thiopental and propofol are the two most commonly used parenteral agents. Thiopental has a long-established track record of safety. Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Etomidate usually is reserved for patients at risk for hypotension and/or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures.

SPECIFIC PARENTERAL AGENTS

Barbiturates

CHEMISTRY AND FORMULATIONS

The three barbiturates used for clinical anesthesia are sodium thiopental (Figure 13-1), thiamylal, and methohexital. Thiopental (PENTOTHAL) is most frequently used for inducing anesthesia. Barbiturates are formulated as the sodium salts and reconstituted in water or isotonic saline to produce alkaline solutions (pHs of 10–11). Once reconstituted, thiobarbiturates are stable in solution for up to 1 week. Mixing with more acidic drugs commonly used during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.

DOSAGES AND CLINICAL USE Recommended intravenous dosing for parenteral anesthetics in a healthy young adult is given in Table 13-2.

The typical induction dose (3–5 mg/kg) of thiopental produces unconsciousness in 10–30 seconds with a peak effect in 1 minute and duration of anesthesia of 5–8 minutes. Neonates and infants usually require a higher induction dose (5–8 mg/kg); elderly and pregnant patients require less (1–3 mg/kg). Dosage calculation based on lean body mass reduces individual variation in dosage requirements. Doses can be reduced by 10–50% after premedication with benzodiazepines, opiates, or α_2 adrenergic agonists, because of their additive hypnotic effect. Thiamylal is approximately equipotent with and in all aspects similar to thiopental. Methohexital (BREVITAL) is threefold more potent but otherwise similar to thiopental in onset and duration of action. Thiopental and thiamylal produce little to no pain on injection; methohexital elicits mild pain. Veno-irritation can be reduced by injection into larger non-hand veins and by prior intravenous injection of lidocaine (0.5–1 mg/kg). Intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction and should be avoided. Thiopental often evokes the taste of garlic just prior to inducing anesthesia. Methohexital and to a lesser degree the other barbiturates can produce excitement phenomena such as muscle tremor, hypertonus, and hiccups. For induction of pediatric patients without IV access, all three drugs can be given per rectum at approximately tenfold the IV dose.

PHARMACOKINETICS AND METABOLISM Pharmacokinetic parameters for parenteral anesthetics are given in Table 13-2. As discussed above, the principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances.

FIGURE 13-2 *Context-sensitive half-time of general anesthetics.* The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites. However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug's metabolic rate. This phenomenon has been termed the *context-sensitive half-time*; that is, the half-time of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as etomidate, propofol, and ketamine increase only modestly with prolonged infusions; others (e.g., diazepam and thiopental) increase dramatically.

All three barbiturates are primarily eliminated by hepatic metabolism and renal excretion of inactive metabolites; a small fraction of thiopental undergoes desulfuration to the longer-acting hypnotic pentobarbital. Each drug is highly protein bound (Table 13-2). Hepatic disease or other conditions that reduce serum protein concentration will decrease the volume of distribution and thereby increase the initial free concentration and hypnotic effect of an induction dose.

SIDE EFFECTS

Nervous System Besides producing general anesthesia, barbiturates reduce the cerebral oxygen consumption ($CMRO_2$) in a dose-dependent manner. As a consequence, cerebral blood flow and intracranial pressure are similarly reduced.

Because it markedly lowers cerebral metabolism, thiopental has been used as a protectant against cerebral ischemia. At least one human study suggests that thiopental may be efficacious in ameliorating ischemic damage in the perioperative setting. Thiopental also reduces intraocular pressure. Perhaps due to their CNS depressant activity, barbiturates are effective anticonvulsants; thiopental in particular is effective in the treatment of status epilepticus.

Cardiovascular The anesthetic barbiturates produce dose-dependent decreases in blood pressure that are due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex.

Thiopental is not contraindicated in patients with coronary artery disease because the ratio of myocardial oxygen supply to demand appears to be adequately maintained within a patient's normal blood pressure range.

Respiratory Barbiturates are respiratory depressants. Induction doses of thiopental decrease minute ventilation and tidal volume with a smaller and inconsistent decrease in respiratory rate; reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates; at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. With the exception of uncommon anaphylactoid reactions, these drugs have little effect on bronchomotor tone and can be used safely in asthmatics.

Other Side Effects

Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. A single induction dose of thiopental does not alter tone of the gravid uterus, but may produce mild transient depression of newborn activity. Drug-induced histamine release is occasionally seen. Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. Unlike inhalational anesthetics and succinylcholine, barbiturates and all other parenteral anesthetics apparently do not trigger malignant hyperthermia.

Propofol

CHEMISTRY AND FORMULATIONS

Propofol (DIPRIVAN Figure 13–1) is the most commonly used parenteral anesthetic in the U.S. The drug is insoluble in aqueous solutions and is formulated only for IV administration as a 1% (10 mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. Significant bacterial contamination of open containers has been associated with serious patient infection; propofol should be either administered or discarded shortly after removal from sterile packaging.

DOSAGE AND CLINICAL USE The induction dose, onset, and duration of anesthesia are similar to thiopental (Table 13–2). Dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination $t_{1/2}$, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10–50% of the induction dose) every 5 minutes or as needed are effective. An infusion of propofol (100–300 $\mu\text{g}/\text{kg}/\text{min}$) produces a more stable drug level and is better suited for longer-term anesthetic maintenance. Sedating doses of propofol are 20–50% of those required for general anesthesia. However, even at these lower doses, caregivers should be prepared for all of the side effects of propofol, particularly airway obstruction and apnea. Propofol elicits pain on injection that can be reduced with lidocaine and the use of larger arm and antecubital veins. Excitatory phenomena during induction with propofol occur at about the same frequency as with thiopental.

PHARMACOKINETICS AND METABOLISM

The pharmacokinetics of propofol are summarized in Table 13–2. Propofol's duration after infusion (shorter than that of thiopental) can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment. The rapid clearance of propofol explains its less severe hangover compared with barbiturates and may allow for a more rapid discharge from the recovery room. Propofol is metabolized in the liver to less active metabolites that are renally excreted. Propofol is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels.

SIDE EFFECTS

Nervous System The CNS effects of propofol are similar to those of barbiturates, but, unlike thiopental, propofol is not a proven acute intervention for seizures.

Cardiovascular Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental; the effect is explained by vasodilation and mild depression of myocardial contractility. Propofol appears to blunt the baroreceptor reflex or is directly vagotonic. As with thiopental, propofol should be used with caution in patients at risk for or intolerant of decreases in blood pressure.

Respiratory and Other Side Effects At equipotent doses, propofol produces a slightly greater degree of respiratory depression than thiopental. Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol has significant antiemetic action and is a good choice for sedation or anesthesia of patients at high risk for nausea and vomiting. Propofol provokes anaphylactoid reactions and histamine release at about the same low frequency as thiopental. Propofol is considered safe for use in pregnant women, and like thiopental, only transiently depresses activity in the newborn.

Etomidate

CHEMISTRY AND FORMULATION

Etomidate (Figure 13–1) is poorly soluble in water and is formulated as a 2 mg/mL solution in 35% propylene glycol. Unlike thiopental, etomidate does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction.

DOSAGE AND CLINICAL USE Etomidate (AMIDATE) is primarily used for anesthetic induction of patients at risk for hypotension.

Induction doses (Table 13–2) are accompanied by a high incidence of pain on injection and myoclonic movements. Lidocaine effectively reduces the pain of injection; myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. Long-term infusions are not recommended for reasons discussed below.

PHARMACOKINETICS AND METABOLISM

An induction dose of etomidate has a rapid onset; redistribution limits the duration of action (Table 13–2). Metabolism occurs in the liver; primarily to inactive compounds. Elimination is both renal (78%) and biliary (22%). Compared to thiopental, the duration of action of etomidate increases less with repeated doses (Figure 13–2).

SIDE EFFECTS

Nervous System The effects of etomidate on cerebral blood flow, metabolism, and intracranial pressure (ICP) and intraocular pressure are similar to those of thiopental. Etomidate is not a proven treatment for seizures.

Cardiovascular Cardiovascular stability after induction is a major advantage of etomidate over either barbiturates or propofol. Induction doses of etomidate typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output. Etomidate has little effect on coronary perfusion pressure while reducing myocardial O₂ consumption. Thus, of all induction agents, etomidate is best suited to maintain cardiovascular stability in patients with coronary artery disease, cardiomyopathy, cerebral vascular disease, or hypovolemia.

Respiratory and Other Side Effects The degree of respiratory depression due to etomidate is less than that due to thiopental. Etomidate may induce hiccups but does not significantly stimulate histamine release. Despite minimal cardiac and respiratory effects, etomidate has two major drawbacks: etomidate has been associated with nausea and vomiting; second, the drug inhibits adrenal biosynthetic enzymes required for the production of cortisol and other steroids, possibly inhibiting the adrenocortical stress response. Even single induction doses of etomidate may mildly and transiently reduce cortisol levels. Thus, while etomidate is not recommended for long-term infusion, it appears safe for anesthetic induction and has some unique advantages in patients prone to hemodynamic instability.

FIGURE 13–3 Structures of inhaled general anesthetics. Note that all inhaled general anesthetic agents except nitrous oxide and halothane are ethers and that fluorine progressively replaces other halogens in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.

Ketamine

CHEMISTRY AND FORMULATION

Ketamine is a congener of phencyclidine (Figure 13–1). Although more lipophilic than thiopental, ketamine is water soluble.

DOSAGE AND CLINICAL USE Ketamine (KETALAR, others) has unique properties that make it useful for anesthetizing patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. Ketamine rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia, but may have their eyes open, move their limbs involuntarily, and breathe spontaneously, a cataleptic state that has been termed *dissociative anesthesia*.

Ketamine typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. Ketamine does not elicit pain on injection or true excitatory behavior as described for methohexital, although involuntary movements produced by ketamine can be mistaken for anesthetic excitement.

PHARMACOKINETICS AND METABOLISM

The onset and duration of an induction dose of ketamine (Table 13–2) are determined by the same distribution/redistribution mechanism operant for all the other parenteral anesthetics.

Ketamine is hepatically metabolized to norketamine, which has reduced CNS activity; norketamine is further metabolized and excreted in urine and bile. Ketamine has a large volume of distribution and rapid clearance that make it suitable for continuous infusion without the drastic lengthening in duration of action seen with thiopental (Table 13–2 and Figure 13–2).

SIDE EFFECTS

Nervous System Ketamine has indirect sympathomimetic activity and produces distinct behavioral effects. The ketamine-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation, lacrimation, and spontaneous limb movements with increased overall muscle tone. Although ketamine does not produce the classic anesthetic state, patients are amnesic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics.

Unlike other parenteral anesthetics, ketamine increases cerebral blood flow and ICP with minimal alteration of cerebral metabolism. These effects can be attenuated by concurrent administration of thiopental and/or benzodiazepines along with hyperventilation. However, given that other anesthetics actually reduce ICP and cerebral metabolism, ketamine is relatively contraindicated for patients with increased ICP or those at risk for cerebral ischemia. The effects of ketamine on seizure activity are mixed. Emergence delirium characterized by hallucinations is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management. Delirium is most frequent in the first hour after emergence and appear to occur less frequently in children; benzodiazepines reduce the incidence of emergence delirium.

Cardiovascular System Unlike other anesthetics, induction doses of ketamine typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most

likely mediated by inhibition of both central and peripheral catecholamine reuptake. Ketamine has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action. Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. Ketamine increases myocardial oxygen consumption and is not an ideal drug for patients at risk for myocardial ischemia.

Respiratory System The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other general anesthetics. Ketamine is a potent bronchodilator and is well-suited for anesthetizing patients at high risk for bronchospasm.

INHALATIONAL ANESTHETICS

Structures of the currently used inhalational anesthetics are shown in Figure 13–3. One of the troublesome properties of the inhalational anesthetics is their low safety margin. The inhalational anesthetics have therapeutic indices (LD_{50}/ED_{50}) that range from 2–4, making these among the most dangerous drugs in clinical use. The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on matching a patient's pathophysiology with drug side-effect profiles. The inhalational anesthetics also vary widely in their physical properties (Table 13–1), which govern the pharmacokinetics of the inhalational agents. Ideally, an inhalational agent would produce a rapid induction of anesthesia and a rapid recovery following discontinuation.

Pharmacokinetic Principles

The fact that these agents behave as gases rather than as liquids requires that different pharmacokinetic constructs be used in analyzing their uptake and distribution. Inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. However, while the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different; indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentrations in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:blood, and fat:blood partition coefficients (Table 13–1) show that inhalational anesthetics are more soluble in some tissues (*e.g.*, fat) than they are in others (*e.g.*, blood), and that there is significant range in the solubility of the various inhalational agents.

In clinical practice, one can monitor the equilibration of a patient with anesthetic gas. Equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. This defines equilibrium because it is the point at which there is no net uptake of anesthetic from the alveoli into the blood. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly (*e.g.*, nitrous oxide, Figure 13–4). If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs because fat represents a huge anesthetic reservoir that will be filled slowly because of the modest blood flow to fat (*e.g.*, halothane, Figure 13–4).

In considering the pharmacokinetics of anesthetics, one important parameter is the speed of anesthetic induction. Anesthesia is produced when anesthetic partial pressure in brain is \geq MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC. While the rate of rise of alveolar partial pressure will be slower for anesthetics that are highly soluble in blood and other tissues, this limitation on speed of induction can be overcome largely by delivering higher inspired partial pressures of the anesthetic.

Elimination of inhalational anesthetics is largely the reverse process of uptake. For agents with low blood and tissue solubility, recovery from anesthesia should mirror anesthetic induction, regardless of the duration of administration. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of administration, because anesthetic accumulated in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC_{awake} , a partial pressure somewhat lower than MAC (Table 13–1).

FIGURE 13-4 Uptake of inhalational general anesthetics. The rise in end-tidal alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least soluble anesthetics, nitrous oxide and desflurane, and slowest with the most soluble anesthetic, halothane.

Halothane

CHEMISTRY AND FORMULATION

Halothane (FLUOTHANE Figure 13-3) is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is light-sensitive and subject to spontaneous breakdown, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with oxygen or air are neither flammable nor explosive.

PHARMACOKINETICS

Halothane has a relatively high blood:gas partition coefficient and high fat:blood partition coefficient (Table 13-1). Thus, induction with halothane is relatively slow, and the alveolar halothane concentration remains substantially lower than the inspired halothane concentration for many hours of administration. Since halothane accumulates in tissues during prolonged administration, the speed of recovery from halothane is lengthened as a function of duration of administration.

Approximately 60–80% of halothane taken up by the body is eliminated unchanged via the lungs in the first 24 hours after its administration. A substantial amount of the halothane not eliminated in exhaled gas is biotransformed by hepatic CYPs. Trifluoroacetylchloride, an intermediate in oxidative metabolism of halothane, can trifluoroacetylate several proteins in the liver. An immune reaction to these altered proteins may be responsible for the rare cases of fulminant halothane-induced hepatic necrosis.

CLINICAL USE Halothane is a potent, nonpungent and well-tolerated agent that usually is used for maintenance of anesthesia and is well tolerated for inhalation induction of anesthesia, most commonly in children, in whom preoperative placement of an intravenous catheter can be difficult. Anesthesia is produced by halothane at end-tidal concentrations of 0.7–1%. The use of halothane in the U.S. has diminished substantially since the introduction of newer inhalational agents with better pharmacokinetic and side-effect profiles.

SIDE EFFECTS

Cardiovascular System The most predictable side effect of halothane is a dose-dependent reduction in arterial blood pressure. Mean arterial pressure typically decreases ~20–25% at MAC concentrations of halothane, primarily as a result of direct myocardial depression, and perhaps an inability of the heart to respond to the effector arm of the baroreceptor reflex. Halothane-induced reductions in blood pressure and heart rate generally disappear after several hours of constant halothane administration, presumably because of progressive sympathetic stimulation.

Halothane dilates the vascular beds of the skin and brain, whereas autoregulation of renal, splanchnic, and cerebral blood flow is inhibited by halothane, leading to reduced perfusion of these organs in the face of reduced blood pressure. Coronary autoregulation is largely preserved. Halothane inhibits hypoxic pulmonary vasoconstriction, leading to increased perfusion to poorly ventilated regions of the lung and an increased alveolar:arterial oxygen gradient.

Sinus bradycardia and atrioventricular rhythms occur frequently during halothane anesthesia but usually are benign and result mainly from a direct depressive effect of halothane on sinoatrial node discharge. Halothane also can sensitize the myocardium to the arrhythmogenic effects of epinephrine.

Respiratory System Spontaneous respiration is rapid and shallow during halothane anesthesia. The decreased alveolar ventilation results in an elevation in arterial CO₂ tension from 40 mm Hg to >50 mm Hg at 1 MAC. The elevated CO₂ does not provoke a compensatory increase in ventilation, because halothane causes a concentration-dependent inhibition of the ventilatory response to CO₂. Halothane also inhibits peripheral chemoceptor responses to arterial hypoxemia. Thus, neither hemodynamic (tachycardia and hypertension) nor ventilatory responses to hypoxemia are observed during halothane anesthesia, making it prudent to monitor arterial oxygenation directly.

Nervous System Halothane dilates the cerebral vasculature, increasing cerebral blood flow under most conditions. This increase in blood flow can increase intracranial pressure in patients with space-occupying intracranial masses, brain edema, or preexisting intracranial hypertension. Thus, halothane is relatively contraindicated in patients at risk for elevated intracranial pressure. Halothane also attenuates autoregulation of cerebral blood flow.

Muscle Halothane causes some relaxation of skeletal muscle *via* its central depressant effects and potentiates the actions of nondepolarizing muscle relaxants (curariform drugs; *see* Chapter 9), increasing both their duration of action and the magnitude of their effect. Halothane and the other halogenated inhalational anesthetics can trigger malignant hyperthermia; this syndrome frequently is fatal and is treated by immediate discontinuation of the anesthetic and administration of dantrolene.

Halothane relaxes uterine smooth muscle, a useful property for manipulation of the fetus (version) in the prenatal period and for delivery of retained placenta.

Kidney, Liver, and GI Tract Patients anesthetized with halothane usually produce a small volume of concentrated urine, a consequence of halothane-induced reduction of renal blood flow and glomerular filtration rate. Halothane-induced changes in renal function are fully reversible and are not associated with long-term nephrotoxicity.

Halothane reduces splanchnic and hepatic blood flow. Halothane can produce fulminant hepatic necrosis in a small number of patients, a syndrome characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia and sometimes accompanied by a rash and peripheral eosinophilia. There is a rapid progression to hepatic failure, with a fatality rate of ~50%. This syndrome occurs in about 1 in 10,000 patients receiving halothane and is referred to as halothane hepatitis. Halothane hepatitis may be the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism (*see* Pharmacokinetics, above).

Isoflurane

CHEMISTRY AND PHYSICAL PROPERTIES

Isoflurane (FORANE, others Figure 13-3) is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or oxygen.

PHARMACOKINETICS

Isoflurane has a blood:gas partition coefficient substantially lower than that of halothane or enflurane (Table 13-1). Consequently, induction with isoflurane and recovery from isoflurane are relatively rapid. More than 99% of inhaled isoflurane is excreted unchanged via the lungs. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen.

CLINICAL USE Isoflurane is typically used for maintenance of anesthesia *after* induction with other agents because of its pungent odor, but induction of anesthesia can be achieved in <10 minutes with an inhaled concentration of 3% isoflurane in O₂; this concentration is reduced to 1–2% for maintenance of anesthesia. Use of drugs (*e.g.*, opioids, nitrous oxide) reduces the concentration of isoflurane required for surgical anesthesia.

SIDE EFFECTS

Cardiovascular System Isoflurane produces a concentration-dependent decrease in arterial blood pressure; cardiac output is maintained and hypotension is the result of decreased systemic vascular resistance. Vasodilation occurs in most vascular beds, particularly in skin and muscle. Isoflurane is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O₂ consumption. Patients anesthetized with isoflurane generally have mildly elevated heart rates as a compensatory response to reduced blood pressure; however, rapid changes in isoflurane concentration can produce both transient tachycardia and hypertension due to isoflurane-induced sympathetic stimulation.

Respiratory System Patients spontaneously breathing isoflurane have a normal respiration rate but a reduced tidal volume, resulting in a marked reduction in alveolar ventilation and an increase in arterial CO₂ tension. Isoflurane depresses the ventilatory response to hypercapnia and hypoxia. While an effective bronchodilator, isoflurane also is an airway irritant and can stimulate airway reflexes during induction, producing coughing and laryngospasm.

Nervous System Isoflurane reduces cerebral metabolic O₂ consumption and causes less cerebral vasodilation than do either enflurane or halothane, making it a preferred agent for neurosurgical procedures. The modest effects of isoflurane on cerebral blood flow can be reversed readily by hyperventilation.

Muscle Isoflurane produces some relaxation of skeletal muscle *via* its central effects. It also enhances the effects of depolarizing and nondepolarizing muscle relaxants. Isoflurane is more potent than halothane in its potentiation of neuromuscular blocking agents. The drug relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

Kidney, Liver, and GI Tract

Isoflurane reduces splanchnic and hepatic blood flows and renal blood flow and glomerular filtration rate. There are no reports of toxicities or long-term sequelae.

Enflurane**CHEMICAL AND PHYSICAL PROPERTIES**

Enflurane (ETHRANE, others Figure 13–3) is a clear, colorless liquid at room temperature with a mild, sweet odor. It is volatile and must be stored in a sealed bottle but is nonflammable and nonexplosive in mixtures of air or oxygen.

PHARMACOKINETICS

Consistent with its blood: gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow (Table 13–1). Enflurane is metabolized to a modest extent (2–8% of absorbed enflurane) by hepatic CYP2E1. Fluoride ions are a by-product of enflurane metabolism, but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with a consequent elevation of serum fluoride.

CLINICAL USE Enflurane is primarily utilized for maintenance rather than induction of anesthesia, although surgical anesthesia can be induced in <10 minutes with an inhaled concentration of 4% in oxygen. Anesthesia can be maintained with concentrations from 1.5% to 3%. Concentrations required to produce anesthesia are reduced when enflurane is coadministered with nitrous oxide or opioids.

SIDE EFFECTS

Cardiovascular System Enflurane causes a concentration-dependent decrease in arterial blood pressure, due, in part, to depression of myocardial contractility and peripheral vasodilation. Enflurane has minimal effects on heart rate.

Respiratory System The respiratory effects of enflurane are similar to those of halothane. Enflurane produces a greater depression of the ventilatory responses to hypoxia and hypercarbia than do either halothane or isoflurane and, like other inhalational anesthetics, is an effective bronchodilator.

Nervous System Enflurane is a cerebral vasodilator that increases intracranial pressure in some patients. The drug reduces cerebral metabolic O₂ consumption and has an unusual property of producing electrical seizure activity. High concentrations of enflurane or profound hypocarbia

during enflurane anesthesia result in a characteristic high-voltage, high-frequency EEG pattern that progresses to spike-and-dome complexes punctuated by frank seizure activity that may be accompanied by peripheral motor manifestations. The seizures are self-limited and are not thought to produce permanent damage. Epileptic patients are not particularly susceptible to enflurane-induced seizures; nonetheless, enflurane generally is not used in patients with seizure disorders.

Muscle Enflurane produces significant skeletal muscle relaxation and noticeably enhances the effects of nondepolarizing muscle relaxants. As with other inhalational agents, enflurane relaxes uterine smooth muscle.

Kidney, Liver, and GI Tract

Enflurane reduces renal blood flow, glomerular filtration rate, and urinary output. These effects are rapidly reversed upon drug discontinuation. There is scant evidence of long-term nephrotoxicity following enflurane use, and it is safe to use in patients with renal impairment provided that the depth of enflurane anesthesia and the duration of administration are not excessive. Enflurane reduces splanchnic and hepatic blood flow in proportion to reduced arterial blood pressure but does not appear to alter liver function or to be hepatotoxic.

Desflurane

CHEMISTRY AND PHYSICAL PROPERTIES

Desflurane (*SUPRANE*, Figure 13–3) is a highly volatile liquid at room temperature (vapor pressure = 681 mm Hg) and thus must be stored in tightly sealed bottles. Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O_2 , air, or N_2O). Desflurane is nonflammable and nonexplosive in mixtures of air or oxygen.

PHARMACOKINETICS

Desflurane partitions poorly into blood, fat, and other peripheral tissues (Table 13–1). Thus, the alveolar and blood concentrations rapidly rise to the level of inspired concentration. Within 5 minutes of administration, the alveolar concentration reaches 80% of the inspired concentration, providing for very rapid induction of anesthesia, rapid changes in depth of anesthesia following changes in the inspired concentration, and rapid emergence from anesthesia. The time to awakening following desflurane is half as long as with halothane or sevoflurane and usually does not exceed 5–10 minutes in the absence of other sedative agents.

Desflurane is minimally metabolized; more than 99% of absorbed desflurane is eliminated unchanged via the lungs.

CLINICAL USE Desflurane is widely used for outpatient surgery because of its fast onset and recovery kinetics. The drug irritates the airway of awake patients, provoking coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with desflurane subsequently administered for maintenance of anesthesia with inhaled concentrations of 6–8% (or lower if coadministered with nitrous oxide or opioids).

SIDE EFFECTS

Cardiovascular System Desflurane lowers blood pressure—primarily by decreasing systemic vascular resistance—and has a modest negative inotropic effect. Thus, cardiac output is preserved, as is perfusion of major organ beds (*e.g.*, splanchnic, renal, cerebral, and coronary). Marked increases in heart rate often occur during induction of desflurane anesthesia and with abrupt increases in the delivered concentration of desflurane; this results from desflurane-induced stimulation of the sympathetic nervous system. The hypotensive effects of desflurane do not wane with increasing duration of administration.

Respiratory System As with halothane and enflurane, desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At concentrations <1 MAC, the net effect is to preserve minute ventilation at concentrations >1 MAC, minute ventilation is markedly depressed, resulting in elevated arterial CO_2 tension (Pa_{CO_2}). Patients spontaneously breathing desflurane at concentrations greater than 1.5 MAC have extreme elevations of Pa_{CO_2} and may become apneic. Desflurane is a bronchodilator; it also is a strong airway irritant and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. Thus, desflurane is not used for induction of anesthesia.

Nervous System Desflurane decreases cerebral vascular resistance and cerebral metabolic O_2 consumption. Under conditions of normocapnia and normotension, desflurane produces an increase

in cerebral blood flow and can increase ICP in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in ICP thus can be prevented by hyperventilation.

Muscle, Kidney, Liver, and GI Tract

Desflurane produces direct skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents. Consistent with its minimal metabolism, desflurane has no reported nephrotoxicity or hepatotoxicity.

Sevoflurane

CHEMISTRY AND PHYSICAL PROPERTIES

Sevoflurane (ULTANE Figure 13–3) is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen. Sevoflurane can undergo an exothermic reaction with desiccated CO₂ absorbent (BARALYME) to produce airway burns or spontaneous ignition, explosion, and fire. Care must be taken to ensure that sevoflurane is not used with an anesthesia machine in which the CO₂ absorbent has been dried by prolonged gas flow through the absorbent. Sevoflurane reaction with desiccated CO₂ absorbent also can produce CO, which can result in serious patient injury.

PHARMACOKINETICS

The low solubility of sevoflurane in blood and other tissues provides for rapid induction of anesthesia, rapid changes in anesthetic depth following changes in delivered concentration, and rapid emergence following discontinuation of administration (Table 13–1).

Approximately 3% of absorbed sevoflurane is biotransformed by hepatic CYP2E1, the predominant product being hexafluoroisopropanol; metabolism of sevoflurane also produces inorganic fluoride. Interaction of sevoflurane with soda lime (CO₂ absorbent) produces decomposition products, one of which, compound A (pentafluoroisopropenyl fluoromethyl ether), may have toxicity (see Side Effects: Kidney, Liver, and Gastrointestinal Tract below).

CLINICAL USE Sevoflurane is widely used, particularly for outpatient anesthesia, because of its rapid recovery profile. It is well-suited for inhalation induction of anesthesia (particularly in children) because it is not irritating to the airway. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2–4%.

SIDE EFFECTS

Cardiovascular System The hypotensive effect of sevoflurane primarily is due to systemic vasodilation, although sevoflurane also produces a concentration-dependent decrease in cardiac output. Unlike isoflurane or desflurane, sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

Respiratory System Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in Pa_{CO₂}. Sevoflurane is not irritating to the airway and is a potent bronchodilator. Thus, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics.

Nervous System Sevoflurane produces effects on cerebral vascular resistance, cerebral metabolic O₂ consumption, and cerebral blood flow similar to those produced by isoflurane and desflurane. Sevoflurane can increase ICP in patients with poor intracranial compliance. The response to hypocapnia is preserved during sevoflurane anesthesia, and increases in ICP can be prevented by hyperventilation.

Muscle Sevoflurane produces skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents.

Kidney, Liver, and GI Tract

Controversy has surrounded the potential nephrotoxicity of compound A (pentafluoroisopropenyl fluoromethyl ether), a chemical produced by interaction of sevoflurane with the CO₂ absorbent soda lime. Although biochemical evidence of transient renal injury has been reported, large clinical studies have shown no evidence of renal impairment following sevoflurane administration. The current FDA recommendation is that sevoflurane be administered with fresh gas flows of at least 2 L/min to minimize accumulation of compound A. Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

Nitrous Oxide

CHEMICAL AND PHYSICAL PROPERTIES

Nitrous oxide (dinitrogen monoxide; N_2O) is a colorless, odorless gas at room temperature (Figure 13–3). It is sold in steel cylinders and must be delivered through calibrated flow meters provided on all anesthesia machines. Nitrous oxide is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

PHARMACOKINETICS

Nitrous oxide is very insoluble in blood and other tissues (Table 13–1). This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration. The rapid uptake of N_2O from alveolar gas serves to concentrate coadministered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N_2O administration, nitrous oxide gas can diffuse from blood to the alveoli, diluting O_2 in the lung. This can produce an effect called diffusional hypoxia. To avoid hypoxia, 100% O_2 rather than air should be administered when N_2O is discontinued.

99.9% of absorbed nitrous oxide is eliminated unchanged via the lungs. Nitrous oxide can interact with vitamin B_{12} resulting in vitamin B_{12} deficiency (megaloblastic anemia and peripheral neuropathy) following long-term nitrous oxide administration. Thus, N_2O is not used as a chronic analgesic or as a sedative in critical care settings.

CLINICAL USE Nitrous oxide is a weak anesthetic agent and produces reliable surgical anesthesia only under hyperbaric conditions. It does produce significant analgesia at concentrations as low as 20% and usually produces sedation in concentrations between 30% and 80%. It frequently is used in concentrations of ~50% to provide analgesia and sedation in outpatient dentistry. Nitrous oxide cannot be used at concentrations >80% because this limits the delivery of adequate O_2 . Consequently, N_2O is used primarily as an adjunct to other anesthetics. Nitrous oxide substantially reduces the requirement for inhalational anesthetics. For example, at 70% nitrous oxide, the MAC for other inhalational agents is reduced by about 60%, allowing for lower concentrations of halogenated anesthetics and a lesser degree of side effects.

One major problem with N_2O is that it will exchange with N_2 in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, nitrous oxide will enter the cavity faster than nitrogen escapes, thereby increasing the volume and/or pressure in this cavity. Examples of air collections that can be expanded by nitrous oxide include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. Nitrous oxide should be avoided in these clinical settings.

SIDE EFFECTS

Cardiovascular System Although N_2O produces a negative inotropic effect on heart muscle *in vitro*, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of nitrous oxide on the sympathetic nervous system. When N_2O is coadministered with halogenated inhalational anesthetics, it generally produces an increase in heart rate, arterial blood pressure, and cardiac output. In contrast, when N_2O is coadministered with an opioid, it generally decreases arterial blood pressure and cardiac output. Nitrous oxide also increases venous tone in both the peripheral and pulmonary vasculature. The effects of N_2O on pulmonary vascular resistance can be exaggerated in patients with preexisting pulmonary hypertension, and the drug generally is not used in these patients.

Respiratory System Nitrous oxide causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. The net effect is that minute ventilation is not significantly changed and Pa_{CO_2} remains normal. Even modest concentrations of N_2O markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O_2 saturation directly in patients receiving or recovering from nitrous oxide.

Nervous System When administered alone, N_2O can significantly increase cerebral blood flow and ICP. When nitrous oxide is coadministered with intravenous anesthetic agents, increases in cerebral blood flow are attenuated or abolished. When N_2O is added to a halogenated inhalational anesthetic, its vasodilatory effect on the cerebral vasculature is slightly reduced.

Muscle Nitrous oxide does not relax skeletal muscle or enhance the effects of neuromuscular blocking drugs. Unlike the halogenated anesthetics, N_2O does not trigger malignant hyperthermia.

Kidney, Liver, and Gastrointestinal Tract Nitrous oxide is neither nephrotoxic nor hepatotoxic.

Xenon

Xenon is an inert gas that is not approved for use in the U.S. and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air. This limits its availability and renders xenon very expensive. Despite these shortcomings, xenon has properties that make it a virtually ideal anesthetic gas that ultimately may be used in critical situations.

Xenon is extremely insoluble in blood and other tissues, providing for rapid induction and emergence from anesthesia (Table 13–1). It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. Most importantly, xenon has minimal side effects. It has no effects on cardiac output or cardiac rhythm and is not thought to have a significant effect on systemic vascular resistance. It also does not affect pulmonary function and is not known to have any hepatic or renal toxicity. Finally, xenon is not metabolized in the human body. Xenon is an anesthetic that may be available in the future if the limitations of availability and cost can be overcome.

ANESTHETIC ADJUNCTS

A general anesthetic is usually given with adjuncts that augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects.

Benzodiazepines

Benzodiazepines (*see* Chapter 16) can produce anesthesia similar to that of barbiturates, but are more commonly used for sedation rather than anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is *midazolam* (VERSED) followed distantly by *diazepam* (VALIUM), and *lorazepam* (ATIVAN). Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis. Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of more rapid onset and shorter duration of effect. Sedative doses of midazolam (0.01–0.07 mg/kg intravenously) reach peak effect in about 2 minutes and provide sedation for about 30 minutes. Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines; thus, titration to the desired effect of smaller doses in this age group is prudent. For either prolonged sedation or general anesthetic maintenance, midazolam is more suitable for infusion than other benzodiazepines, although its duration of action does significantly increase with prolonged infusions (Figure 13–2). Benzodiazepines reduce both cerebral blood flow and metabolism, but at equianesthetic doses are less potent in this respect than are barbiturates. They are effective anticonvulsants and sometimes are given to treat status epilepticus. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea; thus, blood pressure and respiratory rate should be monitored in patients sedated with intravenous benzodiazepines.

α_2 Adrenergic Agonists

The α_2 adrenergic agonist dexmedetomidine (PRECEDEX) is widely used in the intensive care unit setting for short-term sedation of adults, and is beginning to be administered off-label in other clinical scenarios including as an anesthetic adjunct. Activation of the α_{2A} adrenergic receptor by dexmedetomidine produces both sedation and analgesia, but does not reliably provide general anesthesia, even at maximal doses.

Common side effects of dexmedetomidine include hypotension and bradycardia, attributed to decreased catecholamine release mediated by activation of α_{2A} receptors. Nausea and dry mouth also are common. At higher drug concentrations, the α_{2B} subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. Dexmedetomidine produces sedation and analgesia with minimal respiratory depression. Sedation produced by dexmedetomidine is noted to be more akin to natural sleep, with patients relatively easy to arouse. However, dexmedetomidine does not appear to provide reliable amnesia and additional agents may be needed if lack of recall is desirable.

The recommended loading dose is 1 μ g/kg given over 10 minutes, followed by infusion at a rate of 0.2–0.7 μ g/kg/h. Infusions longer than 24 hours are not recommended because of a potential for rebound hypertension. Reduced doses should be considered in patients with risk factors for severe hypotension.

Analgesics

With the exception of ketamine and nitrous oxide, neither parenteral nor currently available inhalational anesthetics are effective analgesics. Thus, analgesics typically are administered with general anesthetics to reduce anesthetic requirement and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, or acetaminophen may provide adequate analgesia for minor surgical procedures. Because they produce rapid and profound analgesia, opioids are the primary analgesics used during the perioperative period.

Fentanyl (SUBLIMAZE), *sufentanil* (SUFENTA), *alfentanil* (ALFENTA), *remifentanil* (ULTIVA), *meperidine* (DEMEROL), and *morphine* are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ -opioid receptors. Their order of potency (relative to morphine) is: sufentanil (1000x) > remifentanil (300x) > fentanyl (100x) > alfentanil (15x) > morphine (1x) > meperidine (0.1x). Pharmacological properties of these agents are discussed in more detail in Chapter 21.

The choice of a perioperative opioid is based primarily on duration of action, given that at appropriate doses, all produce similar analgesia and side effects. Remifentanil has an ultrashort duration of action (~10 minutes) and accumulates minimally with repeated doses or infusion; it is particularly well suited for procedures that are briefly painful but for which little postoperative analgesia is required. Single doses of fentanyl, alfentanil, and sufentanil all have similar intermediate durations of action (30, 20, and 15 minutes, respectively), but recovery after prolonged administration varies considerably. Fentanyl's duration of action lengthens most with infusion, sufentanil's much less so, and alfentanil's the least. After prolonged administration, morphine metabolites have significant analgesic and hypnotic activity.

During the perioperative period, opioids often are given at induction to preempt responses to predictable painful stimuli (e.g., endotracheal intubation and surgical incision). Subsequent doses either by bolus or infusion are titrated to the surgical stimulus and the patient's hemodynamic response. Marked decreases in respiratory rate and heart rate with much smaller reductions in blood pressure are seen to varying degrees with all opioids. Muscle rigidity that can impair ventilation sometimes accompanies larger doses of opioids. The incidence of sphincter of Oddi spasm is increased with all opioids, although morphine appears to be more potent in this regard. The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain. Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

Neuromuscular Blocking Agents

Depolarizing (e.g., succinylcholine) and nondepolarizing muscle relaxants (e.g., pancuronium) often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the IV line prior to injection of a muscle relaxant. Following induction, continued muscle relaxation is desirable for many procedures to aid surgical exposure and to provide additional insurance of immobility. Note: muscle relaxants are not anesthetics and should not be used in lieu of adequate anesthetic depth. The action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as neostigmine or edrophonium (see Chapter 8) combined with a muscarinic receptor antagonist (e.g., glycopyrolate or atropine) (see Chapter 7) to offset the muscarinic activation resulting from esterase inhibition. Other than histamine release by some agents, nondepolarizing muscle relaxants used in this manner have few side effects. However, succinylcholine has multiple serious side effects (e.g., bradycardia, hyperkalemia, and severe myalgia) including induction of malignant hyperthermia in susceptible individuals. Chapter 9 covers the detailed pharmacology of these agents.

LOCAL ANESTHETICS

Local anesthetics bind reversibly to a specific receptor site within the pore of the Na^+ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

CHEMISTRY AND STRUCTURE–ACTIVITY RELATIONSHIP

The typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage (Figure 14–1). A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, local anesthetics with an ester link are hydrolyzed readily by plasma esterases.

Hydrophobicity increases both the potency and the duration of action of the local anesthetics because association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na^+ channels is thought to be hydrophobic, so that receptor affinity for anesthetic agents is greater for more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency- and voltage-dependence of their action.

MECHANISM OF ACTION Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na^+ that normally is produced by a slight depolarization of the membrane (see Chapter 12). This action is due to direct interaction with voltage-gated Na^+ channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse conduction slows, and nerve conduction eventually fails.

Local anesthetics can block K^+ channels at higher concentrations of drug; thus, blockade of conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogs of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally, suggesting that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the plasma membrane. Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

The major mechanism of action of these drugs involves their interaction with one or more specific binding sites within the Na^+ channel (Figure 14–2).

FREQUENCY- AND VOLTAGE-DEPENDENCE OF LOCAL ANESTHETIC ACTION

The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the local anesthetic molecule in its charged form gains access to its binding site within the pore only when the Na^+ channel is in an open state and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na^+ channel.

DIFFERENTIAL SENSITIVITY OF NERVE FIBERS TO LOCAL ANESTHETICS

Generally, treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 14–1). In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small

FIGURE 14-1 *Structural formulas of selected local anesthetics.* Most local anesthetics consist of a hydrophobic (aromatic) moiety (black), a linker region (light blue), and a substituted amine (hydrophilic region, in dark blue). The structures above are grouped by the nature of the linker region. Procaine is a prototypic ester-type local anesthetic; esters generally are well hydrolyzed by plasma esterases, contributing to the relatively short duration of action of drugs in this group. Lidocaine is a prototypic amide-type local anesthetic; these structures generally are more resistant to clearance and have longer durations of action. There are exceptions, including benzocaine (poorly water soluble; used only topically) and the structures with a ketone, an amidine, and an ether linkage. See 11th edition of the parent text, Figure 14-1, for additional details and structures.

myelinated A δ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated A γ , A β , and A α fibers (mediating postural, touch, pressure, and motor information). This differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics; the mechanisms responsible for this apparent specificity are not known.

EFFECT OF pH Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Since local anesthetics are weak bases (typical pK_a values range 8–9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and catecholamines added as vasoconstrictors. Following administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic species that interacts preferentially with Na⁺ channels.

PROLONGATION OF ACTION BY VASOCONSTRICTORS The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. Thus, catecholamines, acting at α -adrenergic receptors in the vasculature, cause vasoconstriction and reduced absorption of local anesthetics in vascular beds where α adrenergic effects predominate (*see* Chapters 6 and 10). In clinical practice, a vasoconstrictor, usually epinephrine, is often added to local anesthetics. The vasoconstrictor performs a dual service. By decreasing the rate of absorption, it not only localizes the anesthetic at the desired site, but reduces systemic toxicity by slowing systemic absorption, thereby favoring metabolism rather than accumulation of absorbed drug. Note, however, that epinephrine dilates skeletal muscle vascular beds through actions at β_2 adrenergic receptors and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

FIGURE 14–2 Structure and function of voltage-gated Na^+ channels. **A.** A two-dimensional representation of the α (center), β_1 (left), and β_2 (right) subunits of the voltage-gated Na^+ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. Ψ indicates sites of demonstrated N-linked glycosylation. Note the repeated structure of the four homologous domains (I through IV) of the α subunit. **Voltage Sensing.** The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward. **Pore.** The S5 and S6 transmembrane segments and the short membrane-associated loop between them (*P loop*) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see Panel **B**). The amino acid residues indicated by circles in the *P loop* are critical for determining the conductance and ion selectivity of the Na^+ channel and its ability to bind the extracellular pore-blocking toxins tetrodotoxin and saxitoxin. **Inactivation.** The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na^+ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (isoleucine–phenylalanine–methionine; IFM) at the position marked **h** appear to serve as an inactivation particle, entering the intracellular mouth of the pore and binding therein to an inactivation gate receptor there. **Modulation.** The gating of the Na^+ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by either protein kinase C (⬠) or cyclic AMP–dependent protein kinase (⊙) reduces Na^+ channel activation. **B.** The four homologous domains of the Na^+ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na^+ channel undergoes during activation and inactivation is diagrammed. Upon depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na^+ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance.

C fibers						
Sympathetic	Postganglionic sympathetic	No	0.3–1.3	0.7–1.3	Vasomotor, visceromotor, sudomotor, pilomotor	++++
Dorsal root	Sensory roots and afferent peripheral nerves	No	0.4–1.2	0.1–2	Pain, temperature, touch	++++

Some of the vasoconstrictor may be absorbed systemically, occasionally to an extent sufficient to cause untoward reactions (*see below*). There also may be delayed wound healing, tissue edema, or necrosis after local anesthesia. These effects seem to occur partly because sympathomimetic amines can cause hypoxia and local tissue damage. The use of vasoconstrictors in local-anesthetic preparations for anatomical regions with limited collateral circulation could produce irreversible hypoxic damage, tissue necrosis, and gangrene, and therefore is contraindicated.

UNDESIRED EFFECTS OF LOCAL ANESTHETICS In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, they have important effects on the CNS, autonomic ganglia, neuromuscular junctions, and all forms of muscle. The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, in local anesthetics with chiral centers, the *S*-enantiomer is less toxic than the *R*-enantiomer.

Central Nervous System

Following absorption, local anesthetics may cause central nervous system (CNS) stimulation (presumably due to suppression of inhibitory neurons), producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure. Airway control and ventilatory support are essential features of treatment in the late stage of intoxication. Benzodiazepines or rapidly acting barbiturates administered intravenously are the drugs of choice for both the prevention and arrest of convulsions (see Chapter 16).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, both lidocaine and procaine may produce a loss of consciousness that is preceded only by symptoms of sedation. Cocaine has a particularly prominent effect on mood and behavior (see Chapter 23).

Cardiovascular System Following systemic absorption, local anesthetics decrease electrical excitability, conduction rate, and force of contraction. Most local anesthetics also cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and effects on the CNS are produced. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. The use of local anesthetics as antiarrhythmic drugs is discussed in Chapter 34. Untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if epinephrine also is present.

Smooth Muscle Local anesthetics depress contractions in gastrointestinal (GI), vascular, and bronchial smooth muscle, although low concentrations initially may produce contraction. Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone of GI musculature (*see* below). Local anesthetics seldom depress uterine contractions directly during intrapartum regional anesthesia.

HYPERSENSITIVITY TO LOCAL ANESTHETICS Rare individuals are hypersensitive to local anesthetics, displaying allergic dermatitis or a typical asthmatic attack. It is important to distinguish allergic reactions from toxic side effects and from effects of coadministered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives such as methylparaben that may provoke an allergic reaction. Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant.

METABOLISM OF LOCAL ANESTHETICS The metabolic fate of local anesthetics is of great practical importance, because their toxicity depends largely on the balance between their rates of absorption and elimination. The rate of absorption of many anesthetics can be reduced by incorporation of a vasoconstrictor in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Since toxicity is related to the free concentration of drug, binding of the anesthetic to proteins in the serum and to tissues reduces the concentration of free drug in the systemic circulation, and consequently reduces toxicity.

Some of the common local anesthetics (*e.g.*, tetracaine) are esters; they are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. Hepatic enzymes also hydrolyze local anesthetic esters. Since spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation.

The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs, the initial reactions involving *N*-dealkylation and subsequent hydrolysis (*see* Chapter 3). However, with *prilocaine*, the initial step is hydrolytic, forming *o*-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution. The amide-linked local anesthetics are extensively (55–95%) bound to plasma proteins, particularly α_1 -acid glycoprotein. Many factors increase (*e.g.*, cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (*e.g.*, oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives (*see* Chapter 34).

COCAINE

Cocaine (Figure 14-1) is an ester of benzoic acid and methylecgonine. The clinically desired actions of cocaine are the blockade of nerve impulses, as a consequence of its local anesthetic properties, and local vasoconstriction, secondary to inhibition of local norepinephrine reuptake. Toxicity and its potential for abuse have steadily decreased the clinical utility of cocaine. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems.

Its euphoric properties are due primarily to inhibition of catecholamine uptake, particularly dopamine, in the CNS. Other local anesthetics do not block the uptake of norepinephrine and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of cocaine. Currently, cocaine is used primarily for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provide anesthesia and shrinking of the mucosa. Because of its abuse potential, cocaine is listed as a schedule II drug by the U.S. Drug Enforcement Agency.

LIDOCAINE

Lidocaine (XYLOCAINE, others), an aminoethylamide (Figure 14–1), is the prototypical amide local anesthetic.

CLINICAL PHARMACOLOGY

Lidocaine produces faster, more intense, longer lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics.

Lidocaine is absorbed rapidly after parenteral administration and from the GI and respiratory tracts. In addition to preparations for injection, an iontophoretic, needle-free drug-delivery system for a solution of lidocaine and epinephrine (IONTOCAINE) is available for dermal procedures and provides anesthesia to a depth of up to 10 mm.

A lidocaine transdermal patch (LIDODERM) is used for relief of pain associated with postherpetic neuralgia. The combination of lidocaine (2.59%) and prilocaine (2.5%) in an occlusive dressing (EMLA ANESTHETIC DISC) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia.

Lidocaine is dealkylated by hepatic CYPs to metabolites with local anesthetic activity.

TOXICITY

The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum lidocaine levels that produce marked CNS effects. The active metabolites may contribute to some of these side effects.

CLINICAL USES

Lidocaine has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic agent (see Chapter 34).

BUPIVACAINE

PHARMACOLOGICAL ACTIONS

Bupivacaine (MARCAINE, SENSORCAINE), is an amide local anesthetic. Levobupivacaine (CHIROCAINE), the S-enantiomer of bupivacaine, also is available. Bupivacaine's long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or the postoperative period. By taking advantage of indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia.

TOXICITY

Bupivacaine is more cardiotoxic than equi-effective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration of large doses of bupivacaine. Bupivacaine dissociates slowly during diastole, so a significant fraction of Na⁺ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole. Thus, the block by bupivacaine is cumulative and substantially more than would be predicted by its local anesthetic potency. Bupivacaine-induced cardiac toxicity can be very difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia. The S-enantiomer and the racemate are equally efficacious and potent, but levobupivacaine may be less cardiotoxic.

OTHER SYNTHETIC LOCAL ANESTHETICS

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. The use of some is restricted to topical application to the eye (see Chapter 63), the mucous membranes, or the skin (see Chapter 62). Many local anesthetics are suitable, however, for infiltration

or injection to produce nerve block; some of them also are useful for topical application. The main categories of local anesthetics are given below; agents are listed alphabetically.

Local Anesthetics Suitable for Injection

ARTICAINE

Articaine (*SEPTOCAINE*) is a recently introduced amino amide, approved in the U.S. for dental and periodontal procedures. It exhibits a rapid onset (1–6 minutes) and duration of action of ~1 hour.

CHLOROPROCAINE

Chloroprocaine (*NESACAINE*), an ester local anesthetic, is a chlorinated derivative of procaine with rapid onset, short duration of action, and reduced acute toxicity due to rapid metabolism (plasma $t_{1/2}$ ~25 seconds). A higher-than-expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine has been reported; this back pain is thought to be due to tetany in the paraspinal muscles, which may be a consequence of Ca^{2+} binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

ETIDOCAINE

Etidocaine (*DURANEST*) is a long-acting amino amide with an onset of action faster than that of bupivacaine and comparable to that of lidocaine, and a duration of action similar to that of bupivacaine. It is no longer marketed in the U.S.

MEPIVACAINE

Mepivacaine (*CARBOCAINE*, *POLOCAINE*) is an intermediate-acting amino amide pharmacologically similar to lidocaine. Mepivacaine, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. Mepivacaine is not effective as a topical anesthetic.

PRILOCAINE

Prilocaine (*CITANEST*) is an intermediate-acting amino amide that is pharmacologically similar to lidocaine, except that it causes little vasodilation and thus can be used without a vasoconstrictor if desired, and its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (see below). As a consequence of the metabolism of the aromatic ring to *o*-toluidine, prilocaine can cause methemoglobinemia. Development of methemoglobinemia is dose dependent, usually appearing after a dose of 8 mg/kg. Methemoglobinemia usually is not a problem in healthy adults but is more common in neonates due to decreased resistance of fetal hemoglobin to oxidant stresses and the immaturity of enzymes that convert methemoglobin back to the ferrous state.

ROPIVACAINE

Ropivacaine (*NAROPIN*), an amino ethylamide, is slightly less potent than bupivacaine in producing anesthesia. In clinical studies, ropivacaine appears to be suitable for both epidural and regional anesthesia, with duration of action similar to that of bupivacaine. Interestingly, it seems to be even more motor sparing than bupivacaine.

PROCAINE

Procaine (*NOVOCAIN*), the first synthetic local anesthetic, is an amino ester (see Figure 14–1) with low potency, slow onset, and short duration of action. Its use now is confined to infiltration anesthesia and occasionally for diagnostic nerve blocks. Its hydrolysis in vivo produces para-aminobenzoic acid, which inhibits the action of sulfonamides. Thus, large doses should not be administered to patients taking sulfonamide drugs.

TETRACAINE

Tetracaine (*PONTOCAINE*), a long-acting amino ester, is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. It is widely used in spinal anesthesia when a drug of long duration is needed. Tetracaine also is incorporated into several topical anesthetic preparations. Tetracaine is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

Local Anesthetics Used Primarily to Anesthetize Mucous Membranes and Skin

Some anesthetics are either too irritating or too ineffective to be applied to the eye. However, they are useful as topical anesthetic agents on the skin and/or mucous membranes. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous

other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations.

Dibucaine (NUPERCAINAL) is a quinoline derivative. Because of its toxicity, it is not available in the U.S. as an injectable preparation; it retains wide popularity outside the U.S. as a spinal anesthetic. It currently is available as a cream and an ointment for use on the skin.

Dyclonine hydrochloride (DYCLONE) has a rapid onset of action and duration of effect comparable to that of procaine. It is absorbed through the skin and mucous membranes. Marketing of dyclonine solutions for clinical use has been discontinued in the U.S. Dyclonine is an active ingredient of OTC medications including sore throat lozenges (SUCRETS, others), a gel for cold sores (TANAC), and a 0.75% solution (SKIN SHIELD) to protect against contact dermatitis.

Pramoxine hydrochloride (ANUSOL, TRONOTHANE, others) is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. Pramoxine produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes. It is too irritating to be used on the eye or in the nose.

Anesthetics of Low Solubility

Some local anesthetics are poorly soluble in water, and consequently are too slowly absorbed to be toxic. They can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking a terminal amino group common to other local anesthetics. Benzocaine (ethyl aminobenzoate; AMERICAINE ANESTHETIC, others) is the prototype. Benzocaine is structurally similar to procaine, but lacks the terminal diethylamino group. It is used in numerous topical preparations. Benzocaine can cause methemoglobinemia (see text concerning methemoglobinemia caused by prilocaine, above).

Local Anesthetics Largely Restricted to Ophthalmological Use

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. Most local anesthetics are too irritating for ophthalmological use. The suitable two compounds are proparacaine (ALCAINE, OPHTHAINE, others) and tetracaine. In addition to being less irritating during administration, proparacaine has the advantage of bearing little antigenic similarity to the other benzoate local anesthetics. For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus, it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case, repeated instillations may be necessary to maintain adequate anesthesia for the duration of the procedure. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting and sloughing of the corneal epithelium, and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For drug delivery, pharmacokinetic, and toxicity issues unique to drugs for ophthalmic use, see Chapter 63.

CLINICAL USES OF LOCAL ANESTHETICS

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages. First, physiological perturbations associated with general anesthesia are avoided; second, neurophysiological responses to pain and stress can be modified beneficially. However, local anesthetics can produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding toxicity. There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous infiltration. Thus, recommended maximum doses serve only as general guidelines.

The following discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration.

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2–10%), and cocaine (1–4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia.

The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). Epinephrine, topically applied, does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. Maximal safe total dosages for topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions.

The introduction of a eutectic mixture of lidocaine (2.5%) and prilocaine (2.5%) (EMLA) bridges the gap between topical and infiltration anesthesia. The efficacy of this combination lies in the fact that the mixture of prilocaine and lidocaine has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. EMLA cream produces anesthesia to a maximum depth of 5 mm and is applied as a cream on intact skin under an occlusive dressing, for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). EMLA must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

Infiltration Anesthesia

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves. Infiltration anesthesia can be so superficial as to include only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of epinephrine (5 µg/mL) to the injection solution; epinephrine also decreases peak concentrations of local anesthetics in blood. Epinephrine-containing solutions should not, however, be injected into tissues supplied by end arteries—for example, fingers and toes, ears, the nose, and the penis. The resulting vasoconstriction may cause gangrene.

The local anesthetics used most frequently for infiltration anesthesia are lidocaine (0.5–1%), procaine (0.5–1%), and bupivacaine (0.125–0.25%). When used without epinephrine, up to 4.5 mg/kg of lidocaine, 7 mg/kg of procaine, or 2 mg/kg of bupivacaine can be employed in adults. When epinephrine is added, these amounts can be increased by one-third.

The advantage of infiltration anesthesia and other regional anesthetic techniques is that it can provide satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas.

Field Block Anesthesia

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic in order to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2–3 cm distal to the site of injection. The same principle can be applied with particular benefit to the scalp, the anterior abdominal wall, and the lower extremity. The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used.

Nerve Block Anesthesia

Injection of a local anesthetic into or around individual peripheral nerves or nerve plexuses produces even greater areas of anesthesia than do the techniques described above. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection. Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck. Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar at the elbow, and blocks of sensory cranial nerves.

Local anesthetic is never intentionally injected into the nerve; this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve

block, but the potential for systemic toxicity and direct neural toxicity limits use of high concentrations. Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories: those with a short (20–45 minutes) duration of action in mixed peripheral nerves, such as procaine; those with an intermediate (60–120 minutes) duration of action, such as lidocaine and mepivacaine; and those with a long (400–450 minutes) duration of action, such as bupivacaine, ropivacaine, and tetracaine. Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 µg/mL). The degree of block prolongation in peripheral nerves due to epinephrine appears to be related to the intrinsic vasodilating properties of the local anesthetic and thus is most pronounced with lidocaine.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve-fiber size, internodal distance, and frequency and pattern of nerve-impulse transmission (see above). Anatomical factors are similarly important. Nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Since removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2–4 hours, lidocaine (1–1.5%) can be used in the amounts recommended above (see “Infiltration Anesthesia”). Mepivacaine (up to 7 mg/kg of a 1–2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2–3 mg/kg of a 0.25–0.375% solution) can be used when a longer duration of action is required. Addition of 5 µg/mL epinephrine slows systemic absorption and, therefore, prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Intravenous Regional Anesthesia (Bier’s Block)

This technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100–150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5–10 minutes. Pain from the tourniquet and the potential for ischemic nerve injury limits tourniquet inflation to 2 hours or less. However, the tourniquet should remain inflated for at least 15–30 minutes to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40–50 mL (0.5 mL/kg in children) of a 0.5% solution without epinephrine is the drug of choice for this technique. The attractiveness of this technique lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (i.e., pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic. Thus, the more cardiotoxic local anesthetics, bupivacaine and etidocaine, are not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand, but can be adapted for the foot and distal leg.

Spinal Anesthesia

Spinal anesthesia follows the injection of local anesthetic into the cerebrospinal fluid (CSF) in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

PHARMACOLOGY OF SPINAL ANESTHESIA

In the U.S., the drugs most commonly used in spinal anesthesia are lidocaine, tetracaine, and bupivacaine. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate to long procedures, and tetracaine for long procedures. The distribution of local anesthetics

determines the height of block. Important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthetic solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (see below). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts. Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block, but the mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain.

Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper-abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a “light” general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

Epidural Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5–0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 µg/mL of fentanyl added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. The duration of action of epidurally administered local anesthetics frequently is prolonged, and systemic toxicity decreased, by addition of epinephrine. Addition of epinephrine also makes inadvertent intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20- to 40-year-old, healthy, nonpregnant patients, each 1–1.5 mL of 2% lidocaine will give an additional segment of anesthesia. The amount needed decreases with increasing age and also decreases during pregnancy and in children.

The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers. A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space.

EPIDURAL AND INTRATHECAL OPIATE ANALGESIA

Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia. Thus, spinal and epidural opioids are used in surgical procedures and for the relief of postoperative and chronic pain. As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (see Chapters 6 and 21). Since conduction in autonomic, sensory, and motor nerves is not affected

by the opioids, blood pressure, motor function, and non-nociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus and nausea and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occurs infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have found the greatest use in the treatment of postoperative and chronic pain. In selected patients, spinal or epidural opioids can provide excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For postoperative analgesia, spinally administered morphine, 0.2–0.5 mg, usually will provide 8–16 hours of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. Many opioids have been used epidurally. Morphine, 2–6 mg, every 6 hours, commonly is used for bolus injections, while fentanyl, 20–50 µg/hour, often combined with bupivacaine, 5–20 mg/hour, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months' duration. The dose of epidural morphine, for example, is far less than the dose of systemically administered morphine that would be required to provide similar analgesia. This reduces the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

THERAPEUTIC GASES: O₂, CO₂, NO, AND He

OXYGEN

Normal Oxygenation

Oxygen makes up 21% of air, with a partial pressure of 21 kPa (158 mm Hg) at sea level. The partial pressure drives the diffusion of oxygen; thus, ascent to elevated altitude reduces the uptake and delivery of oxygen to the tissues. As air is delivered to the distal airways and alveoli, the P_{O₂} decreases by dilution with carbon dioxide and water vapor and by uptake into the blood. Under ideal conditions, when ventilation and perfusion are well matched, the alveolar P_{O₂} will be ~14.6 kPa (110 mm Hg). The corresponding alveolar partial pressures of water and CO₂ are 6.2 kPa (47 mm Hg) and 5.3 kPa (40 mm Hg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and capillary blood. In some diseases, the diffusion barrier for gas transport may be increased; during exercise, when high cardiac output reduces capillary transit time, full equilibration may not occur, and the alveolar–end-capillary P_{O₂} gradient may be increased.

The P_{O₂} in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a P_{O₂} of ~5.3 kPa (40 mm Hg). Together, the diffusional barrier, ventilation–perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial oxygen gradient, which is normally 1.3–1.6 kPa (10–12 mm Hg) when air is breathed and 4.0–6.6 kPa (30–50 mm Hg) when 100% oxygen is breathed.

Oxygen is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of oxygen typically reduces the P_{O₂} of venous blood by an additional 7.3 kPa (55 mm Hg). Although the P_{O₂} at the mitochondria is not known, oxidative phosphorylation can continue at a P_{O₂} of only a few millimeters of mercury.

In the blood, O₂ is carried primarily by hemoglobin and is to a small extent dissolved in solution. The quantity of O₂ combined with hemoglobin depends on the P_{O₂} (Figure 15–1). Hemoglobin is about 98% saturated with oxygen when air is breathed under normal circumstances, and it binds 1.3 mL of oxygen per gram when fully saturated. The steep slope of this curve with falling P_{O₂} facilitates unloading of oxygen from hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing P_{CO₂}, and decreasing pH, as is found in metabolically active tissues, lowers the oxygen saturation for the same P_{O₂} and thus delivers additional oxygen where and when it is most needed. However, the flattening of the curve with higher P_{O₂} indicates that increasing blood P_{O₂} by inspiring oxygen-enriched mixtures can increase the amount of oxygen carried by hemoglobin only minimally. Further increases in blood O₂ content can occur only by increasing the amount of oxygen dissolved in plasma. Because of the low solubility of oxygen (0.226 mL/L/kPa or 0.03 mL/L/mm Hg at 37°C), breathing 100% O₂ can increase the amount of O₂ dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired P_{O₂} is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved oxygen is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 15–1).

Oxygen Deprivation

Classically, there are five causes of hypoxemia: low inspired oxygen fraction (F_IO₂), increased diffusion barrier, hypoventilation, ventilation–perfusion (\dot{V}/\dot{Q}) mismatch, and shunt or venous admixture.

In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of oxygen delivery and oxygen utilization. Oxygen delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased oxygen-carrying capacity of the blood likewise will reduce oxygen delivery, such as occurs with anemia, carbon monoxide poisoning, or hemoglobinopathy. Finally, hypoxia may occur when transport of oxygen from the capillaries to the tissues is decreased (edema) or utilization of the oxygen by the cells is impaired (cyanide toxicity). Our understanding of some of the cellular responses to hypoxia has been advanced by studies of hypoxia-inducible factors.

FIGURE 15-1 Oxyhemoglobin dissociation curve for whole blood. The relationship between P_{O_2} and hemoglobin (Hb) saturation is shown. The P_{50} , or the P_{O_2} resulting in 50% saturation, is indicated as well. An increase in temperature or a decrease in pH (as in working muscle) shifts this relationship to the right, reducing the hemoglobin saturation at the same P_{O_2} and thus aiding in the delivery of oxygen to the tissues.

Oxygen Inhalation

Oxygen inhalation is used primarily to reverse or prevent the development of hypoxia; other consequences usually are minor. However, when oxygen is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

Respiratory System Inhalation of oxygen at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of oxygen inhalation because of a paradoxical increase in the tension of carbon dioxide in tissues, a result of increased oxyhemoglobin in venous blood, which causes less efficient removal of carbon dioxide from the tissues.

In a small number of patients whose respiratory center is depressed by long-term retention of carbon dioxide, injury, or drugs, ventilation is maintained largely by stimulation of carotid and aortic chemoreceptors, commonly referred to as the *hypoxic drive*. The provision of too much oxygen can depress this drive, resulting in respiratory acidosis. In these cases, supplemental oxygen should be titrated carefully to ensure adequate arterial saturation. If hypoventilation results, then mechanical ventilatory support with or without tracheal intubation should be provided.

Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the airspaces while oxygen is absorbed. High oxygen concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis, occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of oxygen administration.

Cardiovascular System Aside from reversing the effects of hypoxia, the physiological consequences of oxygen inhalation on the cardiovascular system are of little significance. Heart rate and cardiac output are slightly reduced; blood pressure changes little. While pulmonary arterial pressure changes little in normal subjects with oxygen inhalation, elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with oxygen therapy or return to sea level. *This table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O_2 tension increases, the amount of dissolved O_2 increases in direct proportion to the P_{O_2} , but the amount of oxygen bound to hemoglobin reaches a maximum of 196 mL O_2 /L (100% saturation of hemoglobin at 15 g/dL). Further increases in O_2 content require increases in dissolved oxygen. At 100% inspired O_2 , dissolved O_2 still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O_2 .

The figures in this table are approximate and are based on the assumptions of 15 g/dL hemoglobin, 50 mL O_2 /L whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial P_{O_2} remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O_2 content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.

shunting of cardiac output, oxygen supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

Metabolism Inhalation of 100% oxygen does not produce detectable changes in oxygen consumption, carbon dioxide production, respiratory quotient, or glucose utilization.

Oxygen Administration

For safety, oxygen cylinders and piping are color-coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to oxygen systems. Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. Only a closed delivery system with an airtight seal to the patient's airway and complete separation of inspired from expired gases can precisely control FIO_2 . In all other systems, the actual delivered FIO_2 will depend on the ventilatory pattern (*i.e.*, rate, tidal volume, inspiratory–expiratory time ratio, and inspiratory flow) and delivery system characteristics.

Low-Flow Systems

Low-flow systems, in which the oxygen flow is lower than the inspiratory flow rate, have a limited ability to raise the FIO_2 because they depend on entrained room air to make up the balance of the inspired gas. The FIO_2 of these systems is extremely sensitive to small changes in the ventilatory pattern. Devices such as face tents are used primarily for delivering humidified gases to patients and cannot be relied on to provide predictable amounts of supplemental oxygen. Nasal cannulae—small, flexible prongs that sit just inside each naris—deliver oxygen at 1–6 L/min. The nasopharynx acts as a reservoir for storing the oxygen, and patients may breathe through either the mouth or nose as long as the nasal passages remain patent. These devices typically deliver 24–28% FIO_2 at 2–3 L/min. Up to 40% FIO_2 is possible at higher flow rates, although this is poorly tolerated for more than brief periods because of mucosal drying. The simple facemask, a clear plastic mask with side holes for clearance of expiratory gas and inspiratory air entrainment, is used when higher concentrations of oxygen delivered without tight control are desired. The maximum FIO_2 of a facemask can be increased from around 60% at 6–15 L/min to >85% by adding a 600- to 1000-mL reservoir bag. With this partial rebreathing mask, most of the inspired volume is drawn from the reservoir, avoiding dilution by entrainment of room air.

High-Flow Systems

The most commonly used high-flow oxygen delivery device is the Venturi mask, which uses a specially designed mask insert to entrain room air reliably in a fixed ratio and thus provides a relatively constant FIO_2 at relatively high flow rates. Typically, each insert is designed to operate at a specific oxygen flow rate, and different inserts are required to change the FIO_2 . Lower delivered FIO_2 values use greater entrainment ratios, resulting in higher total (oxygen plus entrained air) flows to the patient, ranging from 80 L/min for 24% FIO_2 to 40 L/min at 50% FIO_2 . These flow rates still may be lower than the peak inspiratory flows for patients in respiratory distress, and thus the actual delivered oxygen concentration may be lower than the nominal value. Oxygen nebulizers, another type of Venturi device, provide patients with humidified oxygen at 35–100% FIO_2 at high flow rates. Finally, oxygen blenders provide high inspired oxygen concentrations at very high flow rates. These devices mix high-pressure compressed air and oxygen to achieve any concentration of oxygen from 21–100% at flow rates of up to 100 L/min. Despite the high flows, the delivery of high FIO_2 to an individual patient also depends on maintaining a tight-fitting seal to the airway and/or the use of reservoirs to minimize entrainment of diluting room air.

MONITORING OF OXYGENATION

Monitoring and titration are required to meet the therapeutic goal of oxygen therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Noninvasive monitoring of arterial oxygen saturation now is widely available from transcutaneous pulse oximetry, in which oxygen saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Pulse oximetry measures hemoglobin saturation and not PO_2 ; thus, it is insensitive to increases in PO_2 beyond that required to saturate the blood fully. However, pulse oximetry is very useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating oxygen therapy in situations where toxicity from oxygen or side effects of excess oxygen are of concern.

COMPLICATIONS OF OXYGEN THERAPY

Administration of supplemental oxygen is not without potential complications. In addition to the potential to promote absorption atelectasis and depress ventilation, high flows of dry oxygen can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified oxygen thus should be used when prolonged therapy (>1 hour) is required. Finally, any oxygen-enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken both in the operating room and for patients on oxygen at home. Hypoxemia still can occur despite the administration of supplemental oxygen. Furthermore, when supplemental oxygen is administered, desaturation occurs at a later time after airway obstruction or hypoventilation, potentially delaying the detection of these critical events. Therefore, it is essential that oxygen saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

CORRECTION OF HYPOXIA

The primary therapeutic use of oxygen is to correct hypoxia. However, hypoxia is generally a manifestation of an underlying disease, and administration of oxygen thus should be viewed as a symptomatic therapy. Efforts must be directed at correcting the cause of the hypoxia. For example, airway obstruction is unlikely to respond to an increase in inspired oxygen tension without relief of the obstruction. More important, while hypoxemia owing to hypoventilation after a narcotic overdose can be improved with supplemental oxygen administration, the patient remains at risk for respiratory failure if ventilation is not increased through stimulation, narcotic reversal, or mechanical ventilation. The hypoxia that results from most pulmonary diseases can be alleviated at least partially by administration of oxygen, thereby allowing time for definitive therapy to reverse the primary process. Thus, administration of oxygen is used in all forms of hypoxia, with the understanding that the response will vary in a way that generally is predictable from knowledge of the underlying pathophysiology.

REDUCTION OF PARTIAL PRESSURE OF AN INERT GAS

Nitrogen, which constitutes 79% of ambient air, predominates in most gas-filled spaces in the body. In certain situations, such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of these air-filled spaces. Since nitrogen is relatively insoluble, inhalation of high concentrations of oxygen (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of oxygen for air embolism is additionally beneficial because it also helps to relieve the localized hypoxia distal to the embolic vascular obstruction. In the case of decompression sickness, or bends, lowering of inert gas tension in blood and tissues by oxygen inhalation prior to or during a barometric decompression can reduce the degree of supersaturation that occurs after decompression so that bubbles do not form. If bubbles do form in either tissues or the vasculature, administration of oxygen is based on the same rationale as that described for gas embolism.

HYPERBARIC OXYGEN THERAPY

Oxygen is administered at greater than atmospheric pressure for a number of conditions when 100% oxygen at 1 atm is insufficient.

Hyperbaric oxygen therapy has two components: increased hydrostatic pressure and increased oxygen pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased oxygen pressure at the tissue level is the primary therapeutic goal for most of the other indications for hyperbaric oxygen. For example, even a small increase in P_{O_2} in previously ischemic areas may enhance the bactericidal activity of leukocytes and increase angiogenesis. Thus, repetitive brief exposures to hyperbaric oxygen are a useful adjunct in the treatment of chronic refractory osteomyelitis, osteoradionecrosis, or crush injury or for the recovery of compromised skin, tissue grafts, or flaps. Furthermore, increased oxygen tension itself can be bacteriostatic; the spread of infection with *Clostridium perfringens* and production of toxin by the bacteria are slowed when oxygen tensions exceed 33 kPa (250 mm Hg), justifying the early use of hyperbaric oxygen in clostridial myonecrosis (gas gangrene).

Hyperbaric oxygen also is useful in selected instances of generalized hypoxia. In CO poisoning, hemoglobin (Hb) and myoglobin become unavailable for O₂ binding because of the high affinity of these proteins for CO. This affinity is ~250 times greater than the affinity for O₂; thus, an alveolar concentration of CO = 0.4 mm Hg (1/250th that of alveolar O₂, which is ~100 mm Hg),

will compete equally with O_2 for binding sites on Hb. A high PO_2 facilitates competition of O_2 for Hb binding sites as CO is exchanged in the alveoli; i.e., the high PO_2 increases the probability that O_2 rather than CO will bind to Hb once CO dissociates. In addition, hyperbaric O_2 will increase the availability of dissolved O_2 in the blood (see Table 15–1). The occasional use of hyperbaric oxygen in cyanide poisoning has a similar rationale.

Oxygen Toxicity

Oxygen toxicity probably results from increased production of hydrogen peroxide and reactive agents such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms. Decreases of inspired oxygen concentrations remain the cornerstone of therapy for oxygen toxicity.

The pulmonary system, continuously exposed to the highest O_2 tensions in the body, is usually the first to exhibit toxicity; subtle changes in pulmonary function can occur within 8–12 hours of exposure to 100% oxygen. Increases in capillary permeability and decreased pulmonary function can be seen after only 18 hours of exposure. Serious injury and death require much longer exposures. Pulmonary damage is directly related to the inspired oxygen tension, and concentrations of >0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung.

Retrolental fibroplasia can occur when neonates are exposed to increased oxygen tensions; these changes can progress to blindness. The incidence of this disorder has decreased with an improved appreciation of the issues and avoidance of excessive inspired oxygen concentrations. Adults do not seem to develop the disease.

CNS problems are rare, and toxicity occurs only under hyperbaric conditions >200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when oxygen tension is returned to normal. These problems are a further reason to replace oxygen with helium under hyperbaric conditions (see below).

CARBON DIOXIDE

Carbon dioxide (CO_2) is produced by the body's metabolism at approximately the same rate as O_2 consumption, about 3 mL/kg/minute at rest, increasing dramatically with heavy exercise. CO_2 diffuses readily from the cells into the bloodstream, where it is carried partly as bicarbonate ion (HCO_3^-), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of ~ 6 kPa (46 mm Hg) in mixed venous blood. CO_2 is transported to the lung, where it is normally exhaled at the same rate at which it is produced, leaving a partial pressure of ~ 5.2 kPa (40 mm Hg) in the alveoli and in arterial blood. An increase in PCO_2 results in a respiratory acidosis and may be due to decreased ventilation or the inhalation of CO_2 , whereas an increase in ventilation results in decreased PCO_2 and a respiratory alkalosis. Since CO_2 is freely diffusible, changes in blood PCO_2 and pH soon are reflected by intracellular changes in PCO_2 and pH.

Effects of Carbon Dioxide

Carbon dioxide is a rapid, potent stimulus to ventilation. Inhalation of 10% CO_2 can produce minute volumes of 75 L/min in normal individuals. Carbon dioxide acts at multiple sites to stimulate ventilation. Elevated PCO_2 causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion. Circulatory effects of CO_2 result from the combination of direct local effects and centrally mediated effects on the autonomic nervous system. The direct effects are diminished contractility of the heart and vascular smooth muscle (vasodilation). The indirect effects result from the capacity of CO_2 to activate the sympathetic nervous system; these indirect effects generally oppose the local effects of CO_2 . Thus, the balance of opposing local and sympathetic effects determines the total circulatory response to CO_2 . The net effect of CO_2 inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of carbon dioxide appear more important, and total peripheral resistance decreases when the PCO_2 is increased. CO_2 also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased PCO_2 are due to the release of catecholamines.

Hypocarbica results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

Hypercarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. In patients who are hypoventilating from narcotics or anesthetics, increasing PCO₂ may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can be deadly.

Therapeutic Uses

Inhalation of CO₂ is used less commonly today than in the past because there are now more effective treatments for most indications. Inhalation of carbon dioxide has been used during anesthesia to increase the speed of induction and emergence from inhalational anesthesia by increasing minute ventilation and cerebral blood flow. However, this technique results in some degree of respiratory acidosis. Hypocarbica, with its attendant respiratory alkalosis, still has some uses in anesthesia. It constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. Although CO₂ stimulates respiration, CO₂ is not useful in situations where respiratory depression has resulted in hypercarbia or acidosis because further depression results.

CO₂ is commonly used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because CO₂ is highly soluble and does not support combustion. Any inadvertent gas emboli thus are dissolved and eliminated more easily via the respiratory system. CO₂ can be helpful during open cardiac surgery, where the gas is used to flood the surgical field and, because of its density, displaces the air surrounding the open heart, assuring that any gas bubbles trapped are CO₂ rather than insoluble nitrogen. For the same reasons, CO₂ is used to debubble cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO) circuits. It also can be used to adjust pH during bypass procedures when a patient is cooled.

NITRIC OXIDE

Nitric oxide (NO), a free-radical gas long known as an air pollutant and a potential toxin, is an endogenous cell-signaling molecule of great physiological importance. Endogenous NO is produced from L-arginine by a family of enzymes called *NO synthases*. NO activates the soluble guanyl cyclase, increasing cellular cyclic GMP (see Chapter 1). In the vasculature, NO causes relaxation of vascular smooth muscle; basal release of NO by endothelial cells is a primary determinant of resting vascular tone; NO causes vasodilation when synthesized in response to shear stress or a variety of vasodilating agents (see Chapter 32). It also inhibits platelet aggregation and adhesion. Impaired NO production has been implicated in diseases such as atherosclerosis, hypertension, cerebral and coronary vasospasm, and ischemia–reperfusion injury. In the immune system, NO serves as an effector of macrophage-induced cytotoxicity, and overproduction of NO is a mediator of inflammation. In neurons, NO acts as a mediator of long-term potentiation, cytotoxicity resulting from *N*-methyl-D-aspartate (NMDA), and nonadrenergic noncholinergic neurotransmission; NO has been implicated in mediating central nociceptive pathways (see Chapter 6).

Therapeutic Use of NO

Inhaled NO can selectively dilate the pulmonary vasculature with minimal systemic cardiovascular effects. The lack of effect of inhaled NO on the systemic circulation is due to its strong binding to and inactivation by oxyhemoglobin on exposure to the pulmonary circulation. Ventilation–perfusion matching is preserved or improved by NO because inhaled NO is distributed only to ventilated areas of the lung and dilates only those vessels directly adjacent to the ventilated alveoli. Thus, inhaled NO will decrease elevated pulmonary artery pressure and pulmonary vascular resistance and often improve oxygenation. Therapeutic trials of inhaled NO have confirmed its ability to decrease pulmonary vascular resistance and often increase oxygenation, but have generally not demonstrated long-term improvement in terms of morbidity or mortality. Inhaled NO has been approved by the FDA only for use in newborns with persistent pulmonary hypertension and has become the first-line therapy for this disease. Trials of inhaled NO in adult and pediatric acute respiratory distress syndrome, as well as a recent meta-analysis, demonstrate no impact on outcome. Outside of clinical investigation, therapeutic use and benefit of inhaled NO presently are limited to newborns with persistent pulmonary hypertension.

Diagnostic Uses of NO

Inhaled NO can be used during cardiac catheterization to evaluate safely and selectively the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (DL) across the alveolar-capillary unit. NO is more effective than CO₂ in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature.

NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. Measurement of exhaled NO may prove to be useful in diagnosis and assessment of severity of asthma and in respiratory tract infections.

Toxicity of NO

Administered at low concentrations (0.1–50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50–100 ppm. The Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to NO₂. Even low concentrations of NO₂ (2 ppm) have been shown to be highly toxic in animal models, with observed changes in lung histopathology, including loss of cilia, hypertrophy, and focal hyperplasia in the epithelium of terminal bronchioles. Thus, during NO therapy, it is important to keep NO₂ formation at a low level by using appropriate filters and scavengers and high-quality gas mixtures. Chronic low doses of inhaled NO may cause surfactant inactivation and the formation of peroxynitrite by interaction with superoxide. The capacity of NO to inhibit or alter the function of a number of iron- and heme-containing proteins suggests a need for further investigation of the toxic potential of NO under therapeutic conditions.

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. The blood content of methemoglobin generally will not increase to toxic levels with appropriate use of inhaled NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation. Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported.

In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation. Careful monitoring of cardiac output, left atrial pressure, or pulmonary capillary wedge pressure is important in this situation.

The most important requirements for safe NO inhalation therapy include (1) continuous measurement of NO and NO₂ concentrations using either chemiluminescence or electrochemical analyzers; (2) frequent calibration of monitoring equipment; (3) intermittent analysis of blood methemoglobin levels; (4) the use of certified tanks of NO; and (5) administration of the lowest NO concentration required for therapeutic effect.

Methods of Administration

Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1–40 ppm in dose and for periods of a few hours to several weeks in duration. The minimum effective inhaled NO concentration should be determined for each patient to minimize the chance for toxicity. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO₂ concentrations. A constant inspired concentration of NO is obtained by administering NO in nitrogen to the inspiratory limb of the ventilator circuit in either a pulse or continuous mode. While inhaled NO may be administered to spontaneously breathing patients via a closely fitting mask, it usually is delivered during mechanical ventilation. Nasal prong administration is being employed in therapeutic trials of home administration for treatment of primary pulmonary hypertension.

Acute discontinuation of NO inhalation can lead to a rebound pulmonary artery hypertension with an increase in right-to-left intrapulmonary shunting and a decrease in oxygenation. To avoid this phenomenon, a graded decrease of inhaled NO concentration is used in weaning a patient from inhaled NO.

HELIUM

Helium (He) is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses; the gas is supplied in brown cylinders. Helium can be mixed with oxygen and administered by mask or tracheal tube. Under hyperbaric conditions, it can be substituted for the bulk of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, during laser airway surgery, for diving at depth, and most recently, as a label in imaging studies. The determinations of residual lung volume, functional residual capacity, and related lung volumes require a highly diffusible nontoxic gas that is insoluble (and thus does not leave the lung *via* the bloodstream) so that, by dilution, the lung volume can be measured. Helium is well suited to these needs and is much cheaper than alternatives. In these tests, a breath of a known concentration of helium is given, and the concentration of helium then is measured in the mixed expired gas, allowing calculation of the other pulmonary volumes.

Pulmonary gas flow is normally laminar, but with increased flow rate or narrowed flow pathway, a component becomes turbulent. Helium can be added to oxygen to treat the turbulence due to airway obstruction: the density of helium is substantially less than that of air and the viscosity of helium is greater than that of air; addition of helium reduces the Reynolds number of the mixture (the Reynolds number is proportional to density and inversely proportional to viscosity), thereby reducing turbulence. Indeed, flow rates are increased with lower density gases. Thus, with mixtures of helium and oxygen, the work of breathing is less. Several factors limit the utility of this approach, however. Oxygenation is often the principal problem in airway obstruction, and the practical need for increased inspired O₂ concentration may limit the fraction of helium that can be used. Furthermore, even though helium reduces the Reynolds number of the gas mixture, the viscosity of helium is higher than that of air, and the increased viscosity increases the resistance to flow according to Poiseuille's law, whereby flow is inversely proportional to viscosity.

Helium has high thermal conductivity, which makes it useful during laser surgery on the airway. This more rapid conduction of heat away from the point of contact of the laser beam reduces the spread of tissue damage and the likelihood that the ignition point of flammable materials in the airway will be reached. Helium's low density improves the flow through the small endotracheal tubes typically used in such procedures.

Recently, laser-polarized helium has been used as an inhalational contrast agent for pulmonary magnetic resonance imaging.

HYPERBARIC APPLICATIONS The depth and duration of diving activity are limited by oxygen toxicity, inert gas (nitrogen) narcosis, and nitrogen supersaturation when decompressing. Oxygen toxicity is a problem with prolonged exposure to compressed air at 500 kPa (5 atm) or more. This problem can be minimized by dilution of oxygen with helium, which lacks narcotic potential even at very high pressures and is quite insoluble in body tissues. This low solubility reduces the likelihood of bubble formation after decompression, which therefore can be achieved more rapidly. The low density of helium also reduces the work of breathing in the otherwise dense hyperbaric atmosphere. The lower heat capacity of helium also decreases respiratory heat loss, which can be significant when diving at depth.

HYPNOTICS AND SEDATIVES

A *sedative* drug decreases activity, moderates excitement, and calms; a *hypnotic* drug produces drowsiness and facilitates the onset and maintenance of a state of sleep resembling natural sleep and from which the recipient can be aroused easily. The sleep induced by hypnotic drugs does not resemble the artificially induced passive state of suggestibility also called *hypnosis*.

BENZODIAZEPINES

All benzodiazepines in clinical use have the capacity to promote the binding of the major inhibitory neurotransmitter γ -aminobutyric acid (GABA) to GABA_A receptors, thereby enhancing the GABA-induced ionic currents through these channels (*see* Chapter 12). Pharmacological investigations have provided evidence for heterogeneity among sites of binding and action of benzodiazepines and for heterogeneity of subunit composition of the GABA-gated chloride channels of different neurons. A number of distinct mechanisms of action are thought to contribute to the sedative-hypnotic, muscle-relaxant, anxiolytic, and anticonvulsant effects of the benzodiazepines, and specific subunits of the GABA_A receptor are responsible for specific pharmacological properties of benzodiazepines. Although benzodiazepines exert qualitatively similar clinical effects, quantitative differences in their pharmacodynamic spectra and pharmacokinetic properties have led to varying patterns of therapeutic application.

CHEMISTRY

The basic structure of the benzodiazepines is shown in Table 16-1.

Pharmacological Properties

Virtually all effects of the benzodiazepines result from their actions on the central nervous system (CNS). The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only two effects of these drugs result from peripheral actions: coronary vasodilation, seen after intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

A number of benzodiazepine-like effects are classified as *full agonistic effects* (*i.e.*, faithfully mimicking agents such as *diazepam* with relatively low fractional occupancy of binding sites) or *partial agonistic effects* (*i.e.*, producing less intense maximal effects and/or requiring relatively high fractional occupancy compared with agents such as *diazepam*). Some compounds produce effects opposite to those of *diazepam* in the absence of benzodiazepine-like agonists and are termed *inverse agonists*; *partial inverse agonists* also have been recognized (*see* Chapter 1 for a discussion of inverse agonism). The vast majority of effects of agonists and inverse agonists can be reversed or prevented by the benzodiazepine antagonist *flumazenil*, which competes with agonists and inverse agonists for binding to the GABA_A receptor.

CENTRAL NERVOUS SYSTEM While benzodiazepines affect activity at all levels of the neuraxis, some structures are affected preferentially. The benzodiazepines do not produce the same degrees of neuronal depression as do barbiturates and volatile anesthetics. Although the benzodiazepines have similar pharmacological profiles, the drugs differ in selectivity and thus in clinical utility.

As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. The clinical literature often refers to the “anesthetic” effects and uses of certain benzodiazepines, but the drugs do not cause a true general anesthesia because awareness usually persists, and relaxation sufficient to allow surgery cannot be achieved. However, at “preanesthetic” doses, there is amnesia for events subsequent to administration of the drug, possibly creating the illusion of pre-vious anesthesia.

Separating the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects is problematic; measurements of anxiety and sedation are difficult in human beings, and the validity of animal models for anxiety and sedation is uncertain.

Tolerance to Benzodiazepines; Selectivity

Although most patients who ingest benzodiazepines chronically report that drowsiness wanes over a few days, tolerance to the impairment of some measures of psychomotor performance (e.g., visual tracking) usually is not observed. The development of tolerance to the anxiolytic effects of benzodiazepines is a subject of debate. Some benzodiazepines induce muscle hypotonia without

interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. In contrast to effects in animals, there is only a limited selectivity in human beings. Clonazepam in nonsedative doses does cause muscle relaxation, but diazepam and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Experimentally, benzodiazepines inhibit some types of seizure activity. Clonazepam, nitrazepam, and nordazepam have more selective anticonvulsant activity than most other benzodiazepines. Benzodiazepines also suppress ethanol-withdrawal seizures in human beings. However, the development of tolerance to the anticonvulsant effects has limited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders (see Chapter 19).

Only transient analgesia is apparent in humans after intravenous administration of benzodiazepines. Such effects actually may involve the production of amnesia. Unlike barbiturates, benzodiazepines do not cause hyperalgesia.

Effects on the Electroencephalogram and Sleep Stages

The effects of benzodiazepines on the waking electroencephalogram (EEG) resemble those of other sedative-hypnotic drugs. Alpha activity is decreased, but there is an increase in low-voltage fast activity. Tolerance occurs to these effects.

Most benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the time from onset of spindle sleep to the first burst of rapid-eye-movement (REM) sleep. The time spent in REM sleep usually is shortened, but the number of cycles of REM sleep usually is increased, mostly late in the sleep time. Zolpidem and zaleplon suppress REM sleep to a lesser extent and thus may be superior to benzodiazepines for use as hypnotics.

Benzodiazepine administration typically increases total sleep time, largely because of increased time spent in stage 2 (the major fraction of non-REM sleep). The effect is greatest in subjects with the shortest baseline total sleep time. Despite the increased number of REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. With discontinuation of drug, the pattern of drug-induced changes in sleep parameters may “rebound,” with an increase in the amount and density of REM sleep. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

Benzodiazepine use usually imparts a sense of deep or refreshing sleep. It is uncertain to which effect on sleep parameters this feeling can be attributed. As a result, variations in the pharmacokinetic properties of individual benzodiazepines appear to be much more important determinants of their effects on sleep than are any potential differences in their pharmacodynamic properties.

Molecular Targets for Benzodiazepine Actions in the CNS Benzodiazepines likely exert most of their effects by interacting with inhibitory neurotransmitter receptors directly activated by GABA. Benzodiazepines act at GABA_A (ionotropic) receptors (but not at GABA_B [metabotropic] receptors [GPCRs]) by binding to a specific site that is distinct from that of GABA binding. Unlike barbiturates, benzodiazepines do not activate GABA_A receptors directly but rather require GABA to express their effects; *i.e.*, they only modulate the effects of GABA. Benzodiazepines and related compounds can act as agonists, antagonists, or inverse agonists at the benzodiazepine-binding site on GABA_A receptors. Agonists at the benzodiazepine-binding site shift the GABA concentration–response curve to the left, increasing the amount of chloride current generated by GABA_A-receptor activation; inverse agonists shift the curve to the right, reducing the effect of given concentration of GABA. Both these effects are blocked by antagonists at the benzodiazepine-binding site. A pure antagonist (*e.g.*, flumazenil) acting alone at this binding site does not affect GABA_A-receptor function but can reverse the effects of high doses of benzodiazepines. The behavioral and electrophysiological effects of benzodiazepines also can be reduced or prevented by prior treatment with antagonists at the GABA-binding site (*e.g.*, bicuculline).

GABA_A Receptor-Mediated Electrical Events: *In Vivo* Properties

The remarkable safety of the benzodiazepines is likely related to the fact that their effects *in vivo* depend on the presynaptic release of GABA; in the absence of GABA, benzodiazepines have no effects on GABA_A receptor function. Although barbiturates also enhance the effects of GABA at

low concentrations, they directly activate GABA receptors at higher concentrations, which can lead to profound CNS depression (see below). Further, the behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABA-ergic pathways that serve to regulate the firing of neurons containing various monoamines (see Chapter 12). These neurons are known to promote behavioral arousal and are important mediators of the inhibitory effects of fear and punishment on behavior. Finally, inhibitory effects on muscular hypertonia or the spread of seizure activity can be rationalized by potentiation of inhibitory GABA-ergic circuits at various levels of the neuraxis.

Molecular Basis for Benzodiazepine Regulation of GABA_A Receptor-Mediated Electrical Events

The enhancement of GABA-induced chloride currents by benzodiazepines results primarily from an increase in the frequency of bursts of chloride channel opening produced by submaximal amounts of GABA. Inhibitory synaptic transmission measured after stimulation of afferent fibers is potentiated by benzodiazepines at therapeutically relevant concentrations. Measurements of GABA_A receptor-mediated currents indicate that benzodiazepines shift the GABA concentration-response curve to the left without increasing the maximum current evoked with GABA, consistent with a model in which benzodiazepines exert their major actions by increasing the gain of inhibitory neurotransmission mediated by GABA_A receptors. Some data are difficult to reconcile with the hypothesis that actions at GABA_A receptors mediate all effects of benzodiazepines. Low concentrations of benzodiazepines that are not blocked by bicuculline or picrotoxin induce depressant effects on hippocampal neurons; the induction of sleep in rats by benzodiazepines also is insensitive to bicuculline or picrotoxin but is prevented by flumazenil. At higher (hypnotic/amnesic) concentrations, actions of the benzodiazepines may involve other mechanisms, including inhibition of the uptake of adenosine and the resulting potentiation of its actions as a neuronal depressant, as well as the GABA-independent inhibition of Ca²⁺ currents, Ca²⁺-dependent neurotransmitter release, and tetrodotoxin-sensitive Na⁺ channels.

The macromolecular complex containing GABA-regulated chloride channels also may be a site of action of general anesthetics, ethanol, inhaled drugs of abuse, and certain metabolites of endogenous steroids.

RESPIRATION Hypnotic doses of benzodiazepines are without effect on respiration in normal adult subjects, but special care must be taken in the treatment of children and individuals with impaired hepatic function (e.g., alcoholics). At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with chronic obstructive pulmonary disease (COPD), and alveolar hypoxia and/or CO₂ narcosis may result. These drugs can cause apnea during anesthesia or when given with opioids. Patients severely intoxicated with benzodiazepines only require respiratory assistance when they also have ingested another CNS-depressant drug, most commonly ethanol.

In contrast, hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO₂. The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD, although benzodiazepines may improve sleep and sleep structure in some instances. In patients with obstructive sleep apnea (OSA), hypnotic doses of benzodiazepines may exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Caution should be exercised with patients who snore regularly: partial airway obstruction may be converted to OSA under the influence of these drugs.

CARDIOVASCULAR SYSTEM The cardiovascular effects of benzodiazepines are minor in normal subjects except in severe intoxication. In preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate.

GI TRACT Despite anecdotal reports that benzodiazepines improve a variety of “anxiety-related” GI disorders, there is a paucity of evidence. Diazepam markedly decreases nocturnal gastric acid secretion in human beings, but other agents are considerably more effective in acid-peptic disorders (see Chapter 36).

ABSORPTION, FATE, AND EXCRETION The physicochemical and pharmacokinetic properties of the benzodiazepines affect their clinical utility. All have high lipid-water distribution coefficients in the nonionized form; nevertheless, lipophilicity varies more than 50-fold according to the polarity and electronegativity of various substituents.

All benzodiazepines are absorbed completely, with the exception of *clorazepate*; this drug is decarboxylated rapidly in gastric juice to *N*-desmethyldiazepam (nordazepam), which subsequently is absorbed completely. Some benzodiazepines (e.g., *prazepam* and *flurazepam*) reach the systemic circulation only in the form of active metabolites.

Drugs active at the benzodiazepine receptor may be divided into four categories based on their elimination half-lives: (1) ultrashort acting; (2) short-acting ($t_{1/2} < 6$ hours): *triazolam*, the non-benzodiazepine *zolpidem* ($t_{1/2} \sim 2$ hours), and *zopiclone* ($t_{1/2} = 5\text{--}6$ hours); (3) intermediate-acting ($t_{1/2} = 6\text{--}24$ hours): *estazolam* and *temazepam*; and (4) long-acting ($t_{1/2} > 24$ hours): *flurazepam*, *diazepam*, and *quazepam*.

The extent of binding of benzodiazepines and their metabolites to plasma proteins correlates with lipid solubility and ranges from $\sim 70\%$ (*alprazolam*) to nearly 99% (*diazepam*). The concentration in the cerebrospinal fluid is approximately equal to the concentration of free drug in plasma. There is rapid uptake of benzodiazepines into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound), followed by redistribution into tissues that are less well perfused (e.g., muscle and fat). Redistribution is most rapid for drugs with the highest lipid solubility. In the regimens used for nighttime sedation, the rate of redistribution sometimes can have a greater influence than the rate of biotransformation on the duration of CNS effects. Redistribution kinetics of lipophilic benzodiazepines (e.g., *diazepam*) is complicated by enterohepatic circulation. The volumes of distribution of the benzodiazepines are large and in many cases are increased in elderly patients. These drugs cross the placental barrier and are secreted into breast milk.

The benzodiazepines are metabolized extensively by CYPs, particularly CYP 3A4 and 2C19. Some benzodiazepines (e.g., *oxazepam*) are conjugated directly. *Erythromycin*, *clarithromycin*, *ritonavir*, *itraconazole*, *ketoconazole*, *nefazodone*, and grapefruit juice are inhibitors of CYP 3A4 and can affect the metabolism of benzodiazepines. Because active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds, the duration of action of many benzodiazepines bears little relationship to the $t_{1/2}$ of elimination of the drug that has been administered (e.g., the $t_{1/2}$ of *flurazepam* in plasma is ~ 2 hours, but that of a major active metabolite *N*-desalkylflurazepam is ~ 50 hours). Conversely, the rate of biotransformation of agents that are inactivated by the initial reaction is an important determinant of their duration of action; these agents include *oxazepam*, *lorazepam*, *temazepam*, *triazolam*, and *midazolam*. Metabolism of the benzodiazepines occurs in three major stages. In general terms, the substituent at position 1 (or 2) of the diazepine ring is rapidly removed or modified to form metabolites that frequently are biologically active; then position 3 is more slowly hydroxylated, yielding derivatives that are generally active; finally the 3-OH compounds are conjugated with glucuronic acid to inactive products.

Because benzodiazepines do not significantly induce the synthesis of hepatic CYPs, chronic benzodiazepine administration usually does not result in the accelerated metabolism of benzodiazepines or other substances. Cimetidine and oral contraceptives inhibit N-dealkylation and 3-hydroxylation of benzodiazepines, as do ethanol, isoniazid, and phenytoin to a lesser degree. These reactions usually are reduced to a greater extent in elderly patients and in patients with chronic liver disease than are those involving conjugation.

An ideal hypnotic agent would have a rapid onset of action when taken at bedtime, a sufficiently sustained action to facilitate sleep throughout the night, and no residual action by the following morning. *Triazolam* theoretically fits this description most closely. Because of the slow rate of elimination of *desalkylflurazepam*, *flurazepam* (or *quazepam*) might seem to be unsuitable for this purpose. In practice, there appear to be some disadvantages to the use of agents that have a relatively rapid rate of disappearance, including the early-morning insomnia that is experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation. With careful selection of dosage, *flurazepam* and other benzodiazepines with slower rates of elimination than *triazolam* can be used effectively.

Therapeutic Uses

The therapeutic uses and routes of administration of individual benzodiazepines marketed in the U.S. are summarized in Table 16-2. Note that most benzodiazepines can be used interchangeably. Benzodiazepines used as anticonvulsants have a long $t_{1/2}$, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. A short elimination $t_{1/2}$ is desirable for hypnotics,

[†]The therapeutic uses are identified as examples to emphasize that most benzodiazepines can be used interchangeably. In general, the therapeutic uses of a given benzodiazepine are related to its half-life and may not match the marketed indications. The issue is addressed more extensively in the text.

[‡]Half-life of active metabolite may differ. See Appendix II in the 11th edition of the parent text for additional information.

although this carries the drawback of increased abuse liability and severity of withdrawal after drug discontinuation. Antianxiety agents should have a long $t_{1/2}$ despite the risk of neuropsychological deficits caused by drug accumulation.

UNTOWARD EFFECTS At the time of peak concentration in plasma, hypnotic doses of benzodiazepines cause varying degrees of lightheadedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. *All these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol.* These dose-related residual effects can be insidious because most subjects underestimate the degree of their impairment. Residual daytime sleepiness also may occur. The intensity and incidence of CNS toxicity generally increase with age.

Other relatively common side effects are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much rarer. Anticonvulsant benzodiazepines sometimes actually increase the frequency of seizures in patients with epilepsy. Possible adverse effects of altered sleep patterns are discussed below.

Adverse Psychological Effects

Benzodiazepines may cause paradoxical effects. Flurazepam occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, and hypomanic behavior have been reported to occur during use of various benzodiazepines. The release of bizarre uninhibited behavior occurs in some users; hostility and rage may occur in others; these are referred to as disinhibition or dyscontrol reactions. Paranoia, depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and appear to be dose-related. Because of reports of an increased incidence of confusion and abnormal behaviors, triazolam has been banned in the U.K., although the FDA declared triazolam to be safe and effective in low doses of 0.125–0.25 mg. Surveys in the U.K. after the ban found that patients did not have fewer side effects with replacement treatments.

Chronic benzodiazepine use poses a risk for development of dependence and abuse, but not to the same extent as seen with older sedatives and other recognized drugs of abuse. Mild dependence may develop in many patients who have taken therapeutic doses of benzodiazepines on a regular basis for prolonged periods. Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (e.g., insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly; it is prudent to taper the dosage gradually to discontinue therapy. Nonetheless, benzodiazepines are relatively safe drugs. Even huge doses are rarely fatal unless other drugs are taken concomitantly, and true coma is uncommon in the absence of another CNS depressant (e.g., ethanol). Although overdose with a benzodiazepine rarely causes severe cardiovascular or respiratory depression, therapeutic doses can further compromise respiration in patients with COPD or OSA. Abuse of benzodiazepines includes the use of flunitrazepam (ROHYPNOL) as a “date-rape” drug.

Adverse Effects and Drug Interactions

A variety of allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is quite low; these reactions have been associated with the use of flurazepam and triazolam but not with temazepam. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. Ethanol increases both the rate of absorption of benzodiazepines and the associated CNS depression. Valproate and benzodiazepines in combination may cause psychotic episodes.

Novel Benzodiazepine-Receptor Agonists: Zolpidem and Zaleplon

Hypnotics that are structurally dissimilar to benzodiazepines include zolpicon (not available in the U.S.), zolpidem (AMBIENT), zaleplon (SONATA), and indiplon (under review by the FDA); presumably, their therapeutic efficacies are due to agonist effects at the benzodiazepine site of the GABA_A receptor.

Zaleplon and zolpidem are effective in relieving sleep-onset insomnia. The two drugs have similar efficacies and both display sustained hypnotic efficacy without occurrence of rebound insomnia

on abrupt discontinuation. Late-night administration of zolpidem has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas zaleplon has no more side effects than placebo. Tolerance to zaleplon does not appear to occur, nor do rebound insomnia or withdrawal symptoms after stopping treatment. Unlike the benzodiazepines, zolpidem has little effect on the stages of sleep in normal human subjects. The drug is as effective as benzodiazepines in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of zolpidem, the beneficial effects on sleep reportedly persist for up to 1 week, but mild rebound insomnia on the first night also has occurred. Tolerance and physical dependence develop only rarely. An extended-release formulation of zolpidem (AMBIEN CR) is now marketed in the U.S.

Flumazenil: A Benzodiazepine-Receptor Antagonist

Flumazenil (ROMAZICON) is an imidazobenzodiazepine that behaves as a specific benzodiazepine antagonist. Flumazenil binds with high affinity to specific sites on the GABA_A receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands. The drug antagonizes both the electrophysiological and behavioral effects of agonist and inverse-agonist benzodiazepines and β -carbolines. Anticonvulsant effects cannot be relied on for therapeutic utility because the administration of flumazenil may precipitate seizures under certain circumstances (see below).

Flumazenil is available only for intravenous administration. Although absorbed rapidly after oral administration, <25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism; effective oral doses are apt to cause headache and dizziness. On intravenous administration, flumazenil is eliminated almost entirely by hepatic metabolism to inactive products with a $t_{1/2}$ of about 1 hour; the duration of clinical effects usually is only 30–60 minutes.

The primary uses of flumazenil are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced by benzodiazepines administered during either general anesthesia or diagnostic and/or therapeutic procedures.

The administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg flumazenil given over 1–3 minutes usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines; patients with suspected benzodiazepine overdose should respond adequately to a cumulative dose of 1–5 mg given over 2–10 minutes; a lack of response to 5-mg flumazenil strongly suggests that a benzodiazepine is not the major cause of sedation. Additional courses of treatment with flumazenil may be needed within 20–30 minutes should sedation reappear. Flumazenil is not effective in single-drug overdoses with either barbiturates or tricyclic antidepressants. To the contrary, administration of flumazenil in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants. Seizures or other withdrawal symptoms also may be precipitated in patients who had been taking benzodiazepines for protracted periods and in whom tolerance and/or dependence may have developed.

BARBITURATES

The barbiturates are derivatives of 2,4,6-trioxohexahydropyrimidine (Table 16–3) that reversibly depress the activity of all excitable tissues. The CNS is exquisitely sensitive, and even when barbiturates are given in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication. Except for a few specialized uses, barbiturates have been replaced by the much safer benzodiazepines.

Pharmacological Properties

CENTRAL NERVOUS SYSTEM

Sites and Mechanisms of Action on the CNS

Barbiturates act throughout the CNS; nonanesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamic relay neurons, or presynaptic, as in the spinal cord. Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at GABA_A receptors.

Mechanisms underlying the actions of barbiturates on GABA_A receptors appear to be distinct from those of either GABA or the benzodiazepines, a conclusion based on the following observations: (1) barbiturates promote (rather than compete with) the binding of benzodiazepines to GABA_A receptors; (2) barbiturates potentiate GABA-induced chloride currents by prolonging

periods during which bursts of channel opening occur rather than by increasing the frequency of these bursts, as benzodiazepines do; (3) only α and β (not γ) subunits of the receptor/channel are required for barbiturate action; and (4) barbiturate-induced increases in chloride conductance are insensitive to mutations in the β subunit that govern the sensitivity of GABA_A receptors to activation by agonists. In addition, sub-anesthetic concentrations of barbiturates also can reduce glutamate-induced depolarizations of the AMPA subtype of glutamate receptor. Thus, the activation of inhibitory GABA_A receptors and inhibition of excitatory AMPA receptors by barbiturates may explain their CNS-depressant effects.

The barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia. The use of barbiturates for general anesthesia is discussed in Chapter 13. Certain barbiturates, particularly those containing a 5-phenyl substituent (e.g., phenobarbital and mephobarbital), have selective anticonvulsant activity (see Chapter 19). The antianxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of phenobarbital and its congeners, the barbiturates possess a low degree of selectivity and therapeutic index. Thus, it is not possible to achieve a desired effect without evidence of general depression of the CNS. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, the barbiturates increase the reaction to painful stimuli. Hence, they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

Effects on Stages of Sleep

Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, these drugs decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the parameters decreased by barbiturates.

Tolerance

Pharmacodynamic (functional) and pharmacokinetic tolerance to barbiturates can occur. The former contributes more to the decreased effect than does the latter. With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its peak in a few days to a week. Tolerance to the effects on mood, sedation, and hypnosis occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers tolerance to all general CNS-depressant drugs, including ethanol.

PERIPHERAL NERVOUS STRUCTURES

Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters, an effect that may account for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both tubocurarine and decamethonium are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit the passage of current through nicotinic cholinergic receptors. Several distinct mechanisms appear to be involved and little stereoselectivity is evident.

RESPIRATION

Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is diminished by hypnotic doses but usually no more so than during natural sleep. However, neurogenic drive is essentially eliminated by a dose three times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. At still higher doses, the powerful hypoxic drive also fails. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultrashort-acting barbiturates to be used, with suitable precautions, as anesthetic agents.

The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Laryngospasm is a major complication of barbiturate anesthesia.

CARDIOVASCULAR SYSTEM

When given orally in sedative or hypnotic doses, the barbiturates do not produce significant overt cardiovascular effects except for a slight decrease in blood pressure and heart rate such as occurs

in normal sleep. Cardiovascular reflexes are obtunded by partial inhibition of ganglionic transmission; this is most evident in patients with congestive heart failure or hypovolemic shock, whose reflexes already are operating maximally and in whom barbiturates can cause an exaggerated fall in blood pressure. Because barbiturates also impair reflex cardiovascular adjustments to inflation of the lung, positive-pressure respiration should be used cautiously and only when necessary to maintain adequate pulmonary ventilation in patients who are anesthetized or intoxicated with a barbiturate.

Intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when epinephrine and halothane also are present. Direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered.

GI TRACT

Oxybarbiturates tend to decrease the tone of the GI musculature and the amplitude of rhythmic contractions. The locus of action is partly peripheral and partly central, depending on the dose. A hypnotic dose does not significantly delay gastric emptying in human beings. The relief of various GI symptoms by sedative doses is probably largely due to the central-depressant action.

LIVER

The best known effects of barbiturates on the liver are those on the microsomal drug-metabolizing system (see Chapter 3). Acutely, the barbiturates combine with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations.

Chronic administration of barbiturates markedly induces (approximately doubles) the activities of glucuronyl transferases and CYPs 1A2, 2C9, 2C19, and 3A4, thereby increasing the metabolism of a number of drugs and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D, and the barbiturate itself (and thus contributing to tolerance to barbiturates). Many sedative-hypnotics, various anesthetics, and ethanol also are metabolized by and/or induce the microsomal enzymes, and some degree of cross-tolerance therefore can occur. Induction extends to δ -aminolevulinic acid synthetase and can cause dangerous disease exacerbations in persons with acute intermittent porphyria.

KIDNEY

Severe oliguria or anuria may occur in acute barbiturate poisoning, largely as a result of the marked hypotension.

ABSORPTION, FATE, AND EXCRETION For sedative-hypnotic use, the barbiturates usually are administered orally (Table 16–3); absorption is rapid and nearly complete. The onset of action varies from 10–60 minutes, depending on the agent and the formulation, and is delayed by the presence of food in the stomach. When necessary, intramuscular injections of solutions of the sodium salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. The intravenous route usually is reserved for the management of status epilepticus (phenobarbital sodium) or for the induction and/or maintenance of general anesthesia (e.g., thiopental or methohexital).

Barbiturates are distributed widely and readily cross the placenta. Following initial distribution to the CNS of an intravenous dose, the highly lipid-soluble barbiturates undergo redistribution to less vascular tissues, especially muscle and fat, leading to a decline in the concentration of barbiturate in the plasma and brain. With thiopental and methohexital, this results in the awakening of patients within 5–15 minutes of the injection of the usual anesthetic doses (see Chapter 13).

Except for the less lipid-soluble *aprobarbital* and phenobarbital, nearly complete metabolism and/or conjugation of barbiturates in the liver precedes their renal excretion. The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and half-lives are increased during pregnancy partly because of the expanded volume of distribution. Chronic liver disease, especially cirrhosis, often increases the $t_{1/2}$ of the biotransformable barbiturates. Repeated administration, especially of phenobarbital, shortens the $t_{1/2}$ of barbiturates that are metabolized as a result of the induction of microsomal enzymes (see above).

All of these barbiturates will accumulate during repetitive administration unless appropriate adjustments in dosage are made. Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.

Therapeutic Uses

The major uses of individual barbiturates are listed in Table 16–3, mostly uses involving CNS actions of these drugs. As with the benzodiazepines, selection of particular barbiturates for a given therapeutic indication is based primarily on pharmacokinetic considerations.

In addition, there are some hepatic metabolic uses. Because hepatic glucuronyl transferase and the bilirubin-binding Y protein are increased by the barbiturates, phenobarbital has been used successfully to treat hyperbilirubinemia and kernicterus in the neonate. The nondepressant barbiturate *phetharbital* (*N*-phenylbarbital) works equally well. Phenobarbital may improve the hepatic transport of bilirubin in patients with hemolytic jaundice.

UNTOWARD EFFECTS

After-Effects Drowsiness may last for only a few hours after a hypnotic dose of barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea or sometimes may be manifested as overt excitement. The user may awaken slightly intoxicated and feel euphoric and energetic; later, as the demands of daytime activities challenge possibly impaired faculties, the user may display irritability and temper.

Paradoxical Excitement In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with phenobarbital and *N*-methylbarbiturates. Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain and may worsen a patient's perception of pain.

Hypersensitivity Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by phenobarbital and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

Drug Interactions Barbiturates combine with other CNS depressants to cause severe depression; ethanol is the most frequent offender, and interactions with first-generation antihistamines also are common. Isoniazid, methylphenidate, and monoamine oxidase inhibitors also increase the CNS-depressant effects. Other prominent drug interactions occur as a result of the induction of hepatic drug-metabolizing enzymes by barbiturates (*see above*).

OTHER UNTOWARD EFFECTS

BARBITURATE POISONING

The lethal dose of barbiturate varies, but severe poisoning is likely to occur when more than 10 times the full hypnotic dose has been ingested at once. If alcohol or other depressant drugs also are present, the concentrations that can cause death are lower.

The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. Hemodialysis or hemoperfusion is necessary only rarely, and the use of CNS stimulants is contraindicated because they increase the mortality rate (see Chapter 64).

MISCELLANEOUS SEDATIVE-HYPNOTIC DRUGS

Structurally diverse agents have been employed for their sedative-hypnotic properties, including paraldehyde, chloral hydrate, ethchlorvynol, glutethimide, methyprylon, ethinamate, and meprobamate. With the exception of meprobamate, the pharmacological actions of these drugs generally resemble those of the barbiturates: they all are general CNS depressants that can produce profound hypnosis with little or no analgesia; their effects on the stages of sleep are similar to those of the barbiturates; their therapeutic index is limited, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning; their chronic use can result in tolerance and physical dependence; and the syndrome after chronic use can be severe and life-threatening. The use of these drugs is limited.

OTHERS

Etomidate (*AMIDATE*) is used as an intravenous anesthetic, often in combination with fentanyl. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the heart. Its pharmacology and anesthetic uses are described in

Chapter 13. It also is used in some countries as a sedative-hypnotic drug in intensive care units, during intermittent positive-pressure breathing, in epidural anesthesia, and in other situations. The myoclonus commonly seen after anesthetic doses is not seen after sedative-hypnotic doses.

Clomethiazole has sedative, muscle relaxant, and anticonvulsant properties. It is used outside the U.S. for hypnosis in elderly and institutionalized patients, for preanesthetic sedation, and especially in the management of withdrawal from ethanol. Given alone, its effects on respiration are slight, and the therapeutic index is high. However, deaths from adverse interactions with ethanol are relatively frequent.

Propofol (DIPRIVAN) is a rapidly acting and highly lipophilic di-isopropylphenol used in the induction and maintenance of general anesthesia (see Chapter 13), as well as in the maintenance of long-term sedation. Propofol sedation is of a similar quality to that produced by midazolam. Emergence from sedation occurs quickly owing to its rapid clearance. Propofol has found use in intensive care sedation in adults, as well as for sedation during GI endoscopy procedures and transvaginal oocyte retrieval. Propofol is believed to act primarily through enhancement of GABA_A-receptor function. Effects on other ligand-gated and G protein-coupled receptors, however, also have been reported.

NONPRESCRIPTION HYPNOTIC DRUGS

As part of the ongoing systematic review of over-the-counter (OTC) drug products, the FDA has ruled that diphenhydramine is the only ingredient that is recognized as generally safe and effective for use in nonprescription sleep aids. Despite the prominent sedative side effects encountered during the use of antihistamines previously included in OTC sleep aids (e.g., doxylamine and pyrillamine), these agents have been eliminated as ingredients in the OTC nighttime sleep aids marketed in the U.S. With an elimination $t_{1/2}$ of about 9 hours, diphenhydramine at nighttime is associated with prominent residual daytime sleepiness.

MANAGEMENT OF INSOMNIA

Adequate sleep improves the quality of daytime wakefulness, and hypnotics should be used judiciously to avoid its impairment. A number of pharmacological agents are available for the treatment of insomnia. The “perfect” hypnotic would allow sleep to occur with normal sleep architecture rather than produce a pharmacologically altered sleep pattern. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without causing dependence or rebound insomnia on discontinuation. Regular moderate exercise meets these criteria but often is not effective by itself, and many patients may not be able to exercise. However, even small amounts of exercise often are effective in promoting sleep.

Controversy in the management of insomnia revolves around two issues: pharmacological *versus* nonpharmacological treatment and the use of short-acting *versus* long-acting hypnotics. The side effects of hypnotic medications must be weighed against the sequelae of chronic insomnia, which include a fourfold increase in serious accidents. Two aspects of the management of insomnia traditionally have been underappreciated: a search for specific medical causes and the use of nonpharmacological treatments. In addition to appropriate pharmacological treatment, management of insomnia should correct identifiable causes, address inadequate sleep hygiene, eliminate performance anxiety related to falling asleep, provide entrainment of the biological clock so that maximum sleepiness occurs at the hour of attempted sleep, and suppress the use of alcohol and OTC sleep medications.

CATEGORIES OF INSOMNIA Like Gaul, insomnia may be divided into three categories:

1. *Transient insomnia* lasts less than 3 days and usually is caused by a brief environmental or situational stressor. It may respond to attention to sleep hygiene rules. Hypnotics, if prescribed, should be used at the lowest dose and for only 2–3 nights. However, benzodiazepines given acutely before important life events, such as examinations, may result in impaired performance.
2. *Short-term insomnia* lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Again, sleep hygiene education is the first step. Hypnotics may be used adjunctively for 7–10 nights. Hypnotics are best used intermittently during this time, with the patient skipping a dose after 1–2 nights of good sleep.
3. *Long-term insomnia* is insomnia that has lasted for more than 3 weeks; no specific stressor may be identifiable. A more complete medical evaluation is necessary in these patients, but most do not need an all-night sleep study.

INSOMNIA ACCOMPANYING MAJOR PSYCHIATRIC ILLNESSES

Insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment for that illness. In major depressive episodes with insomnia, for example, the selective serotonin reuptake inhibitors, which may cause insomnia as a side effect, usually will result in improved sleep because they treat the depressive syndrome. In patients whose depression is responding to the serotonin reuptake inhibitor but who have persistent insomnia as a side effect of the medication, judicious use of evening trazodone may improve sleep, as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety in patients with anxiety disorders often produces adequate resolution of the accompanying insomnia. Sedative use in the anxiety disorders is decreasing because of a growing appreciation of the effectiveness of other agents, such as β -adrenergic receptor antagonists (see Chapter 10) for performance anxiety and serotonin reuptake inhibitors for obsessive-compulsive disorder and perhaps generalized anxiety disorder. The profound insomnia of patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine-receptor antagonists (see Chapter 18); benzodiazepines, often used adjunctively in this situation to reduce agitation, will result in improved sleep.

INSOMNIA ACCOMPANYING OTHER MEDICAL ILLNESSES

For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia. Adequate pain management in conditions of chronic pain, including terminal cancer pain, will treat both the pain and the insomnia and may make hypnotics unnecessary. Many patients simply manage their sleep poorly. Adequate attention to sleep hygiene, including reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.

CONDITIONED (LEARNED) INSOMNIA

In patients without major psychiatric or medical illness and in whom attention to sleep hygiene is ineffective, attention should be directed to conditioned (learned) insomnia. These patients have associated the bedroom with activities consistent with wakefulness rather than sleep. In such patients, the bed should be used only for sex and sleep. All other activities associated with waking, even such quiescent activities as reading and watching television, should be done outside the bedroom.

LONG-TERM INSOMNIA

Nonpharmacological treatments (see above) are important for all patients with long-term insomnia. Side effects of hypnotic agents may limit their usefulness for insomnia management. Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture; while the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may also aid in the consolidation of learning. The consensus is that hypnotics should not be given to patients with sleep apnea, especially of the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia. These individuals benefit from all-night sleep studies to guide treatment.

INSOMNIA IN OLDER PATIENTS The elderly, like the very young, tend to sleep in a *polyphasic* (multiple sleep episodes per day) pattern rather than the *monophasic* pattern characteristic of younger adults. They may have single or multiple daytime naps in addition to nighttime sleep, making assessment of adequate sleep time difficult. Anyone who naps regularly will have shortened nighttime sleep without evidence of impaired daytime wakefulness, regardless of age. This pattern is exemplified in “siesta” cultures and probably is adaptive.

Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer $t_{1/2}$ for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 of administration may produce daytime confusion and amnesia by week 3 as the level continues to rise, particularly with long-acting hypnotics. For example, diazepam is highly lipid soluble and is excreted by the kidney; because of the increase in body fat and the decrease in renal excretion that typically occur from age 20–80, the $t_{1/2}$ of the drug may increase fourfold over this span.

Elderly people who are living full lives with relatively unimpaired daytime wakefulness may complain of insomnia because they are not sleeping as long as they did when they were younger. Injudicious use of hypnotics in these individuals can produce daytime cognitive impairment and so impair overall quality of life.

Once an older patient has been taking benzodiazepines for an extended period, whether for daytime anxiety or for nighttime sedation, terminating the drug can be a long, involved process. Since attempts at drug withdrawal may not be successful, it may be necessary to leave the patient on the medication, with adequate attention to daytime side effects.

MANAGEMENT OF PATIENTS AFTER LONG-TERM TREATMENT WITH HYPNOTIC AGENTS If a benzodiazepine has been used regularly for more than 2 weeks, it should be tapered rather than discontinued abruptly. In some patients on hypnotics with a short $t_{1/2}$, it is easier to switch first to a hypnotic with a long $t_{1/2}$, and then to taper.

The onset of withdrawal symptoms from medications with a long $t_{1/2}$ may be delayed. Consequently, the patient should be warned about the symptoms associated with withdrawal effects.

PRESCRIBING GUIDELINES FOR THE MANAGEMENT OF INSOMNIA Hypnotics that act at GABA_A receptors (benzodiazepine hypnotics, zolpidem, zopiclone, and zaleplon) are preferred to barbiturates; the newer agents have a greater therapeutic index, are less toxic in overdose, have smaller effects on sleep architecture, and have less abuse potential. Compounds with a shorter $t_{1/2}$ are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness all day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. However, the patient and physician should be aware that early-morning awakening, rebound daytime anxiety, and amnestic episodes also may occur. These undesirable side effects are more common at higher doses.

Benzodiazepines with longer half-lives are favored for patients who have significant daytime anxiety and who may be able to tolerate next-day sedation but would be impaired further by rebound daytime anxiety. These benzodiazepines also are appropriate for patients receiving treatment for major depressive episodes because the short-acting agents can worsen early-morning awakening. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2–4 weeks of treatment) as a result of drug accumulation with repeated administration.

Older agents such as barbiturates, glutethimide, and meprobamate should be avoided for the management of insomnia; they have high abuse potential and are dangerous in overdose.

DRUG THERAPY OF DEPRESSION AND ANXIETY DISORDERS

Major affective and anxiety disorders represent the most common psychiatric illnesses and are those encountered most often by primary-care clinicians. Major depression may represent a spectrum of disorders, varying in severity from mild and self-limited conditions to extraordinarily severe, psychotic, incapacitating, and deadly diseases. The antipsychotic, antianxiety, antimanic, and antidepressant drugs affect cortical, limbic, hypothalamic, and brainstem mechanisms that are of fundamental importance in the regulation of arousal, consciousness, affect, and autonomic functions. Physiological and pharmacological modifications of these brain regions may have important behavioral consequences and useful clinical effects regardless of the underlying cause of any mental disorder. The lack of diagnostic or even syndromal specificity of most psychotropic drugs tends to reduce the chances of finding a discrete mechanistic correlate for a specific disease based simply on the actions of therapeutic agents. There is no definitive link between discrete biological lesions and the pathogenesis of the most severe mental illnesses (other than delirium and dementias). Nonetheless, we can provide effective medical treatment for most psychiatric patients. It would be clinically folly to underestimate the importance of psychological and social factors in the manifestations of mental illnesses or to overlook psychological aspects of the conduct of biological therapies.

CHARACTERIZATION OF DEPRESSIVE AND ANXIETY DISORDERS

The primary clinical manifestations of major depression are significant depression of mood and impairment of function. Some features of depressive disorders overlap those of the anxiety disorders, including *panic-agoraphobia* syndrome, severe phobias, generalized anxiety disorder, social anxiety disorder, posttraumatic stress disorder, and obsessive-compulsive disorder. Extremes of mood also may be associated with psychosis, as manifested by disordered or delusional thinking and perceptions that often are congruent with the predominant mood. Conversely, secondary changes in mood may be associated with psychotic disorders. This overlap of disorders can lead to errors in diagnosis and suboptimal treatment. Mood and anxiety disorders are the most common mental illnesses, each affecting up to 10% of the general population at some time in their lives.

Clinical depression must be distinguished from normal grief, sadness, disappointment, and the dysphoria or demoralization often associated with medical illness. The condition is underdiagnosed and frequently undertreated. Major depression is characterized by feelings of intense sadness and despair, mental slowing and loss of concentration, pessimistic worry, lack of pleasure, self-deprecation, and variable agitation or hostility. Physical changes also occur, particularly in severe depression, including: insomnia or hypersomnia; altered eating patterns, with anorexia and weight loss or sometimes overeating; decreased energy and libido; and disruption of the normal circadian and ultradian rhythms of activity, body temperature, and many endocrine functions. As many as 10–15% of individuals with severe clinical depression, and up to 25% of those with bipolar disorder, display suicidal behavior at some time. Depressed patients usually respond to antidepressant drugs, or, in severe or treatment-resistant cases, to electroconvulsive therapy (ECT). This method remains the most rapid and effective treatment for severe acute depression and sometimes is life-saving for acutely suicidal patients. Efficacy of other forms of biological treatment of depression (e.g., magnetic stimulation of the brain or electrical stimulation of the vagus nerve) is not well established. The decision to treat with an antidepressant is guided by the presenting clinical syndrome, its severity, and by the patient's personal and family history. The lifetime risk for major depression is ~5% in men and 10% in women.

Anxiety disorders may be acute and transient, or more commonly, recurrent or persistent. Symptoms may include mood changes (fear, panic, or dysphoria) or limited abnormalities of thought (obsessions, irrational fears, or phobias) or of behavior (avoidance, rituals or compulsions, "hysterical" conversion signs, or fixation on imagined or exaggerated physical symptoms). Drugs can be beneficial in such disorders, particularly by modifying associated anxiety and depression to facilitate a more comprehensive program of treatment and rehabilitation. Antidepressants and sedative-antianxiety agents are commonly used to treat anxiety disorder.

Antidepressants

Most antidepressants exert important actions on the metabolism of monoamine neurotransmitters and their receptors, particularly norepinephrine (NE) and serotonin (5-HT) (Table 17–1).

PHARMACOLOGICAL PROPERTIES

Tricyclic Antidepressants and Other Norepinephrine-Reuptake Inhibitors Knowledge of the pharmacological properties of antidepressant drugs remains incomplete, and coherent interpretation is limited by a lack of a compelling psychobiological theory of mood disorders. The actions of tricyclic antidepressants include a range of complex, secondary adaptations to their initial and sustained actions as inhibitors of NE neuronal transport (uptake 1, *via* NET; *see* Chapter 2) and variable blockade of 5-HT transport (*via* serotonin transporter [SERT]). Tricyclic antidepressants with secondary-amine side chains or the *N*-demethylated (*nor*) metabolites of agents with tertiary-amine moieties (*e.g.*, amoxapine, desipramine, maprotiline, *norclomipramine*, *nordoxepin*, and *nortriptyline*) are relatively selective inhibitors of NE transport. Most tertiary-amine tricyclic antidepressants also inhibit the reuptake of 5-HT. Trimipramine is exceptional among the tricyclic antidepressants in that it lacks prominent inhibitory effects at monoamine transport.

The tricyclic and other NE-active antidepressants do not block dopamine (DA) transport (*via* DAT); they thereby differ from central nervous system (CNS) stimulants, including cocaine, methylphenidate, and amphetamines (*see* Chapter 10). Nevertheless, they may indirectly facilitate effects of DA by inhibiting the nonspecific transport of DA into noradrenergic terminals in the cerebral cortex. Tricyclic antidepressants also can desensitize D₂ autoreceptors through uncertain mechanisms and with uncertain behavioral contributions.

Tricyclic antidepressants variably interact with receptors (*e.g.*, α adrenergic receptor, muscarinic receptor, H₁ histamine receptor). Interactions with the adrenergic receptors apparently are critical for responses to increased availability of extracellular NE in or near synapses. Most tricyclic antidepressants have at least moderate and selective affinity for α_1 adrenergic receptors, much less for α_2 , and virtually none for β receptors. The α_2 receptors include presynaptic autoreceptors that limit the neurophysiological activity of noradrenergic neurons ascending from the locus ceruleus in brainstem to supply mid- and forebrain projections. The same noradrenergic neurons provide descending projections to the spinal cord preganglionic cholinergic efferents to the peripheral autonomic ganglia (*see* Chapters 6 and 10). Autoreceptor mechanisms also reduce the synthesis of NE, presumably by attenuation of the cyclic AMP-PKA activation of tyrosine hydroxylase, *via* α_2 adrenergic receptor inhibition of adenylyl cyclase. Activation of these autoreceptors also inhibits transmitter release.

The α_2 receptor-mediated, presynaptic, negative-feedback mechanisms are rapidly activated after administration of tricyclic antidepressants. By limiting synaptic availability of NE, such mechanisms normally tend to maintain functional homeostasis. However, with repeated drug exposure, α_2 -receptor responses eventually are diminished, possibly from desensitization secondary to increased exposure to the endogenous agonist (NE) or from prolonged occupation of the NE transporter itself *via* an allosteric effect. Over a period of days to weeks, this adaptation allows the presynaptic production and release of NE to return to, or even exceed, baseline levels. However, long-term treatment eventually can reduce the expression of tyrosine hydroxylase as well as the NE transporter.

The density of functional postsynaptic β adrenergic receptors gradually down-regulates over several weeks of repeated treatment with tricyclics, some selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase (MAO) inhibitors. Combinations of a 5-HT transport inhibitor with a tricyclic antidepressant may have a more rapid β adrenergic receptor-desensitizing effect. Since β -blockers tend to induce or worsen depression in vulnerable persons, it is unlikely that diminished β -receptor signaling contributes directly to the mood-elevating effects of antidepressant treatment. Nevertheless, loss of inhibitory β adrenergic influences on serotonergic neurons may enhance release of 5-HT and thus contribute indirectly to antidepressant effects (*see* Chapter 10).

With tricyclic antidepressant therapy, postsynaptic α_1 adrenergic receptors may be inhibited initially, probably contributing to early hypotensive effects of many tricyclics. Over weeks of treatment, α_1 receptors remain available and may even become more sensitive to NE as clinical mood-elevating effects gradually emerge. Therefore, as antidepressant treatment gradually becomes clinically effective, inactivation of transmitter reuptake continues to be blocked, presynaptic production and release of NE returns to or may exceed baseline levels, and a postsynaptic α_1 adrenergic mechanism is operative.

Additional neuropharmacological changes that may contribute to the clinical effects of tricyclic antidepressants include indirect facilitation of 5-HT (and perhaps DA) neurotransmission through excitatory α_1 "heteroreceptors" on other monoaminergic neurons, or desensitized, inhibitory α_2 autoreceptors, as well as D₂ autoreceptors. Activated release of 5-HT and DA may, in turn, lead to secondary down-regulation of 5-HT₁ autoreceptors, postsynaptic 5-HT₂ receptors, and perhaps D₂ autoreceptors and postsynaptic D₂ receptors.

Other adaptive changes observed in response to long-term treatment with tricyclic antidepressants include altered sensitivity of muscarinic acetylcholine receptors and decreases in gamma-aminobutyric acid (GABA_B) receptors and possibly *N*-methyl-D-aspartate (NMDA) glutamate receptors. In addition, the cyclic AMP-PKA pathway is more activated in some cells, with effects on CREB and brain-derived neurotrophic factor (BDNF). Additional changes may reflect indirect effects of antidepressant treatment or recovery from depressive illness; these include normalization of glucocorticoid release and glucocorticoid receptor sensitivity and shifts in the production of prostaglandins and cytokines and in lymphocyte functions.

The neuropharmacology of tricyclic antidepressants is not explained simply by blockade of the transport-mediated removal of NE, even though this effect undoubtedly is a crucial event that initiates a series of important secondary adaptations. Interactions of antidepressants with monoaminergic synaptic transmission are illustrated in Figure 17-1.

Selective Serotonin Reuptake Inhibitors (SSRIs) The late and indirect actions of these antidepressant and anti-anxiety agents remain less well understood than are those of tricyclic antidepressants, but there are striking parallels between responses in the noradrenergic and serotonergic systems. Like tricyclic antidepressants, which block NE reuptake, the SSRIs block neuronal transport of 5-HT both immediately and chronically, leading to complex secondary responses. Increased synaptic availability of 5-HT results in stimulation of a large number of postsynaptic 5-HT receptor types (see Chapter 11), which may contribute to adverse effects characteristic of this class of drugs, including GI effects (nausea and vomiting) and sexual effects (delayed or impaired orgasm). Stimulation of 5-HT_{2C} receptors may contribute to the agitation or restlessness sometimes induced by SSRIs.

In both serotonergic and noradrenergic neurons, negative feedback mechanisms rapidly emerge to restore homeostasis. In the 5-HT system, 5-HT_1 -subtype autoreceptors (types 1A and 7 at raphe cell bodies and dendrites, type 1D at terminals) suppress serotonergic neurons in the raphe nuclei of the brainstem, inhibiting both tryptophan hydroxylase (probably through reduced phosphorylation-activation) and neuronal release of 5-HT. Repeated treatment leads to gradual down-regulation and desensitization of autoreceptor mechanisms over several weeks (particularly of 5-HT_{1D} receptors at nerve terminals), with a return or increase of presynaptic activity, production, and release of 5-HT. Additional secondary changes include gradual down-regulation of postsynaptic 5-HT_{2A} receptors, which may contribute to antidepressant effects directly and by influencing the function of noradrenergic and other neurons *via* serotonergic heteroreceptors. Many other postsynaptic 5-HT receptors presumably remain available to mediate increased serotonergic transmission and contribute to the mood-elevating and anxiolytic effects of this class of drugs.

Complex late adaptations occur upon repeated treatment with SSRIs, including indirect enhancement of NE output by reduction of tonic inhibitory effects of 5-HT_{2A} heteroreceptors. Finally, similar nuclear and cellular adaptations occur as with the tricyclic antidepressants, including increased intraneuronal cyclic AMP, activation/phosphorylation of transcription factors (*e.g.*, CREB), and increased production of BDNF.

Other Drugs Affecting Monoamine Neurotransmitters

The MAO inhibitor tranylcypromine is amphetamine-like in structure but interacts only weakly at DA transporters. The phenylpiperazine nefazodone, and to a lesser extent, the structurally related trazodone have weak inhibitory actions on 5-HT transport; nefazodone also may have a minor effect on NE transport. This agent also has a prominent direct antagonistic effect at 5-HT_{2A} receptors that may contribute to antidepressant and anxiolytic activity. Both drugs also may inhibit presynaptic 5-HT_1 subtype autoreceptors to enhance neuronal release of 5-HT, though they probably also exert at least partial-agonist effects on postsynaptic 5-HT_1 receptors. Trazodone also blocks cerebral α_1 and H_1 receptors, possibly contributing to its tendency to induce priapism and sedation, respectively.

Finally, the atypical antidepressants mirtazapine and mianserin are structural analogs of 5-HT with potent antagonistic effects at several postsynaptic 5-HT receptor types (including 5-HT_{2A} , 5-HT_{2C} , and 5-HT_3 receptors) and can produce gradual down-regulation of 5-HT_{2A} receptors. Mirtazapine limits the effectiveness of inhibitory α_2 adrenergic heteroreceptors on serotonergic neurons as well as inhibitory α_2 autoreceptors and 5-HT_{2A} heteroreceptors on noradrenergic neurons. These effects may enhance release of amines and contribute to the antidepressant effects of these drugs. Mirtazapine also is a potent histamine H_1 -receptor antagonist and is relatively sedating. Mianserin is not used in the U.S. owing largely to its bone marrow suppression.

FIGURE 17-1 Sites of action of antidepressants. A. In varicosities (“terminals”) of norepinephrine (NE) neurons projecting from brainstem to forebrain, L-tyrosine is oxidized to dihydroxyphenylalanine (L-DOPA) by tyrosine hydroxylase (TH), then decarboxylated to dopamine (DA) by aromatic L-amino acid decarboxylase (AAD) and stored in vesicles, where side-chain oxidation by dopamine β-hydroxylase (DBH) converts DA to NE. Following exocytotic release by depolarization in the presence of Ca²⁺ (inhibited by lithium), NE interacts with postsynaptic α and β adrenergic receptor (R) subtypes as well as presynaptic α₂ autoreceptors. Regulation of NE release by α₂ receptors is principally through attenuation of Ca²⁺ currents and activation of K⁺ currents. Inactivation of trans-synaptic communication occurs primarily by active transport (“reuptake”) into presynaptic terminals (inhibited by most tricyclic antidepressants [TCAs] and stimulants), with secondary deamination (by mitochondrial monoamine oxidase [MAO], blocked by MAO inhibitors). Blockade of inactivation of NE by TCAs initially leads to α₂ receptor-mediated inhibition of firing rates, metabolic activity, and transmitter release from NE neurons; gradually, however, α₂ autoreceptor response diminishes and presynaptic activity

Monoamine Oxidase Inhibitors

The MAOs comprise two structurally related flavin-containing enzymes, designated MAO-A and MAO-B, that share ~70% homology but are encoded by distinct genes. They are localized in mitochondrial membranes and widely distributed throughout the body in nerve terminals, the liver, intestinal mucosa, platelets, and other organs. Within the CNS, MAO-A is expressed predominantly in noradrenergic neurons, while MAO-B is expressed in serotonergic and histaminergic neurons. MAO activity is closely linked functionally with an aldehyde reductase and an aldehyde dehydrogenase, depending on the substrate and tissue.

MAO regulates the metabolic degradation of catecholamines, 5-HT, and other endogenous amines in the CNS and peripheral tissues. Hepatic MAO has a crucial defensive role in inactivating circulating monoamines and compounds (e.g., the indirect-acting sympathomimetic tyramine) that are ingested or originate in the gut and get absorbed into the portal circulation. Inhibition of this enzyme system by MAO inhibitors causes a reduction in metabolism and a subsequent increase in the concentrations of biogenic amines. MAO-A preferentially deaminates Epi, NE, and 5-HT and is selectively inhibited by clorgyline, while MAO-B metabolizes phenethylamine and is inhibited by selegiline. DA and tyramine are metabolized by both MAO isozymes and both types are inhibited by phenelzine, tranylcypromine, and isocarboxazid.

Selective MAO-A inhibitors are more effective in treating major depression than type B inhibitors. The MAO-B inhibitor selegiline is approved for treatment of early Parkinson's disease and acts by potentiating remaining DA in degenerating nigrostriatal neurons and possibly by reducing neuronal damage due to reactive products of the oxidative metabolism of DA or other potential neurotoxins (see Chapter 20). Selegiline also has antidepressant effects, particularly at doses >10 mg that also inhibit MAO-A or yield amphetamine-like metabolites. Several short-acting selective inhibitors of MAO-A (e.g., brofaromine and moclobemide) and toloxatone have at least moderate antidepressant effects and are less likely to potentiate the pressor actions of tyramine and other indirect-acting sympathomimetic amines than are the nonselective, irreversible MAO inhibitors.

Although MAO inhibition occurs rapidly and is usually maximal within days, clinical benefits usually are delayed for several weeks, perhaps reflecting down-regulation of serotonergic and adrenergic receptors. Favorable clinical responses occur when human platelet MAO-B is inhibited by at least 85%, suggesting the need to use aggressive dosages to achieve the maximal therapeutic potential of MAO inhibitors. Finally, despite long-lasting inhibition of MAO by the irreversible inhibitors of MAO, optimal therapeutic benefit appears to require daily dosing.

ABSORPTION AND BIOAVAILABILITY Most antidepressants are fairly well absorbed after oral administration; nefazodone is an exception, with a bioavailability of ~20%. The MAO inhibitors are absorbed readily when given by mouth. High doses of the strongly anticholinergic tricyclic antidepressants (Table 17-1) can slow GI activity and gastric emptying time, resulting in slower or erratic drug absorption and complicating management of acute overdosages. Serum concentrations of most tricyclic antidepressants peak within several hours. Injectable formulations of tricyclic antidepressants are not commercially available in the U.S.

DISTRIBUTION AND SERUM LEVEL MONITORING Once absorbed, tricyclic antidepressants are widely distributed. They are relatively lipophilic and strongly bind to plasma proteins and constituents of tissues, leading to apparent volumes of distribution as high as 10–50 L/kg. The tendency of tricyclic antidepressants and their ring-hydroxy metabolites to accumulate in cardiac tissue adds to their cardiotoxicity. Serum concentrations of antidepressants that correlate meaningfully with clinical effects are only established for a few tricyclic antidepressants (particularly amitriptyline,

FIGURE 17-1 (Continued) returns. Postsynaptically, β adrenergic receptors activate the G_s -adenylyl cyclase (AC)-cyclic AMP (cAMP) pathway. Adrenergic α_1 (and other) receptors activate the phospholipase $C-G_q-IP_3$ pathway with secondary modulation of intracellular Ca^{2+} and protein kinases. Postsynaptic β receptors also desensitize; α_1 receptors do not. **B.** Selective serotonin reuptake inhibitors (SSRIs) have analogous actions to TCAs at 5-HT-containing neurons, and TCAs can interact with serotonergic neurons and receptors. 5-HT is synthesized from L-tryptophan by a relatively rate-limiting tryptophan hydroxylase (TPH); the resulting 5-hydroxytryptophan is deaminated by AAD to 5-hydroxytryptamine (5-HT, serotonin). Following release, 5-HT interacts with a large number of postsynaptic 5-HT receptors that exert their effects through a variety of PLC and AC-mediated mechanisms. Inhibitory autoreceptors include types 5-HT_{1A} and perhaps 5-HT₇ receptor subtypes at cell bodies and dendrites, as well as 5-HT_{1D} receptors at the nerve terminals; these receptors probably become desensitized following prolonged treatment with a SSRI antidepressant that blocks 5-HT transporters. The adrenergic and serotonergic systems also influence each other, in part through complementary heteroreceptor mechanisms (inhibitory α_2 receptors on 5-HT neurons, and inhibitory 5-HT_{1D} and 5-HT_{2A} receptors on noradrenergic neurons).

desipramine, imipramine, and nortriptyline), typically at concentrations of ~100–250 ng/mL (Table 17–2). Toxic effects of tricyclic antidepressants can be expected at serum concentrations >500 ng/mL; levels >1 µg/mL can be fatal. Individual variance in tricyclic antidepressant levels in response to a given dose is as high as ten- to thirtyfold, due largely to genetic control of hepatic CYPs, but the utility of therapeutic drug monitoring in the routine clinical use of antidepressants is limited.

METABOLISM, HALF-LIVES, AND DURATION OF ACTION Tricyclic antidepressants are oxidized by hepatic CYPs, followed by conjugation with glucuronic acid. Hydroxy metabolites frequently retain some pharmacological activity. Conjugation of ring-hydroxylated metabolites with glucuronic acid extinguishes any remaining biological activity. The *N*-demethylated metabolites of several tricyclic antidepressants are pharmacologically active and may accumulate in concentrations approaching or exceeding those of the parent drug and contribute variably to overall

*Half-life is the approximate elimination (β) half-life (limited data for newer agents). Half-life values given in parentheses are those of active metabolites (commonly *N*-demethylated) that contribute to overall duration of action.

†Agents available in slow-release forms that delay absorption but not elimination half-life; venlafaxine also inhibits norepinephrine transport at higher doses.

‡Some serotonin reuptake inhibitors inhibit the hepatic oxidation of other agents: potent inhibition is produced by fluoxetine (2D6 and other CYP isozymes), fluvoxamine (1A2, 2C8, and 3A3/4), paroxetine (2D6), and nefazodone (3A3/4); sertraline produces moderate effects at high doses (2D6 and others); citalopram (2C19) and venlafaxine have weak interactions.

Serum concentrations are levels encountered at typical clinical doses and not intended as guidelines to optimal dosing. Information was obtained from manufacturers' product information summaries.

pharmacodynamic activity. The 8-hydroxy metabolite of amoxapine is pharmacologically active, including antagonistic interactions with D₂ receptors. Amoxapine has some risk of extrapyramidal side effects, including tardive dyskinesia, reminiscent of those of the *N*-methylated congener loxapine, a typical neuroleptic (*see* Chapter 18).

As occurs with the tertiary-amine tricyclic antidepressants, the *N*-demethylated metabolites of SSRIs also are eliminated more slowly, and some are pharmacologically active. Norclomipramine contributes noradrenergic activity. Norfluoxetine is a very long-acting inhibitor of 5-HT transport (elimination $t_{1/2}$ ~10 days) (Table 17–2) that requires several weeks for elimination. Norfluoxetine also competes for hepatic CYPs and thereby elevates levels of other agents, including tricyclic antidepressants. These effects can persist for days after administration of the parent drug has been stopped. Norsertraline (elimination $t_{1/2}$ of 60–70 hours) contributes limited pharmacological activity or risk of drug interactions. Nornefazodone contributes little to the biological activity or duration of action of nefazodone.

With some notable exceptions, inactivation and elimination of most antidepressants occurs over a period of several days. Generally, secondary-amine tricyclic antidepressants and the *N*-demethylated derivatives of SSRIs have elimination half-lives about twice those of the parent drugs. Nevertheless, most tricyclics are almost completely eliminated within 7–10 days; protriptyline is an exception ($t_{1/2}$ ~80 hours). Most MAO inhibitors are long acting, because recovery from their effects requires the synthesis of new enzyme over a period of 1–2 weeks.

At the other extreme, trazodone, nefazodone, and venlafaxine have short half-lives (3–6 hours), as does the active 4-hydroxy metabolite of venlafaxine ($t_{1/2}$ of ~11 hours). The $t_{1/2}$ of bupropion is ~14 hours. Owing to rapid aromatic hydroxylation, the $t_{1/2}$ of nefazodone is very short (~3 hours). The shorter duration of action of these agents usually implies the need for multiple daily doses. Some short-acting antidepressants have been prepared in slow-release preparations (notably bupropion and venlafaxine), to allow less frequent dosing and potentially to temper side effects related to agitation and GI disturbance.

Relative to young adults, antidepressants are metabolized more rapidly by children and more slowly by patients over 60 years of age. Dosages are adjusted accordingly, sometimes to daily doses in children that far exceed those typically given to adults.

The hydrazide MAO inhibitors are thought to be cleaved to liberate pharmacologically active products (e.g., hydrazines) that are inactivated primarily by acetylation. About one-half the population of the U.S. and Europe (and more in certain Asian and Arctic regions) are “slow acetylators” of hydrazine-type drugs, including phenelzine; this genetic trait may contribute to exaggerated effects observed in some patients given standard doses of phenelzine (see Chapters 3 and 4).

INTERACTIONS WITH CYPs The metabolism of most antidepressants depends greatly on the activity of hepatic CYPs (*see* Table 17–2). In general, CYP1A2 and CYP2D6 mediate aromatic hydroxylation, and CYP3A3/4 mediate *N*-dealkylation and *N*-oxidation reactions in the metabolism of antidepressants. Some antidepressants not only are substrates for metabolism by CYPs but also can inhibit the metabolic clearance of other drugs, sometimes producing clinically significant drug interactions. Notable inhibitory interactions include fluvoxamine with CYP1A2; fluoxetine and fluvoxamine with CYP2C9, and fluvoxamine with CYP1A2 and CYP2C19; paroxetine, fluoxetine, and less actively, sertraline with CYP2D6; norfluoxetine with CYP3A4; and fluvoxamine and nefazodone with CYP3A3/4. Citalopram or *S*-citalopram and venlafaxine interact much less with CYPs. Atomoxetine has weak effects on the metabolism of most other agents, but its clearance is inhibited by some SSRIs, including paroxetine. Duloxetine can inhibit the metabolism of agents such as desipramine that are metabolized extensively through CYP2D6, and its own metabolism is inhibited by some SSRIs (*e.g.*, paroxetine). Potentially significant interactions include the tendency for fluvoxamine to increase circulating concentrations of oxidatively metabolized benzodiazepines, clozapine, theophylline, and warfarin. Sertraline and fluoxetine can increase levels of benzodiazepines, clozapine, and warfarin. Paroxetine increases levels of clozapine, theophylline, and warfarin. Fluoxetine also potentiates tricyclic antidepressants and some antiarrhythmics with a narrow therapeutic index (*e.g.*, propafenone; *see* Chapter 34). Nefazodone potentiates benzodiazepines other than lorazepam and oxazepam.

TOLERANCE AND PHYSICAL DEPENDENCE Some tolerance to the sedative and autonomic effects of tricyclic antidepressants and to the nausea commonly associated with SSRIs

tends to develop with continued drug use. Various antidepressants have been used for months or years by patients with severe recurring depression without obvious loss of efficacy, though some therapeutic tolerance may occur, more often with SSRIs than with older agents. Sometimes, this loss of benefit may be overcome by increasing the dose of antidepressant, by temporary addition of lithium or by a small dose of an antipsychotic agent, or by changing to an antidepressant in a different class. To avoid toxicity and precipitation of “serotonin syndrome” (see Drug Interactions), extreme caution is advised when these strategies are employed.

Occasionally, patients show physical dependence on the tricyclic antidepressants, with malaise, chills, coryza, muscle aches, and sleep disturbance following abrupt discontinuation, particularly of high doses. Similar reactions, along with GI and sensory symptoms (paresthesias) and irritability, also occur with abrupt discontinuation of SSRIs, particularly with paroxetine and venlafaxine. Withdrawal reactions from MAO inhibitors may be severe, commencing 24–72 hours after drug discontinuation; such reactions are more common with tranylcypromine and isocarboxazid when used in excess of the usual therapeutic range. Symptoms range from nausea, vomiting, and malaise to nightmares, agitation, psychosis, and convulsions.

Some withdrawal effects may reflect increased cholinergic activity following its inhibition by such agents as amitriptyline, imipramine, and paroxetine, whereas serotonergic mechanisms may contribute to the effects of abrupt discontinuation of SSRIs. Some of these reactions can be confused with clinical worsening of depressive symptoms. Emergence of agitated or manic reactions also has been observed after abrupt discontinuation of tricyclics, indicating that it is wise to discontinue antidepressants gradually over at least a week, or longer when feasible.

Treatment discontinuation of several psychotropic agents has been proposed to increase the risk of recurrence of morbidity to a degree greater than would be predicted by the natural history of untreated illness; this risk probably extends over several months. Evidence for this phenomenon is particularly strong with lithium in bipolar disorder, is likely with some antipsychotics, and may occur with antidepressants. Such risk may be reduced by gradual discontinuation of long-term medication over at least several weeks (see Chapter 18).

ADVERSE EFFECTS Tricyclic antidepressants routinely produce adverse autonomic responses, in part related to their relatively potent antimuscarinic effects, including dry mouth and a sour or metallic taste, epigastric distress, constipation, dizziness, tachycardia, palpitations, blurred vision (poor accommodation and increased risk of glaucoma), and urinary retention. Cardiovascular effects include orthostatic hypotension, sinus tachycardia, and variable prolongation of cardiac conduction times with the potential for arrhythmias, particularly with overdoses.

In the absence of cardiac disease, the principal problem associated with imipramine-like agents is postural hypotension, probably related to anti- α_1 adrenergic actions. Hypotension can be severe, with falls and injuries. Among tricyclics, nortriptyline may be less likely to induce postural blood pressure changes. Tricyclic antidepressants should be avoided following an acute myocardial infarction; in the presence of defects in bundle-branch conduction or slowed repolarization; or when other cardiac depressants (including other psychotropic agents such as thioridazine) are being administered. They have direct cardiac-depressing actions like those of certain antiarrhythmics, related to actions at fast Na^+ channels (see Chapter 34). Mild congestive heart failure and the presence of some cardiac arrhythmias are not absolute contraindications to the short-term use of a tricyclic antidepressant when depression and its associated medical risks are severe, safer alternatives fail, and appropriate medical care is provided. Nevertheless, modern nontricyclic antidepressants—notably the SSRIs—have less risk and are a prudent choice for cardiac patients. ECT also is an option.

Weakness and fatigue are attributable to central effects of tricyclic antidepressants, particularly tertiary amines (Table 17–1) and mirtazapine, all of which have potent central antihistaminic effects. Trazodone and nefazodone also are relatively sedating. Other CNS effects include variable risk of confusion or delirium, largely due to atropine-like effects of tricyclic antidepressants. Epileptic seizures can occur, especially with daily doses of bupropion >450 mg, maprotiline >250 mg, or acute overdoses of amoxapine or tricyclics. The risk of cerebral or cardiac intoxication can increase if such agents are given in relatively high doses, particularly when combined with SSRIs that inhibit their metabolism (Table 17–2). MAO inhibitors can induce sedation or behavioral excitation and have a high risk of inducing postural hypotension.

Miscellaneous toxic effects of tricyclic antidepressants include jaundice, leukopenia, and rashes, but these are very infrequent. Weight gain is a common adverse effect of many antidepressants but is less likely with the SSRIs and is rare with bupropion (Table 17–1). Excessive sweating also is common.

Newer antidepressants generally present fewer or different side effects and toxic risks than older tricyclics and MAO inhibitors. As a group, the SSRIs have a high risk of nausea and vomiting, headache, and sexual dysfunction, including inhibited ejaculation in men and impaired orgasm in women. Adverse sexual effects also occur with tricyclic antidepressants but are less common with bupropion, nefazodone, and mirtazapine. Trazodone can produce priapism in men, presumably due to antiadrenergic actions. Some SSRIs, and perhaps fluoxetine in particular, have been associated with agitation and restlessness that resembles akathisia (see Chapter 18). Bupropion can act as a stimulant, with agitation, anorexia, and insomnia. SSRIs, while generally less likely to produce adverse cardiovascular effects than older antidepressants, can elicit electrophysiological changes in cardiac tissue. SSRIs can also induce the syndrome of inappropriate secretion of antidiuretic hormone with hyponatremia (see Chapter 29). Nefazodone has been associated with increased risk of hepatic toxicity that has prompted its removal in some countries. Such reactions also occur with tricyclic and MAO inhibitor antidepressants but only rarely with SSRIs.

Another risk of antidepressants in vulnerable patients (particularly those with unrecognized bipolar depression) is switching, sometimes suddenly, from depression to hypomanic or manic excitement, or mixed, dysphoric-agitated, manic-depressive states. To some extent this effect is dose-related and is somewhat more likely in adults treated with tricyclic antidepressants than with SSRIs, bupropion, and perhaps with MAO inhibitors. Risk of mania with newer sedating antidepressants, including nefazodone and mirtazapine, also may be relatively low, but some risk of inducing mania can be expected with any treatment that elevates mood.

Safety through the Life Cycle Most antidepressants appear to be safe during pregnancy. Most antidepressants and lithium are secreted in breast milk, at least in small quantities, and their safety in nursing infants is neither established nor safely assumed. For severe depression during pregnancy and lactation, ECT can be a relatively safe and effective alternative.

Major affective disorders are being recognized more often in children, and antidepressants increasingly are used in this age group. Children are vulnerable to the cardiotoxic and seizure-inducing effects of high doses of tricyclic antidepressants. Deaths have occurred in children after accidental or deliberate overdosage with only a few hundred milligrams of drug, and several cases of unexplained sudden death have been reported in preadolescent children treated with desipramine. Most children are relatively protected by vigorous hepatic drug metabolism. Indeed, attaining serum concentrations of desipramine like those encountered in adults (Table 17-2) may require doses of 5 mg/kg of body weight (or more in some school-age children) compared to only 2-3 mg/kg in adults. Note that many trials of tricyclic antidepressants in children have failed to show substantial superiority to placebo, and the efficacy of modern agents, including SSRIs, is not securely established other than for fluoxetine and sertraline. Other antidepressants have received little assessment in juveniles. Antidepressants appear to be more effective in adolescents. In children, they risk inducing agitated states that may represent mania in undiagnosed juvenile bipolar disorder. The possibility of increased suicidal risk in juveniles treated with SSRIs has been suggested, with proposed restrictions and caution on their use.

Among geriatric patients, dizziness, postural hypotension, constipation, delayed micturition, edema, and tremor are found commonly with tricyclic antidepressants. These patients are much more likely to tolerate SSRIs and other modern antidepressants. Risks in geriatric patients are higher due to decreased metabolic clearance of antidepressants and less ability to tolerate them.

Toxic Effects of Acute Overdoses Acute poisoning with tricyclic antidepressants or MAO inhibitors is potentially life-threatening. Fatalities are much less common since modern antidepressants have widely replaced these drugs; however, suicide rates have not declined consistently as clinical usage of modern antidepressants has increased. Deaths have been reported with acute doses of ~2 g of imipramine, and severe intoxication can be expected at doses >1 g, or about a week's supply. If a patient is severely depressed, potentially suicidal, impulsive, or has a history of substance abuse, prescribing a relatively safe antidepressant agent with close clinical follow-up is appropriate. If a potentially lethal agent is prescribed, it is best dispensed in small, sublethal quantities, with the risk that sustained adherence to recommended treatment may be compromised.

Acute poisoning with a tricyclic antidepressant often is clinically complex: brief excitement and restlessness, sometimes with myoclonus, tonic-clonic seizures, or dystonia, followed by rapid development of coma, often with depressed respiration, hypoxia, depressed reflexes, hypothermia, and hypotension. Antidepressants with strong antimuscarinic potency commonly induce an atropine-like syndrome of mydriasis, flushed dry skin and dry mucosae, absent bowel sounds,

urinary retention, and tachycardia or other cardiac arrhythmias. A patient intoxicated with a tricyclic antidepressant must be treated early, ideally in an intensive care unit. Gastric lavage with activated charcoal may be useful, but dialysis and diuresis are ineffective. Coma abates gradually over 1–3 days, and excitement and delirium may reappear. Risk of life-threatening cardiac arrhythmias continues for at least several days, requiring close medical supervision.

Cardiac toxicity and hypotension can be especially difficult to manage in patients with overdoses of tricyclic antidepressants. The most common cardiac effect is sinus tachycardia, due both to anticholinergic effects and diminished uptake of NE. Intravenous sodium bicarbonate can improve hypotension and cardiac arrhythmias, although the precise roles of alkalization versus increased sodium have not been established. Cardiac glycosides and antiarrhythmic drugs such as quinidine, procainamide, and disopyramide are contraindicated, but phenytoin and lidocaine can be used for ventricular arrhythmias. If the prolonged QT interval results in torsades de pointes, magnesium, isoproterenol, and atrial pacing may be employed. Hypotension that does not respond to alkalization should be treated with NE and intravenous fluids.

Effects of MAO inhibitor overdose include agitation, hallucinations, hyperreflexia, fever, and convulsions. Both hypotension and hypertension can occur. Treatment of such intoxication is problematic, but conservative treatment often is successful.

DRUG INTERACTIONS Binding of tricyclic antidepressants to plasma albumin can be reduced by competition with a number of drugs, including phenytoin, aspirin, aminopyrine, scopolamine, and phenothiazines. Barbiturates and many anticonvulsant agents (particularly carbamazepine), as well as cigarette smoking, can increase the hepatic metabolism of antidepressants by inducing CYPs.

Conversely, competition for the metabolism of other drugs by SSRIs can cause significant drug interactions. For example, during the use of combinations of SSRIs with tricyclic antidepressants, serum concentrations of the tricyclic drug may rise to toxic levels. Such an interaction can persist for days after discontinuing fluoxetine due to the prolonged elimination $t_{1/2}$ of norfluoxetine. Several SSRIs are potent inhibitors of hepatic CYPs; venlafaxine, citalopram, and sertraline appear to have relatively low risk of such interactions. Significant interactions may be most likely in persons who are relatively rapid metabolizers through the microsomal oxidase system, including children.

Examples of drug interactions with SSRIs include potentiation of agents metabolized prominently by CYP1A2 (e.g., β adrenergic receptor antagonists, caffeine, several antipsychotic agents, and most tricyclic antidepressants); CYP2C9 (carbamazepine); CYP2C19 (barbiturates, imipramine, propranolol, and phenytoin); CYP2D6 (β adrenergic receptor antagonists, some antipsychotics, and many antidepressants); and CYP3A3/4 (benzodiazepines, carbamazepine, many antidepressants, and several macrolide antibiotics).

Antidepressants potentiate the effects of alcohol and probably other sedatives. The anticholinergic activity of tricyclic antidepressants can add to that of antiparkinsonism agents, antipsychotic drugs of low potency (especially clozapine and thioridazine), or other compounds with antimuscarinic activity to produce toxic effects. Tricyclic antidepressants have prominent and potentially dangerous potentiative interactions with biogenic amines such as NE, which normally are removed from their site of action by neuronal reuptake. However, these inhibitors of NE transport block the effects of indirectly acting amines such as tyramine, which must be taken up by sympathetic neurons to release NE. Presumably by a similar mechanism, tricyclic antidepressants prevent the antihypertensive action of adrenergic neuron blocking agents such as guanadrel. Tricyclic agents and trazodone also can block the centrally mediated antihypertensive action of clonidine.

SSRIs and other agents with 5-HT-potentiating activity can interact dangerously or even fatally with MAO inhibitors (particularly long-acting MAO inhibitors). The resulting reactions are referred to as “serotonin syndrome” and most commonly occur in patients receiving combination therapy with two or more serotonergic agents. Besides the combination of MAO inhibitors with SSRIs, other drug combinations or conditions that increase 5-HT synthesis (e.g., L-tryptophan [L-Trp]) or release (e.g., amphetamines and cocaine), that act as 5-HT agonists (e.g., buspirone, dihydroergotamine, and sumatriptan), or that otherwise increase 5-HT activity (e.g., ECT and lithium) all have been implicated in the development of serotonin syndrome. This syndrome typically includes akathisia-like restlessness, muscle twitches and myoclonus, hyperreflexia, sweating, penile erection, shivering, and tremor as a prelude to more severe intoxication, with seizures and coma. The reaction often is self-limiting if the diagnosis is made quickly and the offending agents are discontinued. Selegiline, moclobemide, and perhaps St. John’s wort preparations also should be considered to have some risk of such interactions.

To avoid drug toxicity and prevent the precipitation of serotonin syndrome, duration of effect should be considered when switching between antidepressants (e.g., a MAO inhibitor should not be started for 5 weeks after discontinuing fluoxetine; 2–3 weeks should elapse between stopping a nonselective MAO inhibitor and initiating therapy with a tricyclic antidepressant).

The hypertensive interaction of MAO inhibitors with indirectly acting pressor phenethylamines requires scrupulous avoidance of many agents, such as over-the-counter cold remedies containing indirect-acting sympathomimetic drugs (see Chapter 10). Fatal intracranial bleeding has occurred in such hypertensive reactions. Headache is a common symptom, and fever frequently accompanies the hypertensive episode. Meperidine should never be used for such headaches (it could prove to be fatal), and blood pressure should be evaluated immediately when a patient taking an MAO inhibitor reports a severe throbbing headache or a feeling of pressure in the head.

Drug Treatment of Mood Disorders

Disorders of mood (*affective disorders*) are very common, with severity ranging from normal grief reactions and dysthymia to severe, incapacitating psychotic and melancholic illnesses that may result in death. The lifetime risk of suicide in severe forms of major affective disorders requiring hospitalization is 10–15%, but as low as 3–5% in less severely ill outpatients. Probably only 30–40% of cases of clinical depression are diagnosed, and a much smaller number are adequately treated. Not all types of grief and misery call for medical treatment, and even severe mood disorders have a high rate of spontaneous remission in time (often months). Antidepressants generally are reserved for the more severe and incapacitating depressive disorders. The most satisfactory results tend to occur in patients who have moderately severe illnesses with “endogenous” or “melancholic” characteristics without psychotic features. Antidepressant agents clearly are effective for adult major depression, but a number of shortcomings continue to be associated with all drugs used to treat affective disorders.

A major problem with antidepressants is that placebo response rates tend to be as high as 30–40% in subjects diagnosed with major depression; thus, clinical distinctions between active drug and placebo are difficult to prove.

Pediatric studies often have failed to show superiority of antidepressant drugs over placebo, particularly with older antidepressants but also with most SSRIs, and the future of tricyclic antidepressant use in children is uncertain. Finally, evidence concerning clinical dose-response and dose-risk relationships is especially limited with the newer antidepressant drugs. Despite lack of consistency and convincingly demonstrated efficacy, the modern antidepressants have largely replaced the tricyclics as first-line options in children, adolescents, and the elderly, largely owing to their relative safety.

CHOICE OF ANTIDEPRESSANT MEDICATION AND DOSING

The usual dosages and dose ranges of antidepressant medications are listed in Table 17–1, along with the severity of common side effects. Although they usually are used initially in divided doses, transition to a single daily dose usually is possible due to the relatively long half-lives and wide range of tolerated concentrations of most antidepressants. With the tricyclic antidepressants, dosing is most safely done with single doses up to the equivalent of 150 mg of imipramine.

Tricyclic and Selective Serotonin Reuptake Inhibitors

SSRIs and other atypical modern agents now are broadly accepted as drugs of first choice, particularly for medically ill or potentially suicidal patients and in the elderly and young. MAO inhibitors commonly are reserved for patients who fail to respond to vigorous trials of at least one of the newer agents and a standard tricyclic antidepressant, administered alone or with lithium to enhance overall therapeutic effectiveness. The somewhat less anticholinergic secondary-amine tricyclics, particularly nortriptyline and desipramine, are alternatives or a second choices for elderly or medically ill patients, particularly if administered in moderate, divided doses (Table 17–1). Patients with severe, prolonged, disabling, psychotic, suicidal, or bipolar depression require vigorous and prompt medical intervention.

MAO Inhibitors

Indications for the MAO inhibitors are limited and must be weighed against their potential toxicity and their complex interactions with other drugs. Thus, the MAO inhibitors generally are considered drugs of late choice for the treatment of severe depression. Nevertheless, MAO inhibitors sometimes are used when vigorous trials of several standard antidepressants have been unsatisfactory and when ECT is refused. In addition, MAO inhibitors may have selective benefits for

conditions other than typical major depression, including illnesses marked by phobias and anxiety or panic as well as dysphoria, and possibly in chronic dysthymic conditions. Similar benefits, however, may be found with imipramine-like agents or SSRIs.

Bipolar Forms of Depression

The safe and effective treatment of bipolar depression is a difficult clinical challenge. This condition sometimes is misdiagnosed in patients with bipolar disorder who present with mixed dysphoric-agitated moods, who then are inappropriately treated with an antidepressant without a mood stabilizing agent to protect against worsening agitation or mania. For this reason, the management of manic, mixed, and depressive mood states in bipolar disorder best relies on lithium or other mood-stabilizing agents, notably the anticonvulsant lamotrigine, as the primary treatment (see Chapter 18). An antidepressant can be added cautiously and temporarily to treat bipolar depression, but the additional benefit and safety of sustained combinations of an antidepressant with a mood stabilizer are unproven. The combination SSRI/atypical antipsychotic (fluoxetine/olanzapine; SYMBYAX) is FDA-approved for treatment of depressive episodes associated with bipolar disorder.

Duration of Treatment

The natural history of major depression (either as unipolar depression or depressive phases of bipolar disorder) is that individual episodes tend to remit spontaneously over 6–12 months; however, there is a high risk of relapse of depression for at least several months after discontinuation of antidepressant treatment. This risk is estimated at 50% within 6 months and 65–70% at 1 year, rising to 85% by 3 years. To minimize this risk, it is best to continue antidepressant medication for at least 6 months following apparent clinical recovery. Continued use of initially therapeutic doses is recommended, although tolerability and acceptance by patients may require flexibility.

Many depressed patients follow a recurring course of episodic illness, often with lesser levels of symptoms and disability between major episodes, and therefore merit consideration of long-term maintenance medication to reduce the risk of recurrence. Such treatment has been tested for as long as 5 years, using relatively high doses of imipramine, with evidence that early dose reduction led to a higher risk of relapse. Long-term supplementation of an antidepressant with lithium may enhance the result. Prolonged maintenance treatment of patients with recurring major depression for more than a year has rarely been evaluated with modern antidepressants, and long-term dose-response data with any antidepressant are very limited. The use of indefinitely prolonged maintenance treatment with an antidepressant is guided by the history of multiple, and especially severe or life-threatening, recurrences and the impression that recurrence risk is greater in older patients. Because rapid discontinuation or sharp reduction in doses of antidepressants and lithium may contribute to excess early recurrence of illness, gradual reduction and close clinical follow-up over at least several weeks are recommended when maintenance treatment is to be discontinued and when stopping continuation therapy within the months following recovery from an acute episode of depression.

PHARMACOTHERAPY OF ANXIETY

Anxiety is a symptom of many psychiatric disorders and an almost inevitable component of many medical and surgical conditions. Symptoms of anxiety commonly are associated with depression and especially with dysthymic disorder (chronic depression of moderate severity), panic disorder, agoraphobia and other specific phobias, obsessive-compulsive disorder, eating disorders, and many personality disorders. Sometimes, no treatable primary illness is found, or if one is found and treated, it may be desirable to deal directly with the anxiety at the same time. In such situations, anti-anxiety medications are frequently and appropriately used.

Currently, the benzodiazepines and the SSRIs are the most commonly employed pharmacotherapies for common clinical anxiety disorders (see Chapter 16). Benzodiazepines sometimes are given to patients presenting with anxiety mixed with symptoms of depression, although their efficacy in altering the core features of severe major depression has not been demonstrated.

The most favorable responses to the benzodiazepines are obtained in situations that involve relatively acute anxiety reactions in medical or psychiatric patients who have either modifiable primary illnesses or primary anxiety disorders. However, this group of anxious patients also has a high response rate to placebo and is likely to undergo spontaneous improvement. Anti-anxiety drugs also are used in the management of more persistent or recurrent primary anxiety disorders. A particularly controversial aspect of the use of benzodiazepines, especially those of high potency, is in long-term management of patients with sustained or recurring symptoms of anxiety; despite clinical

benefit for at least several months, it is unclear if the long-term benefits can be distinguished from nonspecific (“placebo”) effects following development of tolerance on the one hand, or prevention of related withdrawal-emergent anxiety on the other.

The antihistamine hydroxyzine is an effective antianxiety agent, but only at doses (~400 mg/day) that produce marked sedation (see Chapter 24). Propranolol and metoprolol, lipophilic β adrenergic receptor antagonists that enter the CNS, can reduce the autonomic symptoms (nervousness and muscle tremor) associated with specific situational or social phobias but do not appear to be effective in generalized anxiety or panic disorder (see Chapter 10). Similarly, other antiadrenergic agents, including clonidine, may modify autonomic expression of anxiety but are not demonstrably useful in the treatment of severe anxiety disorders.

The azapirones (azaspirodecanediones) (e.g., buspirone [BUSPAR]) are useful in anxiety or dysphoria of moderate intensity. The azapirones have limited antidopaminergic actions in vivo, do not induce clinical extrapyramidal side effects, and do not interact with binding sites for benzodiazepines or facilitate the action of GABA. They are not anticonvulsant (and may even lower seizure threshold slightly), do not appear to cause tolerance or withdrawal reactions, and do not show cross-tolerance with benzodiazepines or other sedatives. Buspirone and several experimental congeners (e.g., gepirone, ipsapirone, and tiospirone) have selective affinity for 5-HT receptors of the 5-HT_{1A} type, for which they appear to be partial agonists (see Chapter 11). Buspirone lacks beneficial actions in severe anxiety with panic attacks. The risk of suicide with buspirone is very low.

OTHER THERAPEUTIC USES OF THESE DRUGS The various antidepressant agents have found broad utility in other disorders that may not be related psychobiologically to the mood disorders. Current applications include rapid but temporary suppression of enuresis with low (e.g., 25 mg) pre-bedtime doses of tricyclic antidepressants, including imipramine and nortriptyline, by uncertain mechanisms in children and in geriatric patients, as well as a beneficial effect of duloxetine on urinary stress incontinence. Antidepressants have a growing role in *attention-deficit/hyperactivity disorder* in children and adults, for which imipramine, desipramine, and nortriptyline appear to be effective, even in patients responding poorly to or who are intolerant of the stimulants (e.g., methylphenidate). Newer NE selective reuptake inhibitors also may be useful in this disorder; atomoxetine is approved for this application. Utility of SSRIs in this syndrome is not established, and bupropion, despite its similarity to stimulants, appears to have limited efficacy.

Antidepressants tend to provide a more sustained and continuous improvement of the symptoms of attention-deficit/hyperactivity disorder than do the stimulants and do not induce tics or other abnormal movements sometimes associated with stimulants. Indeed, desipramine and nortriptyline may effectively treat tic disorders, either in association with the use of stimulants or in patients with both attention deficit disorder and Tourette’s syndrome. Antidepressants also are leading choices in the treatment of severe anxiety disorders, including panic disorder with agoraphobia, generalized anxiety disorder, social phobia, and obsessive-compulsive disorder, as well as for the common comorbidity of anxiety in depressive illness. Antidepressants, especially SSRIs, also are employed in the management of posttraumatic stress disorder, which is marked by anxiety, startle, painful recollection of the traumatic events, and disturbed sleep. Initially, anxious patients often tolerate nonseating antidepressants poorly (Table 17–1), requiring slowly increased doses. Their beneficial actions typically are delayed for several weeks in anxiety disorders, just as they are in major depression.

For panic disorder, tricyclic antidepressants and MAO inhibitors, as well as high-potency benzodiazepines (notably alprazolam, clonazepam, and lorazepam) (see Chapter 16), are effective in blocking the autonomic expression of panic itself, thereby facilitating a comprehensive rehabilitation program. Imipramine and phenelzine are well-studied antidepressants for panic disorder. SSRIs also may be effective, but β adrenergic receptor antagonists, buspirone, and low-potency benzodiazepines usually are not, and bupropion can worsen anxiety.

SSRIs are agents of choice in obsessive-compulsive disorder and in the syndromes of impulse dyscontrol or obsessive preoccupations (e.g., compulsive gambling, trichotillomania, bulimia, but usually not anorexia nervosa and body dysmorphic disorder). Despite their limited benefits, SSRIs offer an important advance in the medical treatment of these often chronic and sometimes incapacitating disorders. The effectiveness of pharmacological treatment for these disorders is greatly enhanced by use of behavioral treatments.

Several psychosomatic disorders may respond at least partly to treatment with tricyclic antidepressants, MAO inhibitors, or SSRIs; among these are chronic pain disorders, including diabetic and other peripheral neuropathic syndromes (for which tertiary-amine tricyclics probably are

superior to fluoxetine, and both duloxetine and venlafaxine also may be effective); fibromyalgia; peptic ulcer and irritable bowel syndrome; hot flashes of menopause; chronic fatigue; cataplexy; tics; migraine; and sleep apnea. These disorders may have some psychobiological relationship to mood or anxiety disorders.

PHARMACOTHERAPY OF PSYCHOSIS AND MANIA

I. DRUGS USED IN THE TREATMENT OF PSYCHOSES

The psychotic disorders include schizophrenia, the manic phase of bipolar (manic-depressive) illness, acute idiopathic psychotic illnesses, and other conditions marked by severe agitation. All exhibit major disturbances in reasoning, often with delusions and hallucinations. Several classes of drugs are effective for symptomatic treatment. Antipsychotic agents also are useful alternatives to electroconvulsive therapy (ECT) in severe depression with psychotic features, and sometimes are used in the management of patients with psychotic disorders associated with delirium or dementia or induced by other agents (e.g., stimulants or L-DOPA).

The term *neuroleptic* is often applied to drugs that have relatively prominent experimental and clinical evidence of antagonism of D₂ dopamine (DA) receptors, with substantial risk of adverse extrapyramidal neurological effects and increased release of prolactin. The term *atypical antipsychotic* is applied to agents that are associated with substantially lower risks of such extrapyramidal effects. Although the antipsychotic drugs have had a revolutionary, beneficial impact on medical and psychiatric practice, their liabilities, especially of the older typical or neuroleptic agents, must be emphasized. Newer antipsychotics are atypical in having less risk of extrapyramidal side effects, but these agents present their own spectrum of adverse effects, including hypotension, seizures, weight gain, and increased risk of type 2 diabetes mellitus and hyperlipidemia.

The psychoses are among the most severe psychiatric disorders, in which there is not only marked impairment of behavior but also a serious inability to think coherently, to comprehend reality, or to gain insight into the presence of these abnormalities. These common disorders (affecting perhaps 1% of the population at some age) typically include symptoms of false beliefs (delusions) and abnormal sensations (hallucinations). Representative syndromes in this category include schizophrenia, brief psychoses, and delusional disorders. Psychotic features also occur in major mood disorders, particularly mania and severe melancholic depression. Psychotic illnesses are characterized by disordered thought processes (as inferred from illogical or highly idiosyncratic communications) with disorganized or irrational behavior and varying degrees of altered mood that can range from excited agitation to severe emotional withdrawal. Idiopathic psychoses characterized by chronically disordered thinking and emotional withdrawal, and often associated with delusions and auditory hallucinations, are called schizophrenia. Acute and recurrent idiopathic psychoses that bear an uncertain relationship to schizophrenia or the major affective disorders also occur. Delusions that are more or less isolated are characteristic of delusional disorder or paranoia.

The beneficial effects of antipsychotic drugs are not limited to schizophrenia. They also are employed in disorders ranging from postsurgical delirium and amphetamine intoxication to paranoia, mania, psychotic depression, and the agitation of Alzheimer's dementia (although their efficacy in this disorder is not proven). They are especially useful in severe depression and possibly in other conditions marked by severe turmoil or agitation.

TRICYCLIC ANTIPSYCHOTIC AGENTS

Several dozen phenothiazine antipsychotic drugs and chemically related agents are used worldwide. Other phenothiazines are marketed primarily for their antiemetic, antihistaminic, or anticholinergic effects.

Pharmacological Properties

Antipsychotic drugs share many pharmacological effects and therapeutic applications. Chlorpromazine and haloperidol are prototypic of the older, standard neuroleptic-type agents. Many antipsychotic drugs, especially chlorpromazine and other agents of low potency, have a prominent sedative effect. This is particularly conspicuous early in treatment, although some tolerance typically develops and can be of added value when very agitated psychotic patients are treated. Despite their sedative effects, neuroleptic drugs generally are not used to treat anxiety disorders or insomnia, largely because of their adverse autonomic and neurologic effects, which paradoxically can include severe anxiety and restlessness (akathisia). The risk of developing adverse extrapyramidal effects, including tardive dyskinesia, following long-term administration of neuroleptic drugs makes them less desirable than several alternative treatments for anxiety disorders (see Chapter 17).

The term *neuroleptic* was intended to contrast the effects of drugs such as chlorpromazine to those of sedatives and other CNS depressants. The neuroleptic syndrome involves suppression of spontaneous movements and complex behaviors, whereas spinal reflexes and unconditioned nociceptive-avoidance behaviors remain intact. In humans, neuroleptic drugs reduce initiative and interest in the environment as well as manifestations of emotion. In clinical use, there may be some initial drowsiness and slowness in response to external stimuli. However, subjects are easily aroused, can answer questions, and retain intact cognition. Ataxia, incoordination, or dysarthria do not occur at ordinary doses. Typically, psychotic patients soon become less agitated, withdrawn or autistic patients sometimes become more responsive and communicative, and aggressive and impulsive behavior diminishes. Gradually (usually over days), psychotic symptoms of hallucinations, delusions, and disorganized or incoherent thinking ameliorate. Neuroleptic agents also exert characteristic neurological effects—including bradykinesia, mild rigidity, tremor, and akathisia—that resemble the signs of Parkinson's disease.

Although the term *neuroleptic* initially encompassed this whole unique syndrome and is still used as a synonym for *antipsychotic*, it now is used to emphasize the more neurological aspects of the syndrome (*i.e.*, the parkinsonian and other extrapyramidal effects). Except for clozapine, aripiprazole, quetiapine, ziprasidone, and low doses of olanzapine and risperidone, antipsychotic drugs available in the U.S. also have effects on movement and posture and can be called neuroleptic. The more general term *antipsychotic* is preferable, as reinforced by the growing number of modern atypical antipsychotic drugs with little extrapyramidal action.

BEHAVIORAL EFFECTS A number of effects in animal behavioral models have been used to predict the efficacy or potential adverse effects of antipsychotic agents. Despite their widespread use, these paradigms generally have not provided important insights into the basis for clinical antipsychotic effects.

EXTRAPYRAMIDAL EFFECTS OF ANTIPSYCHOTICS The acute adverse clinical effects of antipsychotic agents are best mimicked in animals by assessing catalepsy in rats (immobility that allows an animal to be placed in abnormal postures that persist) or dystonia in monkeys. Late dyskinetic effects of antipsychotics are represented by the development of vacuous chewing movements in rats.

A particularly disturbing adverse effect of most antipsychotics is restless activity, termed *akathisia*, which is not readily mimicked by animal behavior. The cataleptic immobility of animals treated with classical antipsychotics resembles the catatonia seen in some psychotic patients and in a variety of metabolic and neurological disorders affecting the CNS. In patients, catatonic signs, along with other features of psychotic illnesses, are sometimes relieved by antipsychotic agents. However, rigidity and bradykinesia, which mimic catatonia, can be induced by administering large doses of potent traditional neuroleptics and by addition of an antimuscarinic-antiparkinson agent.

EFFECTS ON COGNITIVE FUNCTION

Several cognitive functions, including auditory processing and attention, spatial organization, verbal learning, semantic and verbal memory, and executive functions, are impaired in schizophrenia patients. Potent D₂-antagonist neuroleptics have very limited beneficial effects on such functions. Some atypical antipsychotic agents with mixed D₂/5-HT_{2A} activity (including clozapine, quetiapine, olanzapine, and risperidone), as well as the D₂ partial agonist aripiprazole, seem to improve cognitive functioning in psychotic patients. Nevertheless, significant long-term gains in social and occupational function during long-term treatment of chronically psychotic patients with these drugs are not well documented.

EFFECTS ON SLEEP

Antipsychotic drugs have inconsistent effects on sleep patterns but tend to normalize sleep disturbances characteristic of many psychoses and mania. The capacity to prolong and enhance the effect of opioid and hypnotic drugs appears to parallel the sedative, rather than the neuroleptic, potency of a particular agent; thus, potent, less-sedating antipsychotics do not enhance sleep.

EFFECTS ON SPECIFIC AREAS OF THE NERVOUS SYSTEM The antipsychotic drugs affect all levels of the CNS. Theories on the actions of antipsychotic agents are based on their ability to antagonize the actions of DA as a neurotransmitter in the basal ganglia and limbic portions of the forebrain. Although supported by a large body of data, these theories reflect a degree

of circularity in the consideration of antipsychotic drug candidates for development after identifying their antidopaminergic activity.

Cerebral Cortex Since psychosis involves disordered thought processes, cortical effects of antipsychotic drugs are of particular interest. Antipsychotic drugs interact with dopaminergic projections to the prefrontal and deep-temporal (limbic) regions of the cerebral cortex, with relative sparing of these areas from adaptive changes in DA metabolism that would suggest tolerance to the actions of neuroleptics.

Seizure Threshold

Many neuroleptic drugs can lower the seizure threshold and induce discharges in the electroencephalogram (EEG) that are associated with epileptic seizure disorders. Clozapine, olanzapine, and aliphatic phenothiazines with low potency (e.g., chlorpromazine) seem particularly able to do this, while the more potent piperazine phenothiazines and thioxanthenes (notably fluphenazine and thiothixene), risperidone, and quetiapine are much less likely to have this effect. The butyrophenones and molindone variably and unpredictably rarely cause seizures. Clozapine has a clearly dose-related risk of inducing seizures in nonepileptic patients. Antipsychotic agents, especially clozapine, olanzapine, and low-potency phenothiazines and thioxanthenes, should be used with extreme caution, if at all, in untreated epileptic patients and in patients undergoing withdrawal from CNS depressants such as alcohol, barbiturates, or benzodiazepines. Most antipsychotic drugs, especially the piperazines, and the newer atypical agents aripiprazole, quetiapine, risperidone, and ziprasidone, can be used safely in epileptic patients if moderate doses are attained gradually and if concomitant anticonvulsant drug therapy is maintained (see Chapter 19).

Basal Ganglia Because the extrapyramidal effects of many antipsychotic drugs are prominent, a great deal of interest has centered on their actions in the basal ganglia, notably the caudate nucleus, putamen, globus pallidus, and allied nuclei, which play a crucial role in the control of posture and the extrapyramidal aspects of movement. The critical pathogenic role of DA deficiency in this region in Parkinson's disease, the potent activity of neuroleptics as DA receptor antagonists, and the striking resemblance between clinical manifestations of Parkinson's disease and some of the neurological effects of neuroleptic drugs have all focused attention on the role of deficient dopaminergic activity in some of the neuroleptic-induced extrapyramidal effects.

Antagonism of DA-mediated synaptic neurotransmission is an important action of many antipsychotics; this prompted the proposal that many adverse extrapyramidal neurological and neuroendocrinological effects of the neuroleptics are mediated by antidopaminergic effects in the basal ganglia and hypothalamic systems, whereas the antipsychotic effects of neuroleptics are mediated by modification of dopaminergic neurotransmission in the limbic and mesocortical systems. Thus, neuroleptic drugs (but not their inactive congeners) initially increase the rate of production of DA metabolites, the rate of conversion of the precursor amino acid L-tyrosine to L-dihydroxyphenylalanine (L-DOPA) and its metabolites, and initially increase the rate of firing of DA-containing cells in the midbrain. These effects presumably represent adaptive responses of neuronal systems aimed at reducing the impact of impaired synaptic transmission at dopaminergic terminals in the forebrain.

Evidence supporting this interpretation includes the observation that small doses of neuroleptics block behavioral or neuroendocrine effects of systemically administered or intracerebrally injected dopaminergic agonists. Many antipsychotic drugs also block the effects of agonists on DA-sensitive adenylyl cyclase associated with D_1/D_5 -receptors in forebrain tissue (Figure 18–1). Atypical antipsychotic drugs such as clozapine and quetiapine are characterized by low affinity or weak actions in such tests. Initially, the standard antipsychotics increase firing and metabolic activity in dopaminergic neurons. These responses eventually are replaced by diminished presynaptic activity (“depolarization inactivation”) with reduced firing and production of DA, particularly in the extrapyramidal basal ganglia. The timing of these adaptive changes following the administration of neuroleptics correlates well with the gradual evolution of parkinsonian bradykinesia over several days.

Estimated clinical potencies of most antipsychotic drugs correlate well with their relative potencies in vitro to inhibit binding of radioligands to D_2 receptors. Almost all clinically effective antipsychotic agents (with the notable exception of clozapine and quetiapine) have high or moderate affinity for D_2 receptors. Although some antipsychotics (especially thioxanthenes, phenothiazines, and clozapine) bind with relatively high affinity to D_1 receptors, they also block D_2 receptors and D_2 -like receptors, including the D_3 and D_4 subtypes. Butyrophenones and con-

FIGURE 18-1 Sites of action of neuroleptics and lithium. In varicosities (“terminals”) along dopamine (DA) neurons projecting from midbrain to forebrain, tyrosine is oxidized to dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase (TH), the rate-limiting step in catecholamine biosynthesis, then decarboxylated to DA by aromatic L-amino acid decarboxylase (AAD) and stored in vesicles. Following exocytotic release (inhibited by Li^+) by depolarization in the presence of Ca^{2+} , DA interacts with postsynaptic receptors (R) of D_1 and D_2 types (and structurally similar but less prevalent D_1 -like and D_2 -like receptors), as well as with presynaptic D_2 and D_3 autoreceptors. Inactivation of transsynaptic communication occurs primarily by active transport (“reuptake” via DAT) of DA into presynaptic terminals (inhibited by many stimulants), with secondary deamination by mitochondrial monoamine oxidase (MAO). Postsynaptic D_1 receptors, through G_s , activate adenylyl cyclase (AC) to increase cyclic AMP (cAMP), whereas D_2 receptors inhibit AC through G_i . D_2 receptors also activate receptor-operated K^+ channels, suppress voltage-gated Ca^{2+} currents, and stimulate phospholipase C (PLC), perhaps via the $\beta\gamma$ subunits liberated from activated G_i (see Chapter 1), activating the IP_3 - Ca^{2+} pathway, thereby modulating a variety of Ca^{2+} -dependent activities including protein kinases. Lithium inhibits the phosphatase that liberates inositol (I) from inositol phosphate (IP). Both Li^+ and valproate can modify the abundance or function of G proteins and effectors, as well as protein kinases and several cell and nuclear regulatory factors. D_2 -like autoreceptors suppress synthesis of DA by diminishing phosphorylation of rate-limiting TH, and by limiting DA release (possibly through modulation of Ca^{2+} or K^+ currents). In contrast, presynaptic A_2 adenosine receptors (A_2R) activate AC and, via the cyclic AMP–PKA pathway, TH activity. Nearly all antipsychotic agents block D_2 receptors and autoreceptors; some also block D_1 receptors. Initially in antipsychotic treatment, DA neurons activate and release more DA, but following repeated treatment, they enter a state of physiological depolarization inactivation, with diminished production and release of DA, in addition to continued receptor blockade. ER, endoplasmic reticulum.

gens (e.g., haloperidol, pimozide, N-methylspiperone) and experimental benzamide neuroleptics are relatively selective antagonists of D_2 and D_3 receptors, with either high (nemonapride) or low (eticlopride, raclopride, remoxipride) D_4 affinity.

Many other antipsychotic agents are active α_1 adrenergic antagonists. This action may contribute to sedative and hypotensive side effects or may underlie useful psychotropic effects. Many antipsychotic agents (aripiprazole, clozapine, olanzapine, quetiapine, risperidone, and ziprasidone) also have affinity for forebrain 5-HT_{2A} receptors (see Chapter 11). This mixture of moderate affinities for several CNS receptor types (including muscarinic and H_1 receptors) may contribute to the distinct pharmacological profiles of the atypical antipsychotic agent clozapine and other newer atypical antipsychotics.

Limbic System Dopaminergic projections from the midbrain terminate on septal nuclei, the olfactory tubercle and basal forebrain, the amygdala, and other structures within the temporal and prefrontal cerebral lobes and the hippocampus. The DA hypothesis has focused considerable attention on the mesolimbic and mesocortical systems as possible sites where antipsychotic effects are

mediated. Speculations about the pathophysiology of idiopathic psychoses such as schizophrenia have long centered on dopaminergic functions in the limbic system.

Certain important effects of antipsychotic drugs are similar in extrapyramidal and limbic regions; however, the extrapyramidal and antipsychotic actions of these drugs differ in several ways: while some acute extrapyramidal effects of neuroleptics tend to diminish or disappear with time or with concurrent administration of anticholinergic drugs, antipsychotic effects do not. Moreover, dopaminergic subsystems in the forebrain differ functionally and in their physiological responses to drugs: anticholinergic agents block the increased turnover of DA in the basal ganglia induced by neuroleptic agents, but not in dopaminergic terminals of limbic areas; tolerance to the enhanced DA metabolism by antipsychotics is much less prominent in cortical and limbic areas than in extrapyramidal areas.

Newer Dopaminergic Receptors in Basal Ganglia and Limbic System

The discovery that D_3 and D_4 receptors are preferentially expressed in limbic areas has led to efforts to identify selective inhibitors for these receptors that might have antipsychotic efficacy and low risk of extrapyramidal effects. Clozapine has modest selectivity for D_4 receptors over other DA receptor types. D_4 receptors, preferentially localized in cortical and limbic brain regions in relatively low abundance, are upregulated after repeated administration of most typical and atypical antipsychotic drugs. These receptors may contribute to clinical antipsychotic actions, but agents that are D_4 selective or mixed $D_4/5\text{-HT}_{2A}$ antagonists have not proved effective in the treatment of psychotic patients.

D_3 receptors are unlikely to play a pivotal role in antipsychotic drug actions, perhaps because their avid affinity for endogenous DA prevents their interaction with antipsychotics. The subtle and atypical functional activities of cerebral D_3 receptors suggest that D_3 agonists rather than antagonists may have useful psychotropic effects, particularly in antagonizing stimulant-reward and dependence behaviors.

Hypothalamus and Endocrine Systems Endocrine changes occur because of effects of antipsychotic drugs on the hypothalamus or pituitary, including their antidopaminergic actions. Most older antipsychotics and risperidone increase prolactin secretion, probably due to a blockade of the pituitary actions of the tuberoinfundibular dopaminergic neurons. These neurons project from the arcuate nucleus of the hypothalamus to the median eminence, where they deliver DA to the anterior pituitary via the hypophyseoportal blood vessels. D_2 receptors on lactotropes in the anterior pituitary mediate the tonic prolactin-inhibiting action of DA (see Chapter 55).

Correlations between the potencies of antipsychotic drugs in stimulating prolactin secretion and causing behavioral effects are excellent for many types of agents. Aripiprazole, clozapine, olanzapine, quetiapine, and ziprasidone are exceptional in having minimal or transient effects on prolactin, while olanzapine produces only minor, transient increases in prolactin levels. Risperidone has an unusually potent prolactin-elevating effect, even at doses with little extrapyramidal impact. Effects of neuroleptics on prolactin secretion generally occur at lower doses than do their antipsychotic effects. This may reflect their action outside the blood–brain barrier in the adenohypophysis, or differences in the regulation of pituitary and cerebral D_2 receptors. Little tolerance develops to the effect of antipsychotic drugs on prolactin secretion, correlating with a relative lack of up- or down-regulation of pituitary D_2 receptors and their relative sensitivity to DA partial agonists. The hyperprolactinemic effect of antipsychotics is rapidly reversible when the drugs are discontinued. This activity is presumed to be responsible for the galactorrhea that may be associated with their use. Other than due to the effects of hyperprolactinemia, some antipsychotic drugs reduce the secretion of gonadotropins and sex steroids, which can cause amenorrhea in women and sexual dysfunction or infertility in men.

Other autonomic effects of antipsychotic drugs are probably mediated by the hypothalamus, such as an impairment of the body's ability to regulate temperature. Clozapine can induce moderate elevations of body temperature that can be confusing clinically; central effects on temperature regulation and cardiovascular and respiratory function probably contribute to the features of *neuroleptic malignant syndrome* (see Table 18–1).

Brainstem

Clinical doses of antipsychotic agents usually have little effect on respiration. However, vasomotor reflexes mediated by either the hypothalamus or the brainstem are depressed by some antipsychotics, which may lead to hypotension. This risk is associated particularly with older low-potency

Neurological Side Effects of Neuroleptic Drugs

Reaction	Features	Time of Maximal Risk	Proposed Mechanism	Treatment
Acute dystonia	Spasm of muscles of tongue, face, neck, back; may mimic seizures; <i>not</i> hysteria	1–5 days	Unknown	Antiparkinsonian agents are diagnostic and curative*
Akathisia	Motor restlessness; <i>not</i> anxiety or “agitation”	5–60 days	Unknown	Reduce dose or change drug; antiparkinsonian agents, [†] benzodiazepines or propranolol [‡] may help Antiparkinsonian agents helpful [†]
Parkinsonism	Bradykinesia, rigidity, variable tremor, mask facies, shuffling gait	5–30 days; can recur even after a single dose	Antagonism of dopamine	Antiparkinsonian agents helpful [†]
Neuroleptic malignant syndrome	Catatonia, stupor, fever, unstable blood pressure, myoglobinemia; can be fatal	Weeks; can persist for days after stopping neuroleptic	Antagonism of dopamine may contribute	Stop neuroleptic immediately; dantrolene or bromocriptine [§] may help; antiparkinsonian agents not effective
Perioral tremor (“rabbit syndrome”)	Perioral tremor (may be a late variant of parkinsonism)	After months or years of treatment	Unknown	Antiparkinsonian agents often help [†]
Tardive dyskinesia	Oral-facial dyskinesia; widespread choreoathetosis or dystonia	After months or years of treatment (worse on withdrawal)	Excess function of dopamine hypothesized	Prevention crucial; treatment unsatisfactory

*Many drugs have been claimed to be helpful for acute dystonia. Among the most commonly employed treatments are diphenhydramine hydrochloride, 25 or 50 mg intramuscularly, or benztropine mesylate, 1 or 2 mg intramuscularly or slowly intravenously, followed by oral medication with the same agent for a period of days to perhaps several weeks thereafter.

[†]For details regarding the use of oral antiparkinsonian agents, see the text and Chapter 20: Treatment of Central Nervous System Degenerative Disorders.

[‡]Propranolol often is effective in relatively low doses (20–80 mg/day). Selective β_1 adrenergic receptor antagonists are less effective.

[§]Despite the response to dantrolene, there is no evidence of an abnormality of Ca^{2+} transport in skeletal muscle; with lingering neuroleptic effects, bromocriptine may be tolerated in large doses (10–40 mg/day).

antipsychotics and with risperidone. Even in cases of acute overdose with suicidal intent, the antipsychotic drugs usually do not cause life-threatening coma or suppress vital functions.

Chemoreceptor Trigger Zone

Most antipsychotics protect against the nausea- and emesis-inducing effects of apomorphine and certain ergot alkaloids, all of which can interact with central dopaminergic receptors in the chemoreceptor trigger zone (CTZ) of the medulla. The antiemetic effect of most neuroleptics occurs with low doses and can contribute to toxicity of acute overdoses of mixed agents by preventing their elimination by vomiting. Drugs or other stimuli that cause emesis by an action on the nodose ganglion or locally on the GI tract are not antagonized by antipsychotic drugs, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation.

Autonomic Nervous System

Antipsychotic agents have variable antagonistic interactions at peripheral α , 5-HT_{2A/2C}, and H₁ receptors; thus, the drugs' effects on the autonomic nervous system are complex and unpredictable. Chlorpromazine, clozapine, and thioridazine have particularly significant α -adrenergic antagonistic activity. The potent piperazine tricyclic neuroleptics (e.g., fluphenazine, trifluoperazine, haloperidol, and risperidone) have antipsychotic effects even when used in low doses and show little antiadrenergic activity.

The muscarinic-cholinergic blocking effects of most antipsychotic drugs are relatively weak, but the blurred vision commonly associated with chlorpromazine may be due to an anticholinergic action on the ciliary muscle. Chlorpromazine regularly produces miosis, which can be due to α adrenergic blockade. Other phenothiazines can cause mydriasis (especially clozapine and thioridazine, which are potent muscarinic antagonists). Chlorpromazine can cause constipation and decreased gastric acid secretion and motility; clozapine can decrease the efficiency of clearing saliva and severely impair intestinal motility. Decreased sweating and salivation also result from the anticholinergic effects. Acute urinary retention is uncommon but can occur in males with prostatic enlargement. Anticholinergic effects are least frequently caused by the potent antipsychotics such as haloperidol and risperidone. However, olanzapine has substantial anticholinergic activity that may tend to offset its considerable D₂ anti-DA effects on the extrapyramidal system. Clozapine is sufficiently anticholinergic to induce an atropine-like poisoning on overdose. The phenothiazines inhibit ejaculation without interfering with erection. Thioridazine produces this effect with some regularity, sometimes limiting its acceptance by men.

Kidney and Electrolyte Balance

Chlorpromazine may have weak diuretic effects because of a depressant action on the secretion of vasopressin (antidiuretic hormone, ADH), inhibition of reabsorption of water and electrolytes by a direct action on the renal tubule, or both. The syndrome of idiopathic polydipsia and hyponatremia sometimes associated with psychotic illness has responded to clozapine, presumably via CNS actions.

Cardiovascular System

Chlorpromazine has complex actions on the cardiovascular system, directly affecting the heart and blood vessels and indirectly acting through CNS and autonomic reflexes. Chlorpromazine and less potent antipsychotic agents, as well as reserpine, risperidone, and olanzapine, can cause orthostatic hypotension, usually with rapid development of tolerance.

Thioridazine, mesoridazine, and other phenothiazines with low potency, as well as ziprasidone, droperidol, and perhaps high doses of haloperidol, have a potentially clinically significant direct negative inotropic action and a quinidine-like effect on the heart (prolongation of the QTc and PR intervals, blunting of T waves, and depression of the ST segment). Thioridazine in particular causes a high incidence of QTc- and T-wave changes and may rarely produce ventricular arrhythmias and sudden death. These effects are less common with potent antipsychotic agents. Ziprasidone also has the propensity to prolong QTc; thus, extra caution is needed when this agent, thioridazine, or mesoridazine are given in combination with other agents that depress cardiac conduction (see Chapter 34).

MISCELLANEOUS PHARMACOLOGICAL EFFECTS

Interactions of antipsychotic drugs with central neurotransmitters other than DA may contribute to their antipsychotic effects or other actions. For example, many antipsychotics enhance the turnover of acetylcholine, especially in the basal ganglia, perhaps secondary to the blockade of inhibitory dopaminergic heteroreceptors on cholinergic neurons. In addition, there is an inverse relationship between antimuscarinic potency of antipsychotic drugs in the brain and the likelihood

of extrapyramidal effects. Chlorpromazine and low-potency antipsychotic agents, including clozapine and quetiapine, have antagonistic actions at histamine receptors that probably contribute to their sedative effects.

ABSORPTION, DISTRIBUTION, FATE, AND EXCRETION Some antipsychotic drugs have erratic and unpredictable patterns of absorption after oral administration. Parenteral (intramuscular) administration increases the bioavailability of active drug 4–10-fold. Most antipsychotic drugs are highly lipophilic, highly membrane- or protein-bound, and accumulate in the brain, lung, and other tissues with a rich blood supply. They also enter the fetal circulation and breast milk. It is virtually impossible to remove these agents by dialysis.

Elimination half-lives with respect to total concentrations in plasma are typically 20–40 hours. However, complex patterns of delayed elimination may occur with some drugs, particularly the butyrophenones and their congeners. Biological effects of single doses of most antipsychotics usually persist for at least 24 hours, permitting once-daily dosing once the patient has adjusted to initial side effects. Elimination from the plasma may be more rapid than from sites of high lipid content and binding, notably in the CNS; metabolites of some agents have been detected in the urine several months after drug administration was discontinued. Slow removal of drug may contribute to the typically delayed exacerbation of psychosis after stopping drug treatment. Repository (“depot”) preparations of esters of neuroleptic drugs, as well as risperidone incorporated into carbohydrate microspheres, are absorbed and eliminated much more slowly than are oral preparations. For example, half of an oral dose of fluphenazine hydrochloride is eliminated in ~20 hours, while the decanoate ester injected intramuscularly has a $t_{1/2}$ of 7–10 days. Clearance of fluphenazine decanoate and normalization of hyperprolactinemia following repeated dosing can require 6–8 months. Effects of long-acting risperidone (RISPERIDAL CONSTA) are delayed for 2–3 weeks because of slow biodegradation of the microspheres and persist for at least 2 weeks after the injections are discontinued.

The antipsychotic drugs are metabolized largely by hepatic CYPs and by glucuronidation, sulfation, and other conjugation processes. Hydrophilic metabolites of these drugs are excreted in the urine and to some extent in the bile. Most oxidized metabolites of antipsychotic drugs are biologically inactive. Less potent antipsychotic drugs like chlorpromazine may weakly induce their own hepatic metabolism, since their concentrations in blood are lower after several weeks of treatment at the same dosage. Alterations of GI motility also may contribute. The fetus, the infant, and the elderly have diminished capacity to metabolize and eliminate antipsychotic agents; young children tend to metabolize these drugs more rapidly than do adults.

With several antipsychotic agents, bioavailability and drug acceptance by hospitalized patients is somewhat increased with liquid concentrates and rapidly disintegrating tablets that yield peak serum concentrations of chlorpromazine and other phenothiazines within 2–4 hours. Intramuscular administration avoids much of the first-pass enteric metabolism and provides measurable concentrations in plasma within 15–30 minutes. Bioavailability of chlorpromazine may be increased up to tenfold with injections, but the clinical dose usually is decreased by only three- to fourfold. GI absorption of chlorpromazine is modified unpredictably by food and probably is decreased by antacids. Antipsychotic agents bind significantly to membranes and to plasma proteins. Elimination kinetics can be multiphasic and variable with dose, and termination of action may rely on clearance of both active metabolites and the parent compound. Approximate elimination half-lives of clinically employed antipsychotic agents are provided in Table 18–2; see also Appendix II, Pharmacokinetic Data in the 11th edition of the parent text.

TOLERANCE AND PHYSICAL DEPENDENCE

As defined in Chapter 23, the antipsychotic drugs are not addicting, but some degree of physical dependence may occur, with malaise and difficulty in sleeping developing several days after abrupt drug discontinuation after prolonged use.

Loss of efficacy with prolonged treatment is not known to occur with antipsychotic agents, but some tolerance to sedative effects of antipsychotics usually develops over days or weeks. One correlate of tolerance in forebrain dopaminergic systems is the development of supersensitivity, probably mediated by upregulation and sensitization of DA D_2 receptors. These changes may underlie the clinical phenomenon of withdrawal-emergent dyskinesias (e.g., choreoathetosis on abrupt discontinuation of antipsychotic agents, especially following prolonged use of high doses of potent agents) and may contribute to the pathophysiology of tardive dyskinesias.

Although cross-tolerance may occur among antipsychotic drugs, clinical problems occur in making rapid changes from high doses of one type of agent to another. Sedation, hypotension, and other autonomic effects or acute extrapyramidal reactions can result. Clinical worsening of psychotic symptoms is particularly likely after rapid discontinuation of clozapine and is difficult to control with alternative antipsychotics.

PREPARATIONS AND DOSAGE

Table 18–3 summarizes the large number of drugs currently marketed in the U.S. for the treatment of psychotic disorders or mania.

Prochlorperazine (*COMPazine*) has questionable utility as an antipsychotic agent and frequently produces acute extrapyramidal reactions. It is rarely employed in psychiatry, although it is used as an antiemetic. Thiethylperazine (*TORECAN*), marketed only as an antiemetic, is a potent dopaminergic antagonist with many neuroleptic-like properties. At high doses, it may be an efficacious antipsychotic agent. In the U.S., only the decanoates of fluphenazine and haloperidol and an injected carbohydrate microsphere preparation of risperidone are commonly employed as long-acting repository preparations.

TOXIC REACTIONS AND ADVERSE EFFECTS Antipsychotic drugs have a high therapeutic index and are generally safe agents. Most phenothiazines, haloperidol, clozapine, and quetiapine can be used over a wide range of dosages (Table 18–3). Although occasional deaths from overdoses have been reported, fatalities are rare in patients given medical care unless the overdose is complicated by concurrent ingestion of alcohol or other drugs. Adverse effects often are extensions of the many pharmacological actions of these drugs. The most important are those on the cardiovascular, central and autonomic nervous systems, and endocrine system. Other dangerous effects are seizures, agranulocytosis, cardiac toxicity, and pigmentary degeneration of the retina, all of which are rare (*see* below). Therapeutic doses of phenothiazines may cause faintness, palpitations, and anticholinergic effects including nasal stuffiness, dry mouth, blurred vision, constipation, worsening of glaucoma, and urinary retention in males with prostatism.

*Antipsychotic agents for use in children under age 12 years include chlorpromazine, chlorprothixene (>6 years), thioridazine, and triflupromazine (among agents of low potency); and prochlorperazine and trifluoperazine (>6 years) (among agents of high potency). Haloperidol (orally) has also been used extensively in children.

[†]Dosage forms are indicated as follows: I, regular or long-acting injection; L, oral liquid or oral liquid concentrate; O, oral solid; S, suppository; SR, oral, sustained-release.

[‡]Except for the enanthate and decanoate forms of fluphenazine and haloperidol decanoate, dosage can be given intramuscularly up to every 6 hours for agitated patients. Haloperidol lactate has been given intravenously; this is experimental.

[§]Extreme dosage ranges are occasionally exceeded cautiously and only when other appropriate measures have failed.

Adverse Cardiovascular and Cerebrovascular Effects The most common adverse cardiovascular effect is orthostatic hypotension, which may result in syncope, falls, and injuries. Hypotension is most likely to occur with administration of the phenothiazines with aliphatic side chains or atypical antipsychotics. Potent neuroleptics generally produce less hypotension.

Some antipsychotic agents depress cardiac repolarization, as reflected in the QT interval corrected for heart rate (QTc). Prolongations above 500 msec can be dangerous clinically, particularly by increasing the risk of *torsades de pointes*, which often is a precursor of fatal cardiac arrest (see Chapter 34). Such cardiac depressant effects are especially prominent with thioridazine and its active metabolite, mesoridazine, as well as pimozide, high doses of haloperidol, and ziprasidone. These drugs are used cautiously, if at all, in combination with other agents with known cardiac-depressant effects, including tricyclic antidepressants (see Chapter 17), certain antiarrhythmic agents (see Chapter 34), other antipsychotics with similar actions (such as pimozide and thioridazine), or specific DA antagonists (cisapride and metoclopramide; see Chapter 37). Clozapine has rarely been associated with myocarditis and cardiomyopathy. Some clinical observations have suggested increased risk of stroke among elderly patients treated with risperidone and perhaps olanzapine. The clinical significance of these uncommon cardiac and cerebrovascular events remains uncertain.

Adverse Neurological Effects Many neurological syndromes, particularly involving the extrapyramidal motor system, occur following the use of most antipsychotic drugs, especially with the high-potency D₂-receptor antagonists (tricyclic piperazines and butyrophenones). Acute adverse extrapyramidal effects are less likely with aripiprazole, clozapine, quetiapine, thioridazine, and ziprasidone, or low doses of olanzapine or risperidone.

Six distinct neurological syndromes are characteristic of older neuroleptic-antipsychotic drugs. Four of these (acute dystonia, akathisia, parkinsonism, and the rare neuroleptic malignant syndrome) usually appear soon after administration of the drug. Two (tardive dyskinesias or dystonias, and rare perioral tremor) are late-appearing syndromes that evolve during prolonged treatment. The clinical features of these syndromes and guidelines for their management are summarized in Table 18-1.

Certain therapeutic guidelines should be followed to minimize the neurological syndromes that complicate the use of antipsychotic drugs. Routine use of antiparkinson agents in an attempt to avoid early extrapyramidal reactions adds complexity, side effects, and expense to the regimen. Antiparkinson agents are best reserved for cases of overt extrapyramidal reactions that respond favorably to such intervention. The need for such agents for the treatment of acute dystonic reactions ordinarily diminishes with time, but parkinsonism and akathisia typically persist. The thoughtful and conservative use of antipsychotic drugs, particularly modern atypical agents, in patients with chronic or frequently recurrent psychotic disorders almost certainly can reduce the risk of tardive dyskinesia. Although reduction of the dose of an antipsychotic agent is the best way to minimize its adverse neurological effects, this may not be practical in a patient with uncontrollable psychotic illness. The best preventive practice is to use the minimum effective dose of an antipsychotic drug. The growing number of modern atypical antipsychotic agents with a low risk of inducing extrapyramidal side effects provides an alternative for many patients.

Weight Gain and Metabolic Effects Weight gain and its associated long-term complications can occur with extended treatment with most antipsychotic and antimanic drugs. Weight gain is especially prominent with clozapine and olanzapine; somewhat less with quetiapine; even less with fluphenazine, haloperidol, and risperidone; and very low with aripiprazole, molindone, and ziprasidone. Adverse effects of weight gain likely include increased risk of new-onset or worsening of type 2 diabetes mellitus, hypertension, and hyperlipidemia. In some patients with morbid increases in weight, the airway may be compromised (Pickwickian syndrome), especially during sleep (including sleep apnea).

Blood Dyscrasias Mild leukocytosis, leukopenia, and eosinophilia occasionally occur with antipsychotic treatment, particularly with clozapine and less often with phenothiazines of low potency. It is difficult to determine whether leukopenia that develops during the administration of such agents is a forewarning of impending agranulocytosis. This serious complication occurs in not more than 1 in 10,000 patients receiving chlorpromazine or other low-potency agents (other than clozapine); it usually appears within the first 8-12 weeks of treatment.

Bone marrow suppression, or less commonly agranulocytosis, has been associated with the use of clozapine. The incidence approaches 1% within several months of treatment, independent of

dose, without regular monitoring of white blood cell counts. Because blood dyscrasia may develop suddenly, the appearance of fever, malaise, or apparent respiratory infection in a patient being treated with an antipsychotic drug should be followed immediately by a complete blood count. Risk of agranulocytosis is greatly reduced, though not eliminated, by frequent white blood cell counts in patients being treated with clozapine, as is required in the U.S. (weekly for 6 months and biweekly thereafter). The safety of resuming even low doses of clozapine or other antipsychotics following recovery from agranulocytosis should not be assumed.

Skin Reactions

Dermatological reactions to the phenothiazines, including urticaria or dermatitis, occur in ~5% of patients receiving chlorpromazine. Contact dermatitis may occur in personnel who handle chlorpromazine, and there may be a degree of cross-sensitivity to other phenothiazines. Sunburn and photosensitivity resembling severe sunburn occur and require use of an effective sunscreen preparation. Epithelial keratopathy often is observed in patients on long-term therapy with chlorpromazine, and opacities in the cornea and in the lens of the eye have been noted. Pigmentary retinopathy has been reported, particularly following doses of thioridazine in excess of 1000 mg/day. A maximum daily dose of 800 mg currently is recommended. Dermatological reactions to modern atypical antipsychotic agents are uncommon.

GI and Hepatic Effects

A mild jaundice, typically occurring early in therapy, may be seen in some patients receiving chlorpromazine. Pruritus is rare. The reaction probably is a manifestation of hypersensitivity, because eosinophilia and eosinophilic infiltration of the liver occur. For uninterrupted drug therapy in a patient with neuroleptic-induced jaundice, it probably is safest to use low doses of a potent, dissimilar agent. Hepatic dysfunction with other antipsychotic agents is uncommon. Clozapine can cause potentially severe ileus and sialorrhea.

INTERACTIONS WITH OTHER DRUGS The phenothiazines and thioxanthenes, especially those of lower potency, affect the actions of a number of other drugs. Antipsychotic drugs can strongly potentiate the effect of medically prescribed sedatives and analgesics, alcohol, nonprescription sedatives and hypnotics, antihistamines, and cold remedies. Chlorpromazine increases the miotic and sedative effects of morphine and may increase its analgesic actions. The drug markedly increases the respiratory depression produced by meperidine and can be expected to have similar effects when administered concurrently with other opioids. Obviously, neuroleptic drugs inhibit the actions of dopaminergic agonists and levodopa and worsen the neurological symptoms of Parkinson's disease.

The antimuscarinic action of clozapine and thioridazine can cause tachycardia and enhance the peripheral and central effects (confusion, delirium) of other anticholinergic agents, such as the tricyclic antidepressants and antiparkinson agents.

Sedatives or anticonvulsants (e.g., carbamazepine, oxcarbazepine, phenobarbital, and phenytoin, but not valproate) that induce CYPs (see Chapter 3) can enhance the metabolism of antipsychotic and many other agents (including anticoagulants and oral contraceptives), sometimes with significant clinical consequences. Conversely, selective serotonin (5-HT) reuptake inhibitors including fluvoxamine, fluoxetine, paroxetine, venlafaxine, sertraline, and nefazodone (see Chapter 17) compete for these enzymes and can elevate circulating levels of neuroleptics.

DRUG TREATMENT OF PSYCHOSES

SHORT-TERM TREATMENT The antipsychotic drugs are effective in acute psychoses of unknown etiology, including mania, acute idiopathic psychoses, and acute exacerbations of schizophrenia. The best studied indications are for the acute and chronic phases of schizophrenia and in acute mania. Antipsychotic drugs also are used empirically in many other neuromedical and idiopathic disorders with prominent psychotic symptoms or severe agitation.

Neuroleptic agents are effective antipsychotics and are superior to sedatives (e.g., barbiturates and benzodiazepines), or alternatives (e.g., ECT, other medical or psychological therapies). The "target" symptoms for which antipsychotic agents are especially effective include agitation, combativeness, hostility, hallucinations, acute delusions, insomnia, anorexia, poor self-care, negativism, and sometimes withdrawal and seclusiveness. More variable or delayed are improvements in motivation and cognition, including insight, judgment, memory, orientation, and functional recovery. The most favorable prognosis is for patients with acute illnesses of brief duration who had functioned relatively well prior to the illness.

No one drug or combination of drugs selectively affects a particular symptom complex in groups of psychotic patients. Drug responses in individual patients can be determined only by trial and error. Generally, "positive" (irrational thinking, delusions, agitated turmoil, hallucinations) and "negative" symptoms tend to respond (or not) together with overall clinical improvement, a tendency well documented with typical neuroleptics and modern atypical antipsychotic agents. Aripiprazole, clozapine, quetiapine, and ziprasidone induce less bradykinesia and other parkinsonian effects than do typical neuroleptics, and aripiprazole and ziprasidone are minimally sedating. Minimizing such side effects is sometimes interpreted clinically as specific improvement in impoverished affective responsiveness and energy level.

The short-term clinical superiority of modern antipsychotic agents over older neuroleptics has been particularly hard to prove. Nevertheless, in the U.S., the modern atypical agents dominate clinical practice, owing mainly to their perceived superior tolerability and acceptability.

It is important to simplify the treatment regimen and to ensure that the patient is receiving the drug. In cases of suspected severe and dangerous noncompliance or with failure of oral treatment, the patient can be treated with injections of fluphenazine decanoate, haloperidol decanoate, or other long-acting preparations, including risperidone microspheres.

Because the choice of an antipsychotic drug cannot be made reliably on the basis of anticipated therapeutic effect, drug selection often depends on likely tolerability of specific side effects, the need for sedation, or on a previous favorable response. If the patient has a history of cardiovascular disease or stroke and the threat from hypotension is serious, a modern atypical agent or a potent older neuroleptic should be used in the smallest dose that is effective (Table 18–1). For minimizing the risk of acute extrapyramidal symptoms, aripiprazole, clozapine, quetiapine, ziprasidone, or a low dose of olanzapine or risperidone should be considered. If the patient would be seriously discomfited by interference with ejaculation or if there are serious risks of cardiovascular or other autonomic toxicity, low doses of a potent neuroleptic might be preferred. If sedative effects are undesirable, a potent agent (aripiprazole or ziprasidone) is preferable. Small doses of antipsychotic drugs of high or moderate potency may be safest in the elderly, in whom the possible risk of stroke with risperidone and olanzapine must be considered. If hepatic function is compromised or there is a potential threat of jaundice, low doses of a high-potency agent may be used. The physician's experience with a particular drug may outweigh other considerations. Skill in the use of antipsychotic drugs depends on selection of an adequate but not excessive dose, knowledge of what to expect, and judgment as to when to stop therapy or change drugs.

A substantial minority of psychotic patients do poorly with any antipsychotic medicine, including clozapine. If a patient does not improve after a course of seemingly adequate treatment and fails to respond to another drug given in adequate dosage, the diagnosis should be reevaluated.

Usually 2–3 weeks or more are required to demonstrate obvious beneficial effects in schizophrenia patients; maximum benefit in chronically ill patients may require several months. In contrast, improvement of some acutely psychotic or manic patients can be seen within 48 hours. Aggressive dosing with high doses of an antipsychotic drug at the start of an acute episode of psychosis has not been found to increase either the magnitude or the rate of therapeutic responses. However, parenteral agents in moderate doses can bring about rapid sedation and may be useful in acute behavioral control. After the initial response, drugs usually are used in conjunction with psychological, supportive, and rehabilitative treatments.

There is no convincing evidence that combinations of antipsychotic drugs offer clear or consistent advantages. A combination of an antipsychotic drug and an antidepressant may be useful in some cases, especially in depressed psychotic patients or in cases of agitated major depression with psychotic features. The first combination antipsychotic/antidepressant (olanzapine/fluoxetine; SYMBYAX) was approved in the U.S. for treatment of depressive episodes associated with bipolar disorder. However, antidepressants and stimulants are unlikely to reduce apathy and withdrawal in schizophrenia, and they may induce clinical worsening in some cases. Adjunctive addition of lithium or an antimanic anticonvulsant may add benefit in some psychotic patients with prominent affective, aggressive, or resistant symptoms.

Optimal dosage of antipsychotic drugs requires individualization to determine doses that are effective, well tolerated, and accepted by the patient. Dose–response relationships for antipsychotic and adverse effects overlap, and it can be difficult to determine an end-point of a desired therapeutic response. To achieve control of symptoms in the treatment of acute psychoses, the dose of antipsychotic drug is increased as tolerated during the first few days. The dose is then adjusted during the next several weeks as the patient's condition warrants. Severe and poorly controlled agitation usually can be managed safely by use of adjunctive sedation (e.g., with a benzodiazepine such as lorazepam) and close supervision in a secure setting. One must remain alert for acute dystonic reactions, which are especially likely to appear early with aggressive use of potent neuroleptics, and for side effects such as hypotension. After an initial period of stabilization, regimens

based on a single daily dose often are effective and safe. The time of administration may be varied to minimize adverse effects.

Table 18–3 gives the usual and extreme ranges of dosage for antipsychotic drugs used in the U.S. The ranges have been established for the most part in the treatment of young and middle-aged adult patients diagnosed with schizophrenia or mania. Acutely disturbed hospitalized patients often require higher doses of an antipsychotic drug than do more stable outpatients. However, the concept that a low or flexible maintenance dose often will suffice during follow-up care of a partially recovered or chronic psychotic patient is well supported by controlled trials.

LONG-TERM TREATMENT

In reviews of nearly 30 controlled prospective studies involving several thousand schizophrenic patients, the mean overall relapse rate was 58% for patients withdrawn from antipsychotic drugs and given a placebo versus only 16% of those who continued on drug therapy. Daily dosage in chronic cases often can be lowered to 50–200 mg of chlorpromazine or its equivalent without signs of relapse, but rapid dose reduction or discontinuation appears to increase risk of exacerbation or relapse. Flexible therapy in which dosage is adjusted to changing current requirements can be useful and can reduce the incidence of adverse effects.

If the modern or atypical antipsychotic agents have superiority to older neuroleptics, this advantage is most important in the long-term treatment of chronic or recurrent psychotic illnesses, where it is standard practice to continue maintenance treatment with moderate and well-tolerated doses of an antipsychotic agent indefinitely, as long as the clinical indications, benefits, and tolerability remain clear. The only agent with securely proven superiority is clozapine. Nevertheless, there is some evidence that modern atypical antipsychotics may yield superior results in long-term treatment, if only due to superior tolerability and adherence to treatment.

Maintenance with injections of the decanoate ester of fluphenazine or haloperidol every 2–4 weeks, or with long-acting risperidone microspheres every 2–3 weeks, can be very effective. However, an expectation of superiority of long-acting injected antipsychotics is not well supported by available studies, most of which involve randomization of patients who already are largely cooperative with long-term oral treatment.

Special Populations

The treatment of some symptoms and behaviors associated with delirium or dementia is another accepted use for the antipsychotic drugs. They may be administered temporarily while a specific and correctable structural, infectious, metabolic, or toxic cause is vigorously sought. They sometimes are used for prolonged periods when no correctable cause can be found. There are no drugs of choice or clearly established dosage guidelines for such indications, although older neuroleptics of high potency are preferred. Modern atypical agents have not established their place in the management of delirium or dementia. In patients with delirium without likelihood of seizures, frequent small doses (e.g., 2–6 mg) of haloperidol or another potent antipsychotic may be effective in controlling agitation. Agents with low potency should be avoided because of their greater tendency to produce sedation, hypotension, and seizures, and those with central anticholinergic effects may worsen confusion and agitation.

A challenging special population is Parkinson's disease patients with psychotic symptoms related to dopaminergic therapy (see Chapter 20). Standard neuroleptics, risperidone (even in small doses), and olanzapine often produce unacceptable worsening of bradykinesia-akinesia. Clozapine is relatively well tolerated and effective, though more complicated to use. Use of moderate doses of newer agents with very low risk of parkinsonism (aripiprazole, quetiapine, ziprasidone) requires further study.

Most antipsychotics are rapidly effective in the treatment of mania and often are used concomitantly with the institution of lithium or anticonvulsant therapy (see below).

Antipsychotic drugs may have a limited role in the treatment of severe depression, especially in patients with striking agitation or psychotic features; addition of an antipsychotic to an antidepressant in this setting may yield results approaching those obtained with ECT. Antipsychotic agents ordinarily are not used for the treatment of anxiety disorders. The use of clozapine in patients with schizophrenia and a high risk of suicidal behavior may reduce the risk of suicide attempts. Clozapine is the first drug to be FDA-approved for an antisuicide indication.

Drug treatment of childhood psychosis and other behavioral disorders of children is confused by diagnostic inconsistencies and a paucity of controlled trials. Antipsychotics can benefit children with disorders characterized by features that occur in adult psychoses, mania, autism, or Tourette's syndrome. Low doses of the more potent or modern atypical agents usually are preferred in an attempt to avoid interference with daytime activities or performance in school. Attention deficit disorder, with or without hyperactivity, responds poorly to antipsychotic agents, but

often if the condition is not comorbid with bipolar disorder, responds very well to stimulants and some antidepressants. The recommended doses of antipsychotic agents for school-aged children with moderate degrees of agitation are lower than those for acutely psychotic children, who may require daily doses similar to those used in adults (Table 18–3). Doses of modern atypical antipsychotic agents for children and adolescents with psychotic or manic illness usually are started at the lower end of the range prescribed for adults.

Poor tolerance of the adverse effects of the antipsychotic drugs often limits the dose in elderly patients. One should proceed cautiously, using small, divided doses of agents with moderate or high potency, with the expectation that elderly patients will require doses that are one-half or less of those needed for young adults. The potential risk of stroke associated with risperidone and olanzapine in elderly patients should be considered.

MISCELLANEOUS MEDICAL USES FOR ANTIPSYCHOTIC DRUGS

Many antipsychotic agents can prevent vomiting due to specific etiologies when given in relatively low, nonsedative doses (see Chapter 37). Antipsychotic drugs are useful in the management of several syndromes with psychiatric features that also are characterized by movement disorders (e.g., Tourette's syndrome and Huntington's disease). Haloperidol currently is regarded as a drug of choice for these conditions, although it probably is not unique in its antidyskinetic actions. Pimozide also is used; clonidine and tricyclic antidepressants (e.g., nortriptyline) also may be effective in Tourette's syndrome. Antipsychotic drugs are not useful in the management of withdrawal from opioids, and their use in the management of withdrawal from barbiturates, other sedatives, or alcohol is contraindicated because of the high risk of seizures. These drugs can be used safely and effectively in psychoses associated with chronic alcoholism—especially the syndrome known as alcoholic hallucinosis.

II. TREATMENT OF MANIA

ANTIMANIC MOOD-STABILIZING AGENTS: LITHIUM

Evidence for the safety and the efficacy of lithium salts in the treatment of mania and the prevention of recurrent attacks of bipolar manic-depressive illness is both abundant and convincing. However, the limitations and adverse effects of lithium salts have become increasingly well appreciated, and efforts to find alternative antimanic or mood-stabilizing agents have intensified. The most successful alternatives or adjuncts to lithium to date are the anticonvulsants carbamazepine, lamotrigine, and valproic acid.

Pharmacological Properties

Lithium is the lightest of the alkali metals (group Ia); the salts of this monovalent cation share some characteristics with those of Na^+ and K^+ . Traces of the ion occur normally in animal tissues, but Li^+ has no known physiological role. In the U.S., the drug forms are the salts, lithium carbonate and lithium citrate. Therapeutic concentrations of Li^+ have almost no discernible psychotropic effects in normal individuals. Li^+ is not a sedative, depressant, or euphoriant, characteristics that differentiate it from other psychotropic agents. The precise mechanism of action of Li^+ as a mood-stabilizing agent remains unknown.

CENTRAL NERVOUS SYSTEM

A selective action of Li^+ is inhibition of inositol monophosphatase, thereby interfering with the phosphatidylinositol pathway (Figure 18–1). This effect can decrease cerebral inositol concentrations, possibly interfering with neurotransmission mechanisms by affecting the phosphatidylinositol pathway and decreasing the activation of PKC, particularly the α and β isoforms. This effect also is shared by valproic acid (particularly for PKC) but not carbamazepine. A major substrate for cerebral PKC is the myristoylated alanine-rich PKC-kinase substrate (MARCKS) protein, which has been implicated in synaptic and neuronal plasticity. The expression of MARCKS protein is reduced by treatment with both Li^+ and valproate but not by carbamazepine or antipsychotic, antidepressant, or sedative drugs. Both Li^+ and valproate treatment inhibit glycogen synthase kinase-3 β , which is involved in neuronal and nuclear regulatory processes, including limiting expression of the regulatory protein β -catenin. Both Li^+ and valproic acid affect gene expression, increasing DNA binding of the transcription factor activator protein-1 (AP-1) and altering expression of other transcription factors. Treatment with Li^+ and valproate has been associated

with increased expression of the regulatory protein B-cell lymphocyte protein-2 (*bcl-2*), which is associated with protection against apoptotic neuronal degeneration.

ABSORPTION, DISTRIBUTION, AND EXCRETION Li^+ is absorbed readily and almost completely from the GI tract. Complete absorption occurs in ~8 hours, with peak plasma concentrations occurring 2–4 hours after an oral dose. Slow-release preparations of lithium carbonate provide a slower rate of absorption and thereby minimize early peaks in Li^+ plasma concentrations, but absorption can be variable, lower GI tract symptoms may be increased, and elimination rate is not altered with such preparations. Li^+ initially is distributed in the extracellular fluid and then gradually accumulates in various tissues; it does not bind appreciably to plasma proteins. The final volume of distribution (0.7–0.9 L/kg) approaches that of total body water and is much lower than that of most other psychotropic agents, which are lipophilic and protein bound. Passage through the blood–brain barrier is slow, and when a steady state is achieved, the concentration of Li^+ in the cerebrospinal fluid and in brain tissue is ~40–50% of the concentration in plasma. Approximately 95% of a single dose of Li^+ is eliminated in the urine. From one- to two-thirds of an acute dose is excreted during a 6–12-hour initial phase of excretion, followed by slow excretion over the next 10–14 days. The elimination $t_{1/2}$ averages 20–24 hours. With repeated administration, Li^+ excretion increases during the first 5–6 days until a steady state is reached between ingestion and excretion. When Li^+ therapy is stopped, there is a rapid phase of renal excretion followed by a slow 10–14-day phase. Since 80% of the filtered Li^+ is reabsorbed by the proximal tubule, renal clearance of Li^+ is ~20% of that for creatinine, ranging between 15 and 30 mL/min. This rate is somewhat lower in elderly patients (10–15 mL/min). Loading with Na^+ slightly enhances Li^+ excretion, but Na^+ depletion promotes a clinically important degree of retention of Li^+ .

A well-established regimen can be complicated by occasional periods of Na^+ loss, as may occur with intercurrent fever, diarrhea, or other medical illness, with losses or restrictions of fluids and electrolytes, or during treatment with a diuretic. Heavy sweating may be an exception due to a preferential secretion of Li^+ over Na^+ in sweat.

Most of the renal tubular reabsorption of Li^+ occurs in the proximal tubule. Nevertheless, Li^+ retention can be increased by any diuretic that leads to depletion of Na^+ , particularly the thiazides (see Chapter 28). Renal excretion can be increased by administration of osmotic diuretics, acetazolamide or aminophylline, and triamterene. Spironolactone does not increase the excretion of Li^+ . Some nonsteroidal anti-inflammatory agents can facilitate renal proximal tubular reabsorption of Li^+ and thereby increase concentrations in plasma to toxic levels. This interaction appears to be particularly prominent with indomethacin, but also may occur with ibuprofen, naproxen, and COX-2 inhibitors, and possibly less so with sulindac and aspirin. A potential drug interaction can occur with angiotensin-converting enzyme inhibitors, causing lithium retention (see Chapter 29).

Less than 1% of ingested Li^+ leaves the human body in the feces, and 4–5% is secreted in sweat. Li^+ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. Since the ion also is secreted in human milk, women receiving Li^+ should not breast-feed infants.

Dose; Serum-Level Monitoring The recommended therapeutic concentration usually is attained by doses of 900–1500 mg of lithium carbonate per day in outpatients and 1200–2400 mg/day in hospitalized manic patients. The optimal dose tends to be larger in younger and heavier individuals. Because of its low therapeutic index, periodic determination of serum concentrations of Li^+ is crucial. Li^+ cannot be used safely in patients who cannot be tested regularly. Concentrations considered to be effective and acceptably safe are between 0.6 and 1.25 mEq/L. The range of 0.9–1.1 mEq/L is favored for treatment of acutely manic or hypomanic patients. Somewhat lower values (0.6–0.75 mEq/L) are considered adequate and are safer for long-term use for prevention of recurrent manic-depressive illness. Some patients may not relapse at concentrations as low as 0.5–0.6 mEq/L, and lower levels usually are better tolerated.

Serum concentrations of Li^+ have been found to follow a clear dose-effect relationship between 0.4 and 0.9 mEq/L, with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects, and little gain in benefit at levels above 0.75 mEq/L. This pattern indicates the need for individualization of serum levels to obtain a favorable risk-benefit relationship. The concentration of Li^+ in blood usually is measured at a trough of the daily oscillations that result from repetitive administration (*i.e.*, from samples obtained 10–12 hours after the last oral dose of the day). Peaks can be two or three times higher at a steady state. When the peaks are reached, intoxication may result, even when concentrations in morning samples of plasma at the daily nadir are in the acceptable range of 0.6–1 mEq/L. Because of the low margin of safety of Li^+ and because of its

short $t_{1/2}$ during initial distribution, divided daily doses are usually indicated even with slow-release formulations.

TOXIC REACTIONS AND SIDE EFFECTS Toxicity is related to the serum concentration of Li^+ and its rate of rise following administration. Acute intoxication is characterized by vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity are most likely to occur at the absorptive peak of Li^+ and include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the nervous system and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible. Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria. Adverse effects common even in therapeutic dose ranges include nausea, diarrhea, daytime drowsiness, polyuria, polydipsia, weight gain, fine hand tremor, and dermatological reactions, including acne.

A small number of patients treated with Li^+ develop diffuse thyroid enlargement; patients usually remain euthyroid, and overt hypothyroidism is rare. In patients who do develop goiter, discontinuation of Li^+ or treatment with thyroid hormone results in shrinkage of the gland.

The kidneys' ability to concentrate urine decreases during Li^+ therapy. Polydipsia and polyuria occur in patients treated with Li^+ , occasionally to a disturbing degree. Acquired nephrogenic diabetes insipidus can occur in patients maintained at therapeutic plasma concentrations (see Chapter 29). Typically, mild polyuria appears early in treatment and then disappears. Late-developing polyuria is an indication to evaluate renal function, lower the dose of Li^+ , or consider adding a potassium-sparing agent such as amiloride to counteract the polyuria. Polyuria disappears with cessation of Li^+ therapy. Since progressive, clinically significant impairment of renal function is rare, many experts consider these to be incidental findings. Nevertheless, plasma creatinine and urine volume should be monitored during long-term use of Li^+ .

Li^+ routinely causes EEG changes characterized by diffuse slowing, widened frequency spectrum, and potentiation with disorganization of background rhythm. Seizures have been reported in nonepileptic patients with therapeutic plasma concentrations of Li^+ . Myasthenia gravis may worsen during treatment with Li^+ . A benign, sustained increase in circulating polymorphonuclear leukocytes occurs during the chronic use of Li^+ , which reverses within a week after termination of treatment. Allergic reactions such as dermatitis and vasculitis can occur with Li^+ administration. Worsening of acne vulgaris is a common problem, and some patients may experience mild alopecia.

In pregnancy, Li^+ may exacerbate maternal polyuria. Concomitant use of lithium with natriuretics and a low- Na^+ diet during pregnancy can contribute to maternal and neonatal Li^+ intoxication. During postpartum diuresis, one can anticipate potentially toxic retention of Li^+ by the mother. Lithium freely crosses the placenta, and fetal or neonatal lithium toxicity may develop when maternal blood levels are within the therapeutic range. Lithium also is secreted in breast milk of nursing mothers. The use of Li^+ in pregnancy has been associated with neonatal goiter, CNS depression, hypotonia ("floppy baby" syndrome), and cardiac murmur. All of these conditions reverse with time, and no long-term neurobehavioral sequelae have been observed.

The use of Li^+ in early pregnancy may be associated with an increase in the incidence of cardiovascular anomalies of the newborn, especially Ebstein's malformation. The antimanic anti-convulsants valproic acid and probably carbamazepine have an associated risk of irreversible spina bifida that may exceed 1/100, and so do not represent a rational alternative for pregnant women. In balancing the risk versus benefit of using Li^+ in pregnancy, it is important to evaluate the risk of untreated manic-depressive disorder and to consider conservative measures, such as deferring intervention until symptoms arise or using a safer treatment, such as a neuroleptic or ECT.

TREATMENT OF LITHIUM INTOXICATION There is no specific antidote for Li^+ intoxication, and treatment is supportive. Vomiting induced by rapidly rising plasma Li^+ may tend to limit absorption, but fatalities have occurred. Care must be taken to assure that the patient is not Na^+ - and water-depleted. Dialysis is the most effective means of removing the ion from the body and is necessary in severe poisonings, *i.e.*, in patients exhibiting symptoms of toxicity or patients with serum Li^+ concentrations >4 mEq/L in acute overdoses or >1.5 mEq/L in chronic overdoses.

INTERACTIONS WITH OTHER DRUGS

Interactions between Li^+ and diuretics (especially spironolactone and amiloride) and nonsteroidal anti-inflammatory agents have been discussed above (see Absorption, Distribution, and Excretion and Toxic Reactions and Side Effects). Relative to thiazides and other diuretics that deplete Na^+ ,

retention of Li^+ may be limited during administration of the weakly natriuretic agent amiloride as well as the loop diuretic furosemide. Amiloride and other diuretic agents (sometimes with reduced doses of Li^+) have been used safely to reverse the syndrome of diabetes insipidus occasionally associated with Li^+ therapy (see Chapter 29).

Li^+ often is used in conjunction with antipsychotic, sedative, antidepressant, and anticonvulsant drugs. Case reports suggesting a risk of increased CNS toxicity when Li^+ is combined with haloperidol are at variance with many years of experience with this combination. Antipsychotic drugs may prevent nausea, which can be an early sign of Li^+ toxicity. There is no absolute contraindication to the concurrent use of Li^+ and psychotropic drugs. Finally, anticholinergic and other agents that alter GI motility also may alter Li^+ concentrations in blood over time.

Therapeutic Uses

DRUG TREATMENT OF BIPOLAR DISORDER Treatment with Li^+ ideally is conducted in cooperative patients with normal Na^+ intake and with normal cardiac and renal function. Occasionally, patients with severe systemic illnesses are treated with Li^+ , provided that the indications are compelling. Treatment of acute mania and the prevention of recurrences of bipolar illness in otherwise healthy adults or adolescents currently are the only uses approved by the FDA, even though the primary indication for Li^+ treatment is for long-term prevention of recurrences of major affective illness, particularly both mania and depression in bipolar I or II disorders.

Li^+ sometimes is used as an alternative or adjunct to antidepressants in severe, especially melancholic, recurrent depression, as a supplement to antidepressant treatment in acute major depression, including in patients who present clinically with only mild mood elevations or hypomania (bipolar II disorder), or as an adjunct when later response to an antidepressant alone is unsatisfactory. In major affective disorders, Li^+ has stronger evidence of reduction of suicide risk than any other treatment. Clinical experience also suggests the utility of Li^+ in the management of childhood disorders that are marked by adult-like manic depression or by severe changes in mood and behavior, which are probable precursors to bipolar disorder in adults. Evidence of efficacy of Li^+ in many additional episodic disorders (e.g., premenstrual dysphoria, episodic alcohol abuse, and episodic violence) is unconvincing.

FORMULATIONS Most preparations used in the U.S. are tablets or capsules of lithium carbonate. Slow-release preparations of lithium carbonate also are available, as is a liquid preparation of lithium citrate (with 8 mEq of Li^+ , equivalent to 300 mg of carbonate salt, per 5 mL or 1 teaspoonful of citrate liquid). The carbonate salt is favored for tablets and capsules because it is relatively less hygroscopic and less irritating to the gut than other salts, especially the chloride.

DRUG TREATMENT OF MANIA AND PROPHYLACTIC TREATMENT OF BIPOLAR DISORDER Lithium is effective in acute mania, but is rarely employed as a sole treatment due to its slow onset of action, need for monitoring blood Li^+ concentrations, and the difficulties associated with adherence to the therapeutic regimen by highly agitated and uncooperative manic patients. Rather, an antipsychotic or potent sedative benzodiazepine (such as *lorazepam* or *clonazepam*) commonly is used to attain a degree of control of acute agitation. Alternatively, the anticonvulsant sodium valproate can provide rapid antimanic effects, particularly when doses as high as 30 mg/kg and later 20 mg/kg daily are used to rapidly obtain serum concentrations of 90–120 $\mu\text{g}/\text{mL}$. Once patients are stabilized and cooperative, Li^+ can be introduced for longer-term mood stabilization, or the anticonvulsant may be continued alone (*see below*).

Li^+ or an alternative antimanic agent usually is continued for at least several months after full recovery from a manic episode, due to a high risk of relapse or of cycling into depression within 12 months. The clinical decision to recommend more prolonged maintenance treatment is based on balancing the frequency and severity of past episodes of manic-depressive illness, the age and estimated reliability of the patient, and the risk of adverse effects. Regardless of the number of previous episodes of mania or depression, or delay in initiating maintenance treatment, Li^+ remains the best established, long-term treatment to prevent recurrences of mania (and bipolar depression). There is compelling evidence of substantial lowering of risk of suicide and suicide attempts during treatment with lithium but not with either carbamazepine or *divalproex*.

Antimanic anticonvulsants, particularly sodium valproate and carbamazepine, also have been employed prophylactically in bipolar disorder. However, research supporting their long-term use remains limited, and there is growing evidence for the inferiority of carbamazepine compared to lithium (carbamazepine is not FDA-approved for bipolar disorder). *Divalproex*, the sodium salt of

valproic acid, is FDA-approved for mania and is extensively used off-label for long-term prophylactic treatment of bipolar disorder patients. In addition, lamotrigine is the first agent given FDA approval for long-term prophylactic treatment in bipolar disorder without an indication for acute mania; it is particularly effective against bipolar depression with minimal risk of inducing mania. Other anticonvulsants may have utility in bipolar disorder (*topiramate*, *zonisamide*, and the carbamazepine congener *oxcarbazepine*). Relevant pharmacology and dosing guidelines for anticonvulsants are in Chapter 19.

Antipsychotic drugs commonly have been used empirically to manage manic and psychotic illness in bipolar disorder patients. Indeed, standard neuroleptics are a mainstay of the treatment of acute mania (only chlorpromazine is FDA-approved for this indication, although haloperidol has also been widely used) and for manic episodes that break through prophylactic treatment with Li^+ or an anticonvulsant. However, the older antipsychotics are not used routinely for long-term prophylactic treatment in bipolar disorder because their effectiveness is untested, some may worsen depression, and the risk of tardive dyskinesia in these syndromes may be higher than in schizophrenia.

Several modern, better-tolerated antipsychotic agents (olanzapine, quetiapine, and risperidone) have recently received FDA approval for use in acute mania. There is also evidence of antimanic efficacy for aripiprazole and ziprasidone. Olanzapine is FDA-approved for its long-term effectiveness in bipolar disorder I. Other atypical antipsychotic drugs are under investigation for long-term prophylactic treatment of bipolar disorder.

Discontinuation of maintenance treatment with Li^+ carries a high risk of early recurrence and of suicidal behavior over a period of several months, even if the treatment had been successful for several years. Recurrence is much more rapid than is predicted by the natural history of untreated bipolar disorder, in which cycle lengths average ~1 year. When medically feasible, this risk probably can be moderated by slowing the gradual removal of Li^+ . Significant risk also is suspected after rapid discontinuation or even sharp dosage reduction during maintenance treatment with other agents, including antipsychotic, antidepressant, and anti-anxiety drugs.

Novel Treatments for Bipolar Disorder

For bipolar disorder, a critical challenge is to develop safe and effective antidepressants that do not induce mania and mood-stabilizing agents that consistently outperform lithium in broad effectiveness, with improved safety. The clinical successes of valproate and carbamazepine as antimanic agents, and of lamotrigine as a mood-stabilizing agent, have encouraged exploration of other anticonvulsants (see Chapter 19); several anticonvulsants are currently being tested in clinical trials. Aside from extensions of the known principles of applying anticonvulsants and antipsychotics for the treatment of bipolar disorder, some highly innovative concepts have emerged. Given the overlapping actions of lithium and valproate, it may be possible to develop novel antimanic agents that act directly on effector mechanisms that mediate the actions of adrenergic and other neurotransmitter receptors.

PHARMACOTHERAPY OF THE EPILEPSIES

A *seizure* is a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. *Epilepsy* refers to a disorder of brain function characterized by the periodic and unpredictable occurrence of seizures. Epileptic seizures have been classified into *partial* seizures, which begin focally in a cortical site, and *generalized* seizures, which involve both hemispheres widely from the outset. The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body part controlled by this region of cortex. A *simple* partial seizure is associated with preservation of consciousness. A *complex* partial seizure is associated with impairment of consciousness. The majority of complex partial seizures originate from the temporal lobe. Examples of generalized seizures include absence, myoclonic, and tonic-clonic.

Classification of epileptic syndromes guides clinical assessment and management, and in some cases, selection of antiseizure drugs (Table 19–1). More than 40 distinct epileptic syndromes have been categorized into partial versus generalized epilepsies. The partial epilepsies may consist of any of the partial seizure types and account for ~60% of all epilepsies; the etiology commonly consists of a lesion in some part of the cortex (e.g., tumor, developmental malformation, damage due to trauma or stroke), but may also be genetic. The generalized epilepsies account for ~40% of all epilepsies and usually are genetic. The most common generalized epilepsy is juvenile myoclonic epilepsy, accounting for ~10% of all epileptic syndromes. This disorder presents in the early teens and is characterized by myoclonic, tonic-clonic, and often absence seizures. Like most generalized-onset epilepsies, juvenile myoclonic epilepsy is probably due to inheritance of multiple susceptibility genes.

NATURE AND MECHANISMS OF SEIZURES AND ANTISEIZURE DRUGS

PARTIAL EPILEPSIES

Either reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might trigger a seizure. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with γ -aminobutyric acid (GABA) and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively (see Chapter 12). Pharmacological studies showed that antagonists of the GABA_A receptor or agonists of different glutamate-receptor subtypes (NMDA, AMPA, or kainic acid; see Table 12–1) trigger seizures in experimental animals. Conversely, drugs that enhance GABA-mediated synaptic inhibition or glutamate-receptor antagonists inhibit seizures. Such studies support the concept that pharmacological modulation of synaptic function can affect the propensity for seizures.

Electrophysiological analyses during a partial seizure demonstrate that the individual neurons undergo depolarization and fire action potentials at high frequencies. This pattern of rapid firing is characteristic of a seizure but is uncommon during normal neuronal activity. Thus, selective inhibition of this rapid firing would be expected to reduce seizures with minimal unwanted effects. Inhibition of the high-frequency firing may be mediated by reducing the ability of Na⁺ channels to recover from inactivation, thus prolonging the refractory period when another action potential cannot be evoked. Thus, reducing the rate of recovery of Na⁺ channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of carbamazepine, lamotrigine, phenytoin, topiramate, valproic acid, and zonisamide against partial seizures (Figure 19–1).

Enhancing GABA-mediated synaptic inhibition may reduce neuronal excitability and raise the seizure threshold. Several drugs may inhibit seizures by regulating GABA-mediated synaptic inhibition. The principal postsynaptic receptor of synaptically released GABA is the GABA_A receptor (see Chapter 16). Activation of the GABA_A receptor inhibits the postsynaptic cell by increasing Cl⁻ inflow into the cell and hyperpolarizing the neuron. Clinically relevant concentrations of benzodiazepines and barbiturates enhance GABA_A receptor-mediated hyperpolarization through distinct actions on the GABA_A receptor; this enhanced inhibition probably underlies their effectiveness against partial and tonic-clonic seizures (Figure 19–2). At higher concentrations, such as might be used for status epilepticus, these drugs also inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the antiseizure mechanism of tiagabine which inhibits the GABA transporter GAT-1 and reduces neuronal and glial uptake of GABA and thereby enhancing GABA-mediated neurotransmission (Figure 19–2).

Table 19-1

Classification of Epileptic Seizures

Seizure Type	Features	Conventional Antiseizure Drugs	Recently Developed Antiseizure Drugs
<i>Partial seizures:</i>			
Simple partial	Diverse manifestations determined by the region of cortex activated by the seizure (<i>e.g.</i> , if motor cortex representing left thumb, clonic jerking of left thumb results; if somatosensory cortex representing left thumb, paresthesia of left thumb results), lasting ~20–60 seconds. <i>Key feature is preservation of consciousness.</i>	Carbamazepine, phenytoin, valproate	Gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
Complex partial	Impaired consciousness lasting 30 seconds to 2 minutes, often associated with purposeless movements such as lip smacking or hand wringing.	Carbamazepine, phenytoin, valproate	Gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
Partial with secondarily generalized tonic-clonic seizure	Simple or complex partial seizure evolves into a tonic-clonic seizure with loss of consciousness and sustained contractions (tonic) of muscles throughout the body followed by periods of muscle contraction alternating with periods of relaxation (clonic), typically lasting 1 to 2 minutes.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Gabapentin, lamotrigine, levetiracetam, tiagabine, topiramate, zonisamide
<i>Generalized seizures:</i>			
Absence seizure	Abrupt onset of impaired consciousness associated with staring and cessation of ongoing activities typically lasting <30 seconds.	Ethosuximide, valproate	Lamotrigine
Myoclonic seizure	A brief (perhaps a second), shock-like contraction of muscles which may be restricted to part of one extremity or may be generalized.	Valproate	Lamotrigine, topiramate
Tonic-clonic seizure	As described above for partial with secondarily generalized tonic-clonic seizures except that it is not preceded by a partial seizure.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Lamotrigine, topiramate

FIGURE 19-1 Antiseizure drug-enhanced Na⁺ channel inactivation. Some antiseizure drugs (shown in blue text) prolong the inactivation of the Na⁺ channels, thereby reducing the ability of neurons to fire at high frequencies. Note that the inactivated channel itself appears to remain open, but is blocked by the inactivation gate (I). A, activation gate.

FIGURE 19-2 Enhanced GABA synaptic transmission. In the presence of GABA, the GABA_A receptor (structure on left) is opened, allowing an influx of Cl⁻, which in turn increases membrane polarization (see Chapter 16). Some antiseizure drugs (shown in larger blue text) act by reducing the metabolism of GABA. Others act at the GABA_A receptor, enhancing Cl⁻ influx in response to GABA. As outlined in the text, gabapentin acts presynaptically to promote GABA release; its molecular target is currently under investigation. GABA-T, GABA transaminase; GAT-1, GABA transporter.

GENERALIZED-ONSET EPILEPSIES: ABSENCE SEIZURES In contrast to partial seizures, which arise from localized regions of the cerebral cortex, generalized-onset seizures arise from the reciprocal firing of the thalamus and cerebral cortex. For absence seizures, the electroencephalogram (EEG) hallmark is generalized spike-and-wave discharges at a frequency of 3/sec (3 Hz) that represent oscillations between the thalamus and neocortex. The EEG spikes are associated with the firing of action potentials; the following slow wave is associated with prolonged inhibition. One intrinsic property of thalamic neurons that is involved in the generation of the 3-Hz discharges is a particular form of voltage-regulated Ca^{2+} current, the low threshold (“T”) current. In contrast to its small size in most neurons, the T current in many thalamic neurons has a large amplitude. Indeed, bursts of action potentials in thalamic neurons are mediated by activation of the T current. The T current plays an amplifying role in thalamic oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Drugs effective against absence seizures (e.g., *ethosuximide*, valproic acid) are thought to act by inhibition of the T current (Figure 19–3). Thus, inhibition of voltage-regulated ion channels is a common mechanism of action of antiseizure drugs, with anti-partial-seizure drugs inhibiting voltage-activated Na^+ channels and anti-absence-seizure drugs inhibiting voltage-activated Ca^{2+} channels.

GENETIC APPROACHES TO THE EPILEPSIES Most patients with epilepsy are neurologically normal; elucidating mutant genes underlying familial epilepsy in otherwise normal individuals has led to the identification of genes implicated in distinct, albeit rare, idiopathic epilepsy syndromes that account for <1% of all human epilepsies. Interestingly, almost all of the mutant genes encode ion channels that are gated by voltage or ligands. Mutations have been identified in voltage-gated Na^+ and K^+ channels and in channels gated by GABA and acetylcholine. The cellular electrophysiological consequences of some of these mutations may relate to mechanisms of seizures and antiseizure drugs. For example, generalized epilepsy with febrile seizures is caused by a point mutation in the β subunit of a voltage-gated Na^+ channel (*SCN1B*) that appears to interfere with channel inactivation.

ANTISEIZURE DRUGS: GENERAL CONSIDERATIONS

THERAPEUTIC ASPECTS The ideal antiseizure drug would suppress all seizures without causing any unwanted effects. Drugs used currently not only fail to control seizure activity in some patients, but frequently cause unwanted effects that range in severity from minimal impairment of the central nervous system (CNS) to death from aplastic anemia or hepatic failure. The task is to select the drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. Complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. Success varies as a function of seizure type, cause, and other factors. To minimize toxicity, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to concurrent administration of a second agent. However, multiple-drug therapy may be needed, especially when two or more types of seizure occur in the same patient.

FIGURE 19–3 Antiseizure drug-induced reduction of current through T-type Ca^{2+} channels. Some antiseizure drugs (shown in blue text) reduce the flow of Ca^{2+} through T-type Ca^{2+} channels (see Chapter 12), thus reducing the pacemaker current that underlies the thalamic rhythm in spikes and waves seen in generalized absence seizures.

Measurement of drug concentrations in plasma facilitates pharmacotherapy, especially when therapy is initiated, after dosage adjustments, in the event of therapeutic failure, when toxic effects appear, or when multiple-drug therapy is instituted. However, clinical effects of some drugs do not correlate well with their plasma concentrations, and recommended concentrations are only guidelines. The ultimate therapeutic regimen must be determined by clinical assessment of efficacy and toxicity.

Phenytoin

Phenytoin (DILANTIN) is effective against all types of partial and tonic-clonic seizures but not absence seizures.

PHARMACOLOGICAL EFFECTS

Central Nervous System Phenytoin exerts antiseizure activity without causing general CNS depression. In toxic doses, phenytoin may produce excitatory signs and, at lethal levels, a type of decerebrate rigidity.

MECHANISM OF ACTION

Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization. This effect is mediated by a slowing of the rate of recovery of voltage-activated Na⁺ channels from inactivation. At therapeutic concentrations, the effects on Na⁺ channels are selective, without changes in spontaneous activity or in responses to GABA or glutamate. At concentrations five- to tenfold higher, other effects of phenytoin include reduction of spontaneous activity and enhancement of responses to GABA that may underlie some of the toxicity associated with high levels of phenytoin.

PHARMACOKINETIC PROPERTIES Phenytoin is available in rapid-release and extended-release oral forms; once-daily dosing is possible only with extended-release formulations. Due to differences in dissolution and other formulation-dependent factors, the plasma phenytoin level may change upon conversion from one formulation to the other. Different formulations can include either phenytoin or phenytoin sodium; therefore, comparable doses can be approximated by considering “phenytoin equivalents,” but serum level monitoring is necessary to assure therapeutic safety.

Phenytoin is extensively (~90%) bound to serum proteins, mainly albumin. Small variations in the bound fraction dramatically affect the absolute amount of free (active) drug; increased proportions of free drug are evident in the neonate, in patients with hypoalbuminemia, and in uremic patients. Some agents (*e.g.*, valproic acid) can compete with phenytoin for binding sites on plasma proteins; when combined with valproate-mediated inhibition of phenytoin metabolism, marked increases in free phenytoin can result.

Phenytoin's rate of elimination varies as a function of its concentration (*i.e.*, the rate is nonlinear). The plasma $t_{1/2}$ of phenytoin ranges between 6 and 24 hours at plasma concentrations <10 $\mu\text{g/mL}$ but increases with higher concentrations. As a result, plasma concentration increases disproportionately as dosage is increased, even with small adjustments for levels near the therapeutic range.

Phenytoin is largely (95%) metabolized by hepatic CYPs (Table 19–2). The principal metabolite, a parahydroxyphenyl derivative, is inactive. Phenytoin metabolism is saturable, and other substrates of these CYPs can inhibit phenytoin metabolism and increase its plasma concentration. Conversely, phenytoin will reduce the degradation of other drugs that are substrates for these enzymes, such as *warfarin*. The addition of phenytoin to a patient receiving *warfarin* can lead to bleeding disorders (*see* Chapter 54). Other drug interactions arise from phenytoin's capacity to induce CYPs (*see* Chapter 3 and Table 19–2) and increase the degradation of drugs (*e.g.*, oral contraceptives) metabolized by CYP3A4; treatment with phenytoin could enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. The potential teratogenic effects of phenytoin underscore the importance of attention to this interaction. Carbamazepine, *oxcarbazepine*, phenobarbital, and *primidone* also can induce CYP3A4 and likewise might increase degradation of oral contraceptives.

The low aqueous solubility of phenytoin hindered its intravenous use. Fosphenytoin (CEREBYX), a water soluble prodrug, is rapidly converted into phenytoin by phosphatases in liver and erythrocytes. Fosphenytoin is extensively (95–99%) bound to plasma proteins, primarily albumin. This binding is saturable, and fosphenytoin displaces phenytoin from binding sites. Fosphenytoin is useful for adults with partial or generalized seizures when intravenous or intramuscular administration is indicated.

TOXICITY The toxic effects of phenytoin depend on the route of administration, the duration of exposure, and the dosage.

When fosphenytoin is administered intravenously at an excessive rate in the emergency treatment of status epilepticus, the most notable toxic signs are cardiac arrhythmias, with or without hypotension, and/or CNS depression. Cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease but also can develop in young, healthy patients. These complications can be minimized by administering fosphenytoin at a rate of <150 mg of phenytoin sodium equivalent per minute. Acute oral overdosage results primarily in signs referable to the cerebellum and vestibular system; high doses have been associated with marked cerebellar atrophy. Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased seizure frequency, gastrointestinal (GI) symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is an annoying untoward effect in young females. Usually, these phenomena can be diminished by proper adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of rare drug allergy and necessitate drug withdrawal. Moderate elevation of hepatic transaminases sometimes is observed; since these changes are transient and may result in part from induced synthesis of the enzymes, they do not necessitate drug withdrawal.

Gingival hyperplasia, apparently due to altered collagen metabolism, occurs in ~20% of patients during chronic therapy and is probably the most common toxicity in children and young adolescents. It may be more frequent in individuals who also develop coarsened facial features. Toothless portions of the gums are not affected. The condition does not necessarily require withdrawal of medication and can be minimized by good oral hygiene.

A variety of endocrine effects have been reported. Inhibition of vasopressin release has been observed in patients with inappropriate secretion of this hormone. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia has been attributed to altered metabolism of vitamin D and the attendant inhibition of intestinal Ca^{2+} absorption. Phenytoin also increases the metabolism of vitamin K and reduces the concentration of vitamin K-dependent proteins that are important for normal Ca^{2+} metabolism in bone, perhaps explaining why the osteomalacia does not always respond to vitamin D.

Hypersensitivity reactions include morbilliform rash in 2–5% of patients and occasionally more serious skin reactions, including Stevens-Johnson syndrome. Systemic lupus erythematosus and potentially fatal hepatic necrosis have been reported rarely. Hematological reactions include neutropenia and leucopenia, or more rarely, red-cell aplasia, agranulocytosis, and thrombocytopenia. Lymphadenopathy is associated with reduced immunoglobulin A (IgA) production. Hypoprotrombinemia and hemorrhage have occurred in the newborns of mothers who received phenytoin during pregnancy; vitamin K is effective treatment or prophylaxis.

PLASMA DRUG CONCENTRATIONS

A good correlation usually is observed between the total concentration of phenytoin in plasma and its clinical effect. Thus, control of seizures generally is obtained with concentrations $>10 \mu\text{g/mL}$, while toxic effects (e.g., nystagmus) develop at concentrations $\sim 20 \mu\text{g/mL}$.

DRUG INTERACTIONS

Concurrent administration of any drug metabolized by CYP2C9 or CYP2C10 can increase the plasma concentration of phenytoin by decreasing its rate of metabolism. Conversely, drugs that induce hepatic CYPs can increase phenytoin catabolism. Thus, carbamazepine causes a decrease in phenytoin concentration and phenytoin reduces the concentration of carbamazepine. Interaction between phenytoin and phenobarbital is variable.

THERAPEUTIC USES

Epilepsy Phenytoin is effective against partial and tonic-clonic but not absence seizures. Phenytoin preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to temporarily switch between products, care should be taken to select a therapeutically equivalent product and patients should be monitored for loss of seizure control or onset of new toxicities.

Other Uses

Some cases of trigeminal and related neuralgias appear to respond to phenytoin, but carbamazepine is preferred.

ANTISEIZURE BARBITURATES

Most barbiturates have antiseizure properties. The discussion below is limited to the two barbiturates that exert maximal antiseizure action at doses below those required for hypnosis, a property that determines their clinical utility as antiseizure agents. The pharmacology of barbiturates is considered in Chapter 16.

Phenobarbital

Phenobarbital (LUMINAL, others) was the first effective organic antiseizure agent. It has relatively low toxicity, is inexpensive, and is still an effective and widely used drug for this purpose.

Mechanism of Action

Phenobarbital likely inhibits seizures by potentiation of synaptic inhibition through an action on the GABA_A receptor. At therapeutic concentrations, phenobarbital enhances GABA_A receptor-mediated current by increasing the duration of bursts of current without changing their frequency. At levels exceeding therapeutic concentrations, phenobarbital also limits sustained repetitive firing; this may underlie some of the antiseizure effects of higher concentrations of phenobarbital achieved during therapy of status epilepticus.

PHARMACOKINETIC PROPERTIES Oral absorption of phenobarbital is complete but slow; peak plasma concentrations occur several hours after a single dose. Phenobarbital is 40–60% bound to plasma and tissue proteins. Up to 25% of a dose is eliminated by renal excretion of the unchanged drug; the remainder is inactivated by hepatic CYPs. Phenobarbital induces UGTs and several CYPs, thereby stimulating degradation of drugs cleared by these mechanisms (see Table 19–2).

TOXICITY

Sedation, the most frequent undesired effect of phenobarbital, is apparent to some extent in all patients upon drug initiation, but tolerance develops during chronic therapy. Nystagmus and ataxia occur at excessive dosage. Phenobarbital sometimes produces irritability and hyperactivity in children and agitation and confusion in the elderly. Scarlatiniform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1–2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received phenobarbital during pregnancy. As with phenytoin, megaloblastic anemia that responds to folate and osteomalacia that responds to vitamin D occur during chronic phenobarbital therapy.

PLASMA DRUG CONCENTRATIONS

During long-term therapy in adults, the plasma concentration of phenobarbital averages $10 \mu\text{g/mL}$ per daily dose of 1 mg/kg ; in children, the value is $5\text{--}7 \mu\text{g/mL}$ per 1 mg/kg . Although there is no

precise relationship between efficacy and drug concentration, plasma concentrations of 10–35 µg/mL are usually recommended. The relationship between plasma phenobarbital concentration and adverse effects varies with the development of tolerance. Sedation, nystagmus, and ataxia usually are absent at concentrations <30 µg/mL during long-term therapy; adverse effects may be apparent for several days at lower concentrations when therapy is initiated or when dosage is increased. Concentrations >60 µg/mL may be associated with marked intoxication in the nontolerant individual.

Since significant behavioral toxicity may be present despite the absence of overt signs of toxicity, the tendency to maintain patients, particularly children, on excessively high doses of phenobarbital should be resisted. The plasma phenobarbital concentration should be increased above 30–40 µg/mL only if the increment is adequately tolerated and only if it contributes significantly to seizure control.

DRUG INTERACTIONS

Interactions between phenobarbital and other drugs usually involve induction of the hepatic CYPs by phenobarbital (see Table 19–2). Concentrations of phenobarbital in plasma may be elevated by up to 40% during concurrent administration of valproic acid (see below).

THERAPEUTIC USES Phenobarbital is an effective drug for generalized tonic-clonic and partial seizures. It is efficacious, inexpensive, and has low toxicity. However, its sedative effects and its tendency to disturb behavior in children have reduced its use.

Mephobarbital (MEBARAL) is *N*-methylphenobarbital. It is *N*-demethylated in the liver, and most of its activity during long-term therapy results from the accumulation of phenobarbital. Consequently, the pharmacological properties, toxicity, and clinical uses of mephobarbital are the same as those for phenobarbital.

IMINOSTILBENES

Carbamazepine

PHARMACOLOGICAL EFFECTS

Carbamazepine (TEGRETOL, CARBATROL, others) is a primary drug for the treatment of partial and tonic-clonic seizures and is also used for the treatment of trigeminal neuralgia. Although effects of carbamazepine resemble those of phenytoin, the drugs exhibit some important differences. For example, carbamazepine will produce therapeutic responses in manic-depressive patients, including some in whom lithium carbonate is not effective. The mechanisms responsible for these effects of carbamazepine are not clearly understood.

Mechanism of Action

Like phenytoin, carbamazepine appears to limit the repetitive firing of action potentials evoked by a sustained depolarization by slowing the rate of recovery of voltage-activated Na⁺ channels. At therapeutic concentrations, carbamazepine is selective in that there are no effects on spontaneous activity or on responses to GABA or glutamate. The carbamazepine metabolite, 10,11-epoxycarbamazepine, has similar effects and may contribute to the antiseizure efficacy of carbamazepine.

PHARMACOKINETIC PROPERTIES Carbamazepine is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually occur 4–8 hours after oral ingestion but may be delayed by up to 24 hours, especially following the administration of a large dose. The drug distributes rapidly into all tissues. Approximately 75% of carbamazepine binds to plasma proteins, and the drug concentration in the cerebrospinal fluid (CSF) corresponds to the concentration of free drug in plasma.

The predominant pathway of metabolism in humans involves conversion to the 10,11-epoxide. This metabolite is as active as the parent compound, and its concentrations in plasma and brain may reach 50% of those of carbamazepine, especially with concurrent administration of phenytoin or phenobarbital. The 10,11-epoxide is metabolized further to inactive compounds, which are excreted in the urine principally as glucuronides. Carbamazepine also is inactivated by conjugation and hydroxylation. Hepatic CYP3A4 is primarily responsible for biotransformation of carbamazepine. Carbamazepine induces CYP2C, CYP3A4, and UGT, thus enhancing the metabolism of drugs degraded by these enzymes (*e.g.*, oral contraceptives, which are metabolized by CYP3A4).

TOXICITY Acute intoxication with carbamazepine can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, untoward effects include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may

increase, especially with overdosage. Other adverse effects include nausea, vomiting, serious hematological toxicity (aplastic anemia, agranulocytosis), and hypersensitivity reactions (dermatitis, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with carbamazepine is water retention, with decreased osmolality and hyponatremia, especially in elderly patients with cardiac disease.

Some tolerance develops to the neurotoxic effects of carbamazepine, and they can be minimized by gradual increase in dosage. Carbamazepine causes a transient elevation of hepatic transaminases in 5–10% of patients. A transient, mild leukopenia occurs in ~10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. In ~2% of patients, a persistent leukopenia may develop that requires drug withdrawal. Aplastic anemia occurs in 1 in 200,000 patients who are treated; it is not clear whether periodic blood tests can avert the development of irreversible aplastic anemia. The induction of fetal malformations in pregnant women is discussed below.

PLASMA DRUG CONCENTRATIONS

There is no simple relationship between the dose of carbamazepine and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6–12 µg/mL, although considerable variation occurs. Side effects referable to the CNS are frequent at concentrations >9 µg/mL.

DRUG INTERACTIONS

Phenobarbital, phenytoin, and valproic acid may increase the metabolism of carbamazepine by inducing CYP3A4; carbamazepine may enhance the biotransformation of phenytoin. Concurrent administration of carbamazepine may lower concentrations of valproic acid, lamotrigine, tiagabine, and topiramate. Carbamazepine reduces both the plasma concentration and therapeutic effect of haloperidol. The metabolism of carbamazepine may be inhibited by propoxyphene, erythromycin, cimetidine, fluoxetine, and isoniazid.

THERAPEUTIC USES Carbamazepine is useful in patients with generalized tonic-clonic and both simple and complex partial seizures. Renal and hepatic function and hematological parameters should be monitored. The therapeutic use of carbamazepine is discussed below.

Carbamazepine is the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightning tabetic pain associated with bodily wasting. Most patients with neuralgia benefit initially, but only 70% obtain continuing relief. Adverse effects require discontinuation of medication in 5–20% of patients. The therapeutic range of plasma concentrations for antiseizure therapy serves as a guideline for its use in neuralgia. Carbamazepine also has found use in the treatment of bipolar affective disorders (see Chapter 18).

Oxcarbazepine

Oxcarbazepine (TRILEPTAL) (10,11-dihydro-10-oxocarbamazepine) is a keto analog of carbamazepine. Oxcarbazepine is a prodrug: it is rapidly converted to its active metabolite, a 10-monohydroxy derivative, which is inactivated by glucuronidation and eliminated by renal excretion. Its mechanism of action is similar to that of carbamazepine. Oxcarbazepine is a less potent enzyme inducer than is carbamazepine, and substitution of oxcarbazepine for carbamazepine is associated with increased levels of phenytoin and valproic acid, presumably because of reduced induction of hepatic enzymes. Although oxcarbazepine does not appear to reduce the anticoagulant effect of warfarin, it does induce CYP3A4 and thus reduces plasma levels of oral contraceptives. Oxcarbazepine is approved for monotherapy or adjunct therapy for partial seizures in adults and as adjunctive therapy for partial seizures in children ages 4–16.

SUCCINIMIDES

Ethosuximide

PHARMACOLOGICAL EFFECTS Ethosuximide (ZARONTIN) is a primary agent for the treatment of absence seizures.

Mechanism of Action Ethosuximide reduces low threshold Ca^{2+} currents (T currents) in thalamic neurons and thus modulates thalamic 3-Hz spike-and-wave activity. At clinically relevant concentrations, ethosuximide inhibits the T current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. Therapeutic concentrations of ethosuximide do not inhibit sustained repetitive firing or enhance GABA responses.

PHARMACOKINETIC PROPERTIES Absorption of ethosuximide appears to be complete, with peak concentrations in plasma within ~3 hours after a single oral dose. Ethosuximide is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. Approximately 25% of the drug is excreted unchanged in the urine; the remainder is metabolized by hepatic microsomal enzymes. The major metabolite, the hydroxyethyl derivative, accounts for 40% of administered drug, is inactive, and is excreted unchanged and as the glucuronide in urine. The plasma $t_{1/2}$ of ethosuximide is 40–50 hours in adults and ~30 hours in children.

TOXICITY Common dose-related side effects are GI complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccups); some tolerance to these effects develops. Parkinson-like symptoms and photophobia also have occurred. Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a history of psychiatric disturbance. Urticaria and other skin reactions, including Stevens-Johnson syndrome, as well as systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia have been attributed to the drug, and deaths have resulted from bone marrow depression.

PLASMA DRUG CONCENTRATIONS During long-term therapy, the plasma concentration of ethosuximide averages ~2 $\mu\text{g/mL}$ per daily dose of 1 mg/kg. A plasma concentration of 40–100 $\mu\text{g/mL}$ usually is required for satisfactory control of absence seizures.

THERAPEUTIC USES

Ethosuximide is effective against absence seizures but not tonic-clonic seizures. An initial dose of 250 mg in children (3–6 years old) and 500 mg in older children and adults is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to diminish nausea or drowsiness. The usual maintenance dose is 20 mg/kg/day. Use caution if the daily dose exceeds 1500 mg in adults or 750–1000 mg in children. The use of ethosuximide is discussed further below.

VALPROIC ACID

PHARMACOLOGICAL EFFECTS The antiseizure properties of valproic acid (DEPAKENE, others) were discovered serendipitously when it was employed as a vehicle for other compounds that were being screened for antiseizure activity. Its efficacy in animal models parallels its efficacy against absence as well as partial and generalized tonic-clonic seizures in humans.

Mechanism of Action

At therapeutic concentrations, valproic acid inhibits sustained repetitive firing induced by depolarization of mouse cortical or spinal cord neurons, an effect apparently mediated by prolonging the recovery phase of voltage-activated Na^+ channels. Valproic acid does not modify neuronal responses to GABA. Valproic acid also reduces the T Ca^{2+} current at clinically relevant but slightly higher concentrations than those that limit sustained repetitive firing; this effect on T currents in thalamic neurons is similar to that of ethosuximide. Limiting sustained repetitive firing and reducing T currents may contribute to the efficacy of valproic acid against partial and tonic-clonic seizures and absence seizures, respectively.

Another putative antiseizure action of valproic acid involves GABA metabolism. In vitro, valproic acid stimulates the activity of glutamic acid decarboxylase, the GABA synthetic enzyme, and inhibits GABA degradative enzymes.

PHARMACOKINETIC PROPERTIES Valproic acid is absorbed rapidly and completely after oral administration. Peak concentration in plasma is attained in 1–4 hours, or several hours later if the drug is administered in enteric-coated tablets or ingested with meals. Its extent of binding to plasma proteins is usually ~90%, but the bound fraction is reduced as the total concentration of valproic acid is increased through the therapeutic range. Although CSF concentrations of valproic acid suggest equilibration with free drug in the blood, there is evidence for carrier-mediated transport both into and out of the CSF.

The bulk of valproic acid (95%) undergoes hepatic metabolism (*via* UGTs and β -oxidation), with <5% excreted unchanged in urine. Valproic acid is a substrate for CYP2C9 and CYP2C19, but metabolism by these enzymes accounts for a relatively minor portion of its elimination. The metabolites, 2-propyl-2-pentenoic acid and 2-propyl-4-pentenoic acid, are nearly as potent antiseizure agents as valproate, but only the former significantly accumulates in plasma and brain. The $t_{1/2}$ of valproic acid is ~15 hours but is reduced in patients taking other antiepileptic drugs.

TOXICITY The most common side effects are transient GI symptoms, including anorexia, nausea, and vomiting in ~16% of patients. CNS effects include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally, and weight gain has been seen with chronic valproic acid treatment. Elevation of hepatic transaminases is observed in up to 40% of patients and often occurs asymptotically during the first several months of therapy.

A rare complication is fulminant hepatitis. Children <2 years of age with other medical conditions who were given multiple antiseizure agents were especially likely to suffer fatal hepatic injury; there were no deaths reported for patients >10 years old who received only valproate. Acute pancreatitis and hyperammonemia have been associated with the use of valproic acid. Valproic acid can produce teratogenic effects such as neural tube defects.

PLASMA DRUG CONCENTRATIONS

Therapeutic effects of valproic acid occur with plasma levels of 30–100 µg/mL, but there is a poor correlation between the plasma concentration and efficacy. There appears to be a threshold at ~30–50 µg/mL, the concentration at which binding sites on plasma albumin approach saturation.

DRUG INTERACTIONS

Valproic acid inhibits the metabolism of drugs that are substrates for CYP2C9, including phenytoin and phenobarbital. Valproic acid also inhibits UGT and thus inhibits the metabolism of lamotrigine and lorazepam. Valproic acid is highly bound to albumin and can displace phenytoin and other drugs; this displacement can exacerbate valproic acid's inhibition of phenytoin metabolism. The concurrent administration of valproate and clonazepam rarely has been associated with the development of absence status epilepticus.

THERAPEUTIC USES Valproate is effective in the treatment of absence, myoclonic, partial, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5–10 mg/kg/day to a maximum daily dose of 60 mg/kg. Divided doses should be given when the total daily dose exceeds 250 mg. The therapeutic uses of valproate in epilepsy are discussed further below.

BENZODIAZEPINES

The benzodiazepines are used primarily as sedative-antianxiety drugs (see Chapters 16 and 17) but also have broad antiseizure properties. Clonazepam (KLONOPIN) and *clorazepate* (TRANXENE-SD, others) have been approved in the U.S. for the long-term treatment of certain types of seizures. *Diazepam* (VALIUM, DIASTAT; others) and *lorazepam* (ATIVAN) have well-defined roles in the management of status epilepticus.

Mechanism of Action

Antiseizure actions of the benzodiazepines largely result from their capacity to enhance GABA-mediated synaptic inhibition (see Chapter 16). At therapeutic concentrations, benzodiazepines act at GABA_A receptors and increase the frequency, but not duration, of openings at GABA-activated Cl⁻ channels. At higher concentrations, diazepam and other benzodiazepines can reduce sustained, high-frequency firing of neurons. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with diazepam, they are considerably higher than those associated with antiseizure or anxiolytic effects in ambulatory patients.

PHARMACOKINETIC PROPERTIES Benzodiazepines are well absorbed orally, and peak plasma concentrations are usually reached within 1–4 hours. After intravenous administration, they redistribute in a manner typical of highly lipid-soluble agents (see Chapters 1 and 16). CNS effects develop rapidly but wane quickly as the drugs move to other tissues. Diazepam redistributes rapidly ($t_{1/2}$ of redistribution, ~1 hour). The extent of binding of benzodiazepines to plasma proteins correlates with lipid solubility, ranging from 99% for diazepam to ~85% for clonazepam.

The major metabolite of diazepam, *N*-desmethyl-diazepam, is somewhat less active than the parent drug and may act as a partial agonist. This metabolite also is produced by the rapid decarboxylation of clorazepate. Both diazepam and *N*-desmethyl-diazepam are slowly hydroxylated to other active metabolites such as *oxazepam*. The $t_{1/2}$ of diazepam in plasma is 1–2 days; that of *N*-desmethyl-diazepam is ~60 hours. Clonazepam is metabolized principally by reduction of the nitro group to produce inactive 7-amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The $t_{1/2}$ of clonazepam in plasma is 1 day. Lorazepam is metabolized chiefly by conjugation with glucuronic acid; its $t_{1/2}$ in plasma is ~14 hours.

TOXICITY The principal side effects of long-term oral therapy with clonazepam are drowsiness and lethargy. These occur in ~50% of patients initially, but tolerance often develops with continued administration. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation. Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances (aggression, hyperactivity, irritability, difficulty in concentration), especially in children, can be very troublesome. Anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated and status epilepticus may be precipitated if the drug is discontinued abruptly. Cardiovascular and respiratory depression may occur after the intravenous administration of diazepam, clonazepam, or lorazepam, particularly if other antiseizure agents or central depressants have been administered previously.

PLASMA DRUG CONCENTRATIONS

Because tolerance affects the relationship between drug concentration and drug antiseizure effect, plasma concentrations of benzodiazepines are of limited value.

THERAPEUTIC USES Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in children, but tolerance to its antiseizure effects usually develops within 1–6 months, after which some patients will not respond to clonazepam at any dosage. The initial dose of clonazepam for adults should not exceed 1.5 mg/day and for children 0.01–0.03 mg/kg/day. Dose-dependent side effects are reduced if two or three divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25–0.5 mg/day in children and 0.5–1 mg/day in adults. The maximal recommended dose is 20 mg/day for adults and 0.2 mg/kg/day for children.

Diazepam is an effective agent for treatment of status epilepticus, but its short duration of action is a disadvantage, leading to the more frequent use of lorazepam. Although diazepam is not useful as an oral agent for the treatment of seizure disorders, clorazepate is effective in combination with certain other drugs in the treatment of partial seizures (*see below*). The maximal initial dose of clorazepate is 22.5 mg/day in three portions for adults and 15 mg/day in two doses in children. Clorazepate is not recommended for children under the age of 9.

OTHER ANTISEIZURE DRUGS

Gabapentin

Gabapentin (NEURONTIN) is an antiseizure drug that consists of a GABA molecule covalently bound to a lipophilic cyclohexane ring. Gabapentin was designed to be a centrally active GABA agonist.

PHARMACOLOGICAL EFFECTS AND MECHANISMS OF ACTION Gabapentin's efficacy in animal models parallels that of valproic acid and distinguishes gabapentin from phenytoin and carbamazepine. Despite its design as a GABA agonist, gabapentin does not mimic GABA when applied to neurons in primary culture. Gabapentin may promote release of GABA. The drug binds a protein in cortical membranes with an amino acid sequence identical to that of the $\alpha 2\delta$ subunit of the L type voltage-sensitive Ca^{2+} channel but does not affect Ca^{2+} currents of the T, N, or L types in dorsal root ganglion cells.

PHARMACOKINETICS Gabapentin is absorbed after oral administration and excreted unchanged, mainly in the urine. Its $t_{1/2}$, when used as monotherapy, is 4–6 hours. It has no known interactions with other antiseizure drugs.

THERAPEUTIC USES

When combined with other antiseizure drugs, gabapentin is effective for partial seizures, with or without secondary generalization. Gabapentin (900 or 1800 mg/day) monotherapy is equivalent to carbamazepine (600 mg/day) for newly diagnosed partial or generalized epilepsy. Gabapentin also is used off-label for the treatment of migraine, chronic pain, and bipolar disorder. Gabapentin usually is effective at 900–1800 mg daily in three divided doses, although 3600 mg may be required in some patients. Therapy usually is begun with a low dose (300 mg once on the first day), which is increased in daily increments of 300 mg until an effective dose is reached.

TOXICITY Overall, gabapentin is well tolerated. The most common adverse effects are somnolence, dizziness, ataxia, and fatigue. These effects usually are mild and resolve within 2 weeks of onset during continued treatment.

Lamotrigine

Lamotrigine (LAMICTAL) was developed as an antifolate agent, based on the model that reducing folate would combat seizures. The antiseizure effect of lamotrigine is unrelated to its antifolate properties.

PHARMACOLOGICAL EFFECTS AND MECHANISMS OF ACTION Lamotrigine blocks sustained repetitive firing of neurons and delays recovery from inactivation of recombinant Na⁺ channels, mechanisms similar to those of phenytoin and carbamazepine that may explain lamotrigine's actions on partial and secondarily generalized seizures. However, lamotrigine is effective against a broader spectrum of seizures than phenytoin and carbamazepine, suggesting additional actions that may include inhibiting synaptic release of glutamate.

PHARMACOKINETICS AND DRUG INTERACTIONS Lamotrigine is completely absorbed from the GI tract and is metabolized primarily by glucuronidation. The plasma $t_{1/2}$ of a single dose is 15–30 hours. Administration of phenytoin, carbamazepine, or phenobarbital reduces the $t_{1/2}$ and plasma concentrations of lamotrigine. Conversely, addition of valproic acid markedly increases plasma concentrations of lamotrigine, likely by inhibiting glucuronidation. Addition of lamotrigine to valproic acid produces a reduction of valproate concentrations by ~25% over a few weeks. Concurrent use of lamotrigine and carbamazepine may be associated with increased levels of the 10,11-epoxide of carbamazepine and clinical toxicity.

THERAPEUTIC USE Lamotrigine is useful for monotherapy and add-on therapy of partial and secondarily generalized tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults.

Patients already taking antiseizure drugs that induce hepatic enzymes (e.g., carbamazepine, phenytoin, phenobarbital, or primidone) should be given lamotrigine initially at 50 mg/day for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/day each week up to a maintenance dose of 300–500 mg/day divided into two doses. For patients taking valproic acid in addition to an enzyme-inducing antiseizure drug, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/day for 2 weeks; the dose then can be increased by 25–50 mg/day every 1–2 weeks up to a maintenance dose of 100–150 mg/day divided into two doses.

TOXICITY Common adverse effects when lamotrigine is added to another antiseizure drug are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in children (~0.8%) is higher than in adults (0.3%).

Levetiracetam

Levetiracetam (KEPPRA) is the S-enantiomer of α -ethyl-2-oxo-1-pyrrolidineacetamide.

PHARMACOLOGICAL EFFECTS AND MECHANISM OF ACTION Levetiracetam exhibits clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. The mechanism by which levetiracetam exerts these antiseizure effects is unknown.

PHARMACOKINETICS AND DRUG INTERACTIONS Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% of which is unchanged drug; 24% of the drug is metabolized by hydrolysis of the acetamide group. Levetiracetam neither induces nor is a high-affinity substrate for CYPs or glucuronidases and thus does not interact with other antiseizure drugs, oral contraceptives, or anticoagulants.

THERAPEUTIC USE; TOXICITY The addition of levetiracetam to other antiseizure medications in adults with refractory partial seizures improved control in one clinical trial. Insufficient evidence is available on use of levetiracetam as monotherapy for partial or generalized epilepsy. The drug is well tolerated; adverse effects include somnolence, asthenia, and dizziness.

Tiagabine

Tiagabine (GABITRIL) is a derivative of nipecotic acid.

PHARMACOLOGICAL EFFECTS AND MECHANISM OF ACTION Tiagabine inhibits the GABA transporter, GAT-1, and thereby reduces GABA uptake into neurons and glia.

As a consequence, tiagabine prolongs the synaptic dwell time of GABA and increases the duration of synaptic inhibition.

PHARMACOKINETICS Tiagabine is rapidly absorbed after oral administration, extensively bound to serum or plasma proteins, and metabolized in the liver by CYP3A. Its $t_{1/2}$ (~8 hours) is shortened by 2–3 hours when the drug is coadministered with hepatic enzyme-inducers such as phenobarbital, phenytoin, or carbamazepine.

THERAPEUTIC USE Tiagabine is effective as add-on therapy of refractory partial seizures, with or without secondary generalization. Its efficacy as monotherapy for newly diagnosed or refractory partial and generalized epilepsy has not been established.

TOXICITY Adverse effects include dizziness, somnolence, and tremor, which are mild to moderate in severity and appear shortly after initiation of therapy. Tiagabine-enhanced effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures, suggesting that tiagabine may be contraindicated in patients with generalized absence epilepsy; patients with a history of spike-and-wave discharges have been reported to have exacerbations of their EEG abnormalities.

Topiramate

Topiramate (TOPAMAX) is a sulfamate-substituted monosaccharide.

PHARMACOLOGICAL EFFECTS AND MECHANISMS OF ACTION Topiramate reduces voltage-gated Na^+ currents in cerebellar granule cells and may act in a manner similar to phenytoin. In addition, topiramate activates a hyperpolarizing K^+ current, enhances postsynaptic GABA_A -receptor currents, and also limits activation of the AMPA-kainate-subtype(s) of glutamate receptor. Topiramate also is a weak carbonic anhydrase inhibitor.

PHARMACOKINETICS Topiramate is rapidly absorbed after oral administration, exhibits little (10–20%) binding to plasma proteins, and is mainly excreted unchanged in the urine. Its $t_{1/2}$ is ~1 day. Reduced plasma concentrations of estradiol occur with concurrent topiramate, suggesting that low-dose oral contraceptives should be avoided in this setting.

THERAPEUTIC USE Topiramate is equivalent to valproic acid and carbamazepine in children and adults with newly diagnosed partial and primary generalized epilepsy; the drug is also effective as monotherapy for refractory partial epilepsy and refractory generalized tonic-clonic seizures. Topiramate also is more effective than placebo against both drop attacks and tonic-clonic seizures in patients with Lennox-Gastaut syndrome.

TOXICITY Topiramate is well tolerated. Common adverse effects are somnolence, fatigue, weight loss, and nervousness. The drug can precipitate renal calculi (probably due to inhibition of carbonic anhydrase). Topiramate has been associated with cognitive impairment; patients may also complain about a change in the taste of carbonated beverages.

Zonisamide

Zonisamide (ZONEGRAN) is a sulfonamide derivative.

PHARMACOLOGICAL EFFECTS AND MECHANISMS OF ACTION Zonisamide inhibits both the T-type Ca^{2+} currents and the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na^+ channels in a manner similar to that of phenytoin and carbamazepine.

PHARMACOKINETICS Zonisamide is almost completely absorbed after oral administration, has a long $t_{1/2}$ (~63 hours), and is ~40% bound to plasma protein. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized zonisamide and a glucuronide of the CYP3A4 metabolite, sulfamoylacetil phenol. Phenobarbital, phenytoin, and carbamazepine decrease the plasma concentration/dose ratio of zonisamide, whereas lamotrigine increases this ratio. Zonisamide has little effect on the plasma concentrations of other antiseizure drugs.

THERAPEUTIC USE Clinical trials of patients with refractory partial seizures demonstrated that addition of zonisamide to other drugs was superior to placebo. Its efficacy as monotherapy for newly diagnosed or refractory epilepsy remains unproven.

TOXICITY Zonisamide is well tolerated. Adverse effects include somnolence, ataxia, anorexia, nervousness, and fatigue. Approximately 1% of individuals develop renal calculi during treatment with zonisamide, probably related to its ability to inhibit carbonic anhydrase.

GENERAL PRINCIPLES AND CHOICE OF DRUGS FOR THE THERAPY OF THE EPILEPSIES

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity (*see* Table 19–1). A balancing of efficacy and unwanted effects in the individual patient provides the optimal therapeutic choice.

The first consideration is whether to initiate treatment. For example, drug therapy may not be necessary after an isolated tonic-clonic seizure in a healthy young adult who lacks a family history of epilepsy and who has a normal neurological exam, EEG, and brain magnetic resonance imaging (MRI) scan—a setting where the risk of a drug reaction approximates the likelihood of seizure recurrence in the next year (15%). Alternatively, a similar seizure occurring in an individual with a positive family history of epilepsy, an abnormal neurological exam, an abnormal EEG, and an abnormal MRI carries a recurrence risk of 60% that favors initiation of therapy.

Unless extenuating circumstances exist (*e.g.*, status epilepticus), therapy should be initiated with a single drug, typically in dosage expected to provide a plasma concentration in the lower portion of the therapeutic range. To minimize dose-related adverse effects, therapy may be initiated at reduced dosage, increasing dosage at appropriate intervals, as required for control of seizures or as limited by toxicity, preferably assisted by monitoring of plasma drug concentrations.

Faulty compliance is the most frequent cause for failure of therapy with antiseizure drugs; regularity of medication is essential. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in ~50% of patients. If a seizure occurs despite therapeutic drug levels, the physician should assess the presence of potential precipitating factor (*e.g.*, sleep deprivation, concurrent febrile illness, or drugs, including caffeine or over-the-counter medications). If compliance is confirmed yet seizures persist, another drug should be substituted. Unless serious adverse effects of the drug dictate otherwise, dosage always should be reduced gradually when a drug is discontinued to minimize risk of seizure recurrence. In the case of partial seizures in adults, the diversity of available drugs permits selection of a second drug that acts by a distinct mechanism.

In the event that therapy with a second single drug also is inadequate, many physicians resort to treatment with two drugs simultaneously. This decision should not be taken lightly, because most patients obtain optimal seizure control with fewest unwanted effects when taking a single drug. Nonetheless, some patients will not be controlled adequately without the simultaneous use of two or more antiseizure drugs. No properly controlled studies have systematically compared one particular drug combination with another, and the chances of complete control with this approach are not high. It seems wise to select two drugs that act by distinct mechanisms (*e.g.*, one that promotes Na⁺ channel inactivation, another that enhances GABA-mediated synaptic inhibition). Additional issues are the unwanted effects of each drug and the potential drug interactions. Many of these drugs induce expression of CYPs and thereby alter the metabolism of themselves and/or other drugs (*see* Table 19–2).

DURATION OF THERAPY

*Antiseizure drugs are typically continued for at least 2 years. If the patient is seizure-free after 2 years, consideration should be given to discontinuing therapy. Factors associated with high risk for recurrent seizures following drug discontinuation include EEG abnormalities, a known structural lesion, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. The risk of recurrent seizures is ~25% in low-risk individuals and >50% in high-risk individuals. Typically, 80% of recurrences occur within 4 months of discontinuing therapy. The clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (*e.g.*, loss of driving privileges) against the implications of continuing medication (*e.g.*, cost, unwanted effects, implications of diagnosis of epilepsy). Ideally, tapering is performed over a period of several months.*

SIMPLE AND COMPLEX PARTIAL AND SECONDARILY GENERALIZED TONIC-CLONIC SEIZURES

Carbamazepine and phenytoin are the most effective overall drugs for monotherapy of partial or generalized tonic-clonic seizures. The choice between carbamazepine and phenytoin requires

assessment of toxic effects of each drug. Decreased libido and impotence were associated with both drugs (carbamazepine 13%, phenytoin 11%). Between carbamazepine and valproic acid, carbamazepine provides superior control of complex partial seizures. Overall, data demonstrate that carbamazepine and phenytoin are preferable for treatment of partial seizures, but phenobarbital and valproic acid are also efficacious. Control of secondarily generalized tonic-clonic seizures does not differ significantly with carbamazepine, phenobarbital, or phenytoin, and valproic acid is as effective as carbamazepine. Since secondarily generalized tonic-clonic seizures usually coexist with partial seizures, these data indicate that among drugs introduced before 1990, carbamazepine and phenytoin are the first-line drugs here.

A key issue is choosing the optimal drug for initiating treatment in the patient newly diagnosed with partial or generalized onset epilepsy. This issue may appear unimportant since ~50% of newly diagnosed patients become seizure free with the first drug, whether old or new drugs are used. However, responsive patients typically receive the initial drug for several years, underscoring the importance of proper drug selection. Phenytoin, carbamazepine, and phenobarbital induce hepatic CYPs, thereby complicating use of multiple antiseizure drugs as well as impacting metabolism of oral contraceptives, warfarin, and others. These drugs also enhance metabolism of endogenous compounds including gonadal steroids and vitamin D, potentially impacting reproductive function and bone density. By contrast, most of the newer drugs have little if any effect on the CYPs. Factors arguing against use of recently introduced drugs include higher costs and less clinical experience with the compounds. Unfortunately, prospective studies comparing newly introduced antiseizure drugs with drugs available before 1990 have not been performed such that one drug can be declared clearly superior. Although many experts advocate the use of gabapentin, lamotrigine, and topiramate as initial therapy for newly diagnosed partial or mixed seizure disorders, none of these drugs is FDA-approved for these indications.

ABSENCE SEIZURES

Data indicate that ethosuximide and valproic acid are equally effective in the treatment of absence seizures; 50–75% of newly diagnosed patients can be rendered free of seizures following therapy with either drug. In the event that tonic-clonic seizures are present or emerge during therapy, valproic acid is the agent of first choice. Lamotrigine is also effective for newly diagnosed absence epilepsy but is not FDA-approved for this indication.

MYOCLONIC SEIZURES

Valproic acid is the drug of choice for myoclonic seizures in juvenile myoclonic epilepsy, in which myoclonic seizures often coexist with tonic-clonic and absence seizures. No trials have examined any of the newly introduced drugs for patients with juvenile myoclonic epilepsy or other idiopathic generalized epilepsy syndromes.

FEBRILE CONVULSIONS

Two to four percent of children experience a convulsion associated with a febrile illness; 25–33% of these will have another febrile convulsion. Only 2–3% become epileptic in later years. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (i.e., the febrile seizure lasted more than 15 minutes, was one-sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is ~10%. For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered diazepam at the onset of fever may prevent recurrent seizures and avoid side effects of chronic therapy. Uncertain efficacy and substantial side effects argue against the use of chronic phenobarbital therapy for prophylactic purposes in this condition.

SEIZURES IN INFANTS AND YOUNG CHILDREN

Infantile spasms with hypsarrhythmia are refractory to the usual antiseizure agents; glucocorticoids are commonly used. Vigabatrin (γ -vinyl GABA) is efficacious in comparison to placebo, although constriction of visual fields has been reported in some adults treated with vigabatrin. Vigabatrin has orphan drug status in the U.S. for the treatment of infantile spasms and is available elsewhere.

Lamox-Gastaut syndrome is a severe form of epilepsy that usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Lamotrigine is an effective and well-tolerated drug for this treatment-resistant form of epilepsy; addition of lamotrigine to other antiseizure drugs may improve seizure control. Topiramate also has demonstrated efficacy in Lamox-Gastaut syndrome.

STATUS EPILEPTICUS AND OTHER CONVULSIVE EMERGENCIES

Status epilepticus is a neurological emergency. Mortality for adults is ~20%. The goal of treatment is rapid termination of behavioral and electrical seizure activity; the longer the episode of status epilepticus is untreated, the more difficult it is to control and the greater the risk of permanent brain damage. Critical to the management are a clear plan, prompt treatment with effective drugs in adequate doses, and attention to hypoventilation and hypotension. Since the high doses of drugs used may cause hypoventilation, it may be necessary to assist respiration temporarily. Drugs should be administered intravenously. Four regimens have similar success rates of 44–65%: diazepam followed by phenytoin; lorazepam; phenobarbital; and phenytoin alone. Studies show no significant differences with respect to recurrences or adverse reactions.

ANTISEIZURE THERAPY AND PREGNANCY

Antiseizure therapy has importance implications for women's health. The efficacy of oral contraceptives is reduced by concomitant use of antiseizure drugs (failure rate of 3.1/100 years versus 0.7/100 years in nonepileptic controls); this may relate to the increased rate of oral contraceptive metabolism caused by antiseizure drugs that induce hepatic enzymes (Table 19–2); particular caution is needed with antiseizure drugs that induce CYP3A4.

Infants of epileptic mothers are at twice the risk of major congenital malformations than offspring of nonepileptic mothers. These malformations include congenital heart defects and neural tube defects. A causal role for antiseizure drugs is suggested by association of congenital defects with higher concentrations of a drug or with polytherapy compared to monotherapy. Phenytoin, carbamazepine, valproate, and phenobarbital all have been associated with teratogenic effects. The antiseizure drugs introduced after 1990 have teratogenic effects in animals but whether such effects occur in humans is uncertain. One consideration for a woman with epilepsy who wishes to become pregnant is a trial period without antiseizure medication; monotherapy with careful attention to drug levels is another alternative. Polytherapy with toxic levels should be avoided. Folate supplementation (0.4 mg/day) is recommended for all women of childbearing age to reduce the likelihood of neural tube defects, and this is appropriate for epileptic women as well.

Antiseizure drugs that induce CYPs are associated with vitamin K deficiency in the newborn, possibly resulting in coagulopathy and intracerebral hemorrhage. Treatment of the mother with vitamin K₁, 10 mg/day during the last 2–4 weeks of gestation, has been recommended for prophylaxis.

TREATMENT OF CENTRAL NERVOUS SYSTEM DEGENERATIVE DISORDERS

Parkinson's disease (PD), Huntington's disease (HD), Alzheimer's disease (AD), and amyotrophic lateral sclerosis (ALS) are characterized by progressive and irreversible loss of neurons from specific regions of the brain. The pharmacotherapy of these neurodegenerative disorders is limited mostly to symptomatic treatments that do not alter the course of the underlying disease.

SELECTIVE NEURONAL VULNERABILITY

A striking feature of these disease processes is their specificity for particular types of neurons. In PD there is extensive destruction of the dopaminergic neurons of the substantia nigra; neurons in the cortex and many other areas of the brain are unaffected. In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even varies dramatically in different functional cortical regions. In HD, the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum. In ALS, there is loss of spinal motor neurons and the cortical neurons that provide their descending input. Currently, the processes of neural injury are viewed as the interaction of genetic and environmental influences with the intrinsic physiological characteristics of the affected populations of neurons.

Genetic predisposition plays a role in the etiology of neurodegenerative disorders. HD is transmitted by autosomal dominant inheritance, and the molecular nature of the genetic defect has been defined (*see below*). Most cases of PD, AD, or ALS are sporadic, but familial links occur and studies of familial disease are yielding clues to the pathogenesis of the disorders. Mutations in four different proteins can lead to genetically determined forms of PD: α -synuclein, an abundant synaptic protein; parkin, a ubiquitin hydrolase; UCHL1, which also participates in ubiquitin-mediated degradation of proteins in the brain; and DJ-1, a protein thought to be involved in the neuronal response to stress. Mutations in the genes encoding the amyloid precursor protein (APP) and proteins known as the presenilins, which may be involved in APP processing, lead to inherited forms of AD. Mutations in the gene encoding copper-zinc superoxide dismutase (*SOD1*) account for ~2% of cases of adult-onset ALS.

Apolipoprotein E (apoE) is a genetic risk factor for AD. There are four distinct isoforms of apoE, which is involved in transport of cholesterol and lipids in blood. Although all the isoforms function equally well, individuals who are homozygous for the apoE 4 allele ("4/4") have a much higher lifetime risk of AD than do those homozygous for the apoE 2 allele ("2/2"). The mechanism by which the apoE 4 protein increases the risk of AD is not known.

The decline in metabolic activity with age, oxidative stress, and the local production of oxygen radicals from the metabolism of dopamine via the Fenton reaction (Figure 20–1) may play roles in the etiology of some of these diseases.

PARKINSON'S DISEASE

CLINICAL OVERVIEW AND PATHOPHYSIOLOGY Parkinsonism has four cardinal features: bradykinesia (slowness and poverty of movement), muscular rigidity, resting tremor (which usually abates during voluntary movement), and an impairment of postural balance leading to disturbances of gait and falling. The pathological hallmark of PD is a loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta (SNpc) that provide dopaminergic innervation to the striatum (caudate and putamen). Progressive loss of dopaminergic neurons is a feature of normal aging; however, symptoms of PD coincide with excessive loss (70–80%) of these neurons. Without treatment, PD progresses over 5–10 years to a rigid, akinetic state in which patients are incapable of caring for themselves. Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has altered radically the prognosis of PD; in most cases, good functional mobility can be maintained for many years, and the life expectancy increased substantially. Several disorders other than PD also may produce parkinsonism, including some relatively rare neurodegenerative disorders, stroke, and intoxication with dopamine-receptor antagonists. Drugs in common clinical use that may cause parkinsonism include antipsychotics such as *haloperidol* and *thorazine* (*see Chapter 18*) and antiemetics such as *prochlorperazine* and *metoclopramide* (*see Chapter 37*). Parkinsonism arising from other causes usually is refractory to all forms of treatment.

FIGURE 20–1 Production of free radicals by the metabolism of dopamine. Dopamine is converted by monoamine oxidase (MAO) and aldehyde dehydrogenase (AD) to 3,4-dihydroxyphenylacetic acid (DOPAC), producing hydrogen peroxide (H₂O₂). In the presence of ferrous iron, H₂O₂ undergoes spontaneous conversion, forming a hydroxyl-free radical (the Fenton reaction).

DOPAMINE SYNTHESIS, METABOLISM, AND ACTION

Dopamine, a catecholamine, is synthesized in the terminals of dopaminergic neurons from tyrosine and stored, released, and metabolized by processes described in Chapter 6 and summarized in Figures 20–2 and 20–3. The actions of dopamine in the brain are mediated by dopamine receptors, all of which are heptahelical G protein–coupled receptors (GPCRs) (see Chapter 1). The five dopamine receptors can be divided into two groups on the basis of their pharmacological and structural properties (Figure 20–4). The D₁ and D₅ proteins have a long intracellular carboxy-terminal tail and are members of the class defined pharmacologically as D₁; they stimulate the formation of cyclic AMP and phosphatidylinositol hydrolysis. The D₂, D₃, and D₄ receptors share a large third intracellular loop and are of the D₂ class. They decrease cyclic AMP formation and modulate K⁺ and Ca²⁺ currents. Each of the five dopamine receptor proteins has a distinct anatomical distribution in the brain. The D₁ and D₂ proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D₄ and D₅ proteins are largely extrastriatal, whereas D₃ expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.

FIGURE 20–2 Dopaminergic terminal. Dopamine (DA) is synthesized in neuronal terminals from tyrosine by the sequential actions of tyrosine hydroxylase (TH), producing the intermediary L-dihydroxyphenylalanine (L-DOPA), and aromatic L-amino acid decarboxylase (AAD). In the terminal, DA is transported into storage vesicles by a vesicular membrane transporter (T). Release, triggered by depolarization and entry of Ca²⁺, allows dopamine to act on a variety of postsynaptic GPCRs for DA. The D₁ and D₂ receptors are important in brain regions involved in PD. The differential actions of DA on postsynaptic targets bearing different types of DA receptors have important implications for the function of neural circuits. The actions of DA are terminated by reuptake into the nerve terminal (where DA may be restored or metabolized) or uptake into the postsynaptic cell (where DA is metabolized). Metabolism occurs by the sequential actions of the enzymes catechol-O-methyltransferase (COMT), monoamine oxidase (MAO), and aldehyde dehydrogenase (AD). 3MT, 3-methoxytyramine; DOPAC, 3,4-dihydroxyphenylacetic acid; HVA, 3-methoxy-4-hydroxy-phenylacetic acid (see Figure 20–3). In humans, HVA is the principal metabolite of DA. (From Cooper *et al.*, 1996, with permission.)

NEURAL MECHANISM OF PARKINSONISM

The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Figure 20-5). The net effect of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex; the net effect of stimulating the indirect pathway at the level of

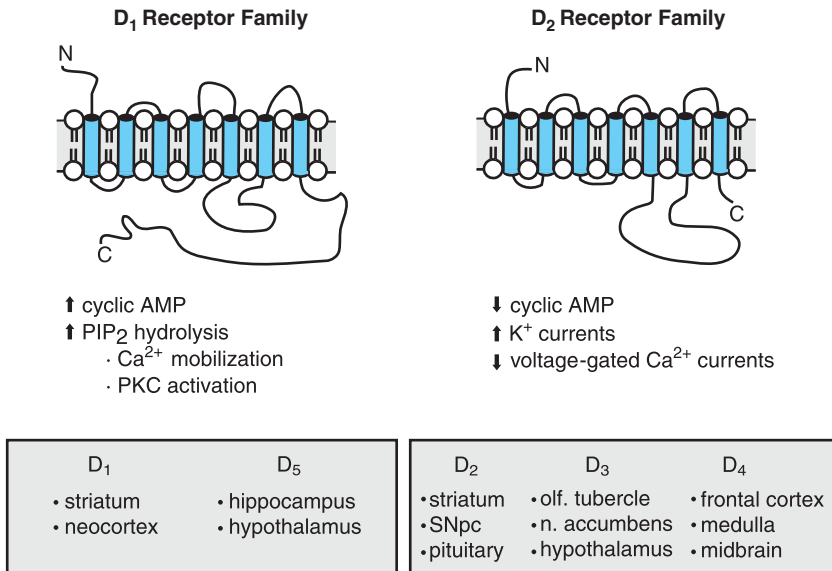

FIGURE 20-4 Distribution and characteristics of dopamine receptors in the central nervous system. SNpc, substantia nigra pars compacta.

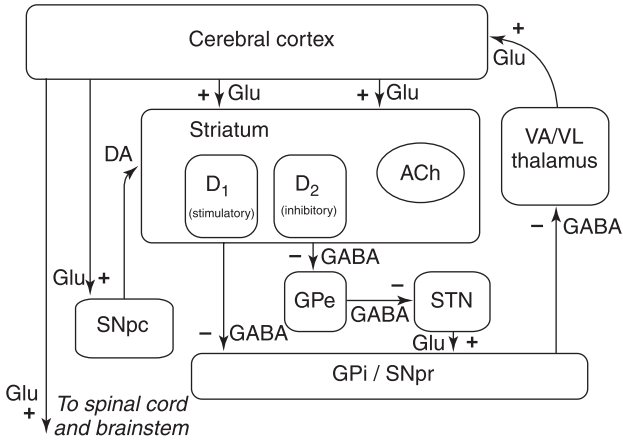

FIGURE 20-5 Schematic wiring diagram of the basal ganglia. The striatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of cerebral cortex. The striatum contains projection neurons expressing predominantly D₁ or D₂ dopamine receptors, as well as interneurons that use acetylcholine (ACh) as a neurotransmitter. Outflow from the striatum proceeds along two routes. The direct pathway, from the striatum to the substantia nigra pars reticulata (SNpr) and globus pallidus interna (GPe), uses the inhibitory transmitter GABA. The indirect pathway, from the striatum through the globus pallidus externa (GPe) and the subthalamic nucleus (STN) to the SNpr and GPe consists of two inhibitory GABAergic links and one excitatory glutamatergic projection (Glu). The substantia nigra pars compacta (SNpc) provides dopaminergic innervation to the striatal neurons, giving rise to both the direct and indirect pathways, and regulates the relative activity of these two paths. The SNpr and GPe are the output structures of the basal ganglia and provide feedback to the cerebral cortex through the ventroanterior and ventrolateral nuclei of the thalamus (VA/VL).

the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex. The key feature of this model of basal ganglia function that accounts for the symptoms observed in PD as a result of loss of dopaminergic neurons is the differential effect of dopamine on the direct and indirect pathways (Figure 20-6). The striatal neurons of the direct pathway express primarily the excitatory D₁ dopamine receptor protein, whereas the striatal neurons forming the indirect pathway

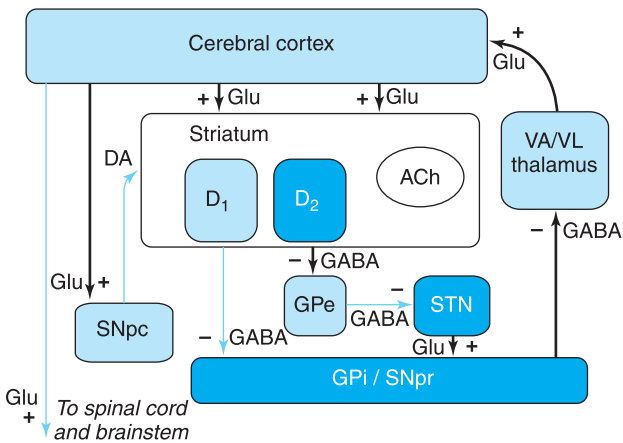

FIGURE 20-6 The basal ganglia in Parkinson's disease. The primary defect is destruction of the dopaminergic neurons of the SNpc. The striatal neurons that form the direct pathway from the striatum to the SNpr and GPe express primarily the excitatory D₁ dopamine receptor, whereas the striatal neurons that project to the GPe and form the indirect pathway express the inhibitory D₂ dopamine receptor. Thus, loss of the dopaminergic input to the striatum has a differential effect on the two outflow pathways; the direct pathway to the SNpr and GPe is less active (structures in light blue), whereas the activity in the indirect pathway is increased (structures in dark blue). The net effect is that neurons in the SNpr and GPe become more active. This leads to increased inhibition of the VA/VL thalamus and reduced excitatory input to the cortex. (See legend to Figure 20-5 for definitions of anatomical abbreviations.)

express primarily the inhibitory D_2 type. Thus, dopamine released in the striatum tends to increase the activity of the direct pathway and reduce the activity of the indirect pathway. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and globus pallidus interna (GPi) to the thalamus and reduce excitation of the motor cortex. Despite limitations, the model has utility for the rational design and use of pharmacological agents in PD. First, it suggests that to restore the balance of the system through stimulation of dopamine receptors, the complementary effect of actions at both D_1 and D_2 receptors, as well as the possibility of adverse effects that may be mediated by D_3 , D_4 , or D_5 receptors, must be considered. Second, it explains why replacement of dopamine is not the only approach to the treatment of PD. Drugs that inhibit cholinergic receptors are also effective; although their mechanisms of action are not completely understood, their effects are likely mediated at the level of the striatal projection neurons, which normally receive cholinergic input from striatal cholinergic interneurons. Few clinically useful drugs for parkinsonism are presently available based on actions through γ -aminobutyric acid (GABA) and glutamate receptors.

TREATMENT OF PARKINSON'S DISEASE

Commonly used medications and their dosage ranges for the treatment of PD are summarized in Table 20-1.

Levodopa

Levodopa (L-DOPA, LARODOPA, L-3,4-dihydroxyphenylalanine), the metabolic precursor of dopamine, is the single most-effective agent in the treatment of PD; the therapeutic and adverse effects of levodopa result from its decarboxylation to dopamine. Oral levodopa is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the drug in plasma usually peak between 0.5 and 2 hours after an oral dose. The $t_{1/2}$ in plasma is short (1–3 hours). The rate and extent of absorption of levodopa depend on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa. Competition for absorption sites in the small bowel from dietary amino acids also may alter absorption of levodopa; administration of levodopa with meals delays absorption and reduces peak plasma concentrations. A membrane transporter for aromatic amino acids facilitates entry of the drug into the CNS, and competition between dietary protein and levodopa may occur at this level. In the brain, levodopa is converted to dopamine by decarboxylation, primarily within the

Commonly Used Medications for the Treatment of Parkinson's Disease

Agent	Typical Initial Dose	Total Daily Dose— Useful Range	Comments
Carbidopa/levodopa	25 mg carbidopa + 100 mg levodopa (“25/100” tablet), twice or three times a day	200–1200 mg levodopa	
Carbidopa/levodopa sustained release	50 mg carbidopa + 200 mg levodopa (“50/200 sustained release” tablet) twice a day	200–1200 mg levodopa	Bioavailability 75% of immediate release form
Bromocriptine	1.25 mg twice a day	3.75–40 mg	Titrate slowly
Pergolide*	0.05 mg once a day	0.75–5 mg	Titrate slowly
Ropinirole	0.25 mg three times a day	1.5–24 mg	
Pramipexole	0.125 mg three times a day	1.5–4.5 mg	
Entacapone	200 mg with each dose of levodopa/carbidopa	600–2000 mg	
Tolcapone	100 mg twice a day or three times a day	200–600 mg	May be hepatotoxic; requires monitoring of liver enzymes
Selegiline	5 mg twice a day	2.5–10 mg	
Amantadine	100 mg twice a day	100–200 mg	
Trihexyphenidyl HCl	1 mg twice a day	2–15 mg

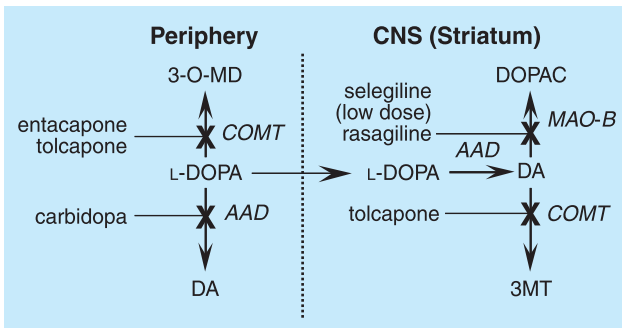

FIGURE 20-7 Pharmacological preservation of L-DOPA and striatal dopamine. The principal site of action of inhibitors of catechol-O-methyltransferase (COMT) (such as tolcapone and entacapone) is in the peripheral circulation. They block the O-methylation of levodopa (L-DOPA) and increase the fraction of the drug available for delivery to the brain. Tolcapone also has effects in the CNS. Inhibitors of MAO-B, such as low-dose selegiline and rasagiline, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores. AAD, aromatic L-amino acid decarboxylase; DA, dopamine; DOPAC, 3,4-dihydroxyphenylacetic acid; MAO, monoamine oxidase; 3MT, 3-methoxytyramine; 3-O-MD, 3-O-methyl DOPA.

presynaptic terminals of dopaminergic neurons in the striatum. The dopamine thus produced is responsible for the therapeutic effectiveness of levodopa in PD; after release, the dopamine is either transported back into dopaminergic terminals or postsynaptic cells, where it may be restored in granules (neurons) or metabolized by MAO and COMT (neurons and nonneurons) (Figure 20-3).

In practice, levodopa is generally administered with a peripherally acting inhibitor of aromatic L-amino acid decarboxylase (AAD) (e.g., carbidopa, benserazide) that does not penetrate well into the CNS. In the absence of decarboxylase inhibition, levodopa is largely decarboxylated in the intestinal mucosa and at other peripheral sites so that little of the parent drug reaches the cerebral circulation and probably <1% penetrates the CNS. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood-brain barrier (see Figure 20-7) and reduces the incidence of nausea and other GI side effects due to peripheral conversion of the drug to dopamine. Generally, a dose of 75 mg/day of carbidopa is sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of carbidopa/levodopa (SINEMET, ATAMET) is the 25/100 form, containing 25 mg carbidopa and 100 mg levodopa, 3–4 times daily. Administration of supplemental carbidopa (LODOSYN) may be beneficial in refractory cases.

Levodopa therapy can affect all the signs and symptoms of PD. In early PD, the duration of the beneficial effects of levodopa may exceed the plasma lifetime of the drug, suggesting that the nigrostriatal dopamine system retains some capacity to store and release dopamine. A principal limitation of the long-term use of levodopa therapy is that with time this apparent “buffering” capacity is lost, and the patient’s motor state may fluctuate dramatically with each dose of levodopa. A common problem is the development of the “wearing off” phenomenon: each dose of levodopa effectively improves mobility for a period of time, perhaps 1–2 hours, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of *dyskinesias*, excessive and abnormal involuntary movements that occur most often when the plasma levodopa concentration is high. Dyskinesias or dystonia may be triggered when the level is rising or falling, and these movements can be as uncomfortable and disabling as the rigidity and akinesia of PD. In the later stages of PD, patients may fluctuate rapidly between being “off,” having no beneficial effects from their medications, and being “on” but with disabling dyskinesias, a situation called the *on/off phenomenon*.

Due to the on/off phenomena and concerns about the exact role of dopamine’s contribution to free radical generation and tissue damage, most practitioners use levodopa only when the symptoms of PD cause functional impairment. When levodopa levels are maintained constant by intravenous infusion, dyskinesias and fluctuations are greatly reduced, and the clinical improvement is maintained for up to several days after returning to oral levodopa dosing. A sustained-release formulation and division of the total daily dose into more frequently administered portions have been used to overcome the on/off phenomenon.

In addition to motor fluctuations and nausea, several other adverse effects may be observed with levodopa treatment. A common and dose-limiting adverse effect is the induction of hallucinations and confusion, particularly in the elderly and in those with preexisting cognitive dysfunction. Conventional antipsychotic agents, such as the phenothiazines, are effective against levodopa-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D₂ dopamine receptor. A recent approach has been to use the "atypical" antipsychotic agents (e.g., clozapine and quetiapine), which are effective in the treatment of psychosis but do not cause or worsen parkinsonism. Peripheral decarboxylation of levodopa and release of dopamine into the circulation may activate vascular dopamine receptors and produce orthostatic hypotension. Actions of dopamine at α and β adrenergic receptors may induce cardiac arrhythmias, especially in patients with preexisting conduction disturbances. Administration of levodopa with nonspecific inhibitors of MAO (e.g., phenelzine, tranylcypromine) accentuates the actions of levodopa and may precipitate life-threatening hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors must be discontinued at least 14 days before levodopa is administered (note that this prohibition does not include the MAO-B subtype-specific inhibitor selegiline, which, as discussed below, often is administered safely in combination with levodopa). Abrupt withdrawal of levodopa or other dopaminergic medications may precipitate the neuroleptic malignant syndrome more commonly observed after treatment with dopamine antagonists.

DOPAMINE-RECEPTOR AGONISTS Direct agonists of striatal dopamine receptors offer several potential advantages. Since enzymatic conversion of these drugs is not required for activity, they do not depend on the functional capacities of the nigrostriatal neurons. Most dopamine-receptor agonists in clinical use have durations of action substantially longer than that of levodopa and are useful in the management of dose-related fluctuations in motor state. Finally, if free radical formation from dopamine metabolism actually contributes to neuronal death, then dopamine-receptor agonists may modify the course of the disease by reducing endogenous release of dopamine as well as the need for exogenous levodopa.

Four orally administered dopamine-receptor agonists are available for treatment of PD: two older agents, *bromocriptine* (PARLODEL) and *pergolide* (PERMAX); and two newer, more selective compounds, *ropinirole* (REQUIP) and *pramipexole* (MIRPEX). Bromocriptine and pergolide are ergot derivatives with similar therapeutic actions and adverse effects. Bromocriptine is a D₂ agonist and a partial D₁ antagonist; pergolide is an agonist of both receptor types. Ropinirole and pramipexole have selective activity at D₂ and D₃ receptors and little or no activity at receptors of the D₁ class. All four drugs are well absorbed orally and can relieve the clinical symptoms of PD. The duration of action of the dopamine agonists (8–24 hours) often is longer than that of levodopa (6–8 hours), and they are particularly effective in the treatment of patients who have developed on/off phenomena. All four also may produce hallucinosis or confusion and may worsen orthostatic hypotension.

The principal distinction between the newer agents and the older ergot derivatives is in their tolerability and speed of titration. Initial treatment with bromocriptine or pergolide may cause nausea, fatigue, and profound hypotension; they should be initiated at low dosage. Symptoms usually are transient, but require slow upward adjustment of the dose over a period of weeks to months. Ropinirole and pramipexole can be initiated more quickly, achieving therapeutically useful doses in a week or less. They generally cause less GI disturbance than do the ergot derivatives, but they can produce nausea and somnolence. The somnolence can be quite severe; and it is prudent to advise patients of this possibility and to switch to another treatment if sleepiness interferes with daily life or poses a hazard (driving, *etc.*). Recent reports have associated long-term use of pergolide with significant cardiac valvular disease, and the drug has been withdrawn from the U.S. market.

The introduction of pramipexole and ropinirole has changed the clinical use of dopamine agonists in PD. These selective agonists are well tolerated and are used increasingly as initial treatment for PD rather than as adjuncts to levodopa. This change has been driven by two factors: (1) the belief that because of their longer duration of action, dopamine agonists may be less likely than levodopa to induce on/off effects and dyskinesias and (2) the concern that levodopa may contribute to oxidative stress, thereby accelerating loss of dopaminergic neurons. Many experts favor dopamine agonists as initial therapy in younger patients with PD and levodopa as the initial treatment in older patients who may be more vulnerable to the adverse cognitive effects of the agonists.

Apomorphine (APOKYN) is a dopaminergic agonist that can be administered by subcutaneous injection. It has high affinity for D₄ receptors; moderate affinity for D₂, D₃, D₅, and adrenergic α_{1D} , α_{2B} , and α_{2C} receptors; and low affinity for D₁ receptors. Apomorphine is used as a "rescue therapy" for the acute intermittent treatment of "off" episodes in patients with a fluctuating response to

dopaminergic therapy. Apomorphine shares the side effects of the oral dopamine agonists; it is highly emetogenic and requires pre- and posttreatment antiemetic therapy (generally, oral trimethobenzamide [TIGAN, 300 mg three times daily], started 3 days prior to the initial dose of apomorphine and continued at least during the first 2 months of therapy). Based on reports of profound hypotension and loss of consciousness when apomorphine is administered with ondansetron, the concomitant use of apomorphine with antiemetic drugs of the 5-HT₃ antagonist class is contraindicated. Other potentially serious side effects of apomorphine include QT prolongation, injection-site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior. Because of these potential adverse effects, use of apomorphine is appropriate only when other measures, such as oral dopamine agonists or COMT inhibitors, have failed to control the “off” episodes. Apomorphine therapy should be initiated in a setting where the patient can be monitored carefully, beginning with a 2-mg test dose. If this is tolerated, apomorphine can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require three or more injections daily.

CATECHOL-O-METHYLTRANSFERASE INHIBITORS Catechol-O-Methyltransferase (COMT) metabolizes levodopa as well as dopamine, producing the pharmacologically inactive compounds 3-*O*-methyl DOPA (from levodopa) and 3-methoxytyramine (from dopamine) (Figure 20–7). Approximately 99% of an orally administered dose of levodopa does not reach the brain but, rather, is decarboxylated to dopamine, which causes nausea and hypotension. Addition of an AAD inhibitor (*e.g.*, carbidopa) reduces the formation of dopamine but increases the fraction of levodopa that is methylated by COMT. COMT inhibitors will block this peripheral conversion of levodopa to 3-*O*-methyl DOPA, increasing both the plasma $t_{1/2}$ of levodopa as well as the fraction that reaches the CNS.

Two COMT inhibitors are available for this use, *tolcapone* (TASMAR) and *entacapone* (COMTAN). Tolcapone has a relatively long duration of action, allowing for administration two to three times a day, and appears to act by both central and peripheral inhibition of COMT. The duration of action of entacapone is short, around 2 hours, so it usually is administered simultaneously with each dose of levodopa/carbidopa. The action of entacapone is attributable principally to peripheral inhibition of COMT. The common adverse effects of these agents are similar to those observed in patients treated with levodopa/carbidopa alone and include nausea, orthostatic hypotension, vivid dreams, confusion, and hallucinations. An adverse effect associated with tolcapone is hepatotoxicity; tolcapone should be used only in patients who have not responded to other therapies and with appropriate monitoring of hepatic transaminases. Entacapone has not been associated with hepatotoxicity and requires no special monitoring. Entacapone also is available in fixed-dose combinations with levodopa/carbidopa (STALEVO).

SELECTIVE MAO-B INHIBITORS Two isozymes of MAO (MAO-A and MAO-B) oxidize monoamines and both are present in the periphery and GI tract; MAO-B is the predominant form in the striatum and is responsible for most of the oxidative metabolism of dopamine in the brain. At low-to-moderate doses (10 mg/day or less), *selegiline* (ELDEPRYL) selectively and irreversibly inhibits MAO-B. Unlike nonspecific inhibitors of MAO (*e.g.*, phenelzine, tranylcypromine, isocarboxazid), selegiline does not inhibit peripheral metabolism of catecholamines and can be taken safely with levodopa. Selegiline does not cause the lethal potentiation of indirectly acting sympathomimetic amines such as dietary tyramine. Doses of selegiline higher than 10 mg daily can produce inhibition of MAO-A and should be avoided.

Since it may retard dopamine degradation in the striatum, selegiline has been used as a symptomatic treatment for PD, although its benefit is modest. A putative action of selegiline is to retard the metabolism of dopamine, reduce free radical production and oxidative stress, and thereby confer neuroprotective effects. Selegiline is generally well tolerated in patients with early or mild PD. In patients with more advanced PD or underlying cognitive impairment, selegiline may accentuate the adverse motor and cognitive effects of levodopa therapy. Metabolites of selegiline include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. A related compound, rasagiline, also acts through inhibition of MAO-B but does not form these undesirable metabolites. Rasagiline shows efficacy in early and advanced PD but is not yet approved for use in the U.S. Selegiline, like the nonspecific MAO inhibitors, can lead to the development of stupor, rigidity, agitation, and hyperthermia after administration of the analgesic meperidine; the basis of this interaction is uncertain. There are reports of adverse effects resulting from interactions between selegiline and tricyclic antidepressants and between selegiline and SSRIs. The

combination of selegiline and SSRIs seems well tolerated in patients with PD, but the concomitant administration of selegiline and serotonergic drugs should be done with caution.

MUSCARINIC RECEPTOR ANTAGONISTS Antagonists of muscarinic acetylcholine (ACh) receptors were used widely for the treatment of PD before the discovery of levodopa. The biological basis for the therapeutic actions of anticholinergics is not completely understood. These drugs probably act in the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons. The agents acting as muscarinic antagonists currently used in the treatment of PD include *trihexyphenidyl* (ARTANE, 2–4 mg three times per day), *benztropine mesylate* (COGENTIN, 1–4 mg two times per day), and *diphenhydramine hydrochloride* (BENADRYL, 25–50 mg three to four times per day; *diphenhydramine* also is a histamine H₁ antagonist; see Chapter 24). All have modest antiparkinsonian activity that is useful in the treatment of early PD or as an adjunct to dopaminergic therapy. The adverse effects of these drugs are a result of their anticholinergic properties (principally sedation and mental confusion, but also constipation, urinary retention, and blurred vision through cycloplegia); these drugs must be used with caution in patients with narrow-angle glaucoma.

AMANTADINE *Amantadine* (SYMMETREL) is an antiviral agent used for the prophylaxis and treatment of influenza A (see Chapter 49). The drug also appears to alter dopamine release in the striatum, has anticholinergic properties, and blocks NMDA glutamate receptors. Presumably through a combination of these mechanisms, amantidine has modest antiparkinsonian activity, and is used as initial therapy of mild PD. Amantidine also may be helpful as an adjunct in patients on levodopa with dose-related fluctuations and dyskinesias. Amantidine usually is administered in a dose of 100 mg twice a day and is well tolerated. Dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, have been observed occasionally, but these effects are mild and reversible.

ALZHEIMER'S DISEASE

CLINICAL OVERVIEW AD produces an impairment of cognitive abilities that is gradual in onset but relentless in progression. Impairment of short-term memory usually is the first clinical feature; retrieval of distant memories is preserved relatively well. As the condition progresses, additional cognitive abilities are impaired, among them the ability to calculate, exercise visuospatial skills, and use common objects and tools (ideomotor apraxia). The level of arousal or alertness of the patient is not affected until the condition is very advanced, nor is there motor weakness, although muscular contractures are an almost universal feature of advanced stages of the disease. Death, most often from a complication of immobility such as pneumonia or pulmonary embolism, usually ensues within 6–12 years of onset. The diagnosis of AD is based on careful clinical assessment of the patient and appropriate laboratory tests to exclude other disorders that may mimic AD; at present, no direct antemortem confirmatory test exists.

Pathophysiology

AD is characterized by marked atrophy of the cerebral cortex and loss of cortical and subcortical neurons. The pathological hallmarks of AD are senile plaques, which are spherical accumulations of the protein β -amyloid accompanied by degenerating neuronal processes, and abundant neurofibrillary tangles, composed of paired helical filaments and other proteins. In advanced AD, senile plaques and neurofibrillary tangles are most abundant in the hippocampus and associative regions of the cortex, whereas areas such as the visual and motor cortices are relatively spared. This corresponds to the clinical features of marked impairment of memory and abstract reasoning, with preservation of vision and movement.

NEUROCHEMISTRY

Direct analysis of neurotransmitter content in the cerebral cortex shows a reduction of many transmitter substances that parallels neuronal loss, with a striking and disproportionate deficiency of ACh due to atrophy and degeneration of subcortical cholinergic neurons, particularly those in the basal forebrain (nucleus basalis of Meynert) that provide cholinergic innervation to the whole cerebral cortex. Although the conceptualization of AD as a “cholinergic deficiency syndrome” in parallel with the “dopaminergic deficiency syndrome” of PD provides a useful framework, the deficit in AD is far more complex, involving multiple neurotransmitter systems, including serotonin, glutamate, and neuropeptides, with destruction of not only cholinergic neurons but also the cortical and hippocampal targets that receive cholinergic input.

TREATMENT OF ALZHEIMER'S DISEASE The treatment of AD has involved attempts to augment the cholinergic function of the brain. Precursors of ACh synthesis, such as *choline chloride* and *phosphatidyl choline (lecithin)* do not produce clinically significant effects; however, inhibitors of acetylcholinesterase (AChE; see Chapter 8) have shown efficacy.

Four inhibitors of AChE currently are approved by the FDA for treatment of AD: *tacrine* (1,2,3,4-tetrahydro-9-aminoacridine; COGNEX), *donepezil* (ARICEPT), *rivastigmine* (EXCELON), and *galantamine* (RAZADYNE). Tacrine is a potent centrally acting inhibitor of AChE. Oral tacrine, in combination with lecithin, produces modest effects on memory performance, and the side effects of tacrine often are significant and dose-limiting; abdominal cramping, anorexia, nausea, vomiting, and diarrhea are observed in up to one-third of patients receiving therapeutic doses, and elevations of serum transaminases are observed in up to 50% of those treated. Because of significant side effects, tacrine is not used widely clinically. Donepezil is a selective inhibitor of AChE in the CNS with little effect on peripheral AChE. It produces modest improvements in cognitive scores in AD patients and has a long $t_{1/2}$, allowing once-daily dosing. Rivastigmine and galantamine are dosed twice daily and produce a similar degree of cognitive improvement. Adverse effects associated with donepezil, rivastigmine, and galantamine are similar in character but generally less frequent and less severe than those observed with tacrine: nausea, diarrhea, vomiting, and insomnia. Donepezil, rivastigmine, and galantamine are not associated with the hepatotoxicity that limits the use of tacrine.

An alternative strategy for the treatment of AD is the use of the NMDA glutamate-receptor antagonist memantine (NAMENDA). Memantine produces a use-dependent blockade of NMDA receptors. In patients with moderate-to-severe AD, use of memantine is associated with a reduced rate of clinical deterioration. Whether this is due to a true disease-modifying effect, possibly reduced excitotoxicity, or is a symptomatic effect of the drug is unclear. Adverse effects of memantine usually are mild and reversible and may include headache or dizziness.

HUNTINGTON'S DISEASE

CLINICAL FEATURES HD is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in midlife. Symptoms develop insidiously, either as a movement disorder manifest by brief, jerk-like movements of the extremities, trunk, face, and neck (chorea) or as personality changes or both. Fine motor incoordination and impairment of rapid-eye-movements are early features. Occasionally, choreic movements are less prominent and bradykinesia and dystonia predominate. As the disorder progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is affected, but affected persons rarely lose their memory of family, friends, and the immediate situation. Such persons often become irritable, anxious, and depressed. Less frequently, paranoia and delusional states are manifest. The outcome of HD is invariably fatal; over a course of 15–30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility.

PATHOLOGY AND PATHOPHYSIOLOGY

HD is characterized by prominent neuronal loss in the striatum (caudate/putamen). Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to ventrolateral. Other areas of the brain also are affected, although much less severely; one result is a prominent decrease in striatal GABA concentrations, whereas somatostatin and dopamine concentrations are relatively preserved. In most adult-onset cases, the medium spiny neurons that project to the GPi and SNpr (the indirect pathway) appear to be affected earlier than those projecting to the GPe (the direct pathway; see Figure 20–8). The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements. In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset cases. In these cases, the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.

GENETICS

HD is an autosomal dominant disorder with nearly complete penetrance. In affected individuals, the short arm of chromosome 4 contains a polymorphic (CAG)_n trinucleotide repeat that is significantly expanded in all individuals with HD; this trinucleotide repeat is the genetic alteration

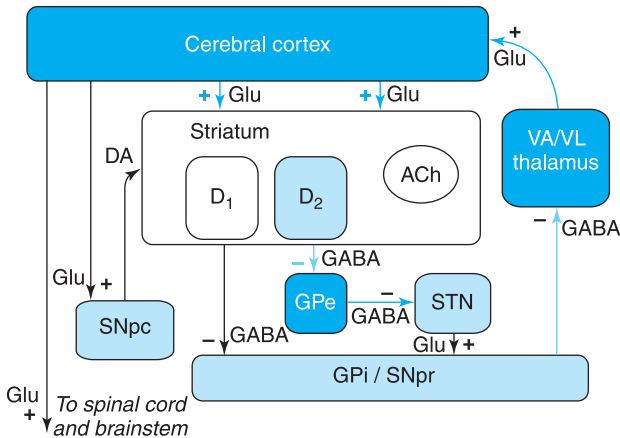

FIGURE 20-8 *The basal ganglia in Huntington's disease.* HD is characterized by loss of neurons from the striatum. The neurons that project from the striatum to the GPe and form the indirect pathway are affected earlier in the course of the disease than those which project to the GPi. This leads to a loss of inhibition of the GPe. The increased activity in this structure, in turn, inhibits the STN, SNpr, and GPi, resulting in a loss of inhibition to the VA/VL thalamus and increased thalamocortical excitatory drive. Structures in light blue have reduced activity in HD, whereas structures in dark blue have increased activity. (See legend to Figure 20-5 for definitions of anatomical abbreviations.)

responsible for HD and is increased from the normal range (9–34 triplets) to 40–100 triplets in HD patients. Several other neurodegenerative diseases also arise through expansion of a CAG repeat, including hereditary spinocerebellar ataxias and Kennedy's disease, a rare inherited disorder of motor neurons. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a gene designated IT15 that encodes a protein of ~348,000 Da. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5' end of IT15 and is followed directly by a second, shorter repeat of (CCG)_n that encodes proline. The protein, named huntingtin, does not resemble any other known protein, and the normal function of the protein has not been identified. The HD gene is expressed widely throughout the body, with high levels in brain, pancreas, intestine, muscle, liver, adrenals, and testes. Although the striatum is most severely affected, neurons in all regions of the brain express similar levels of IT15 mRNA.

SYMPTOMATIC TREATMENT OF HUNTINGTON'S DISEASE No current treatment slows the progression of HD, and many medications can impair function because of side effects. Treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. *Fluoxetine* (see Chapter 17) is effective treatment for both the depression and the irritability manifest in symptomatic HD; *carbamazepine* (see Chapter 19) also is effective for depression. Paranoia, delusional states, and psychosis usually require treatment with antipsychotic drugs, but the doses required often are lower than those usually used in primary psychiatric disorders. These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, *clozapine*, *quetiapine* (see Chapter 18), or carbamazepine may be more effective for treatment of paranoia and psychosis.

The movement disorder of HD *per se* only rarely justifies pharmacological therapy. For those with large-amplitude chorea causing frequent falls and injury, dopamine-depleting agents such as *tetrabenazine* and *reserpine* (see Chapter 32) can be tried, although patients must be monitored for hypotension and depression. Antipsychotic agents also can be used, but these often do not improve overall function because they decrease fine motor coordination and increase rigidity. Many HD patients exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious use of sedative or anxiolytic *benzodiazepines* can be very helpful. In juveniles-

onset cases, where rigidity rather than chorea predominates, dopamine agonists variably improve rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to *clonazepam*, *valproic acid*, and other anticonvulsants.

AMYOTROPHIC LATERAL SCLEROSIS

CLINICAL FEATURES AND PATHOLOGY

ALS is a disorder of the motor neurons of the ventral horn of the spinal cord and the cortical neurons that provide their afferent input, characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Sensory function generally is spared, as is cognitive, autonomic, and oculomotor activity. ALS usually is progressive and fatal, with most affected patients dying of respiratory compromise and pneumonia after 2–3 years. The pathology of ALS corresponds closely to the clinical features: prominent loss of the spinal and brainstem motor neurons that project to striated muscles (although the oculomotor neurons are spared), as well as loss of the large pyramidal motor neurons in layer V of motor cortex, which are the origin of the descending corticospinal tracts. In familial cases (FALS, ~10% of cases, usually with an autosomal dominant pattern of inheritance), Clarke's column and the dorsal horns sometimes are affected. Mutations in SOD1 account for ~20% of cases of FALS; many of the mutations of SOD1 associated with the disease do not reduce the capacity of the enzyme to perform its primary function, the catabolism of superoxide radicals. More than 90% of ALS cases are not associated with abnormalities of SOD1 or any other known gene. The cause of the motor neuron loss in sporadic ALS is unknown.

TREATMENT OF ALS WITH RILUZOLE The only currently approved therapy for ALS is *riluzole* (2-amino-6-[trifluoromethoxy]benzothiazole; RILUTEK), an agent with complex actions in the nervous system. Riluzole is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by both CYP-mediated hydroxylation and glucuronidation. Its $t_{1/2}$ is ~12 hours. *In vitro*, riluzole inhibits glutamate release, blocks postsynaptic NMDA- and kainate-type glutamate receptors, and inhibits voltage-dependent Na^+ channels. In clinical trials, riluzole has modest but genuine effects on the survival of patients with ALS. The recommended dose is 50 mg every 12 hours, taken 1 hour before or 2 hours after a meal. Riluzole usually is well tolerated, although nausea or diarrhea may occur. Rarely, riluzole may produce hepatic injury with elevations of serum transaminases; thus, periodic monitoring is recommended. Although the effect of riluzole on ALS is small (mean extension of survival ~60 days), it represents a significant therapeutic advance in the treatment of a disease refractory to all previous drugs.

SYMPTOMATIC THERAPY OF ALS: SPASTICITY Spasticity is a clinical feature of ALS that often leads to considerable pain and discomfort and reduces mobility, which already is compromised by weakness. Furthermore, spasticity is the feature of ALS that is most amenable to present forms of treatment. *Spasticity* is an increase in muscle tone characterized by an initial resistance to passive displacement of a limb at a joint, followed by a sudden relaxation (the so-called clasp-knife phenomenon). Spasticity is the result of the loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected. Whole repertoires of movement can be generated directly at the spinal cord level; it is beyond the scope of this chapter to describe these in detail. In general, pyramidal pathways that use glutamate as a neurotransmitter are impaired, with relative preservation of the other descending pathways, resulting in hyperactive deep-tendon reflexes, impaired fine motor coordination, increased extensor tone in the legs, and increased flexor tone in the arms. The gag reflex often is overactive as well.

The most useful agent for the symptomatic treatment of spasticity in ALS is *baclofen* (LIORESAL), a GABA_B receptor agonist. Initial doses of 5–10 mg/day are recommended, but the dose can be increased to as much as 200 mg/day if necessary. If weakness occurs, the dose should be lowered. In addition to oral administration, baclofen also can be delivered directly into the space around the spinal cord by use of a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression and should be only used by physicians trained in delivering chronic intrathecal therapy. *Tizanidine* (ZANFLEX), an agonist of α_2 adrenergic receptors in the CNS, reduces muscle spasticity and is assumed to act by increasing presynaptic inhibition of motor neurons. Tizanidine is used most widely in the treatment of spasticity in multiple sclerosis or after stroke but may be effective in patients with ALS. Treatment should be initiated at a low dose of 2–4 mg at

bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit the dose that can be administered. Benzodiazepines (*see* Chapter 16) such as *clonazepam* (KLONIPIN) are effective antispasmodics but may contribute to respiratory depression in patients with advanced ALS. *Dantrolene* (DANTRIUM), approved in the U.S. for the treatment of muscle spasm, can exacerbate muscular weakness and thus is not used in ALS (*see* Chapter 9).

OPIOID ANALGESICS

The term opioid refers broadly to all compounds related to opium, a natural product derived from the poppy. Opiates are drugs derived from opium and include the natural products morphine, codeine, and thebaine, and many semisynthetic derivatives. Endogenous opioid peptides, or endorphins, are the naturally occurring ligands for opioid receptors. Opiates exert their effects by mimicking these peptides. The term narcotic is derived from the Greek word for "stupor"; it originally referred to any drug that induced sleep, but it now is associated with opioids.

The diverse functions of the endogenous opioid system include the best known sensory role, prominent in inhibiting responses to painful stimuli; a modulatory role in gastrointestinal (GI), endocrine, and autonomic functions; an emotional role, evident in the powerful rewarding and addicting properties of opioids; and a cognitive role in the modulation of learning and memory. The endogenous opioid system has considerable diversity in endogenous ligands (>12) but only 4 major receptor types.

ENDOGENOUS OPIOID PEPTIDES

Three distinct families of classical opioid peptides have been identified: the *enkephalins*, *endorphins*, and *dynorphins*. Each family derives from a distinct precursor protein, prepro-opiomelanocortin (POMC), preproenkephalin, and preprodynorphin, respectively, which are encoded by distinct genes. Each precursor is subject to complex cleavages and posttranslational modifications that result in the synthesis of multiple active peptides. The opioid peptides share a common amino-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu), the *opioid motif*. This motif is followed by C-terminal extensions yielding peptides ranging from 5 to 31 residues (Table 21–1).

The major opioid peptide derived from POMC is β -endorphin. In addition to β -endorphin, the POMC precursor also is processed into the nonopioid peptides adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (α -MSH), and β -lipotropin β -LPH). Proenkephalin contains multiple copies of met-enkephalin, as well as a single copy of leu-enkephalin. Prodynorphin contains three peptides of differing lengths that all begin with the leu-enkephalin sequence: dynorphin A, dynorphin B, and neoendorphin (Figure 21–1).

A novel endogenous opioid peptide with significant sequence homology to dynorphin A was alternatively termed nociceptin or orphanin FQ (now termed N/OFQ; Table 21–1). The substitution of Phe for Tyr in the opioid motif is sufficient to abolish interactions with the three classical opioid peptide receptors. N/OFQ has behavioral and pain modulatory properties distinct from those of the three classical opioid peptides.

OPIOID RECEPTORS

Three classical opioid receptor types, μ , δ , and κ , have been studied extensively; the N/OFQ receptor system is still being defined. Highly selective ligands that allowed for type-specific labeling of the three classical opioid receptors (*e.g.*, DAMGO for μ , DPDPE for δ , and U-50,488 and U-69,593 for κ) made possible the definition of ligand-binding characteristics of each of the receptor types and the determination of anatomical distribution of the receptors using autoradiographic techniques. Each major opioid receptor has a unique anatomical distribution in brain, spinal cord, and the periphery.

Receptor-selective antagonists and agonists have aided the study of the biological functions of opioid receptors. Commonly used antagonists are cyclic analogs of *somatostatin* such as CTOP as μ -receptor antagonists, a derivative of naloxone called *naltrindole* as a δ -receptor antagonist, and a bivalent derivative of *naltrexone* called *nor-binaltorphimine* (nor-BNI) as a κ -receptor antagonist. In general, functional studies using selective agonists and antagonists have revealed substantial parallels between μ and δ receptors and dramatic contrasts between μ/δ and κ receptors. *In vivo* infusions of selective antagonists and agonists also were used to establish the receptor types involved in mediating various opioid effects (Table 21–2).

Most of the clinically used opioids are relatively selective for μ receptors, reflecting their similarity to morphine (Tables 21–3 and 21–4). However, drugs that are relatively selective at standard doses may interact with additional receptor subtypes when given at sufficiently high doses, leading to possible changes in their pharmacological profile. This is especially true as doses are escalated to overcome tolerance. Some drugs, particularly mixed agonist–antagonist agents, interact with more than one receptor class at usual clinical doses and may act as an agonist at one receptor and an antagonist at another.

The actions listed for antagonists are seen with the antagonist alone. All the correlations in this table are based on studies in rats and mice, which occasionally show species differences. Thus, any extensions of these associations to humans are tentative. Clinical studies do indicate that μ receptors elicit analgesia spinally and supraspinally. Preliminary work with a synthetic opioid peptide, [D-Ala²,D-Leu⁵]enkephalin, suggests that intrathecal δ agonists are analgesic in humans.

Opioid Receptor Signaling and Consequent Intracellular Events

COUPLING OF OPIOID RECEPTORS TO SECOND MESSENGERS

The μ , δ and κ receptors are coupled, via pertussis toxin–sensitive G proteins, to inhibition of adenylyl cyclase activity, activation of receptor-linked K⁺ currents, and suppression of voltage-gated Ca²⁺ currents. The hyperpolarization of membrane potential by K⁺-current activation and the limiting of Ca²⁺ entry by suppression of Ca²⁺ currents are tenable but unproven mechanisms for explaining opioid inhibition of neurotransmitter release and pain transmission. Opioid receptors couple to an array of second-messenger systems, including activation of MAP kinases and the phospholipase C (PLC)–mediated cascade. Prolonged exposure to opioids results in adaptations at multiple levels within these signaling cascades that may relate to effects such as tolerance, sensitization, and withdrawal.

RECEPTOR DESENSITIZATION, INTERNALIZATION, AND SEQUESTRATION AFTER CHRONIC EXPOSURE TO OPIOIDS

Tolerance refers to a decrease in effectiveness of a drug with its repeated administration (see Chapter 23). Transient administration of opioids leads to a phenomenon called acute tolerance, whereas sustained administration leads to the development of classical or chronic tolerance. Short-term receptor desensitization, which may underlie the development of tolerance, probably involves phosphorylation of the μ and δ receptors by PKC. A number of other kinases have been implicated in desensitization, including PKA and β -adrenergic receptor kinase.

Long-term tolerance may be associated with increases in adenylyl cyclase activity—a counter-regulation to the decreased cyclic AMP levels seen after acute opioid administration. Chronic treatment with μ -receptor opioids causes superactivation of adenylyl cyclase. This effect is prevented by pretreatment with pertussis toxin, demonstrating involvement of G_{i/o} proteins, and also by cotransfection with scavengers of G protein– $\beta\gamma$ dimers, indicating a role for this complex in superactivation. Recent data, described in the 11th edition of the parent text, argue that opioid tolerance may be related not to receptor desensitization but rather to a lack of desensitization.

EFFECTS OF CLINICALLY USED OPIOIDS

Morphine and most other clinically used opiates exert their effects through μ opioid receptors and affect a wide range of physiological systems. They produce analgesia, affect mood and rewarding behavior (*see* Chapter 23), and alter respiratory, cardiovascular, GI, and neuroendocrine function. δ -Opioid receptor agonists also are potent analgesics in animals and some have proved useful in humans. Agonists selective for κ receptors produce analgesia that is mediated primarily at spinal

sites. Respiratory depression and miosis may be less severe with κ agonists. Instead of euphoria, κ receptor agonists produce dysphoric and psychotomimetic effects. In neural circuits mediating reward and analgesia, μ and κ agonists have antagonistic effects (*see* below).

Mixed agonist–antagonist compounds were developed in the hope that they would have less addictive potential and respiratory depression than morphine and related drugs. In practice, for the same degree of analgesia, the same intensity of side effects occurs. A “ceiling effect” limits the amount of analgesia attainable with these drugs. Some mixed agonist–antagonist drugs, such as *pentazocine* and *nalorphine*, can produce severe psychotomimetic effects that are not reversible with naloxone (and thus may not be mediated *via* classical opioid receptors). These drugs also can precipitate withdrawal in opioid-tolerant patients, further limiting their clinical use.

Analgesia

Morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. The analgesia occurs without loss of consciousness. When therapeutic doses of morphine are given to patients with pain, they report that the pain is less intense, less discomforting, or entirely gone; drowsiness commonly occurs. In addition to relief of distress, some patients experience euphoria.

When morphine in the same dose is given to a normal, pain-free individual, the experience may be unpleasant. Nausea is common, and vomiting may occur. There may be feelings of drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced. Morphine does not have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant motor incoordination.

The relief of pain by morphine-like opioids is relatively selective, in that other sensory modalities are not affected. Patients frequently report that the pain is still present, but they feel more comfortable. Continuous dull pain is relieved more effectively than sharp intermittent pain, but sufficient amounts of opioid can relieve even the severe pain associated with renal or biliary colic.

Mood Alterations and Rewarding Properties

The mechanisms by which opioids produce euphoria, tranquility, and other mood alterations (including rewarding properties) are not entirely clear. However, the neural systems that mediate opioid reinforcement are distinct from those involved in physical dependence and analgesia. Behavioral and pharmacological data point to the role of dopaminergic pathways, particularly involving the nucleus accumbens, in drug-induced reward. There is ample evidence for interactions between opioids and *dopamine* in mediating opioid-induced reward (*see* Chapter 23).

Other Central Nervous System Effects

Whereas opioids are used primarily for analgesia, they produce a host of other effects, as summarized below. High doses of opioids can produce muscular rigidity in humans. Chest wall rigidity severe enough to compromise respiration is not uncommon during anesthesia with fentanyl, *alfentanil*, *remifentanil*, and *sufentanil*.

EFFECTS ON THE HYPOTHALAMUS

Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. However, chronic high dosage may increase body temperature.

NEUROENDOCRINE EFFECTS

Morphine acts in the hypothalamus to inhibit the release of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH), thus decreasing circulating concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and ACTH. As a result of the decreased concentrations of pituitary trophic hormones, plasma concentrations of sex steroids and cortisol decline. Thyrotropin secretion is relatively unaffected.

The administration of μ agonists increases the concentration of prolactin in plasma, probably by reducing the dopaminergic inhibition of its secretion. The administration of morphine or β -endorphin has little effect on the concentration of growth hormone in plasma. With chronic administration, tolerance develops to the effects of morphine on hypothalamic releasing factors. Patients maintained on methadone reflect this phenomenon; in women, menstrual cycles that had been disrupted by intermittent use of heroin return to normal; in men, circulating concentrations of LH and testosterone return to the normal range.

MIOSIS Morphine and most μ and κ agonists cause constriction of the pupil by an excitatory action on the parasympathetic nerve innervating the pupil. After toxic doses of μ agonists, the miosis is marked, and pinpoint pupils are pathognomonic; however, marked mydriasis occurs if asphyxia intervenes. Some tolerance to the miotic effect develops, but addicts with high circulating levels of opioids continue to have constricted pupils. Therapeutic doses of morphine increase accommodation and lower intraocular pressure in normal and glaucomatous eyes.

CONVULSIONS In animals, high doses of morphine and related opioids produce convulsions. Several mechanisms appear to be involved, and different types of opioids produce seizures with different characteristics. Morphine-like drugs excite certain groups of neurons, especially hippocampal pyramidal cells; these excitatory effects probably result from inhibition of the release of GABA by interneurons. Selective δ agonists produce similar effects. These actions may contribute to the seizures that are produced by some agents at doses only moderately higher than those required for analgesia, especially in children. With most opioids, however, convulsions occur only at doses far in excess of those required to produce profound analgesia, and seizures are not seen when potent μ agonists are used to produce anesthesia. Naloxone is more potent in antagonizing convulsions produced by some opioids (*e.g.*, morphine, methadone, and *propoxyphene*) than those produced by others (*e.g.*, *meperidine*). The production of convulsant metabolites of the latter drug may be partially responsible (*see below*). Anticonvulsant agents may not always be effective in suppressing opioid-induced seizures (*see Chapter 19*).

RESPIRATION Morphine-like opioids depress respiration at least partly by a direct effect on the brainstem respiratory centers. This respiratory depression is discernible even with doses too small to disturb consciousness and increases progressively as the dose is increased. In humans, death from morphine poisoning is nearly always due to respiratory arrest. Therapeutic doses of morphine in humans depress all phases of respiratory activity (rate, minute volume, and tidal exchange) and also may produce irregular and periodic breathing. The diminished respiratory volume is due primarily to a slower rate of breathing; with toxic amounts, the rate may fall to three or four breaths per minute. Although effects on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard morphine doses in the absence of underlying pulmonary dysfunction. One important exception is when opioids are administered parenterally to women shortly before delivery, which can lead to transient respiratory depression in the neonate because of transplacental passage of opioids. The combination of opioids with other medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics, may increase the risk of respiratory depression. Maximal respiratory depression occurs within 5–10 minutes of intravenous administration of morphine or within 30–90 minutes of intramuscular or subcutaneous administration, respectively.

Maximal respiratory depression occur more rapidly with more lipid-soluble agents. After therapeutic doses, respiratory minute volume may be reduced for as long as 4–5 hours. The respiratory depression by opioids involves a reduction in the responsiveness of the brainstem respiratory centers to CO_2 . Opioids also depress the pontine and medullary centers involved in regulating respiratory rhythmicity.

COUGH Morphine and related opioids also depress the cough reflex, at least partly by direct action on a cough center in the medulla. There is no obligatory relationship between depression of respiration and depression of coughing, and antitussive agents are available that do not depress respiration (*see below*). Suppression of cough by such agents appears to involve receptors in the medulla that are less sensitive to naloxone than those responsible for analgesia.

NAUSEANT AND EMETIC EFFECTS Nausea and vomiting produced by morphine-like drugs are caused by direct stimulation of the chemoreceptor trigger zone in the area postrema of the medulla. Nausea and vomiting are relatively uncommon in recumbent patients given therapeutic doses of morphine, but nausea occurs in ~40% and vomiting in 15% of ambulatory patients given 15 mg of the drug subcutaneously. This suggests that a vestibular component also is operative. All clinically useful μ agonists produce some degree of nausea and vomiting. Antagonists to the 5-HT₃ serotonin receptor have supplanted phenothiazines as the drugs of choice for the treatment of opioid-induced nausea and vomiting. Gastric prokinetic agents such as *metoclopramide* also are useful anti-nausea and antiemetic drugs (*see Chapter 37*).

CARDIOVASCULAR SYSTEM In the supine patient, therapeutic doses of morphine-like opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses do produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Therefore, when supine patients assume the upright position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by morphine involves several mechanisms. Morphine and some other opioids provoke release of histamine, which sometimes plays a large role in the hypotension. However, vasodilation usually is only partially blocked by H₁ antagonists, but it is effectively reversed by naloxone. Morphine also blunts the reflex vasoconstriction caused by increased Pco_2 (*see Chapter 15*).

Effects on the myocardium are not significant in normal individuals. In patients with coronary artery disease but no acute medical problems, 8–15 mg morphine administered intravenously produces a decrease in oxygen consumption, left ventricular end-diastolic pressure, and cardiac work; effects on cardiac index usually are slight. In patients with acute myocardial infarction, the cardiovascular responses to morphine may be more variable than in normal subjects, and hypotension may be more pronounced.

Morphine may exert its well-known therapeutic effect in the treatment of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial O_2 consumption and helping to relieve ischemia. Morphine can mimic the phenomenon of ischemic preconditioning, where a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated by δ receptor modulation of a mitochondrial ATP-sensitive K^+ channel in cardiac myocytes.

Morphine-like opioids should be used with caution in patients who have a decreased blood volume because the drugs can aggravate hypovolemic shock. Morphine should be used with great care in patients with cor pulmonale because deaths after ordinary therapeutic doses have been reported. The concurrent use of certain phenothiazines may increase the risk of morphine-induced hypotension.

GASTROINTESTINAL TRACT

Stomach Morphine and other μ agonists usually decrease gastric acid secretion, although stimulation sometimes occurs. Activation of opioid receptors on parietal cells enhances secretion, but indirect effects, including increased secretion of somatostatin from the pancreas and reduced release of acetylcholine, predominate in most circumstances. Low doses of morphine decrease gastric motility, prolonging gastric emptying time; this can increase the likelihood of esophageal reflux. The tone of the antral portion of the stomach and of the first part of the duodenum is increased, which can make therapeutic intubation of the duodenum more difficult. Passage of the gastric contents through the duodenum may be delayed by as much as 12 hours, and the absorption of orally administered drugs is retarded.

Small Intestine Morphine diminishes biliary, pancreatic, and intestinal secretions and delays digestion of food in the small intestine. Resting tone is increased, and periodic spasms are observed. The amplitude of the nonpropulsive type of rhythmic, segmental contractions usually is enhanced, but propulsive contractions are decreased markedly. The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the hypertonicity. Water is absorbed more completely because of the delayed passage of bowel contents, and intestinal secretion is decreased; this increases the viscosity of the bowel contents.

Large Intestine Propulsive peristaltic waves in the colon are diminished or abolished after administration of morphine, and tone is increased to the point of spasm. The resulting delay in the passage of bowel contents causes considerable desiccation of the feces, which, in turn, retards their advance through the colon. The amplitude of the nonpropulsive type of rhythmic contractions of the colon usually is enhanced. The tone of the anal sphincter is augmented, and reflex relaxation in response to rectal distension is reduced. These actions, combined with inattention to the normal sensory stimuli for defecation reflex owing to the central actions of the drug, contribute to morphine-induced constipation.

BILIARY TRACT After the subcutaneous injection of 10 mg *morphine sulfate*, the sphincter of Oddi constricts, and the pressure in the common bile duct may rise more than tenfold within 15 minutes; this effect may persist for 2 hours or more. Fluid pressure also may increase in the gallbladder, producing symptoms that vary from epigastric distress to typical biliary colic. All opioids can cause biliary spasm. *Atropine* only partially prevents morphine-induced biliary spasm, but opioid antagonists prevent or relieve it. *Nitroglycerin* (0.6–1.2 mg) administered sublingually also decreases the elevated intrabiliary pressure.

SKIN

Therapeutic doses of morphine cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. These changes may be due in part to the release of histamine and may be responsible for the sweating and pruritus that occasionally follow the systemic administration of morphine. Histamine release probably accounts for the urticaria commonly seen at the site of injection, which is not mediated by opioid receptors and is not blocked by naloxone. It is seen with morphine and meperidine but not with oxymorphone, methadone, fentanyl, or sufentanil.

Pruritus is a common and potentially disabling complication of opioid use. It can be caused by intraspinal or systemic injections of opioids, but it appears to be more intense after intraspinal administration. The effect appears to be mediated largely by dorsal horn neurons and is reversed by naloxone.

Tolerance and Physical Dependence

The development of tolerance and physical dependence with repeated use is a characteristic feature of all the opioid drugs. *Tolerance* to the effect of opioids or other drugs simply means that the drug loses its effectiveness over time and an increased dose is required to produce the same physiological response. *Dependence* refers to a complex and poorly understood set of changes in the homeostasis of an organism that causes a disturbance of the homeostatic set point of the organism if the drug is stopped. This disturbance often is revealed when administration of an opioid is stopped abruptly, resulting in *withdrawal*. *Addiction* is a behavioral pattern characterized by compulsive use of a drug and overwhelming involvement with its procurement and use. Tolerance and dependence are physiological responses seen in all patients and are not predictors of addiction (see Chapter 23).

MORPHINE AND RELATED OPIOID AGONISTS

Morphine is the standard against which newer analgesics are measured. However, responses of an individual patient may vary dramatically with different μ -opioid receptor agonists. For example, some patients unable to tolerate morphine may have no problems with an equianalgesic dose of methadone, whereas others can tolerate morphine and not methadone. If problems are encountered with one drug, another should be tried.

ABSORPTION, DISTRIBUTION, FATE, AND EXCRETION

Rectal absorption In general, the opioids are absorbed readily from the GI tract; absorption through the rectal mucosa is adequate, and a few agents (e.g., morphine, hydromorphone) are available in suppositories. The more lipophilic opioids also are absorbed readily through the nasal or buccal

mucosa. Those with the greatest lipid solubility also can be absorbed transdermally. Opioids are absorbed readily after subcutaneous or intramuscular injection and can penetrate the spinal cord adequately after epidural or intrathecal administration. Small amounts of morphine introduced epidurally or intrathecally into the spinal canal can produce profound analgesia that may last 12–24 hours. However, because of the hydrophilic nature of morphine, there is rostral spread of the drug in cerebrospinal fluid (CSF), and side effects, especially respiratory depression, can emerge up to 24 hours later as the opioid reaches supraspinal respiratory control centers. With highly lipophilic agents such as hydromorphone or fentanyl, rapid absorption by spinal neural tissues produces very localized effects and segmental analgesia. The duration of action is shorter because of distribution of the drug in the systemic circulation, and the severity of respiratory depression may be more directly proportional to its concentration in plasma owing to a lesser degree of rostral spread. However, patients receiving epidural or intrathecal fentanyl still should be monitored for respiratory depression.

With most opioids, including morphine, the effect of a given dose is less after oral than after parenteral administration because of variable but significant first-pass metabolism in the liver. The bioavailability of oral preparations of morphine is ~25%. The shape of the time–effect curve also varies with the route of administration, so the duration of action often is somewhat longer with the oral route. If adjustment is made for variability of first-pass metabolism and clearance, adequate relief of pain can be achieved with oral administration of morphine. Satisfactory analgesia in cancer patients is associated with a very broad range of steady-state concentrations of morphine in plasma (16–364 ng/mL).

When morphine and most opioids are given intravenously, they act promptly. However, the more lipid-soluble compounds act more rapidly than morphine after subcutaneous administration because of differences in the rates of absorption and entry into the CNS. Compared with more lipid-soluble opioids such as codeine, heroin, and methadone, morphine crosses the blood–brain barrier at a considerably lower rate.

Distribution and Fate About one-third of morphine in the plasma is protein-bound after a therapeutic dose. Morphine itself does not persist in tissues, and 24 hours after the last dose, tissue concentrations are low.

The major pathway for the metabolism of morphine is conjugation with glucuronic acid. The two major metabolites formed are *morphine-6-glucuronide* and *morphine-3-glucuronide*. Small amounts of morphine-3,6-diglucuronide also may be formed. Although the 3- and 6-glucuronides are quite polar, both still can cross the blood–brain barrier to exert significant clinical effects. Morphine-3-glucuronide has little affinity for opioid receptors but may contribute to excitatory effects of morphine. Morphine-6-glucuronide has pharmacological actions indistinguishable from those of morphine. Morphine-6-glucuronide given systemically is about twice as potent as morphine; with chronic administration, it accounts for a significant portion of morphine's analgesic actions. Indeed, with chronic oral dosing, the blood levels of morphine-6-glucuronide typically exceed those of morphine. Morphine-6-glucuronide is excreted by the kidney. In renal failure, morphine-6-glucuronide can accumulate, perhaps explaining morphine's potency and long duration in patients with compromised renal function. In adults, the $t_{1/2}$ of morphine is ~2 hours; the $t_{1/2}$ of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of morphine are recommended based on its smaller volume of distribution and the general decline in renal function in the elderly. *N*-Dealkylation also is important in the metabolism of some congeners of morphine.

CODEINE In contrast to morphine, codeine is ~60% as effective orally as parenterally as an analgesic and as a respiratory depressant. Codeine analogs such as *levorphanol*, oxycodone, and methadone have a high ratio of oral-to-parenteral potency. The greater oral efficacy of these drugs reflects lower first-pass metabolism. Once absorbed, codeine is metabolized by the liver, and its metabolites are excreted chiefly as inactive forms in the urine. A relatively small fraction (~10%) of administered codeine is *O*-demethylated to morphine, and free and conjugated morphine can be found in the urine after therapeutic doses of codeine. Codeine has an exceptionally low affinity for opioid receptors, and the analgesic effect of codeine is due to its conversion to morphine. However, its antitussive actions may involve distinct receptors that bind codeine itself. The $t_{1/2}$ of codeine in plasma is 2–4 hours.

The conversion of codeine to morphine is effected by CYP2D6. Genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as

an analgesic for ~10% of the Caucasian population. Other polymorphisms can lead to enhanced metabolism and thus increased sensitivity to codeine's effects. Thus, it is important to consider the possibility of metabolic enzyme polymorphism in any patient who does not receive adequate analgesia from codeine or other opioid prodrugs. A genetic test to identify these CYP2D6 polymorphisms is FDA-approved.

TRAMADOL *Tramadol* (ULTRAM) is a synthetic codeine analog that is a weak μ -opioid receptor agonist. Part of its analgesic effect is produced by inhibition of uptake of NE and 5-HT. In the treatment of mild-to-moderate pain, tramadol is as effective as morphine or meperidine. However, for the treatment of severe or chronic pain, tramadol is less effective. Tramadol is as effective as meperidine in the treatment of labor pain and may cause less neonatal respiratory depression.

HEROIN Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-monoacetylmorphine (6-MAM), which, in turn, is hydrolyzed to morphine. Heroin and 6-MAM are more lipid soluble than morphine and enter the brain more readily. Evidence suggests that morphine and 6-MAM are responsible for the pharmacological actions of heroin. Heroin is excreted mainly in the urine largely as free and conjugated morphine.

UNTOWARD EFFECTS AND PRECAUTIONS Morphine and related opioids produce a wide spectrum of unwanted effects, including respiratory depression, nausea, vomiting, dizziness, mental clouding, dysphoria, pruritus, constipation, increased pressure in the biliary tract, urinary retention, hypotension, and rarely delirium. Increased sensitivity to pain after analgesia has worn off also may occur.

A number of factors may alter a patient's sensitivity to opioid analgesics, including the integrity of the blood-brain barrier. For example, when morphine is administered to a newborn infant in weight-appropriate doses extrapolated from adults, unexpectedly profound analgesia and respiratory depression may be observed. This is due to the immaturity of the blood-brain barrier in neonates. Morphine is hydrophilic, so proportionately less morphine normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than morphine. In adults, the *duration* of the analgesia produced by morphine increases progressively with age, while the *degree* of analgesia for a given dose changes little. Changes in pharmacokinetics only partly explain this. The patient with severe pain may tolerate larger doses of morphine. However, as the pain subsides, the patient may exhibit sedation and even respiratory depression as the stimulatory effects of pain are diminished. The reasons for this effect are unclear.

All opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease because increased bioavailability after oral administration or cumulative effects may occur. Renal disease also significantly alters the pharmacokinetics of morphine, codeine, *dihydrocodeine*, meperidine, and propoxyphene. Although single doses of morphine are well tolerated, the active metabolite, morphine-6-glucuronide, may accumulate with continued dosing, and symptoms of opioid overdose may result. This metabolite also may accumulate during repeated administration of codeine to patients with impaired renal function. When repeated doses of meperidine are given to such patients, the accumulation of normeperidine may cause tremor and seizures. Similarly, the repeated administration of propoxyphene may lead to naloxone-insensitive cardiac toxicity caused by the accumulation of norpropoxyphene.

Morphine and related opioids must be used cautiously in patients with compromised respiratory function (*e.g.*, emphysema, kyphoscoliosis, or severe obesity). In patients with cor pulmonale, death has occurred after therapeutic doses of morphine. Although many patients with such conditions seem to be functioning within normal limits, they are already using compensatory mechanisms, such as increased respiratory rate. Many have chronically elevated levels of plasma CO₂ and may be less sensitive to the stimulating actions of CO₂. The further imposition of the depressant effects of opioids can be disastrous. The respiratory-depressant effects of opioids and the related capacity to elevate intracranial pressure must be considered in the presence of head injury or an already elevated intracranial pressure. While head injury *per se* does not constitute an absolute contraindication to the use of opioids, the possibility of exaggerated depression of respiration and the potential need to control ventilation of the patient must be considered. Finally, since opioids may produce mental clouding and side effects such as miosis and vomiting, which are important signs in following the clinical course of patients with head injuries, the advisability of their use must be weighed carefully against these risks.

Morphine causes histamine release, which can cause bronchoconstriction and vasodilation, and should be avoided in patients with a history of asthma. Other μ -receptor agonists that do not release histamine, such as the fentanyl derivatives, may be better choices for such patients.

Patients with reduced blood volume are considerably more susceptible to the vasodilatory effects of morphine and related drugs, and these agents must be used cautiously in patients with hypotension from any cause.

OTHER μ -RECEPTOR AGONISTS

Levorphanol

Levorphanol (LEVO-DROMORAN) is the only commercially available opioid agonist of the morphinan series. The D-isomer (dextrorphan) is relatively devoid of analgesic action but may have inhibitory effects at NMDA receptors.

The pharmacological effects of levorphanol closely parallel those of morphine, but it may produce less nausea and vomiting. Levorphanol is metabolized less rapidly than morphine and has a $t_{1/2}$ of ~12–16 hours; thus, repeated administration at short intervals may lead to accumulation of the drug in plasma.

Meperidine and Congeners

Meperidine is predominantly a μ -receptor agonist and acts principally on the CNS and the neural elements in the bowel. Meperidine is no longer recommended for the treatment of chronic pain because of concerns over metabolite toxicity. It should not be used for longer than 48 hours or in doses >600 mg/day.

PHARMACOLOGICAL PROPERTIES Meperidine produces a *pattern* of effects similar but not identical to that described for morphine. The analgesic effects of meperidine are detectable ~15 minutes after oral administration, peak in ~1–2 hours, and subside gradually. The onset of analgesic effect is faster (within 10 minutes) after subcutaneous or intramuscular administration, and the effect reaches a peak in ~1 hour that corresponds closely to peak concentrations in plasma. In clinical use, the duration of effective analgesia is ~1.5–3 hours. In general, 75–100 mg meperidine hydrochloride (*pethidine*, DEMEROL) given parenterally is approximately equivalent to 10 mg morphine, and in equianalgesic doses, meperidine produces as much sedation, respiratory depression, and euphoria as does morphine. In terms of total analgesic effect, meperidine is about one-third as effective when given orally as when administered parenterally. A few patients may experience dysphoria.

Meperidine causes less constipation than morphine even when given over prolonged periods of time; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. Clinical doses of meperidine slow gastric emptying sufficiently to delay absorption of other drugs.

Meperidine is metabolized chiefly in the liver, with a $t_{1/2}$ of ~3 hours. In patients with cirrhosis, the bioavailability of meperidine is increased to as much as 80%, and the $t_{1/2}$ of both meperidine and normeperidine are prolonged. Approximately 60% of meperidine in plasma is protein-bound. Only a small amount of meperidine is excreted unchanged.

UNTOWARD EFFECTS, PRECAUTIONS, AND CONTRAINDICATIONS In patients or addicts who are tolerant to the depressant effects of meperidine, large doses repeated at short intervals may produce an excitatory syndrome, including hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of normeperidine, the demethylated metabolite, which has a $t_{1/2}$ of 15–20 hours compared with 3 hours for meperidine. Opioid antagonists may block the convulsant effect of normeperidine. Since normeperidine is eliminated by the kidney and the liver, decreased renal or hepatic function increases the likelihood of such toxicity.

Meperidine crosses the placental barrier and increases the percentage of babies who exhibit delayed respiration, decreased respiratory minute volume, or decreased oxygen saturation or who require resuscitation; if present, these conditions can be treated with naloxone. Meperidine produces less respiratory depression in the newborn than does an equianalgesic dose of morphine or methadone.

INTERACTIONS WITH OTHER DRUGS

Severe reactions may follow the administration of meperidine to patients being treated with MAO inhibitors. An excitatory reaction ("serotonin syndrome") with delirium, hyperthermia, headache,

hyper- or hypotension, rigidity, convulsions, coma, and death may be due to the ability of meperidine to block neuronal reuptake of 5-HT and the resulting serotonergic overactivity. Therefore, meperidine and its congeners should not be used in patients taking MAO inhibitors. Potentiation owing to inhibition of hepatic CYPs also can be observed in patients taking MAO inhibitors, necessitating a reduction in the doses of opioids.

Chlorpromazine and tricyclic antidepressants increase the respiratory-depressant and sedative effects of meperidine. Increased respiratory depression is not seen with concomitant use of diazepam. Treatment with phenobarbital or phenytoin increases systemic clearance and decreases oral bioavailability of meperidine; this is associated with an elevation of the plasma concentration of normeperidine. Concomitant administration of amphetamine has been reported to enhance the analgesic effects of meperidine and its congeners while counteracting sedation.

THERAPEUTIC USES Meperidine is used for analgesia. Single doses of meperidine appear to be effective in the treatment of postanesthetic shivering. Meperidine, 25–50 mg, is used frequently with antihistamines, glucocorticoids, acetaminophen, or nonsteroidal anti-inflammatory drugs (NSAIDs) to prevent or ameliorate infusion reactions that accompany the intravenous administration of amphotericin B, aldesleukin (interleukin-2), trastuzumab, and alemtuzumab.

CONGENERS OF MEPERIDINE

Diphenoxylate

Diphenoxylate is a meperidine congener that is approved for the treatment of diarrhea (see Chapter 37). Diphenoxylate hydrochloride is available only in combination with atropine sulfate (LOMOTIL, others). The recommended daily dosage of diphenoxylate for the treatment of diarrhea in adults is 20 mg in divided doses. Difenoxin (MOTOFEN), a metabolite of diphenoxylate, has actions similar to those of the parent compound.

Loperamide

Loperamide (IMODIUM, others), like diphenoxylate, is a piperidine derivative; it penetrates poorly into the CNS. Loperamide slows GI motility by effects on the circular and longitudinal muscles of the intestine, presumably via interactions with opioid receptors in the intestine. In controlling chronic diarrhea, loperamide is as effective as diphenoxylate, and little tolerance develops.

Fentanyl and Congeners

Fentanyl is a synthetic opioid related to the phenylpiperidines. The actions of fentanyl and congeners are similar to those of other μ -receptor agonists. Fentanyl is a popular anesthetic because of its relatively short time to peak analgesic effect, rapid termination of effect after small bolus doses, and cardiovascular safety (see Chapter 13).

PHARMACOLOGICAL PROPERTIES

Fentanyl is ~100 times more potent than morphine, and sufentanil is ~1000 times more potent than morphine. These drugs are most commonly administered intravenously, although both also are commonly administered epidurally and intrathecally for acute postoperative and chronic pain management. Fentanyl and sufentanil are far more lipid soluble than morphine, greatly reducing the risk of delayed respiratory depression from rostral spread of intraspinally administered narcotic to respiratory centers. The time to peak analgesic effect after intravenous administration of fentanyl and sufentanil is less than that for morphine and meperidine, with peak analgesia being reached after 5 minutes, as opposed to 15 minutes. Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the effects of these drugs become more lasting, with durations of action becoming similar to those of longer-acting opioids (see below).

Fentanyl and its derivatives decrease the heart rate and can mildly decrease blood pressure. However, these drugs do not release histamine and generally provide a marked degree of cardiovascular stability. Direct depressant effects on the myocardium are minimal. For this reason, high doses of fentanyl or sufentanil are commonly used as the primary anesthetic for patients undergoing cardiovascular surgery or for patients with poor cardiac function. Fentanyl and sufentanil undergo hepatic metabolism and renal excretion. Therefore, with the use of higher doses or prolonged infusions, fentanyl and sufentanil become longer acting.

THERAPEUTIC USES

Fentanyl citrate (SUBLIMAZE) and sufentanil citrate (SUFENTA) have gained widespread popularity as anesthetic adjuvants (see Chapter 13). They are used commonly either intravenously, epidurally, or intrathecally (e.g., epidural use for postoperative or labor analgesia). Epidural and

intrathecal infusions, with or without local anesthetic, are used in the management of chronic malignant pain and selected cases of nonmalignant pain. Transdermal patches (DURAGESIC) that provide sustained release of fentanyl for 48 hours or more are available. However, factors promoting increased absorption (e.g., fever) can lead to relative overdosage and increased side effects (see alternative routes of administration, below).

Methadone and Congeners

Methadone is a long-acting μ -receptor agonist with properties qualitatively similar to those of morphine.

PHARMACOLOGICAL ACTIONS The outstanding properties of methadone are its analgesic activity, its oral efficacy, extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for >24 hours after a single dose, and on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of morphine.

ABSORPTION, FATE, AND EXCRETION Methadone is absorbed well from the GI tract and can be detected in plasma within 30 minutes of oral ingestion; it reaches peak concentrations at ~4 hours. After therapeutic doses, ~90% of methadone is bound to plasma proteins. Peak concentrations in the brain occur within 1–2 hours of subcutaneous or intramuscular administration, which correlates well with the intensity and duration of analgesia. Methadone also is absorbed from the buccal mucosa.

Methadone undergoes extensive biotransformation in the liver. The major metabolites, the results of *N*-demethylation and cyclization to form pyrrolidines and pyrroline, are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of methadone excreted in the urine is increased when the urine is acidified. The $t_{1/2}$ of methadone is 15–40 hours.

Methadone is firmly bound to protein in various tissues, including brain, and accumulates gradually with repeated administration. When administration is stopped, low plasma concentrations are maintained by slow release from extravascular binding sites; this process probably accounts for the relatively mild but protracted withdrawal syndrome. Rifampin and phenytoin accelerate methadone metabolism and can precipitate withdrawal symptoms.

THERAPEUTIC USES The primary uses of *methadone hydrochloride* (DOLOPHINE, others) are relief of chronic pain, treatment of opioid abstinence syndromes, and treatment of heroin users. It should not be used in labor.

The onset of analgesia occurs 10–20 minutes after parenteral administration and 30–60 minutes after oral use. The typical oral dose is 2.5–15 mg depending on the severity of the pain and the response of the patient. Care must be taken when escalating the dosage because of the prolonged $t_{1/2}$ of the drug and its tendency to accumulate over a period of several days with repeated dosing. Despite its longer plasma half-life, the duration of the analgesic action of single doses of methadone is essentially the same as that of morphine. With repeated use, cumulative effects are seen, so either lower dosages or longer intervals between doses become possible.

Propoxyphene

PHARMACOLOGICAL ACTIONS

Although slightly less selective than morphine, propoxyphene binds primarily to μ opioid receptors and produces analgesia and other CNS effects that are similar to those seen with morphine-like opioids. It is likely that at equianalgesic doses the incidence of side effects such as nausea, anorexia, constipation, abdominal pain, and drowsiness are similar to those of codeine.

As an analgesic, propoxyphene is about one-half to two-thirds as potent as codeine given orally. A dose of 90–120 mg of propoxyphene hydrochloride administered orally would equal the analgesic effects of 60 mg codeine, a dose that usually produces about as much analgesia as 600 mg aspirin. Combinations of propoxyphene and aspirin, like combinations of codeine and aspirin, afford a higher level of analgesia than does either agent alone.

*After oral administration, concentrations of propoxyphene peak at 1–2 hours. There is great variability between subjects in the rate of clearance; average $t_{1/2}$ of propoxyphene in plasma after a single dose is 6–12 hours, which is longer than that of codeine. In humans, the major route of metabolism is *N*-demethylation to yield norpropoxyphene, which has a $t_{1/2}$ of 30 hours and may accumulate to toxic levels with repeated doses.*

THERAPEUTIC USES

Propoxyphene is recommended for the treatment of mild-to-moderate pain. Given acutely, the commonly prescribed combination of 32 mg propoxyphene with aspirin may not produce more analgesia than aspirin alone, and doses of 65 mg of the hydrochloride or 100 mg of the napsylate are suggested. Propoxyphene is given most often in combination with aspirin or acetaminophen. The wide popularity of propoxyphene is largely a result of unrealistic overconcern about the addictive potential of codeine.

ACUTE OPIOID TOXICITY

Acute opioid toxicity may result from clinical overdosage, accidental overdosage in addicts, or attempts at suicide. Occasionally, a delayed type of toxicity may occur from the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed, and therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly. It is difficult to define the exact amount of any opioid that is toxic or lethal to humans. In nontolerant individuals, serious toxicity may follow the oral ingestion of 40–60 mg of methadone. A normal, pain-free adult is not likely to die after oral doses of morphine of <120 mg or to have serious toxicity with <30 mg parenterally.

SYMPTOMS AND DIAGNOSIS

The triad of coma, pinpoint pupils, and depressed respiration strongly suggests opioid poisoning. A patient who has taken an overdose of an opioid usually is stuporous or, if a large overdose has been taken, may be in a coma. The respiratory rate will be very low, or the patient may be apneic and cyanotic. As the respiratory exchange decreases, blood pressure, at first likely to be near normal, will fall progressively. If oxygenation is restored early, the blood pressure will improve; if hypoxia persists untreated, there may be capillary damage, and measures to combat shock may be required. The pupils will be symmetrical and pinpoint in size; if hypoxia is severe, they may be dilated. Urine formation is depressed, body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may obstruct the airway. Frank convulsions occasionally occur in infants and children. When death ensues, it is nearly always from respiratory failure. Even if respiration is restored, death still may occur as a result of complications that develop during the period of coma, such as pneumonia or shock. Noncardiogenic pulmonary edema is seen commonly with opioid poisoning.

TREATMENT Establish a patent airway and ventilate the patient. Opioid antagonists (see below) can produce dramatic reversal of the severe respiratory depression; naloxone is the treatment of choice. The safest approach is to dilute the standard naloxone dose (0.4 mg) and slowly administer it intravenously, monitoring arousal and respiratory function. With care, it usually is possible to reverse the respiratory depression without precipitating a major withdrawal syndrome. If no response is seen with the first dose, additional doses can be given. Patients should be observed for rebound increases in sympathetic nervous system activity, which may result in cardiac arrhythmias and pulmonary edema. For reversing opioid poisoning in children, the initial dose of naloxone is 0.01 mg/kg. If no effect is seen after a total dose of 10 mg, one can reasonably question the accuracy of the diagnosis. Pulmonary edema sometimes associated with opioid overdosage may be countered by positive-pressure respiration. Tonic-clonic seizures, occasionally seen as part of the toxic syndrome with meperidine and propoxyphene, are ameliorated by treatment with naloxone.

OPIOID AGONIST/ANTAGONISTS AND PARTIAL AGONISTS

Drugs such as *nalbuphine* and *butorphanol* are competitive μ -receptor antagonists that exert analgesic actions by acting as agonists at κ receptors. Pentazocine qualitatively resembles these drugs, but it may be a weaker μ -receptor antagonist or partial agonist while retaining its κ -agonist activity. Buprenorphine, in contrast, is a partial agonist at μ receptors. The clinical use of these drugs is limited by undesirable side effects and limited analgesic effects.

Pentazocine

The CNS effects produced by pentazocine generally are similar to those of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at κ opioid receptors. Higher doses of pentazocine (60–90 mg) elicit dysphoric and psychotomimetic effects; these effects may involve activation of supraspinal κ receptors and sometimes are reversed by naloxone.

The cardiovascular responses to pentazocine differ from those seen with typical μ -receptor agonists, in that high doses cause an increase in blood pressure and heart rate. Pentazocine acts as a weak antagonist or partial agonist at μ -opioid receptors. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients dependent on morphine or other μ -receptor agonists, pentazocine may precipitate withdrawal. Ceiling effects for analgesia and respiratory depression are observed above 50–100 mg pentazocine.

Tablets for oral use now contain pentazocine hydrochloride (equivalent to 50 mg of the base) and naloxone hydrochloride (equivalent to 0.5 mg of the base; TALWIN NX), which reduces the potential use of tablets as a source of injectable pentazocine. After oral ingestion, naloxone is destroyed rapidly by the liver; however, if the material is dissolved and injected, the naloxone produces aversive effects in subjects dependent on opioids. An oral dose of ~50 mg pentazocine results in analgesia equivalent to that produced by 60 mg codeine orally.

Nalbuphine

Nalbuphine is an agonist–antagonist opioid with a spectrum of effects that qualitatively resembles that of pentazocine; however, nalbuphine is a more potent antagonist at μ receptors and is less likely to produce dysphoria.

PHARMACOLOGICAL ACTIONS AND SIDE EFFECTS

An intramuscular dose of 10 mg nalbuphine is equianalgesic to 10 mg morphine, with similar onset and duration of analgesia. Nalbuphine depresses respiration as much as morphine. However, it exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression or analgesia. In contrast to pentazocine and butorphanol, 10 mg nalbuphine given to patients with stable coronary artery disease does not increase cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are relatively stable when nalbuphine is given to patients with acute myocardial infarction. Nalbuphine produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are most common. At much higher doses (70 mg), psychotomimetic side effects (e.g., dysphoria, racing thoughts, and distortions of body image) can occur. Nalbuphine is metabolized in the liver and has a $t_{1/2}$ in plasma of 2–3 hours. Given orally, nalbuphine is 20–25% as potent as when given intramuscularly.

THERAPEUTIC USES

Nalbuphine hydrochloride (NUBAIN) is used to produce analgesia. Because it is an agonist–antagonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed. The usual adult dose is 10 mg parenterally every 3–6 hours; this may be increased to 20 mg in nontolerant individuals.

Butorphanol

Butorphanol is a morphinan congener with a profile of actions similar to that of pentazocine.

PHARMACOLOGICAL ACTIONS AND SIDE EFFECTS

In postoperative patients, a parenteral dose of 2–3 mg butorphanol produces analgesia and respiratory depression approximately equal to that produced by 10 mg morphine or 80–100 mg meperidine; the onset, peak, and duration of action are similar to those that follow the administration of morphine. The plasma $t_{1/2}$ of butorphanol is ~3 hours. Like pentazocine, analgesic doses of butorphanol produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased.

The major side effects of butorphanol are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence of psychotomimetic side effects is lower than that with equianalgesic doses of pentazocine, they are qualitatively similar. Physical dependence on butorphanol can occur.

THERAPEUTIC USES

Butorphanol tartrate (STADOL) is better suited for the relief of acute than chronic pain. Because of its side effects on the heart, it is less useful than morphine or meperidine in patients with congestive heart failure or myocardial infarction. The usual dose is 1–4 mg of the tartrate given intramuscularly or 0.5–2 mg given intravenously every 3–4 hours. A nasal formulation (STADOL NS) is available and has proven to be effective.

Buprenorphine

Buprenorphine is a semisynthetic, lipophilic opioid derived from thebaine that is 25–50 times more potent than morphine.

PHARMACOLOGICAL ACTIONS AND SIDE EFFECTS

About 0.4 mg buprenorphine is equianalgesic with 10 mg morphine given intramuscularly. Although variable, the duration of analgesia usually is longer than that of morphine. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of morphine.

Buprenorphine appears to be a partial μ -receptor agonist and may cause symptoms of abstinence in patients who have been receiving μ -receptor agonists for several weeks. It antagonizes the respiratory depression produced by anesthetic doses of fentanyl about as well as does naloxone without completely reversing opioid pain relief. The respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by even high doses of naloxone once the effects have been produced due to slow dissociation of buprenorphine from opioid receptors. Therefore, plasma levels of buprenorphine may not parallel clinical effects. Cardiovascular and other side effects (e.g., sedation, nausea, vomiting, dizziness, sweating, and headache) appear to be similar to those of morphine-like opioids.

Administered sublingually, buprenorphine (0.4–0.8 mg) produces satisfactory analgesia in postoperative patients. Concentrations peak within 5 minutes of intramuscular injection and within 1–2 hours of oral or sublingual administration. The $t_{1/2}$ of ~3 hours bears little relationship to the rate of disappearance of effects (see above). Most of the drug is excreted unchanged in the feces. About 96% of the circulating drug is bound to protein.

THERAPEUTIC USES

Buprenorphine (BUPRENEX; SUBUTEX) is used as an analgesic and as a maintenance drug for opioid-dependent subjects. The usual intramuscular or intravenous dose for analgesia is 0.3 mg given every 6 hours. Sublingual doses of 0.4–0.8 mg also produce effective analgesia. Buprenorphine is metabolized to norbuprenorphine by CYP3A4. Thus, care should be taken in treating patients who also are taking known inhibitors of CYP3A4 (e.g., azole antifungals, macrolide antibiotics, and HIV protease inhibitors) or drugs that induce CYP3A4 activity (e.g., anticonvulsants and rifampin).

Buprenorphine is approved by the FDA for the treatment of opioid addiction. Treatment is initiated with buprenorphine alone administered sublingually, followed by maintenance therapy with a combination of buprenorphine and naloxone (SUBOXONE) to minimize abuse potential. The partial agonist properties of buprenorphine limit its usefulness for the treatment of addicts who require high maintenance doses of opioids. However, conversion to maintenance treatment with higher doses of methadone, a full agonist, is possible.

OPIOID ANTAGONISTS

These agents have obvious therapeutic utility in the treatment of opioid overdose. As the understanding of the role of endogenous opioid systems in pathophysiological states (e.g., shock, stroke, spinal cord and brain trauma) increases, additional therapeutic indications for these antagonists may develop.

Pharmacological Properties

If endogenous opioid systems have not been activated, the pharmacological actions of opioid antagonists depend on whether or not an opioid agonist has been administered previously, on the pharmacological profile of that opioid, and on the degree to which physical dependence on an opioid has developed.

EFFECTS IN THE ABSENCE OF OPIOID DRUGS Subcutaneous doses of naloxone (NARCAN) up to 12 mg produce no discernible subjective effects, and 24 mg causes only slight drowsiness. Naltrexone (REVIA) also appears to be a relatively pure antagonist but with higher oral efficacy and a longer duration of action. At doses in excess of 0.3 mg/kg naloxone, normal subjects show increased systolic blood pressure and decreased performance on tests of memory. High doses of naltrexone appeared to cause mild dysphoria in one study but almost no subjective effect in several others.

Although high doses of antagonists might be expected to alter the actions of endogenous opioid peptides, the detectable effects usually are both subtle and limited. This most likely reflects the low levels of tonic activity of the opioid systems. In this regard, analgesic effects can be differentiated from endocrine effects, in which naloxone causes readily demonstrable changes in hormone levels (see below). Interestingly, naloxone appears to block the analgesic effects of placebo medications and acupuncture.

Endogenous opioid peptides participate in the regulation of pituitary secretion by exerting tonic inhibitory effects on the release of certain hypothalamic releasing hormones (see Chapter 55). Thus, the administration of naloxone or naltrexone increases the secretion of GnRH and CRH and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. Naloxone stimulates the release of prolactin in women.

ANTAGONISTIC ACTIONS Small doses (0.4–0.8 mg) of naloxone given intramuscularly or intravenously prevent or promptly reverse the effects of μ -receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1–2 minutes. Sedative effects are reversed, and blood pressure, if depressed, returns to normal. Higher doses of naloxone are required to antagonize the respiratory-depressant effects of buprenorphine; 1 mg naloxone intravenously completely blocks the effects of 25 mg heroin. Naloxone reverses the psychotomimetic and dysphoric effects of agonist–antagonist agents such as pentazocine, but much higher doses (10–15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1–4 hours. Antagonism of opioid effects by naloxone often is accompanied by “overshoot” phenomena. For example, respiratory rate depressed transiently by opioids becomes higher than that before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported.

EFFECTS IN PHYSICAL DEPENDENCE In subjects who are dependent on morphine-like opioids, small subcutaneous doses of naloxone (0.5 mg) precipitate a moderate-to-severe withdrawal syndrome that is very similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in ~2 hours. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Higher doses of naloxone will precipitate a withdrawal syndrome in patients dependent on pentazocine, butorphanol, or nalbuphine. Naloxone produces overshoot phenomena suggestive of early acute physical dependence 6–24 hours after a μ agonist.

TOLERANCE AND PHYSICAL DEPENDENCE Even after prolonged administration of high doses, discontinuation of naloxone is not followed by any recognizable withdrawal syndrome, and the withdrawal of naltrexone, another relatively pure antagonist, produces very few signs and symptoms. However, long-term administration of antagonists increases the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists. Naltrexone and naloxone have little or no potential for abuse.

ABSORPTION, FATE, AND EXCRETION Although absorbed readily from the GI tract, naloxone is almost completely metabolized by the liver before reaching the systemic circulation and thus must be administered parenterally. The $t_{1/2}$ of naloxone is ~1 hour, but its clinically effective duration of action can be even less.

Compared with naloxone, naltrexone retains much more of its efficacy by the oral route, and its duration of action approaches 24 hours after moderate oral doses. Peak concentrations in plasma are reached within 1–2 hours and the $t_{1/2}$ of ~3 hours does not change with long-term use. Naltrexone is much more potent than naloxone, and 100-mg oral doses given to patients addicted to opioids produce concentrations in tissues sufficient to block the euphorogenic effects of 25-mg intravenous doses of heroin for 48 hours.

Therapeutic Uses

Opioid antagonists have established uses in the treatment of opioid-induced toxicity, especially respiratory depression; in the diagnosis of physical dependence on opioids; and as therapeutic agents in the treatment of compulsive users of opioids (Chapter 23). Naltrexone is also FDA-approved for the treatment of alcohol abuse.

TREATMENT OF OPIOID OVERDOSAGE Naloxone hydrochloride should be used cautiously for opiate overdose because it also can precipitate withdrawal in dependent subjects and cause undesirable cardiovascular side effects. By carefully titrating the dose of naloxone, it usually is possible to antagonize the respiratory-depressant actions without eliciting a full withdrawal syndrome. The duration of action of naloxone is relatively short, and it often must be given repeatedly or by continuous infusion. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression secondary to the intravenous or intramuscular administration of opioids to the mother. In the neonate, the initial dose is 10 $\mu\text{g}/\text{kg}$ given intravenously, intramuscularly, or subcutaneously.

CENTRALLY ACTIVE ANTITUSSIVE AGENTS

Cough is a useful physiological mechanism that serves to clear the respiratory passages of foreign material and excess secretions and should not be suppressed indiscriminately. Chronic cough sometimes can prevent rest or sleep or contribute to fatigue, especially in elderly patients. In such situations, the physician should use a drug that will reduce the frequency or intensity of the coughing. The cough reflex is complex, involving the central and peripheral nervous systems and the smooth muscle of the bronchial tree. It has been suggested that irritation of the bronchial mucosa causes bronchoconstriction, which, in turn, stimulates cough receptors (which probably represent a specialized type of stretch receptor) located in tracheobronchial passages. Afferent conduction from these receptors is *via* the vagus nerve; central components of the reflex probably include several mechanisms or centers that are distinct from the mechanisms involved in the regulation of respiration.

The opioid analgesics discussed earlier (codeine and hydrocodone are the opioids most commonly used to suppress cough), as well as a number of nonopioid agents reduce cough as a result of their central actions. Cough suppression often occurs with lower doses of opioids than those needed for analgesia. A 10- or 20-mg oral dose of codeine, although ineffective for analgesia, produces a demonstrable antitussive effect, and higher doses produce even more suppression of chronic cough.

DEXTROMETHORPHAN Dextromethorphan (D-3-methoxy-*N*-methylmorphinan) is the D-isomer of the codeine analog methorphan; unlike the L-isomer, it has no analgesic or addictive properties and does not act through opioid receptors. The drug acts centrally to elevate the threshold for coughing; its potency is nearly equal to that of codeine, but it produces fewer subjective and GI side effects. In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5–6 hours. Its toxicity is low, but extremely high doses may produce CNS depression.

THERAPEUTIC USES OF OPIOID ANALGESICS

Opioids remain the mainstay of pain treatment. Useful guidelines for their administration have been developed for a number of clinical situations, including treatment of acute pain, trauma, cancer, nonmalignant chronic pain, and pain in children. In the case of cancer pain, adherence to standardized protocols can improve pain management significantly. Guidelines for the oral and parenteral dosing of opioids are presented in Table 21–5.

In general, it is recommended that opioids always be combined with other analgesic agents, such as NSAIDs or acetaminophen. In this way, one can take advantage of additive analgesic effects and minimize the dose of opioids and thus undesirable side effects. In some situations, NSAIDs can provide analgesia equal to that produced by 60 mg codeine. This “opioid sparing” strategy is the backbone of the “analgesic ladder” for pain management proposed by the WHO. Weaker opioids can be supplanted by stronger opioids in cases of moderate or severe pain. In addition, analgesics always should be dosed in a continuous or “around the clock” fashion rather than on an as-needed basis for chronic severe pain. This provides more consistent analgesic levels and avoids unnecessary suffering.

Factors guiding the selection of specific opioid compounds for pain treatment include potency, pharmacokinetic characteristics, and the routes of administration available. A more potent compound could be useful when high doses of opioid are required so that the medicine can be given in a smaller volume. Duration of action also is an important consideration. In cases where a lower addiction risk is required or in patients unable to tolerate other opioids, a partial agonist or mixed agonist–antagonist compound might be a rational choice.

Morphine is available for oral use in standard and controlled-release preparations. Owing to first-pass metabolism, morphine is two to six times less potent orally than it is parenterally. This is important to remember when converting a patient from parenteral to oral medication. There is wide variability in the first-pass metabolism, and the dose should be titrated to the patient's needs. In children who weigh <50 kg, morphine can be given at 0.1 mg/kg every 3–4 hours parenterally or at 0.3 mg/kg orally.

Codeine is used widely owing to its high oral/parenteral potency ratio. Orally, codeine at 30 mg is approximately equianalgesic to 600 mg aspirin. Combinations of codeine with aspirin or acetaminophen usually provide additive actions, and at these doses, analgesic efficacy can exceed that of 60 mg codeine. Many drugs can be used instead of morphine or codeine, as shown in Table 21–5. Oxycodone (ROXICODINE, others), with its high oral/parenteral potency ratio, is used widely in combination with aspirin (PERCODAN, others) or acetaminophen (PERCOCET 2.5/325, others). Oxycodone also is available in a sustained-release formulation for chronic pain management

Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical response is necessary. Because there is not complete cross tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose when changing drugs and to retitrate to response.

Caution: Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics.

¹*Caution:* Doses listed for patients with body weight less than 50 kg cannot be used as initial starting doses in babies less than 6 months of age. Consult the *Clinical Practice Guideline for Acute Pain Management: Operative or Medical Procedures and Trauma* section on management of pain in neonates for recommendations.

²For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences.

³*Caution:* Codeine doses above 65 mg often are not appropriate due to diminishing incremental analgesia with increasing doses but continually increasing constipation and other side effects.

⁴*Caution:* Doses of aspirin and acetaminophen in combination opioid/NSAID preparations must also be adjusted to the patient's body weight. Maximum acetaminophen dose: 4 gm/day in adults, 90 mg/kg/day in children.

⁵Doses for moderate pain not necessarily equivalent to 30 mg oral or 10 mg parenteral morphine.

(OXYCONTIN). Unfortunately, this formulation has been subject to widespread abuse leading to serious consequences, including death, and the FDA has strengthened warnings for this drug (see Chapter 23).

It also may be helpful to employ other drugs that enhance opioid analgesia and that may add beneficial effects of their own. For example, the combination of an opioid with a small dose of amphetamine may augment analgesia while reducing the sedative effects. Certain antidepressants, such as amitriptyline and desipramine, also may enhance opioid analgesia, and they may have analgesic actions in some types of neuropathic pain. Other potentially useful adjuvants include antihistamines, anticonvulsants such as carbamazepine and phenytoin, and glucocorticoids.

Alternative Routes of Administration

In addition to the traditional oral and parenteral formulations for opioids, other methods of administration have been developed in an effort to improve therapeutic efficacy while minimizing side effects.

PATIENT-CONTROLLED ANALGESIA (PCA) With this modality, the patient has limited control of the dosing of opioid from an infusion pump within tightly mandated parameters. PCA can be used for intravenous or epidural infusion. This technique avoids any delays in administration and permits greater dosing flexibility than other regimens, better adapting to individual differences in responsiveness to pain and to opioids. It also gives the patient a greater sense of control.

INTRASPINAL INFUSION Administration of opioids into the epidural or intrathecal space provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. This permits the use of doses substantially lower than those required for oral or parenteral administration (Table 21-6), thereby decreasing systemic side effects. However, epidural opioids have their own dose-dependent side effects, such as itching, nausea, vomiting, respiratory depression, and urinary retention. Administration of hydrophilic opioids (DURAMORPH, others) permits more rostral spread of the compound, allowing it to directly affect supraspinal sites. As a consequence, after intraspinal morphine, delayed respiratory depression can be observed for as long as 24 hours after a bolus dose. Nausea and vomiting are more prominent symptoms with intraspinal morphine. However, supraspinal analgesic centers also can be stimulated, possibly leading to synergistic analgesic effects.

Analogous to the relationship between systemic opioids and NSAIDs, intraspinal narcotics often are combined with local anesthetics. This permits the use of lower doses of both agents,

minimizing local anesthetic–induced complications of motor blockade and opioid-induced complications. Epidural opioid administration is widely used in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn. Intrathecal administration of opioids as a bolus (“spinal” anesthesia) also is popular for acute pain management. Chronic intrathecal infusions generally are reserved for use in chronic pain patients.

Rectal administration is an alternative for patients with difficulty swallowing or oral pathology and who prefer a less invasive route than parenteral. This route is not well tolerated in children. Onset of action is seen within 10 minutes.

CLINICAL SUMMARY

Opioid analgesics provide symptomatic relief of pain, but the underlying disease remains. The clinician must weigh the benefits against any potential risk to the patient, which may be quite different in an acute versus chronic disease.

Acutely, opioids will reduce the intensity of pain; physical signs (*e.g.*, abdominal rigidity) generally will remain. Relief of pain can facilitate history taking, examination, and the patient’s ability to tolerate diagnostic procedures. Patients should not be evaluated inadequately because of the physician’s unwillingness to prescribe narcotics, or over concerns of obscuring the progression of underlying disease.

The problems that arise in the relief of pain associated with chronic conditions are more complex. Repeated daily administration of opioid analgesics eventually will produce tolerance and some degree of physical dependence. The degree will depend on the particular drug, the frequency of administration, and the quantity administered. The decision to control any chronic symptom, especially pain, by the repeated administration of an opioid must be made carefully. When pain is due to chronic nonmalignant disease, measures other than opioid drugs should be employed if possible. Such measures include the use of NSAIDs, local nerve blocks, antidepressant drugs, electrical stimulation, acupuncture, hypnosis, or behavioral modification. However, highly selected subpopulations of chronic nonmalignant pain patients can be maintained adequately on opioids for extended periods of time.

In the usual doses, morphine-like drugs relieve suffering by altering the emotional component of the painful experience, as well as by producing analgesia. Control of pain, especially chronic pain, must include attention to both psychological factors and the social impact of the illness that sometimes play dominant roles in determining the suffering experienced by the patient. In addition to emotional support, the physician also must consider the substantial variability in the patient’s capacity to tolerate pain and the response to opioids. Some patients may require considerably more than the average dose of a drug to experience any relief from pain; others may require dosing at shorter intervals. Some clinicians, out of an exaggerated concern for the possibility of inducing addiction, prescribe initial doses of opioids that are too small or given too infrequently to alleviate pain and then respond to the patient’s continued complaints with an even more exaggerated concern about drug dependence. Infants and children may receive inadequate treatment for pain than are adults owing to communication difficulties, lack of familiarity with appropriate pain assessment methodologies, and inexperience with the use of strong opioids in children.

PAIN OF TERMINAL ILLNESS AND CANCER PAIN Opioids are not indicated in all cases of terminal illness, but the analgesia, tranquility, and even euphoria afforded by the use of opioids can make the final days far less distressing for the patient and family. Although physical dependence and tolerance may develop, this possibility should in no way prevent physicians from fulfilling their primary obligation to ease the patient’s discomfort. The physician should not wait until the pain becomes agonizing. This sometimes may entail the regular use of opioid analgesics in substantial doses. Such patients, while they may be physically dependent, are not “addicts” even though they require large doses on a regular basis (*see* Chapter 23).

Most experts in pain management recommend that opioids be administered at sufficiently short, fixed intervals so that pain is continually under control and patients do not dread its return. *Less drug is needed to prevent the recurrence of pain than to relieve it.* Morphine remains the opioid of choice in most of these situations, and the route and dose should be adjusted to the needs of the individual patient. Oral morphine is adequate in most situations. Sustained-release preparations of oral morphine and oxycodone are available that can be administered at 8-, 12- or 24-hour intervals

(morphine) or 8- to 12-hour intervals (oxycodone). Superior control of pain often can be achieved with fewer side effects using the same daily dose; a decrease in the fluctuation of plasma concentrations of morphine may be partially responsible.

Constipation is exceedingly common with opioids, and stool softeners and laxatives should be initiated early. Amphetamines have demonstrable mood-elevating and analgesic effects and enhance opioid-induced analgesia. However, not all terminal patients require the euphoriant effects of amphetamine, and some experience side effects, such as anorexia. Although tolerance does develop to oral opioids, many patients obtain relief from the same dosage for weeks or months. In cases where one opioid loses effectiveness, switching to another may improve pain relief. “Cross-tolerance” among opioids exists, but cross-tolerance among related μ -receptor agonists is not complete.

PHARMACOLOGY AND TOXICOLOGY OF ETHANOL

The two-carbon alcohol *ethanol*, $\text{CH}_3\text{CH}_2\text{OH}$, is a CNS depressant that is widely available to adults; its use is legal and accepted in many societies, and its abuse is a societal problem. The relevant pharmacological properties of ethanol include effects on the gastrointestinal (GI), cardiovascular, and central nervous systems (CNS), effects on disease processes, and effects on prenatal development. Ethanol disturbs the fine balance between excitatory and inhibitory influences in the brain, producing disinhibition, ataxia, and sedation. Tolerance to ethanol develops after chronic use, and physical dependence is demonstrated on alcohol withdrawal (*see* Chapter 23). Understanding the cellular and molecular mechanisms of these myriad effects of ethanol *in vivo* requires an integration of knowledge from multiple biomedical sciences (the terms *ethanol* and *alcohol* are used interchangeably in this chapter).

Compared with other drugs, surprisingly large amounts of alcohol are required for physiological effects, resulting in its consumption more as a food than a drug. The alcohol content of beverages typically ranges from 4–6% (volume/volume) for beer, 10–15% for wine, and 40% and higher for distilled spirits (the “proof” of an alcoholic beverage is twice its percentage of alcohol; *e.g.*, 40% alcohol is 80 proof). A glass of beer or wine, a mixed drink, or a shot of spirits contains ~14 g alcohol, or ~0.3 mol ethanol. Consumption of 1–2 mol over a few hours is not uncommon. Since the ratio of ethanol in end-expiratory alveolar air and ethanol in the blood is relatively consistent, blood alcohol levels (BALs) in human beings can be estimated readily by the measurement of alcohol levels in expired air; the partition coefficient for ethanol between blood and alveolar air is ~2000:1. Because of the causal relationship between excessive alcohol consumption and vehicular accidents, there has been a near-universal adoption of laws attempting to limit the operation of vehicles while under the influence of alcohol. Legally allowed BALs typically are set at or below 80 mg% (80 mg ethanol/100 mL blood; 0.08% w/v), which is equivalent to a concentration of 17 mM ethanol in blood. A 12-oz bottle of beer, a 5-oz glass of wine, and a 1.5-oz “shot” of 40% liquor each contains ~14 g ethanol, and the consumption of one of these beverages by a 70-kg person would produce a BAL of ~30 mg%. Note that this is only an approximation; a number of factors influence the BAL, including the rate of drinking, gender, body weight and water percentage, and the rates of metabolism and stomach emptying (*see* “Acute Alcohol Intoxication” below).

PHARMACOLOGICAL PROPERTIES

Absorption, Distribution, and Metabolism

After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total-body water (0.5–0.7 L/kg). Peak blood levels occur ~30 minutes after ingestion of ethanol when the stomach is empty. Because absorption occurs more rapidly from the small intestine than from the stomach, delays in gastric emptying (owing, for example, to the presence of food) slow ethanol absorption. Because of first-pass metabolism by gastric and liver alcohol dehydrogenase (ADH), oral ingestion of ethanol leads to lower BALs than would be obtained if the same quantity were administered intravenously. Gastric metabolism of ethanol is lower in women than in men, which may contribute to the greater susceptibility of women to ethanol. *Aspirin* increases ethanol bioavailability by inhibiting gastric ADH. Ethanol is metabolized largely by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by aldehyde dehydrogenase (ALDH) (Figure 22–1). Each metabolic step requires NAD^+ ; thus, oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD^+ (~1.3 kg). This greatly exceeds the supply of NAD^+ in the liver; indeed, NAD^+ availability limits ethanol metabolism to ~8 g (~170 mmol)/hr in a 70-kg adult, or ~120 mg/kg/hr. Thus, hepatic ethanol metabolism functionally saturates at relatively low blood levels compared with the high BALs achieved, and ethanol metabolism is a zero-order process (constant amount per unit time). Small amounts of ethanol are excreted in urine, sweat, and breath, but metabolism to acetate accounts for 90–98% of ingested ethanol, mostly owing to hepatic metabolism by ADH and ALDH. CYP2E1 also can contribute (Figure 22–1), especially at higher ethanol concentrations and when its activity is induced. Catalase also can produce acetaldehyde from ethanol, but hepatic H_2O_2 availability usually is too low to support significant flux of ethanol through this pathway. Although CYP2E1 usually is not a major factor in ethanol metabolism, it can be an important site of interactions of ethanol with other drugs. CYP2E1 is induced by chronic consumption of ethanol, increasing the clearance of its substrates and activating certain toxins such as CCl_4 . There can be decreased clearance of the same

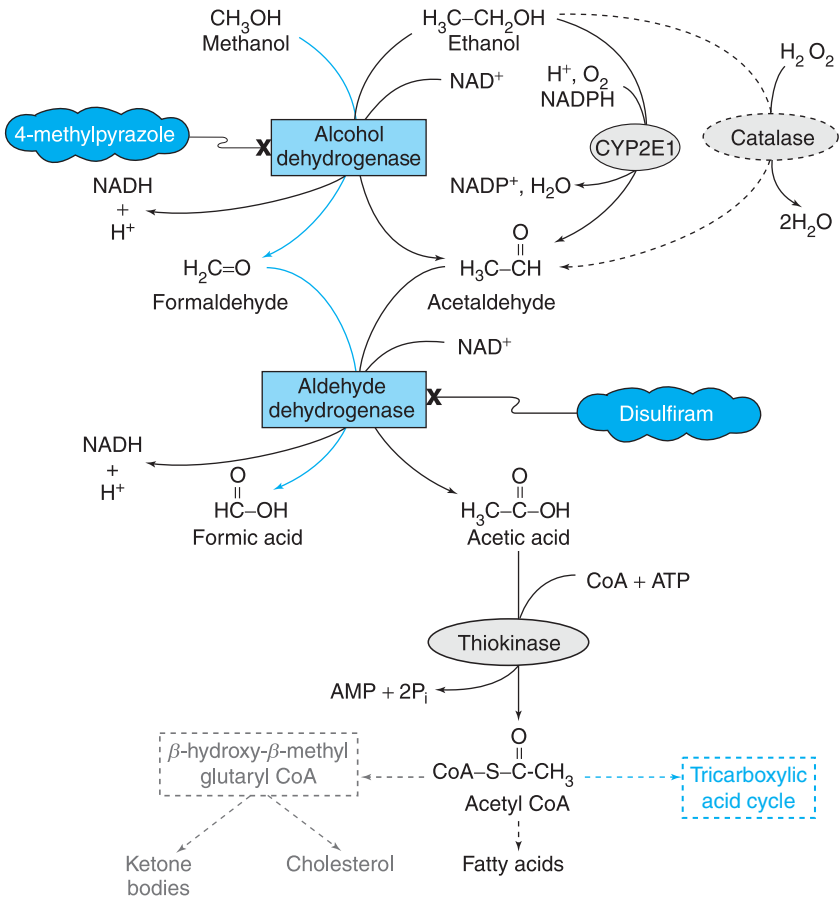

FIGURE 22-1 Metabolism of ethanol and methanol.

drugs, however, after acute consumption of ethanol because ethanol competes with them for oxidation by the enzyme system (e.g., *phenytoin* and *warfarin*). The large increase in the hepatic $\text{NADH}:\text{NAD}^+$ ratio during ethanol oxidation has profound consequences in addition to limiting the rate of ethanol metabolism. Enzymes requiring NAD^+ are inhibited; thus, lactate accumulates, activity of the tricarboxylic acid cycle is reduced, and acetyl coenzyme A (acetyl CoA) accumulates (and it is produced in quantity from ethanol-derived acetic acid; Figure 22-1). The combination of increased NADH and elevated acetyl CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides. Ketone bodies accrue, exacerbating lactic acidosis. Ethanol metabolism by the CYP2E1 pathway produces elevated NADPH , limiting the availability of NADPH for the regeneration of reduced glutathione (GSH), thereby enhancing oxidative stress.

The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H_2O_2 and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol's effect on gram-negative flora in the GI tract. Effects of heavy ethanol ingestion on various organs are summarized below; damage to tissues very likely reflects the poor nutritional status of alcoholics (malabsorption and lack of vitamins A and D and thiamine), suppression of immune function by ethanol, and a variety of other generalized effects.

The one-carbon alcohol *methanol* also is metabolized by ADH and ALDH, with damaging consequences (see below). Competition between methanol and ethanol for ADH forms the basis of the use of ethanol in methanol poisoning. Several drugs inhibit alcohol metabolism, including *4-methylpyrazole*, an ADH inhibitor useful in ethylene glycol poisoning, and *disulfiram*, an ALDH

inhibitor used in treating alcoholism (*see* below). Ethanol also can competitively inhibit the metabolism of other substrates of ADH and CYP2E1, such as methanol and ethylene glycol, and therefore is an effective antidote.

EFFECTS OF ETHANOL ON PHYSIOLOGICAL SYSTEMS

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (Act 2, Scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring overconfidence with physical impairment:

Porter: . . . and drink, sir, is a great provoker of three things.

Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [cutaneous vasodilation], sleep [CNS depression], and urine [a consequence of the inhibition of antidiuretic hormone [vasopressin] secretion, exacerbated by volume loading]. Lechery, sir, it provokes and unprovokes: it provokes the desire but it takes away] the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and disheartens him, makes him stand to and not stand to [the imagination desires what the corpus cavernosum cannot deliver]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

More recent research has added details to Shakespeare's enumeration—*see* the bracketed additions to the Porter's words above and the section on organ systems below—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of modest concentrations of ethanol on the CNS. The sections below detail ethanol's effects on physiological systems.

Central Nervous System

Although the public often views alcoholic drinks as stimulating, ethanol primarily is a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other depressants such as barbiturates and benzodiazepines, can have antianxiety actions and produce behavioral disinhibition at a wide range of dosages. Individual signs of intoxication vary from expansive and vivacious affect to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function generally is impaired, and a condition of general anesthesia ultimately prevails. However, there is little margin between the anesthetic actions and lethal effects (usually owing to respiratory depression).

About 10% of alcohol drinkers progress to levels of consumption that are physically and socially detrimental. Chronic abuse is accompanied by tolerance, dependence, and craving for the drug (see below for a discussion of neuronal mechanisms; see also Chapter 23). Alcoholism is characterized by compulsive use despite clearly deleterious social and medical consequences. Alcoholism is a progressive illness, and brain damage from chronic alcohol abuse contributes to the deficits in cognitive functioning and judgment seen in alcoholics. Alcoholism is a leading cause of dementia in the U.S. Chronic alcohol abuse results in shrinkage of the brain owing to loss of both white and gray matter. The frontal lobes are particularly sensitive to damage by alcohol, and the extent of damage is determined by the amount and duration of alcohol consumption, with older alcoholics being more vulnerable than younger ones. Ethanol itself is neurotoxic. Although malnutrition or vitamin deficiencies probably play roles in complications of alcoholism such as Wernicke's encephalopathy and Korsakoff's psychosis, most of the alcohol-induced brain damage in Western countries is due to alcohol itself. In addition to loss of brain tissue, alcohol abuse also reduces brain metabolism (as determined by positron-emission tomography), and this hypometabolic state rebounds to a level of increased metabolism during detoxification. The magnitude of decrease in metabolic state is determined by the number of years of alcohol use and the age of the patients (see "Mechanisms of CNS Actions" below).

Cardiovascular System

SERUM LIPOPROTEINS AND CARDIOVASCULAR EFFECTS In most countries, the risk of mortality due to coronary heart disease (CHD) is correlated with a high dietary intake of saturated fat and elevated serum cholesterol levels. France is an exception to this rule, with relatively low mortality from CHD despite the consumption of high quantities of saturated fats by the French (the "French paradox"). Epidemiological studies suggest that widespread wine consumption

(20–30 g ethanol/day) is one of the factors conferring a cardioprotective effect, with one to three drinks per day resulting in a 10–40% decreased risk of CHD compared to abstainers. In contrast, daily consumption of greater amounts of alcohol leads to an increased incidence of noncoronary causes of cardiovascular failure, such as arrhythmias, cardiomyopathy, and hemorrhagic stroke, offsetting the beneficial effects of alcohol on coronary arteries; *i.e.*, alcohol has a J-shaped dose-mortality curve. Reduced risks for CHD are seen at intakes as low as one-half drink per day. Young women and others at low risk for heart disease derive little benefit from light-to-moderate alcohol intake, whereas those of both sexes who are at high risk and who may have had a myocardial infarction clearly benefit. Data based on a number of prospective, cohort, cross-cultural, and case-control studies in diverse populations consistently reveal lower rates of angina pectoris, myocardial infarction, and peripheral artery disease in those consuming light (1–20 g/day) to moderate (21–40 g/day) amounts of alcohol.

One possible mechanism by which alcohol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in high-density lipoprotein (HDL; see Chapter 35), have been associated with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol levels. Ethanol-induced increases in HDL-cholesterol thus could antagonize cholesterol accumulation in arterial walls, lessening the risk of infarction. Approximately half the risk reduction associated with ethanol consumption is explained by changes in total HDL levels. HDL is found as two subfractions, named HDL₂ and HDL₃. Increased levels of HDL₂ (and possibly also HDL₃) are associated with reduced risk of myocardial infarction. Levels of both subfractions are increased following alcohol consumption and decrease when alcohol consumption ceases. Apolipoproteins A-I and A-II are constituents of HDL; some HDL particles contain only the former, whereas others are composed of both. Increased levels of both apolipoproteins A-I and A-II are associated with individuals who are daily heavy drinkers. In contrast, there are reports of decreased serum apolipoprotein(a) [Apo(a)] levels following acute alcohol consumption. Elevated Apo(a) levels have been associated with an increased risk for the development of atherosclerosis.

Although the cardioprotective effects of ethanol initially were noted in wine drinkers, all forms of alcoholic beverages confer cardioprotection. A variety of alcoholic beverages increase HDL levels while decreasing the risk of myocardial infarction. The flavonoids found in red wine (and purple grape juice) may have an additional antiatherogenic role by protecting low-density lipoprotein (LDL) from oxidative damage. Oxidized LDL has been implicated in several steps of atherogenesis. Another way in which alcohol consumption could play a cardioprotective role is by altering factors involved in blood clotting. Thrombosis is important in the genesis of myocardial infarctions; alcohol consumption elevates the levels of tissue plasminogen activator, a clot-dissolving enzyme (see Chapter 54), decreasing the likelihood of clot formation. Decreased fibrinogen concentrations seen following ethanol consumption also could be cardioprotective, and epidemiological studies have linked the moderate consumption of ethanol to an inhibition of platelet activation.

Should abstainers from alcohol be advised to consume ethanol in moderate amounts? *No.* There have been no randomized clinical trials to test the efficacy of daily alcohol use in reducing rates of CHD and mortality, and it is inappropriate for physicians to advocate alcohol ingestion solely to prevent heart disease. Many abstainers avoid alcohol because of a family history of alcoholism or for other health reasons, and it is imprudent to suggest that they begin drinking. Other lifestyle changes or medical treatments should be encouraged if patients are at risk for the development of CHD.

HYPERTENSION Heavy alcohol use can raise diastolic and systolic blood pressure. Studies indicate a positive, nonlinear association between alcohol use and hypertension that is unrelated to age, education, smoking status, or the use of oral contraceptives. Consumption above 30 g alcohol/day (>two standard drinks) is associated with a 1.5–2.3 mm Hg rise in diastolic and systolic blood pressure. A time effect also has been demonstrated, with diastolic and systolic blood pressure elevation being greatest for persons who consumed alcohol within 24 hours of examination. Women may be at greater risk than men. The mechanism(s) by which alcohol induces hypertension are not well understood.

The prevalence of hypertension attributable to excess alcohol consumption is not known, but studies suggest a range of 5–11%. The prevalence probably is higher for men than for women because they consume more alcohol. A reduction in or cessation of alcohol use in heavy drinkers may

reduce the need for antihypertensive medication or reduce the blood pressure to the normal range. A safe amount of alcohol consumption for hypertensive patients who are light drinkers (1–2 drinks per occasion and <14 drinks per week) has not been determined. Factors to consider are a personal history of ischemic heart disease, a history of binge drinking, or a family history of alcoholism or of cerebrovascular accident. Hypertensive patients with any of these risk factors should abstain from alcohol use.

CARDIAC ARRHYTHMIAS Alcohol has a number of pharmacological effects on cardiac conduction, including prolongation of ventricular repolarization (as indicated by a prolongation of the QT interval) and sympathetic stimulation. Atrial arrhythmias associated with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Some 15–20% of idiopathic cases of atrial fibrillation may be induced by chronic ethanol use. Ventricular tachycardia may be responsible for the increased risk of unexplained sudden death that has been observed in persons who are alcohol-dependent. During continued alcohol use, treatment of these arrhythmias may be more resistant to cardioversion, digoxin, or Ca²⁺-channel blocking agents (*see* Chapter 34). Patients with recurrent or refractory atrial arrhythmias should be questioned carefully about alcohol use.

CARDIOMYOPATHY Ethanol is known to have dose-related toxic effects on both skeletal and cardiac muscles. Numerous studies have shown that alcohol can depress cardiac contractility and lead to cardiomyopathy. Echocardiography demonstrates global hypokinesis. Fatty acid ethyl esters (formed from the enzymatic reaction of ethanol with free fatty acids) appear to play a role in the development of this disorder. Approximately half of all patients with idiopathic cardiomyopathy are alcohol-dependent. Although the clinical signs and symptoms of idiopathic and alcohol-induced cardiomyopathy are similar, alcohol-induced cardiomyopathy has a better prognosis if patients are able to stop drinking. Women are at greater risk of alcohol-induced cardiomyopathy than are men. Since 40–50% of persons with alcohol-induced cardiomyopathy who continue to drink die within 3–5 years, abstinence remains the primary treatment. Some patients respond to diuretics, angiotensin-converting enzyme inhibitors, and vasodilators.

STROKE Clinical studies indicate an increased incidence of hemorrhagic and ischemic stroke in persons who drink >40–60 g/day. Many cases of stroke follow prolonged binge drinking, especially when stroke occurs in younger patients. Proposed etiological factors include alcohol-induced (1) cardiac arrhythmias and associated thrombus formation, (2) high blood pressure from chronic alcohol consumption and subsequent cerebral artery degeneration, (3) acute increases in systolic blood pressure and alterations in cerebral artery tone, and (4) head trauma. The effects on hemostasis, fibrinolysis, and blood clotting are variable and could prevent or precipitate acute stroke. The effects of alcohol on the formation of intracranial aneurysms are controversial, but the statistical association disappears when one controls for tobacco use and gender.

Skeletal Muscle

Chronic, heavy, daily alcohol consumption is associated with decreased muscle strength, even when adjusted for other factors such as age, nicotine use, and chronic illness. Heavy doses of alcohol also can cause irreversible damage to muscle, reflected by a marked increase in the activity of creatine kinase in plasma. Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity. Approximately 50% of chronic heavy drinkers have evidence of type II fiber atrophy. These changes correlate with reductions in muscle protein synthesis and serum carnosinase activities. Most patients with chronic alcoholism show electromyographical changes, and many show evidence of a skeletal myopathy similar to alcoholic cardiomyopathy.

Body Temperature

Ingestion of ethanol causes a feeling of warmth because alcohol enhances cutaneous and gastric blood flow. Increased sweating also may occur. Heat is lost more rapidly, and the internal body temperature falls. After consumption of large amounts of ethanol, the central temperature-regulating mechanism itself becomes depressed, and the fall in body temperature may become pronounced. The action of alcohol in lowering body temperature is greater and more dangerous when the ambient environmental temperature is low. Studies of deaths from hypothermia suggest that alcohol is a major risk factor in these events. Patients with ischemic limbs secondary to peripheral vascular disease are particularly susceptible to cold damage.

Diuresis

Alcohol inhibits the release of vasopressin (antidiuretic hormone; *see* Chapter 29) from the posterior pituitary gland, resulting in enhanced diuresis. The volume loading that accompanies imbibing complements the diuresis that occurs as a result of reduced vasopressin secretion. Alcoholics have less urine output than do control subjects in response to a challenge dose with ethanol, suggesting that tolerance develops to the diuretic effects of ethanol. Alcoholics withdrawing from alcohol exhibit increased vasopressin release and a consequent retention of water, as well as dilutional hyponatremia.

Gastrointestinal System

ESOPHAGUS Alcohol frequently is either the primary etiologic factor or one of multiple causal factors associated with esophageal dysfunction. Ethanol also is associated with the development of esophageal reflux, Barrett's esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer. When compared with nonalcoholic nonsmokers, alcohol-dependent patients who smoke have a tenfold increased risk of developing cancer of the esophagus. There is little change in esophageal function at low blood alcohol concentrations, but at higher blood alcohol concentrations, a decrease in peristalsis and decreased lower esophageal sphincter pressure occur. Patients with chronic reflux esophagitis may respond to proton pump inhibitors (*see* Chapter 36) and abstinence from alcohol.

STOMACH Heavy alcohol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol appears to stimulate gastric secretions by exciting sensory nerves in the buccal and gastric mucosa and promoting the release of gastrin and histamine. Beverages containing more than 40% alcohol also have a direct toxic effect on gastric mucosa. While these effects are seen most often in chronic heavy drinkers, they can occur after moderate and short-term alcohol use. The diagnosis may not be clear because many patients have normal endoscopic examinations and upper gastrointestinal radiographs. Clinical symptoms include acute epigastric pain that is relieved with antacids or H₂ receptor antagonists (*see* Chapter 36).

Alcohol is not thought to play a role in the pathogenesis of peptic ulcer disease. Unlike acute and chronic gastritis, peptic ulcer disease is not more common in alcoholics. Nevertheless, alcohol exacerbates the clinical course and severity of ulcer symptoms. It appears to act synergistically with Helicobacter pylori to delay healing. Acute bleeding from the gastric mucosa, while uncommon, can be a life-threatening emergency. Upper GI bleeding is associated more commonly with esophageal varices, traumatic rupture of the esophagus, and clotting abnormalities.

INTESTINES Many alcoholics have chronic diarrhea as a result of malabsorption in the small intestine. The major symptom is frequent loose stools. The rectal fissures and pruritus ani that frequently are associated with heavy drinking probably are related to chronic diarrhea. The diarrhea is caused by structural and functional changes in the small intestine; the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes frequently are reversible after a period of abstinence. Treatment is based on replacing essential vitamins and electrolytes, slowing transit time with an agent such as loperamide (*see* Chapter 38), and abstaining from all alcoholic beverages. Patients with severe magnesium deficiencies (serum Mg²⁺ < 1 mEq/L) or symptomatic patients (a positive Chvostek's sign or asterixis) should receive 1 g magnesium sulfate intravenously or intramuscularly every 4 hours until the serum Mg²⁺ concentration is >1 mEq/L.

PANCREAS Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. While pancreatitis can occur after a single episode of heavy alcohol use, prolonged heavy drinking is common in most cases. Acute alcoholic pancreatitis is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Computed tomography is being used increasingly for diagnostic testing. While most attacks are not fatal, hemorrhagic pancreatitis can develop and lead to shock, renal failure, respiratory failure, and death. Management usually involves intravenous fluid replacement—often with nasogastric suction—and opioid pain medication. The etiology of acute pancreatitis probably is related to a direct toxic metabolic effect of alcohol on pancreatic acinar cells. Fatty acid esters and cytokines appear to play a major role.

Two-thirds of patients with recurrent alcoholic pancreatitis will develop chronic pancreatitis. Chronic pancreatitis is treated by replacing the endocrine and exocrine deficiencies that result

from pancreatic insufficiency. The development of hyperglycemia often requires insulin for control of blood-sugar levels. Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (see Chapter 37). The average lipase dose is 4000–24,000 units with each meal and snack. Many patients with chronic pancreatitis develop a chronic pain syndrome. While opioids may be helpful, non-narcotic methods for pain relief such as anti-inflammatory drugs, tricyclic antidepressants, exercise, relaxation techniques, and self-hypnosis are preferred treatments for this population because cross-dependence to other drugs is common among alcoholics. In particular, for patients receiving chronic opioid therapy for chronic pancreatitis, treatment contracts and frequent assessments for signs of addiction are important.

LIVER Ethanol produces a constellation of dose-related deleterious effects in the liver. The primary effects are fatty infiltration of the liver, hepatitis, and cirrhosis. Because of its intrinsic toxicity, alcohol can injure the liver in the absence of dietary deficiencies. The accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. This accumulation results from inhibition of both the tricarboxylic acid cycle and the oxidation of fat, in part, owing to the generation of excess NADH produced by the actions of ADH and ALDH (see Figure 22–1).

Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. Alcohol can affect stellate cells in the liver directly; chronic alcohol use is associated with transformation of stellate cells into collagen-producing, myofibroblast-like cells, resulting in deposition of collagen around terminal hepatic venules. The histological hallmark of alcoholic cirrhosis is the formation of Mallory bodies, which are thought to be due to an altered cytokeratin intermediate cytoskeleton. The molecular mechanisms for alcoholic cirrhosis are not well understood but could be due to a variety of effects of ethanol and its metabolites on phospholipid peroxidation, GSH metabolism, free radical production and proinflammatory cytokines. In addition, other factors can accelerate or enhance the development of liver cirrhosis.

Acetaminophen-induced hepatic toxicity (see Chapter 26) has been associated with alcoholic cirrhosis as a result of alcohol-induced increases in microsomal production of toxic acetaminophen metabolites. Hepatitis C appears to be an important cofactor in the development of end-stage alcoholic liver disease.

Several strategies to treat alcoholic liver disease have been evaluated. Prednisolone may improve survival in patients with severe alcoholic hepatitis and hepatic encephalopathy. Nutrients such as S-adenosylmethionine and polyunsaturated lecithin have been found to have beneficial effects in nonhuman primates and are undergoing clinical trials. Other medications that have been tested include oxandrolone, propylthiouracil, and colchicine. At present, none of these drugs is approved for use in the U.S. for the treatment of alcoholic liver disease. The current primary treatment for liver failure is transplantation in conjunction with abstinence from ethanol. Long-term outcome studies suggest that patients who are alcohol-dependent have survival rates similar to those of patients with other types of liver disease. Alcoholics with hepatitis C may respond to interferon-2 α (see Chapter 52).

Vitamins and Minerals

The almost complete lack of protein, vitamins, and most other nutrients in alcoholic beverages predisposes those who consume large quantities of alcohol to nutritional deficiencies. Alcoholics often present with these deficiencies owing to decreased intake, decreased absorption, or impaired utilization of nutrients. The peripheral neuropathy, Korsakoff's psychosis, and Wernicke's encephalopathy seen in alcoholics probably are caused by deficiencies of the B complex of vitamins (particularly thiamine), although direct toxicity produced by alcohol itself has not been ruled out. Chronic alcohol abuse decreases the dietary intake of retinoids and carotenoids and enhances the metabolism of retinol by the induction of degradative enzymes. Retinol and ethanol compete for metabolism by ADH; vitamin A supplementation, therefore, should be monitored carefully in alcoholics when they are consuming alcohol to avoid retinol-induced hepatotoxicity. The chronic consumption of alcohol inflicts an oxidative stress on the liver owing to the generation of free radicals, contributing to ethanol-induced liver injury. The antioxidant effects of α -tocopherol (vitamin E) may ameliorate some of this ethanol-induced toxicity in the liver. Plasma levels of α -tocopherol often are reduced in myopathic alcoholics compared with alcoholic patients without myopathy.

Chronic alcohol consumption has been implicated in osteoporosis (see Chapter 61). The reasons for this decreased bone mass remain unclear, although impaired osteoblastic activity has been implicated. Acute administration of ethanol produces an initial reduction in serum parathyroid

hormone (PTH) and Ca^{2+} levels, followed by a rebound increase in PTH that does not restore Ca^{2+} levels to normal. The hypocalcemia observed after chronic alcohol intake also appears to be unrelated to effects of alcohol on PTH levels, and alcohol likely inhibits bone remodeling by a mechanism independent of Ca^{2+} -regulating hormones. Vitamin D also may play a role. Since vitamin D requires hydroxylation in the liver for activation, alcohol-induced liver damage can indirectly affect the role of vitamin D in intestinal and renal absorption of Ca^{2+} .

Alcoholics tend to have lowered serum and brain levels of magnesium, which may contribute to their predisposition to brain injuries such as stroke. Deficits in intracellular magnesium levels may disturb cytoplasmic and mitochondrial bioenergetic pathways, potentially leading to calcium overload and ischemia. Although there is general agreement that total magnesium levels are decreased in alcoholics, it is less clear that this also applies to ionized Mg^{2+} , the physiologically active form. Magnesium sulfate sometimes is used in the treatment of alcohol withdrawal, but its efficacy has been questioned.

Sexual Function

Despite the widespread belief that alcohol can enhance sexual activities, the opposite effect is noted more often. Many drugs of abuse, including alcohol, have disinhibiting effects that may lead initially to increased libido. With excessive, long-term use, however, alcohol often leads to a deterioration of sexual function. While alcohol cessation may reverse many sexual problems, patients with significant gonadal atrophy are less likely to respond to discontinuation of alcohol consumption.

Both acute and chronic alcohol use can lead to impotency in men. Increased blood alcohol concentrations lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. Additionally, many chronic alcoholics develop testicular atrophy and decreased fertility; the mechanisms are complex and likely involve altered hypothalamic function and a direct toxic effect of alcohol on Leydig cells. Testosterone levels may be depressed, but many men who are alcohol-dependent have normal testosterone and estrogen levels. Gynecomastia is associated with alcoholic liver disease and is related to increased cellular response to estrogen and to accelerated metabolism of testosterone.

Sexual function in alcohol-dependent women is less clearly understood. Many female alcoholics complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development. Some data suggest that fertility rates are lower for alcoholic women. The presence of comorbid disorders such as anorexia nervosa or bulimia can aggravate the problem. The prognosis for men and women who become abstinent is favorable in the absence of significant hepatic or gonadal failure.

Hematological and Immunological Effects

Chronic alcohol use is associated with a number of anemias. Microcytic anemia can occur because of chronic blood loss and iron deficiency. Macrocytic anemias and increases in mean corpuscular volume are common and may occur in the absence of vitamin deficiencies. Normochromic anemias also can occur owing to effects of chronic illness on hematopoiesis. In the presence of severe liver disease, morphological changes can include the development of burr cells, schistocytes, and ringed sideroblasts. Alcohol-induced sideroblastic anemia may respond to vitamin B_6 replacement. Alcohol use also is associated with reversible thrombocytopenia, although platelet counts under 20,000 per mm^3 are rare. Bleeding is uncommon unless there is an alteration in vitamin K_1 -dependent clotting factors due to impaired liver function (*see* Chapter 54); other proposed mechanisms for increased bleeding have focused on platelet trapping in the spleen and marrow.

Alcohol also affects granulocytes and lymphocytes. Effects include leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. These disorders may play a role in alcohol-related liver disease. In some patients, depressed leukocyte migration into inflamed areas may account in part for the poor resistance of alcoholics to some types of infection (*e.g.*, *Klebsiella* pneumonia, listeriosis, and tuberculosis). Alcohol consumption also may alter the distribution and function of lymphoid cells by disrupting cytokine regulation, in particular regulation involving interleukin 2 (IL-2). Alcohol appears to play a role in the development of infection with the human immunodeficiency virus-1 (HIV). *In vitro* studies with human lymphocytes suggest that alcohol can suppress CD4 T-lymphocyte function and enhance *in vitro* replication of HIV. Moreover, persons who abuse alcohol have higher rates of high-risk sexual behavior.

ACUTE ETHANOL INTOXICATION

An increased reaction time, diminished fine motor control, impulsivity, and impaired judgment become evident when the concentration of ethanol in the blood is 20–30 mg/dL. More than 50% of persons are grossly intoxicated by a concentration of 150 mg/dL. In fatal cases, the average concentration is ~400 mg/dL, although alcohol-tolerant individuals often can withstand comparable BALs. The definition of intoxication varies by state and country. In the U.S., most states set the ethanol level defined as intoxication at 80 mg/dL. There is increasing evidence that lowering the limit to 50–80 mg/dL can reduce motor vehicle injuries and fatalities significantly. While alcohol can be measured in saliva, urine, sweat, and blood, measurement of levels in exhaled air remains the primary method of assessing the level of intoxication.

Many factors, such as body weight and composition and the rate of absorption from the GI tract, determine the concentration of ethanol in the blood after ingestion of a given amount of ethanol. On average, the ingestion of three standard drinks (42 g ethanol) on an empty stomach results in a maximum blood concentration of 67–92 mg/dL in men. After a mixed meal, the maximal blood concentration from three drinks is 30–53 mg/dL in men. Concentrations of alcohol in blood will be higher in women than in men consuming the same amount of alcohol because, on average, women are smaller than men, have less body water per unit of weight into which ethanol can distribute, and have less gastric ADH activity than men. For individuals with normal hepatic function, ethanol is metabolized at a rate of one standard drink every 60–90 minutes.

The characteristic signs and symptoms of alcohol intoxication are well known. Nevertheless, an erroneous diagnosis of drunkenness may occur with patients who appear inebriated but who have not ingested ethanol. Diabetic coma, for example, may be mistaken for severe alcoholic intoxication. Drug intoxication, cardiovascular accidents, and skull fractures also may be confused with alcohol intoxication. The odor of the breath of a person who has consumed ethanol is due not to ethanol vapor but to impurities in alcoholic beverages. Breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that after alcohol consumption. BALs are necessary to confirm the presence or absence of alcohol intoxication.

The treatment of acute alcohol intoxication is based on the severity of respiratory and CNS depression. Acute alcohol intoxication can be a medical emergency, and a number of young people die every year from this disorder. Patients who are comatose and who exhibit evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance. The stomach may be lavaged, but care must be taken to prevent pulmonary aspiration of the return flow. Since ethanol is freely miscible with water, ethanol can be removed from blood by hemodialysis.

Acute alcohol intoxication is not always associated with coma, and careful observation is the primary treatment. Usual care involves observing the patient in the emergency room for 4–6 hours while the patient metabolizes the ingested ethanol. BALs will be reduced at a rate of ~15 mg/dL/hr. During this period, some individuals may display extremely violent behavior. Sedatives and antipsychotic agents have been employed to quiet such patients, but great care must be taken when using sedatives to treat these patients because of possible synergistic CNS depressant effects.

CLINICAL USES OF ETHANOL

Dehydrated alcohol may be injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol also have been employed for inoperable pain. For example, lumbar paravertebral injections of ethanol may destroy sympathetic ganglia and thereby produce vasodilation, relieve pain, and promote healing of lesions in patients with vascular disease of the lower extremities.

Systemically administered ethanol is confined to the treatment of poisoning by methyl alcohol and ethylene glycol. Treatment consists of sodium bicarbonate to combat acidosis, hemodialysis, and the administration of ethanol, which slows the formation of methanol's metabolites, formaldehyde and formic acid, by competing with methanol for metabolism by ADH (Figure 22–1). Formic acid causes nerve damage; its effects on the retina and optic nerve can cause blindness.

The use of alcohol to treat patients in alcohol withdrawal or obstetrical patients with premature contractions is no longer recommended. Some medical centers continue to use alcohol to prevent or reduce the risk of alcohol withdrawal in postoperative patients, but administering a combination of a benzodiazepine with haloperidol or clonidine may be more appropriate.

MECHANISMS OF CNS EFFECTS OF ETHANOL

Acute Intoxication

Alcohol perturbs the balance between excitatory and inhibitory influences in the brain, resulting in anxiolysis, ataxia, and sedation. This is accomplished by either enhancing inhibitory or antagonizing excitatory neurotransmission. Although ethanol was long thought to act nonspecifically by disordering lipids in cell membranes, ethanol likely produces its effects by simultaneously altering the functioning of a number of proteins that can affect neuronal excitability. A key issue has been to identify proteins that determine neuronal excitability and are sensitive to ethanol at the concentrations (5–20 mM) that produce behavioral effects. Candidate proteins include ion channels in the CNS, and cell signaling enzymes such as protein kinase C- γ and components of signaling pathways such as the MAP kinase and cAMP/PKA pathways. The best studied of these include ligand-gated γ -aminobutyric acid A (GABA_A) receptors, whose function is markedly enhanced by a number of classes of sedative, hypnotic, and anesthetic agents, including barbiturates, benzodiazepines, and volatile anesthetics (*see* Chapter 13), neuronal nicotinic acetylcholine receptors (*see* Chapter 8), and excitatory ionotropic glutamate receptors, including *N*-methyl-D-aspartate (NMDA) and non-NMDA receptor classes (*see* Chapter 12).

Tolerance and Dependence

Tolerance is defined as a reduced behavioral or physiological response to the same dose of ethanol (*see* Chapter 23). There is a marked acute tolerance that is detectable soon after administration of ethanol. Acute tolerance can be demonstrated by measuring behavioral impairment at the same BALs on the ascending limb of the absorption phase of the BAL—time curve (minutes after ingestion of alcohol) and on the descending limb of the curve as BALs are lowered by metabolism (one or more hours after ingestion). Behavioral impairment and subjective feelings of intoxication are much greater at a given BAL on the ascending than on the descending limb. There also is a chronic tolerance that develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance often has a metabolic component owing to induction of alcohol-metabolizing enzymes.

Physical dependence is demonstrated by the elicitation of a withdrawal syndrome when alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of alcohol consumption and include sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and in severe cases, seizures. In addition, two or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, fever, and tachycardia. Delirium tremens can be fatal. Another aspect of dependence is craving and drug-seeking behavior, often termed *psychological dependence*.

Genetic Influences

The acceptance of alcoholism and addiction as “brain diseases” led to a search for biological causes. It has long been appreciated that alcoholism “runs in families”; a series of adoption (cross-fostering) and twin studies showed that human alcohol dependence does, indeed, have a genetic component. Although the genetic contribution varies among studies, it generally is in the range of 40–60%, which means that environmental variables also are critical for individual susceptibility to alcoholism.

The search for the genes and alleles responsible for alcoholism is complicated by the polygenic nature of the disease and the general difficulty in defining multiple genes responsible for complex diseases. One fruitful area of research has been the study of why some populations (mainly Asian) are protected from alcoholism. This has been attributed to genetic differences in alcohol- and aldehyde-metabolizing enzymes. Specifically, genetic variants of ADH that exhibit high activity and variants of ALDH that exhibit low activity protect against heavy drinking. This is so because alcohol consumption by individuals who have these variants results in accumulation of acetaldehyde, which produces a variety of unpleasant effects. These effects are similar to those of disulfiram therapy (see below), but the prophylactic, genetic form of inhibition of alcohol consumption is more effective than the pharmacotherapeutic approach, which is applied after alcoholism has developed.

In contrast to these protective genetic variants, there are little consistent data about genes responsible for increased risk for alcoholism. Several large-scale genetic studies of alcoholism currently are in progress, and these efforts, together with genetic studies in laboratory animals, may lead to identification of genes influencing susceptibility to alcoholism.

TERATOGENIC EFFECTS: FETAL ALCOHOL SYNDROME

Children born to alcoholic mothers display a common pattern of distinct dysmorphology known as *fetal alcohol syndrome* (FAS). The diagnosis of FAS typically is based on the observance of a triad of abnormalities in the newborn, including (1) a cluster of craniofacial abnormalities, (2) CNS dysfunction, and (3) pre- and/or postnatal stunting of growth. Hearing, language, and speech disorders also may become evident as the child ages. Children who do not meet all the criteria for a diagnosis of FAS still may show physical and mental deficits consistent with a partial phenotype, termed *fetal alcohol effects* (FAEs) or *alcohol-related neurodevelopmental disorders*. The incidence of FAS is believed to be in the range of 0.5–1/1000 live births in the general U.S. population, with rates as high as 2–3/1000 in African-American and Native-American populations. A lower socioeconomic status of the mother rather than racial background *per se* appears to be primarily responsible for the higher incidence of FAS observed in those groups. The incidence of FAEs is likely higher than that of FAS, making alcohol consumption during pregnancy a major public health problem. FAS is the most common cause of preventable mental retardation in the Western world, with afflicted children consistently scoring lower than their peers on a variety of IQ tests.

Craniofacial abnormalities commonly observed in the diagnosis of FAS consist of a pattern of microcephaly, a long and smooth philtrum, shortened palpebral fissures, a flat midface, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum. The severity of alcohol effects can vary greatly and depends on the drinking patterns and amount of alcohol consumed by the mother. Maternal drinking in the first trimester has been associated with craniofacial abnormalities; facial dysmorphology also is seen in mice exposed to ethanol at the equivalent time in gestation.

CNS dysfunction following in utero exposure to alcohol manifests in the form of hyperactivity, attention deficits, mental retardation, and learning disabilities. It now is clear that FAS represents the severe end of a spectrum of alcohol effects. A number of studies have documented intellectual deficits, including mental retardation, in children not displaying the craniofacial deformities or retarded growth seen in FAS. Although cognitive improvements are seen with time, decreased IQ scores of FAS children tend to persist as they mature, indicating that the deleterious prenatal effects of alcohol are irreversible. Although a correlation exists between the amount of alcohol consumed by the mother and infant scores on mental and motor performance tests, there is considerable variation in performance on such tests among children of mothers consuming similar quantities of alcohol. The peak BAL reached may be a critical factor in determining the severity of deficits seen in the offspring. Although the evidence is not conclusive, there is a suggestion that even moderate alcohol consumption (2 drinks per day) in the second trimester of pregnancy is correlated with impaired academic performance of offspring at age 6. Maternal age also may be a factor. Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol.

Children exposed prenatally to alcohol most frequently present with attentional deficits and hyperactivity, even in the absence of intellectual deficits or craniofacial abnormalities. Furthermore, attentional problems have been observed in the absence of hyperactivity, suggesting that the two phenomena are not necessarily related. Fetal alcohol exposure also has been identified as a risk factor for alcohol abuse by adolescents. Apart from the risk of FAS or FAEs to the child, the intake of high amounts of alcohol by a pregnant woman, particularly during the first trimester, greatly increases the chances of spontaneous abortion.

PHARMACOTHERAPY OF ALCOHOLISM

Currently, three drugs are approved in the U.S. for treatment of alcoholism: *disulfiram* (ANTABUSE), *naltrexone* (REVIA), and *acamprosate*. Disulfiram has a long history of use but has fallen into disfavor because of its side effects and problems with patient adherence to therapy. Naltrexone and acamprosate were introduced more recently. The goal of these medications is to assist the patient in maintaining abstinence.

Naltrexone

Naltrexone is chemically related to the highly selective opioid-receptor antagonist *naloxone* (NARCAN) but has higher oral bioavailability and a longer duration of action. Neither drug has appreciable opioid-receptor agonist effects. These drugs were used initially in the treatment of opioid overdose and dependence because of their ability to antagonize all the actions of opioids (*see* Chapters 21 and 23). Animal research and clinical experience suggested that naltrexone might reduce alcohol consumption and craving; this was confirmed in clinical trials. There is evidence

that naltrexone blocks activation by alcohol of dopaminergic pathways in the brain that are thought to be critical to reward.

Naltrexone helps to maintain abstinence by reducing the urge to drink and increasing control when a “slip” occurs. It is not a “cure” for alcoholism and does not prevent relapse in all patients. Naltrexone works best when used in conjunction with some form of psychosocial therapy, such as cognitive behavioral therapy. It typically is administered after detoxification and given at a dose of 50 mg/day for several months. Adherence to the regimen is important to ensure the therapeutic value of naltrexone and has proven to be a problem for some patients. The most common side effect of naltrexone is nausea, which is more common in women than in men and subsides if the patients abstain from alcohol. When given in excessive doses, naltrexone can cause liver damage. It is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease.

Nalmefene (REVEX) is another opioid antagonist that appears promising in preliminary clinical tests. It has a number of advantages over naltrexone, including greater oral bioavailability, longer duration of action, and lack of dose-dependent liver toxicity.

Disulfiram

*Disulfiram (tetraethylthiuram disulfide; ANTABUSE) was taken in the course of an investigation of its potential anthelmintic efficacy by two Danish physicians, who became ill at a cocktail party and were quick to realize that the compound had altered their responses to alcohol. They initiated a series of pharmacological and clinical studies that provided the basis for the use of disulfiram as an adjunct in the treatment of chronic alcoholism. Similar responses to alcohol ingestion are produced by various congeners of disulfiram, namely, cyanamide, the fungus *Coprinus atramentarius*, the hypoglycemic *sulfonylureas*, *metronidazole*, certain *cephalosporins*, and animal charcoal.*

Disulfiram, given alone, is a relatively nontoxic substance, but it inhibits ALDH activity and causes the blood acetaldehyde concentration to rise to 5–10 times above the level achieved when ethanol is given to an individual not pretreated with disulfiram. Acetaldehyde, produced as a result of the oxidation of ethanol by ADH, ordinarily does not accumulate in the body because it is further oxidized almost as soon as it is formed primarily by ALDH. Following the administration of disulfiram, both cytosolic and mitochondrial forms of ALDH are irreversibly inactivated to varying degrees, and the concentration of acetaldehyde rises. It is unlikely that disulfiram itself is responsible for the enzyme inactivation in vivo; several active metabolites of the drug, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH in vitro. These metabolites reach significant concentrations in plasma following the administration of disulfiram.

The ingestion of alcohol by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. Within 5–10 minutes, the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is replaced by pallor, and the blood pressure may fall to shock levels.

Alarming reactions may result from the ingestion of even small amounts of alcohol in persons being treated with disulfiram. The use of disulfiram as a therapeutic agent thus is not without danger, and it should be attempted only under careful medical and nursing supervision. Patients must be warned that as long as they are taking disulfiram, the ingestion of alcohol in any form will make them sick and may endanger their lives. Patients must learn to avoid disguised forms of alcohol, as in sauces, fermented vinegar, cough syrups, and even aftershave lotions and back rubs.

The drug never should be administered until the patient has abstained from alcohol for at least 12 hours. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1–2 weeks. Maintenance dosage then ranges from 125–500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH.

Disulfiram and/or its metabolites can inhibit many enzymes with crucial sulfhydryl groups; thus, disulfiram has a wide spectrum of biological effects. It inhibits hepatic CYPs and thereby interferes with the metabolism of phenytoin, chlordiazepoxide, barbiturates, warfarin, and other drugs.

Disulfiram by itself usually is innocuous, but it may cause acneform eruptions, urticaria, lassitude, tremor, restlessness, headache, a garlic-like or metallic taste, and mild GI disturbances. Peripheral neuropathies, psychosis, and ketosis also have been reported.

Acamprosate

Acamprosate (*N*-acetylhomotaurine, calcium salt), an analog of GABA, is used widely in Europe for the treatment of alcoholism and was approved recently for use in the U.S. A number of double-blind, placebo-controlled studies have demonstrated that acamprosate decreases drinking frequency and reduces relapse drinking in abstinent alcoholics. It acts in a dose-dependent manner (1.3–2 g/day) and appears to have efficacy similar to that of naltrexone. Acamprosate generally is well tolerated, with diarrhea being the main side effect. No abuse liability has been noted. The drug undergoes minimal metabolism in the liver, is excreted primarily by the kidneys, and has an elimination $t_{1/2}$ of 18 hours after oral administration. Concomitant use of disulfiram appears to increase the effectiveness of acamprosate, without any adverse drug interactions being noted. The mechanism of action of acamprosate is obscure, although there is some evidence that it modulates the function of NMDA receptors in brain.

Other Agents

Ondansetron, a 5-HT₃-receptor antagonist and antiemetic drug (see Chapters 11 and 37), reduces alcohol consumption in laboratory animals and currently is being tested in humans. Preliminary findings suggest that ondansetron is effective in the treatment of early-onset alcoholics, who respond poorly to psychosocial treatment alone, although the drug does not appear to work well in other types of alcoholics. Ondansetron administration lowers the amount of alcohol consumed, particularly by drinkers who consume <10 drinks per day. It also decreases the subjective effects of ethanol on 6 of 10 scales measured, including the desire to drink, while at the same time not having any effect on the pharmacokinetics of ethanol.

Topiramate, a drug used for treating seizure disorders (see Chapter 19), appears useful for treating alcohol dependence. Compared with the placebo group, patients taking topiramate achieved more abstinent days and a lower craving for alcohol. The mechanism of action of topiramate is not well understood but is distinct from that of other drugs used for the treatment of dependence (e.g., opioid antagonists), suggesting that it may provide a new and unique approach to pharmacotherapy of alcoholism.

DRUG ADDICTION AND DRUG ABUSE

DRUG DEPENDENCE

Although many physicians are concerned about “creating addicts,” relatively few individuals begin their drug addiction problems by misuse of prescription drugs. Confusion exists because the correct use of prescribed medications for pain, anxiety, and even hypertension commonly produces tolerance and physical dependence. These are *normal* physiological adaptations to repeated use of drugs from many different categories. Tolerance and physical dependence are explained in more detail later, but it must be emphasized that they *do not* imply abuse or addiction. This distinction is important because patients with pain sometimes are deprived of adequate opioid medication simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped abruptly.

DEFINITIONS While tolerance and physical dependence are biological phenomena that can be defined precisely in the laboratory and diagnosed accurately in the clinic, there is an arbitrary aspect to the definitions of the overall behavioral syndromes of abuse and addiction. The most influential system of diagnosis for mental disorders is that published by the American Psychiatric Association (APA). The APA diagnostic system uses the term *substance dependence* instead of “addiction” for the overall behavioral syndrome. It also applies the same general criteria to all types of drugs regardless of their pharmacological class. Although accepted widely, this terminology can lead to confusion between *physical dependence* and *psychological dependence*. The term *addiction*, when used here, refers to compulsive drug use, the entire substance-dependence syndrome. This should not be confused with physical dependence alone. *Addiction* is not used as a pejorative term but rather for clarity of communication.

The APA defines *substance dependence* (addiction) as a cluster of symptoms indicating that the individual continues use of the substance despite significant substance-related problems. Evidence of tolerance and withdrawal symptoms are included in the list of symptoms, but neither tolerance nor withdrawal is necessary or sufficient for a diagnosis of substance dependence. Dependence (addiction) requires three or more of the symptoms, whereas abuse can be diagnosed when only one or two symptoms are present. The chronic, relapsing nature of dependence (addiction) fulfills criteria for a chronic disease, but because of the voluntary component at initiation, the disease concept is controversial.

ORIGINS OF SUBSTANCE DEPENDENCE Many variables operate simultaneously to influence the likelihood that a given person will become a drug abuser or an addict. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 23–1).

Agent (Drug) Variables Drugs that reliably produce intensely pleasant feelings (euphoria) are more likely to be taken repeatedly. *Reinforcement* refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused.

Reinforcing properties of drugs are associated with their capacity to increase neuronal activity in critical brain areas (see Chapter 12). Cocaine, amphetamine, ethanol, opioids, cannabinoids, and nicotine all reliably increase extracellular fluid dopamine (DA) levels in the ventral striatum, specifically the nucleus accumbens region.

In contrast, drugs that block DA receptors generally produce bad feelings, i.e., dysphoric effects. Despite strong correlative findings, a causal relationship between DA and euphoria/dysphoria has not been established.

The abuse liability of a drug is enhanced by rapidity of onset because effects that occur soon after administration are more likely to initiate the chain of events that leads to loss of control over drug taking. The history of cocaine use illustrates the changes in abuse liability of the same compound, depending on the form and the route of administration (e.g., “crack” cocaine).

Although the drug variables are important, they do not fully explain the development of abuse and addiction. Most people who experiment with drugs that have a high risk of producing addiction (addiction liability) do not intensify their drug use and lose control. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 23–2), but this does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, there are other variables listed in the categories of host factors and environmental conditions that influence the development of addiction.

Host (User) Variables In general, effects of drugs vary among individuals. Even blood levels can show wide variation when the same dose of a drug on a milligram per kilogram basis is given to different people. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion and in receptor-mediated responses may contribute to the different degrees of reinforcement or euphoria observed among individuals (*see* Chapters 3 and 4).

Environmental Variables Initiating and continuing illegal drug use appear to be influenced significantly by societal norms and peer pressure. Taking drugs may be seen initially as a form of rebellion against authority. In some communities, drug users and drug dealers are role models who seem to be successful and respected; thus, young people emulate them. There also may be a paucity of other options for pleasure, diversion, or income. These factors are particularly important in communities where educational levels are low and job opportunities scarce.

PHARMACOLOGICAL PHENOMENA

Tolerance While abuse and addiction are complex conditions combining the many variables outlined earlier, there are a number of relevant pharmacological phenomena that occur independently of social and psychological dimensions. First are the changes in the way the body responds to a drug with repeated use. *Tolerance*, the most common response to repetitive use of the same drug, can be defined as the reduction in response to the drug after repeated administrations. Figure 23–1 shows an idealized dose–response curve for an administered drug. As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). Thus, a higher dose is required to produce the same effect that once was obtained at a lower dose. As outlined in Table 23–3, there are many forms of tolerance, likely arising *via* multiple mechanisms.

Tolerance develops to some drug effects much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and addicts tend to increase their dose in order to reexperience that elusive “high.” In contrast, tolerance to the gastrointestinal (GI) effects of opiates develops more slowly. The discrepancy between tolerance to euphorigenic effects (rapid) and tolerance to effects on vital functions (slow), such as respiration and blood pressure, can lead to potentially fatal accidents in sedative abusers.

Innate tolerance refers to genetically determined sensitivity (or lack of sensitivity) to a drug that is observed the first time that the drug is administered.

Acquired tolerance can be divided into three major types: pharmacokinetic, pharmacodynamic, and learned tolerance, and includes acute, reverse, and cross-tolerance.

*Pharmacokinetic, or dispositional, tolerance refers to changes in the distribution or metabolism of a drug after repeated administrations such that a given dose produces a lower blood concentration than the same dose did on initial exposure (*see* Chapter 1).*

FIGURE 23–1 Shifts in a dose–response curve with tolerance and sensitization. With tolerance, there is a shift of the curve to the right such that doses higher than initial doses are required to achieve the same effects. With sensitization, there is a leftward shift of the dose–response curve such that for a given dose, there is a greater effect than seen after the initial dose.

Cross-tolerance

Pharmacodynamic tolerance *refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is reduced* (see Chapters 1 and 12).

Learned tolerance *refers to a reduction in the effects of a drug owing to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called behavioral tolerance. This simply describes the skills that can be developed through repeated experiences with attempting to function despite a state of mild-to-moderate intoxication.*

Conditioned tolerance (*situation-specific tolerance*) *develops when environmental cues such as sights, smells, or situations consistently are paired with the administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, etc., there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug always is taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur even before the drug reaches its sites of action. If the drug always is preceded by the same cues, the adaptive response to the drug will be learned, and this will prevent the full manifestation of the drug's effects (tolerance).*

The term acute tolerance refers to rapid tolerance developing with repeated use on a single occasion.

Sensitization

With stimulants such as cocaine or amphetamine, reverse tolerance, or sensitization, can occur. This refers to an increase in response with repetition of the same dose of the drug (learned drug effect). Sensitization results in a shift to the left of the dose–response curve (Figure 23-1). Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually ~1 day. It has been postulated that stimulant psychosis results from a sensitized response after long periods of use.

Cross-tolerance occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same structural and mechanistic category. Understanding cross-tolerance is important in the medical management of persons dependent on any drug. Detoxification is a form of treatment for drug dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence (see below).

Physical Dependence

Physical dependence is a *state* that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. Drugs can affect numerous systems that previously were in equilibrium; these systems find a new balance in the presence of inhibition or stimulation by a specific drug. A person in this adapted or physically dependent state requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems again must go through a process of readjusting to a new equilibrium without the drug.

WITHDRAWAL SYNDROME The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence. Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. Withdrawal symptoms have at least two origins: (1) removal of the drug of dependence

and (2) CNS hyperarousal owing to readaptation to the absence of the drug of dependence. Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Withdrawal symptoms are characteristic for a given category of drugs and tend to be *opposite* to the original effects produced by the drug before tolerance developed. Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain medications repeatedly. These symptoms in themselves do not imply that the individual is involved in abuse or addiction. Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than gradually.

CLINICAL ISSUES

Abuse of combinations of drugs across pharmacologic categories is common. Alcohol is so widely available that it is combined with practically all other categories. Some combinations reportedly are taken because of their interactive effects. An example is the combination of heroin and cocaine (“speedball”). Alcohol and cocaine is another very common combination. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician must be aware of these possible combinations because each drug may require specific treatment.

CNS Depressants

ETHANOL Experimentation with ethanol is almost universal, and a high proportion of users find the experience pleasant. More than 90% of American adults report experience with ethanol, and ~70% report some level of current use. The lifetime prevalence of alcohol abuse and alcohol addiction (alcoholism) in the U.S. is 5–10% for men and 3–5% for women. Ethanol is classed as a depressant because it indeed produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems (*see* Chapter 22).

Tolerance, Physical Dependence, and Withdrawal The symptoms of mild intoxication by alcohol vary; some experience motor incoordination and sleepiness, while others initially become stimulated and garrulous. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at toxic levels. The initial sensitivity (innate tolerance) to alcohol varies greatly among individuals and is related to family history of alcoholism. Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300–400 mg/dL) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose, and thus the margin of safety (therapeutic index) is decreased.

Heavy consumers of alcohol acquire tolerance and develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. Eventually, they may awaken during the night and take a drink to avoid the restlessness produced by falling alcohol levels. The alcohol-withdrawal syndrome (Table 23–4) generally depends on the size of the average daily dose and usually is “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life-threatening until they occur in conjunction with other problems, such as infection, trauma, malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of *delirium tremens* becomes likely (Table 23–4).

Alcohol produces cross-tolerance to other sedatives such as *benzodiazepines*. This tolerance is operative in abstinent alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives, making the combination more dangerous. This is particularly true for benzodiazepines, which are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol.

The chronic use of alcohol and other sedatives is associated with the development of depression, and the risk of suicide among alcoholics is one of the highest of any diagnostic category. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve after weeks to months of abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics, *e.g.*, thiamine deficiency.

Alcohol is toxic to many organ systems. As a result, the medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and GI effects, and

malnutrition, in addition to the CNS dysfunctions outlined earlier. Ethanol readily crosses the placental barrier, producing the *fetal alcohol syndrome*, a major cause of mental retardation (*see* Chapter 22).

Pharmacological Interventions

Detoxification A patient who presents in a medical setting with an alcohol-withdrawal syndrome should be considered to have a potentially lethal condition. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 23–4, a short-acting benzodiazepine such as *oxazepam* (SERAX) can be used at a dose of 15–30 mg every 4–6 hours according to the stage and severity of withdrawal; some authorities recommend a long-acting benzodiazepine unless there is demonstrated liver impairment. When there are complicating medical problems or a history of seizures, hospitalization is required.

Other Measures Detoxification is only the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is accomplished mainly by behavioral approaches. *Disulfiram* (ANTABUSE; *see* Chapter 22) has been useful in some programs that focus behavioral efforts on ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, the second step in ethanol metabolism, resulting in the accumulation of acetaldehyde, which produces an unpleasant flushing reaction when alcohol is ingested. Knowledge of this unpleasant reaction helps the patient to resist taking a drink. Although quite effective pharmacologically, disulfiram has not been found to be effective in controlled clinical trials because so many patients failed to take it.

Naltrexone (REVIA; *see* Chapter 22) has been shown to block some of the reinforcing properties of alcohol and has resulted in a decreased rate of relapse in the majority of published double-blind clinical trials. It works best in combination with behavioral treatment programs that encourage adherence to medication and to remaining abstinent from alcohol. A depot preparation with a duration of 30 days (VIVITROL) recently received FDA approval and may improve medication adherence, the major problem with the use of medications in alcoholism.

Acamprosate is a competitive inhibitor of the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor that is proposed to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse. In several European studies, *acamprosate* has been shown to promote abstinence, either alone or in combination with *naltrexone*.

BENZODIAZEPINES Benzodiazepines are among the most commonly prescribed drugs worldwide; they are used mainly for the treatment of anxiety disorders and insomnia (*see* Chapters 16 and 17). Considering their widespread use, intentional abuse of prescription benzodiazepines is

Table 23–5

relatively rare. When a benzodiazepine is taken for up to several weeks, there is little tolerance and no difficulty in stopping the medication when the condition no longer warrants its use. After several months, the proportion of patients who become tolerant increases, and reducing the dose or stopping the medication produces withdrawal symptoms (Table 23–5). It can be difficult to distinguish withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was prescribed initially. Some patients may increase their dose over time because tolerance definitely develops to the sedative effects. Many patients and their physicians, however, contend that antianxiety benefits continue to occur long after tolerance to the sedating effects. Moreover, these patients continue to take the medication for years according to medical directions without increasing their dose and are able to function very effectively as long as they take the benzodiazepine. The degree to which tolerance develops to the anxiolytic effects of benzodiazepines is a subject of controversy. There is, however, good evidence that significant tolerance does not develop to all benzodiazepine actions because some effects of acute doses on memory persist in patients who have taken benzodiazepines for years. Patients with a history of alcohol- or other drug-abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

Pharmacological Interventions If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms (Table 23–5) may occur during this outpatient detoxification, but in most cases the symptoms are mild. If anxiety symptoms return, a nonbenzodiazepine such as *bupirone* may be prescribed, but this agent usually is less effective than benzodiazepines for treatment of anxiety in these patients. Some authorities recommend transferring the patient to a long- $t_{1/2}$ benzodiazepine during detoxification; other recommended medications include the anticonvulsants *carbamazepine* and *phenobarbital*.

The specific benzodiazepine receptor antagonist *flumazenil* has been found useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia (see Chapter 16).

Deliberate abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological problem requiring knowledge of the pharmacokinetics of each drug.

BARBITURATES AND NONBENZODIAZEPINE SEDATIVES The use of barbiturates and other nonbenzodiazepine sedating medications has declined greatly in recent years owing to the increased safety and efficacy of newer medications (see Chapters 16 and 17). Abuse problems with barbiturates resemble those seen with benzodiazepines. Treatment of abuse and addiction should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn. Prescription of sedative medications can change the physiology of sleep with subsequent tolerance to these medication effects. When the sedative is stopped, there is a rebound effect with worsened insomnia. This medication-induced insomnia requires detoxification by gradual dose reduction.

Nicotine

Because nicotine (*see* Chapter 9) provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. The dependence produced by nicotine can be extremely durable, as exemplified by the high failure rate among smokers who try to quit. Although >80% of smokers express a desire to quit, only 35% try to stop each year, and <5% are successful in unaided attempts to quit.

Cigarette (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (≤ 5 cigarettes/day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 seconds; each puff producing discrete reinforcement. With 10 puffs per cigarette, the one-pack-per-day smoker reinforces the habit 200 times daily (Table 23–6)

Pharmacological Interventions The nicotine withdrawal syndrome can be alleviated by nicotine-replacement therapy, available with (*e.g.*, NICOTROL INHALER and NICOTROL NASAL SPRAY) or without (*e.g.*, NICORETTE GUM and others and NICODERM TRANSDERMAL PATCH, NICOTROL TRANSDERMAL PATCH, and others) a prescription. Figure 23–2 shows the blood nicotine concentrations achieved by different methods of nicotine delivery. Because nicotine gum and a nicotine patch do not achieve the *peak levels* seen with cigarettes, they do not produce the same magnitude of subjective effects as nicotine. These methods do, however, suppress the symptoms of nicotine withdrawal. Thus, smokers should be able to transfer their dependence to the alternative delivery system and gradually reduce the daily nicotine dose with minimal symptoms. Although this results in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. Comparisons with placebo treatment show large benefits of nicotine replacement at 6 weeks, but the effect diminishes with time. The nicotine patch produces a steady blood level (Figure 23–2) and seems to have better patient compliance than that observed with nicotine gum. Verified abstinence rates at 12 months are reported to be in the range of 20%, which is worse than the success rate for any other addiction. The necessary goal of complete abstinence contributes to the poor success rate; when ex-smokers “slip” and begin smoking a little, they usually relapse quickly to their prior level of dependence. A sustained-release preparation of the antidepressant *bupropion* (*see* Chapter 17), improves abstinence rates among smokers. Newer agents such as the cannabinoid (CB-1) receptor antagonist *rimonabant* also have been reported to increase abstinence rates in clinical trials. A combination of behavioral treatment with nicotine replacement to ease withdrawal and an anticraving medication to reduce relapse is currently considered the treatment of choice.

Opioids

Opioid drugs are used primarily for the treatment of pain (see Chapter 21). Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus, opioid drugs also are taken outside medical channels for the purpose of obtaining the effects on mood. Separating the mechanism of analgesia from that of euphoria has not been achieved, and the standard medications for severe pain remain the opioids.

Heroin is the most important opiate that is abused. There is no legal supply of heroin for clinical use in the U.S., however; heroin is widely available on the illicit market. The purity of illicit street

heroin in the U.S. has increased from ~4 mg heroin per 100-mg bag (range: 0–8 mg; the rest is filler, such as quinine) to 45–75% purity in many large cities, with some samples testing as high as 90%. This means that the level of physical dependence among heroin addicts is relatively high and that users who interrupt regular dosing will develop more severe withdrawal symptoms. The more potent supplies can be smoked or administered nasally (snorted) rather than injected, thus making the initiation of heroin use accessible to people who would not insert a needle into their veins.

Tolerance, Dependence, and Withdrawal Injection of a heroin solution produces a variety of sensations described as warmth, taste, or high and intense pleasure (“rush”) often compared with sexual orgasm. There are some differences among the opioids in their acute effects, with *morphine* producing more of a histamine-releasing effect and *mepredine* producing more excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and hydromorphone in double-blind tests. Thus, the popularity of heroin may be due to its availability on the illicit market and its rapid onset. After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility, crosses the blood–brain barrier quickly, and is deacetylated to the active metabolites 6-monoacetyl morphine and morphine. After the intense euphoria, which lasts from 45 seconds to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3–5 hours, depending on the dose. Experienced users may inject 2–4 times per day. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (Figure 23–3). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids. For example, the hypothalamic–pituitary–gonadal axis and the hypothalamic–pituitary–adrenal axis are abnormal in heroin addicts. Women on heroin have irregular menses, and men have a variety of sexual performance

FIGURE 23-3 Differences in responses to heroin and methadone. A person who injects heroin (↑) several times per day oscillates between being sick and being high. In contrast, the typical methadone patient remains in the “normal” range (indicated in gray) with little fluctuation after dosing once per day. problems. Mood also is affected. Heroin addicts are relatively docile and compliant after taking heroin, but during withdrawal, they become irritable and aggressive.

Based on patient reports, tolerance develops early to the euphoria-producing effects of opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. If a supply is available, the dose can be increased progressively 100 times. Even in highly tolerant individuals, the possibility of overdose remains if tolerance is exceeded. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as *fentanyl* (SUBLIMAZE, others).

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. There is a significant risk for opioid abuse and dependence among physicians and other health care workers who have access to potent opioids, thus tempting them toward unsupervised experimentation.

Opioids frequently are used in combinations with other drugs. A common combination is heroin and cocaine (“speedball”). Users report an improved euphoria because of the combination, and there is evidence of an interaction, because cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic cocaine users.

The mortality rate for street heroin users is very high. Early death comes from involvement in crime to support the habit; from uncertainty about the dose, the purity, and even the identity of what is purchased on the street; and from serious infections associated with nonsterile drugs and sharing of injection paraphernalia. Heroin users commonly acquire bacterial infections producing skin abscesses; endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and acquired immune deficiency syndrome (AIDS).

As with other addictions, the first stage of treatment addresses physical dependence and consists of detoxification. The opioid-withdrawal syndrome (Table 23-7) is very unpleasant but not life-threatening. It begins within 6–12 hours after the last dose of a short-acting opioid and as long as 72–84 hours after a very long-acting opioid medication. Heroin addicts go through early stages of this syndrome frequently when heroin is scarce or expensive. Some therapeutic communities as a matter of policy elect not to treat withdrawal so that the addict can experience the suffering while being given group support. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5–10 days) and intense. *Methadone* withdrawal is slower in onset and lasts longer. Protracted withdrawal also is likely to be longer with methadone.

Pharmacological Interventions Opioid withdrawal signs and symptoms can be treated by two different pharmacological approaches. The first and most commonly used approach consists of transfer to a prescription opioid medication and then gradual dose reduction. The same principles of detoxification apply as for other types of physical dependence. It is convenient to change the patient to a long-acting drug such as methadone. The initial dose of methadone is typically 20–30 mg. This is a test dose to determine the level needed to reduce observed withdrawal symptoms. The first day’s total dose then can be calculated depending on the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral *clonidine* (CATAPRES, others) an α_2 adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. Many of the autonomic symptoms of opioid withdrawal such as nausea, vomiting, cramps, sweating, tachycardia, and hypertension result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine can alleviate many of the symptoms of opioid withdrawal except generalized aches and opioid craving. When using clonidine to treat withdrawal, the dose must be titrated according to the stage and severity of withdrawal, beginning with 0.2 mg orally. Postural hypotension commonly occurs when clonidine treatment is used for withdrawal.

Cocaine and Other Psychostimulants

COCAINE Chronic cocaine users total 3.6 million in the U.S. The number of frequent users (at least weekly) has remained steady since 1991 at ~640,000. Not all users become addicts; a key factor is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, “crack”) suitable for smoking and the hydrochloride powder form suitable for nasal or intravenous use. Drug abuse in men occurs about twice as frequently as in women. However, smoked cocaine use is particularly common in young women of childbearing age, who may use cocaine in this manner as commonly as do men.

The reinforcing effects of cocaine and cocaine analogs correlate best with their effectiveness in blocking the transporter that recovers DA from the synapse. This leads to increased DA concentrations at critical brain sites. However, cocaine also blocks both norepinephrine (NE) and serotonin (5-HT) reuptake, and chronic use of cocaine produces changes in these neurotransmitter systems.

The general pharmacology and legitimate use of cocaine are discussed in Chapter 14. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drugs. Involuntary motor activity, stereotyped behavior, and paranoia may occur after repeated doses. Irritability and increased risk of violence are found among heavy chronic users. The $t_{1/2}$ of cocaine in plasma is ~50 minutes, but inhalant (“crack”) users typically desire more cocaine after 10–30 minutes. Intranasal and intravenous uses also result in a high of shorter duration than would be predicted by plasma cocaine levels, suggesting that a declining

plasma concentration is associated with termination of the high and resumption of cocaine seeking. The major route for cocaine metabolism involves hydrolysis of each of its two ester groups. Benzoyllecgonine, produced on loss of the methyl group, represents the major urinary metabolite and can be found in the urine for 2–5 days after a binge. As a result, benzoyllecgonine tests are useful for detecting cocaine use; heavy users have detectable amounts of the metabolite in their urine for up to 10 days following a binge. Cocaine frequently is used in combination with other drugs (see above). An important metabolic interaction occurs when cocaine and alcohol are taken concurrently. Some cocaine is transesterified to cocaethylene, which is equipotent to cocaine in blocking DA reuptake.

Since cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required (Table 23–8). Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous and behavioral treatments based on reinforcing cocaine-free urine tests result in significant improvement in the majority of cocaine users.

AMPHETAMINE AND RELATED AGENTS Subjective effects similar to those of cocaine are produced by *amphetamine*, *dextroamphetamine*, *methamphetamine*, *phenmetrazine*, *methylphenidate*, and *diethylpropion*. Amphetamines increase synaptic DA primarily by stimulating presynaptic release rather than by blockade of reuptake. Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly and methamphetamine is thought to be neurotoxic in DA and 5-HT neurons. Methamphetamine can be produced in small, clandestine laboratories starting with ephedrine, and access to this previously widely available nonprescription stimulant has been restricted.

Caffeine Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs. It mildly increases NE and DA release and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract and is distributed rapidly throughout all tissues and easily crosses the placental barrier (see Chapter 27). Many of caffeine's effects are believed to occur by means of competitive antagonism at adenosine receptors. Adenosine is a neuromodulator that influences a number of functions in the CNS (see Chapters 12 and 27). The mild sedating effects that occur when adenosine activates particular adenosine-receptor subtypes can be antagonized by caffeine.

Tolerance occurs rapidly to the stimulating effects of caffeine. Thus, a mild withdrawal syndrome has been produced in controlled studies by abrupt cessation of as little as 1–2 cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare. Although a withdrawal syndrome can be demonstrated, few caffeine users report loss of control of caffeine intake or significant difficulty in reducing or stopping caffeine, if desired. Thus, caffeine is not listed in the category of addicting stimulants. It is a concern nonetheless that drinks marketed to the young and active are little more than flavored caffeine delivery systems (e.g., caffeinated water).

Cannabinoids (Marijuana)

The cannabis plant has been cultivated for centuries both for the production of hemp fiber and for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, Δ -9-tetrahydrocannabinol (Δ -9-THC), produces most of the characteristic pharmacological effects of smoked marijuana.

Surveys have shown that marijuana is the most commonly used illegal drug in the U.S. Cannabinoid receptors CB-1 (mainly CNS) and CB-2 (peripheral) have been identified and cloned. An

endogenous arachidonic acid derivative *anandamide* is a known agonist ligand. While the physiological function of these receptors and their endogenous ligands are incompletely understood, they are likely to have important functions because they are dispersed widely with high densities in the cerebral cortex, hippocampus, striatum, and cerebellum. Specific CB-1 antagonists have been developed and are in controlled clinical trials. One of these, *rimonabant*, has been reported to reduce relapse in cigarette smokers and to produce weight loss in obese patients.

The pharmacological effects of Δ -9-THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effect sought after by most users is the “high” and “mellowing out.” This effect is described as different from the stimulant high and the opiate high. The effects vary with dose, but the typical marijuana smoker experiences a high that lasts ~2 hours. During this time, there is impairment of cognitive functions, perception, reaction time, learning, and memory. Impairments of coordination and tracking behavior have been reported to persist for several hours beyond the perception of the high. These impairments have obvious implications for the operation of a motor vehicle and performance in the workplace or at school.

Marijuana also produces complex behavioral changes such as giddiness and increased hunger. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur; several surveys indicate that 50–60% of marijuana users have reported at least one anxiety experience. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana because smoking permits the regulation of dose according to the effects.

One of the most controversial of the reputed effects of marijuana is the production of an “amotivational syndrome”; however, there are no data that demonstrate a causal relationship between marijuana smoking and these behavioral characteristics. There is no evidence that marijuana use damages brain cells or produces any permanent functional changes.

Several medicinal benefits of marijuana have been described. These include antinausea effects that have been applied to the relief of side effects of anticancer chemotherapy, muscle-relaxing effects, anticonvulsant effects, and reduction of intraocular pressure for the treatment of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Thus, there is no clear advantage of marijuana over conventional treatments for any of these indications.

TOLERANCE, DEPENDENCE, AND WITHDRAWAL

Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also disappears rapidly. Withdrawal symptoms and signs typically are not seen. In fact, relative to the number of marijuana smokers, few patients ever seek treatment for marijuana addiction. A withdrawal syndrome in human subjects has been described following close observation of marijuana users given regular oral doses of the agent on a research ward (Table 23–9). This syndrome, however, is only seen clinically in persons who use marijuana on a daily basis and stop abruptly. Compulsive or regular marijuana users do not appear to be motivated by fear of withdrawal symptoms, although this has not been studied systematically.

Psychedelic Agents

Perceptual distortions that include hallucinations, illusions, and disorders of thinking such as paranoia can be produced by toxic doses of many drugs. These phenomena also may be seen during toxic withdrawal from sedatives such as alcohol. There are, however, certain drugs that have as their primary effect the production of disturbances of perception, thought, or mood at low doses with minimal effects on memory and orientation. These are commonly called *hallucinogenic drugs*, but their use does not always result in frank hallucinations. In the late 1990s, the use of “club drugs” at

all-night dance parties became popular. Such drugs include *methylenedioxyamphetamine* (MDMA, “ecstasy”), *lysergic acid diethylamide* (LSD), *phencyclidine* (PCP), and *ketamine* (KETALAR). They often are used in association with illegal sedatives such as *flunitrazepam* (ROHYPNOL) or *γ-hydroxybutyrate* (GHB), drugs that have the reputation of being particularly effective in preventing memory storage and have been implicated in “date rape.”

While psychedellic effects can be produced by a variety of different drugs, major psychedellic compounds come from two main categories. The indoleamine hallucinogens include LSD, *N,N-dimethyltryptamine* (DMT), and *psilocybin*. The phenethylamines include *mescaline*, *dimethoxymethylamphetamine* (DOM), *methylenedioxyamphetamine* (MDA), and MDMA. Both groups have a relatively high affinity for 5-HT₂ receptors (see Chapter 11), but they differ in their affinity for other subtypes of 5-HT receptors. There is a good correlation between the relative affinity of these compounds for 5-HT₂ receptors and their potency as hallucinogens in human beings.

LSD LSD is the most potent hallucinogenic drug and produces significant psychedellic effects with a total dose of as little as 25–50 μg. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp-sized papers impregnated with varying doses of LSD (50–300 μg or more).

The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40–60 minutes, peaking at 2–4 hours, and gradually returning to baseline over 6–8 hours. At a dose of 100 μg, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items such as the pattern of hairs on the back of the hand.

A “bad trip” usually consists of severe anxiety, although at times it is marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders.

Tolerance, Physical Dependence, and Withdrawal Frequent, repeated use of psychedellic drugs is unusual, and thus tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after 3–4 daily doses, but no withdrawal syndrome has been observed.

Pharmacological Intervention Because of the unpredictability of psychedellic drug effects, any use carries some risk. Dependence and addiction do not occur, but users may require medical attention because of “bad trips.” Severe agitation may require medication (e.g., *diazepam*, 20 mg orally), although “talking down” by reassurance has been shown to be effective and is the management of first choice. A particularly troubling after-effect of the use of LSD and similar drugs is the occurrence of episodic visual disturbances in a small proportion of former users. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. There now is an official diagnostic category called the *hallucinogen persisting perception disorder*. The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages. The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, neuroleptics, and anxiety states.

MDMA (“ECSTASY”) AND MDA MDMA and MDA are phenylethylamines that have stimulant as well as psychedellic effects. Acute effects are dose-dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets and lasts 3–6 hours, although dosage and potency of street samples are variable (~100 mg/tablet). There is possible neurotoxicity with the use of MDMA.

PHENCYCLIDINE (PCP) PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classed as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s,

first in an oral form and then in a smoked version enabling a better regulation of the dose. The effects of PCP have been observed in normal volunteers under controlled conditions. As little as 50 $\mu\text{g}/\text{kg}$ produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged nonreactive pupils.

PCP binds with high affinity to sites located in the cortex and limbic structures, resulting in blocking of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors (*see* Chapter 12). LSD and other psychedelics do not bind to NMDA receptors. There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogs that block NMDA receptors but with fewer psychoactive effects.

Pharmacological Intervention Overdose must be treated by life support because there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma may last 7–10 days. The agitated or psychotic state produced by PCP can be treated with *diazepam*. Prolonged psychotic behavior requires neuroleptic medication (*see* Chapter 18), although those with significant anticholinergic effects such as *chlorpromazine* should be avoided.

HISTAMINE, BRADYKININ, AND THEIR ANTAGONISTS

HISTAMINE

HISTORY The discovery of histamine (β -aminoethylimidazole) and the understanding of its actions parallel that of the development of the discipline of pharmacology. A complete description of the history of the discovery of histamine and its actions appears in the 11th Edition of the parent text.

Chemistry

Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by two methylene groups (Figure 24–1). The pharmacologically active form at all histamine receptors is the monocationic $N\gamma$ –H tautomer, i.e., the charged form of the species depicted above, although different chemical properties of this monocation may be involved in interactions with the H_1 and H_2 receptors. The four classes of histamine receptors (H_1 – H_4) can be activated differently by analogs of histamine (Table 24–1). Thus, 2-methylhistamine preferentially elicits responses mediated by H_1 receptors, whereas 4(5)-methylhistamine has a preferential effect on H_2 receptors. A chiral analog of histamine with restricted conformational freedom, (R)- α -methylhistamine, is the preferred agonist at H_3 -receptor sites, although it is a weak agonist of the H_4 receptor as well. Indeed, a number of compounds have activity at both the H_3 and H_4 receptors.

Distribution and Biosynthesis of Histamine

DISTRIBUTION

Almost all mammalian tissues contain histamine in amounts ranging from <1 to >100 $\mu\text{g/g}$. Concentrations in plasma and other body fluids generally are very low, but human cerebrospinal fluid (CSF) contains significant amounts. The mast cell is the predominant storage site for histamine in most tissues; in the blood, it is the basophil. The concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial tree mucosa, and intestinal mucosa.

SYNTHESIS, STORAGE, AND METABOLISM

Histamine is formed by the decarboxylation of the amino acid histidine by the enzyme L-histidine decarboxylase (Figure 24–1). Every mammalian tissue that contains histamine is capable of synthesizing it from histidine by virtue of its content of L-histidine decarboxylase. Mast cells and basophils synthesize histamine and store it in secretory granules. At the secretory granule pH of ~ 5.5 , histamine is positively charged and complexed with negatively charged acidic groups on proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of histamine in secretory granules is slow; when tissues rich in mast cells are depleted of their histamine stores, it may take weeks before concentrations return to normal levels. Non–mast cell sites of histamine formation or storage include the epidermis, the gastric mucosa, neurons within the central nervous system (CNS), and cells in regenerating or rapidly growing tissues. Turnover is rapid at these nonmast cell sites because the histamine is released continuously rather than stored. Since L-histidine decarboxylase is an inducible enzyme, the histamine-forming capacity at these sites is subject to regulation. Histamine, in the amounts normally ingested or formed by bacteria in the GI tract, is metabolized rapidly and eliminated in the urine.

Release and Functions of Endogenous Histamine

Histamine has important physiological roles. After its release from storage granules as a result of the interaction of antigen with immunoglobulin E (IgE) antibodies on the mast cell surface, histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. In addition, certain clinically useful drugs can act directly on mast cells to release

FIGURE 24-1 Pathways of histamine metabolism in humans. There are two major paths of histamine metabolism in humans. The more important of these involves ring methylation to form *N*-methylhistamine, catalyzed by histamine-*N*-methyltransferase, which is distributed widely. Most of the *N*-methylhistamine formed is then converted to *N*-methylimidazoleacetic acid by monoamine oxidase (MAO). Alternatively, histamine may undergo oxidative deamination catalyzed mainly by the nonspecific enzyme diamine oxidase (DAO), yielding imidazoleacetic acid, which is then converted to imidazoleacetic acid riboside. These metabolites have little or no activity and are excreted in the urine. Measurement of *N*-methylhistamine in urine affords a more reliable index of histamine production than assessment of histamine itself. Artificially elevated levels of histamine in urine arise from genitourinary tract bacteria that can decarboxylate histidine.

histamine, thereby explaining some of their untoward effects. Histamine has a major role in the regulation of gastric acid secretion and also modulates neurotransmitter release.

ROLE IN ALLERGIC RESPONSES

The principal target cells of immediate hypersensitivity reactions are mast cells and basophils. As part of the allergic response to an antigen, antibodies (IgE) are generated that bind to the surfaces

of mast cells and basophils via high-affinity F_{ϵ} receptors that are specific for IgE. This receptor, $F_{\epsilon}RI$, consists of α , β , and two γ chains. The IgE molecules function as receptors for antigens and, via $F_{\epsilon}RI$, interact with signal-transduction systems in the membranes of sensitized cells (see Chapter 27).

RELEASE OF OTHER AUTACOIDS

The release of histamine only partially explains the biological effects that ensue from immediate hypersensitivity reactions. This is so because a broad spectrum of other inflammatory mediators is released on mast cell activation.

Stimulation of IgE receptors also activates phospholipase A_2 (PLA_2), leading to the production of a host of mediators, including platelet-activating factor (PAF) and metabolites of arachidonic acid. Leukotriene D_4 , which is generated in this way, is a potent contractor of the smooth muscle of the bronchial tree (see Chapters 25 and 27). Kinins also are generated during some allergic responses. Thus, the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to the major symptoms of the allergic response (see below).

HISTAMINE RELEASE BY DRUGS, PEPTIDES, VENOMS, AND OTHER AGENTS

Many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain substances. Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders may elicit the response. The phenomenon may account for unexpected anaphylactoid reactions. Vancomycin-induced "red-man syndrome" involving upper body and facial flushing and hypotension may be mediated through histamine release.

Some venoms, such as that of the wasp, contain potent histamine-releasing peptides. Since basic polypeptides are released on tissue injury, they constitute pathophysiological stimuli to secretion for mast cells and basophils. Anaphylatoxins (C3a and C5a), which are low-molecular-weight peptides released during activation of complement, may act similarly.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion of acid, and moderate bronchospasm also occur frequently.

INCREASED PROLIFERATION OF MAST CELLS AND BASOPHILS; GASTRIC CARCINOID TUMORS

In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that urticate (i.e., sting) when stroked. In systemic mastocytosis, overproliferation of mast cells also is found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of GI effects such as peptic ulceration. Episodes of mast cell activation with attendant systemic histamine release are precipitated by a variety of stimuli, including exertion, emotional upset, exposure to heat, and exposure to drugs that release histamine directly or to which patients are allergic. In myelogenous leukemia, excessive numbers of basophils are present in the blood, raising its histamine content to high levels that may contribute to chronic pruritus. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy "geographical" flush.

GASTRIC ACID SECRETION

Acting at H_2 receptors, histamine is a powerful gastric secretagogue and evokes a copious secretion of acid from parietal cells (see Figure 36-1); it also increases the output of pepsin and intrinsic factor. Although the secretion of gastric acid also is evoked by stimulation of the vagus nerve and by the enteric hormone gastrin, presumably by activation of M_3 and CCK_2 receptors on the parietal cell, acetylcholine and gastrin also stimulate histamine release from the enterochromaffin-like cell. There is no doubt that histamine is the dominant physiological mediator of acid secretion: blockade of H_2 receptors not only eliminates acid secretion in response to histamine but also causes nearly complete inhibition of responses to gastrin and vagal stimulation. The regulation of gastric acid secretion and the clinical utility of H_2 antagonists are discussed in Chapter 36.

CENTRAL NERVOUS SYSTEM

There is substantial evidence that histamine functions as a neurotransmitter in the CNS. Histamine, histidine decarboxylase, and enzymes that catalyze the degradation of histamine are distributed nonuniformly in the CNS and are concentrated in synaptosomal fractions of brain homogenates. H_1 receptors are found throughout the CNS and are densely concentrated in the hypothalamus. Histamine increases wakefulness via H_1 receptors, explaining the potential for sedation by classical antihistamines. Histamine acting through H_1 receptors inhibits appetite. Histamine-containing neurons may participate in the regulation of drinking, body temperature, and the secretion of vasopressin (antidiuretic hormone), as well as in the control of blood pressure and the perception of pain.

Pharmacological Effects

RECEPTOR-EFFECTOR COUPLING AND MECHANISMS OF ACTION Histamine receptors are G protein-coupled receptors (GPCRs) and details of their pharmacodynamic actions and agonist and antagonist ligands are presented in Table 24–1. The pharmacologic definition of H_1 , H_2 , and H_3 receptors generally is clear: relatively specific agonists and antagonists are available. However, the H_4 receptor exhibits 35–40% homology to the H_3 receptor, and the two are harder to distinguish pharmacologically. High-affinity H_3 agonists interact with H_4 receptors as well, albeit with reduced potency, as do the H_3 antagonists *burimamide* and *clobenpropit*. Several nonimidazole compounds are selective H_3 antagonists. The atypical antipsychotic agent *clozapine* is an effective H_1 -receptor antagonist, a weak H_3 -receptor antagonist, but a putative H_4 -receptor agonist. Many neuroleptics are H_1 - and H_2 -receptor antagonists, but it is unclear whether interactions with H receptors play a role in the effects of antipsychotic agents. The finding of high constitutive activity of the human H_3 receptor has sparked a reexamination of the potential role of inverse agonists (see Chapter 1) of H_3 receptors as therapeutic modulators of H_3 -receptor-mediated inhibition of histamine release from histaminergic neurons. H_1 receptors also are reported to express intrinsic or constitutive activity; thus, many H_1 antagonists may function as inverse agonists. H_2 -receptor stimulation increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils. Activation of H_3 and H_4 receptors decreases cellular cyclic AMP; H_3 receptors also may function as presynaptic autoinhibitory receptors on histaminergic neurons.

H_1 AND H_2 RECEPTORS Once released, histamine can exert local or widespread effects on smooth muscles and glands. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion (see above). Other, less prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H_1 receptors. Gastric secretion results from the activation of H_2 receptors and, accordingly, can be inhibited by H_2 -receptor antagonists (see Chapter 36).

H_3 AND H_4 RECEPTORS H_3 receptors are expressed mainly in the CNS, especially in the basal ganglia, hippocampus, and cortex. H_3 receptors function as autoreceptors on histaminergic neurons. H_3 antagonists promote wakefulness; conversely, H_3 agonists promote sleep. H_4 receptors are on immune active cells such as eosinophils and neutrophils, as well as in the GI tract and CNS. Activation of H_4 receptors on eosinophils induces a cellular shape change, chemotaxis, and up-regulation of adhesion molecules such as CD11b/CD18 and ICAM-1 suggesting that the histamine released from mast cells acts at H_4 receptors to recruit eosinophils. H_4 antagonists may be useful inhibitors of allergic and inflammatory responses.

CARDIOVASCULAR SYSTEM Histamine characteristically causes dilation of resistance vessels, an increase in capillary permeability, and an overall fall in systemic blood pressure. In some vascular beds, histamine will constrict veins, contributing to the extravasation of fluid and edema formation upstream of the capillaries and postcapillary venules.

Vasodilation Vasodilation, the most important vascular effect of histamine, involves both H_1 and H_2 receptors distributed throughout the resistance vessels in most vascular beds. Activation of either the H_1 or H_2 receptor can elicit maximal vasodilation, but the responses differ. H_1 receptors have a higher affinity for histamine and mediate an endothelium–NO–dependent dilation that is relatively rapid in onset and short-lived. By contrast, activation of H_2 receptors (stimulating the cyclic AMP–PKA pathway in smooth muscle) causes dilation that develops more slowly and is more sustained.

Increased “Capillary” Permeability This effect of histamine on small vessels results in outward passage of plasma protein and fluid into the extracellular spaces, an increase in the flow of lymph and its protein content, and edema formation. H_1 receptors on endothelial cells are the major mediators of this response.

Increased permeability results mainly from actions of histamine on postcapillary venules, where histamine causes the endothelial cells to contract and separate at their boundaries and thus to expose the basement membrane, which is freely permeable to plasma protein and fluid. The gaps between endothelial cells also may permit passage of circulating cells that are recruited to the tissues during the mast cell response. Recruitment of circulating leukocytes is promoted by H_1 -receptor-mediated up-regulation of leukocyte adhesion. This process involves histamine-induced expression of the adhesion molecule P-selectin on the endothelial cells.

Triple Response of Lewis

Intradermal histamine injection elicits a characteristic phenomenon known as the triple response. This consists of (1) a localized red spot extending for a few millimeters around the site of injection that appears within a few seconds and reaches a maximum in about a minute; (2) a brighter red flush, or “flare,” extending about 1 cm or so beyond the original red spot and developing more slowly; and (3) a wheal that is discernible in 1–2 minutes and occupies the same area as the original small red spot at the injection site. The initial red spot results from the direct vasodilating effect of histamine (H_1 -receptor-mediated NO production), the flare is due to histamine-induced stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine’s capacity to increase capillary permeability (edema formation).

Heart

Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca^{2+} and speeds heart rate by hastening diastolic depolarization in the sinoatrial (SA) node. It also acts directly to slow atrioventricular (AV) conduction, to increase automaticity, and in high doses especially, to elicit arrhythmias. With the exception of slowed AV conduction, which involves mainly H_1 receptors, all these effects are largely attributable to H_2 receptors and cyclic AMP accumulation. If histamine is given intravenously, direct cardiac effects of histamine are overshadowed by baroreceptor reflexes elicited by the reduced blood pressure. Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, and as their permeability increases, plasma escapes from the circulation. Resembling surgical or traumatic shock, these effects diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

EXTRAVASCULAR SMOOTH MUSCLE Histamine stimulates or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H_1 receptors (linked to G_q and Ca^{2+} mobilization); relaxation (for the most part) is due to activation of H_2 receptors. Minute doses of histamine will evoke intense bronchoconstriction in patients with bronchial asthma and certain other pulmonary diseases. Although the spasmogenic influence of H_1 receptors is dominant in bronchial muscle, H_2 receptors with dilator function also are present. Thus, histamine-induced bronchospasm is potentiated slightly by H_2 blockade.

H_1 -RECEPTOR ANTAGONISTS

STRUCTURE-ACTIVITY RELATIONSHIP All the available H_1 -receptor antagonists are reversible competitive inhibitors of the interaction of histamine with H_1 receptors. Like histamine, many H_1 antagonists contain a substituted ethylamine moiety. Unlike histamine, which has a primary amino group and a single aromatic ring, most H_1 antagonists have a tertiary amino group linked by a two- or three-atom chain to two aromatic substituents (e.g., diphenhydramine).

DIPHENHYDRAMINE (an ethanolamine)

Pharmacological Properties

Most H_1 antagonists have similar pharmacological actions and therapeutic applications. Their effects are largely predictable from knowledge of the consequences of the activation of H_1 receptors by histamine.

SMOOTH MUSCLE Within the vascular tree, the H_1 antagonists inhibit both the vasoconstrictor effects of histamine and, to a degree, the more rapid vasodilator effects that are mediated by activation of H_1 receptors on endothelial cells (synthesis/release of NO and other mediators).

CAPILLARY PERMEABILITY H_1 antagonists strongly block the increased capillary permeability and formation of edema and wheal brought about by histamine.

FLARE AND ITCH

H_1 antagonists suppress both the flare component of the triple response and the itching caused by intradermal injection of histamine.

IMMEDIATE HYPERSENSITIVITY REACTIONS: ANAPHYLAXIS AND ALLERGY

During hypersensitivity reactions, histamine is one of the many potent autacoids released (see above), and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by histamine antagonists thus also varies accordingly.

CENTRAL NERVOUS SYSTEM The first-generation H_1 antagonists can both stimulate and depress the CNS. Stimulation occasionally is encountered in patients given conventional doses, who become restless, nervous, and unable to sleep. Central excitation is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, accompanies therapeutic doses of the older H_1 antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Some of the H_1 antagonists are more likely to depress the CNS than others, and patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., diphenhydramine) are particularly prone to cause sedation and are used as OTC somnolents. Indeed, these drugs cannot be tolerated or used safely by many patients unless given only at bedtime. Patients may experience an antihistamine “hangover” in the morning, resulting in sedation with or without psychomotor impairment.

LORATADINE (a tricyclic piperidine)

The second-generation (“non-sedating”) H_1 antagonists (e.g., loratadine, cetirizine, and fexofenadine) are largely excluded from the brain when given in therapeutic doses because they do not cross the blood–brain barrier. An interesting and useful property of certain H_1 antagonists is the capacity to counter motion sickness (see Chapters 7 and 37). This effect was first observed with dimenhydrinate and subsequently with diphenhydramine (the active moiety of dimenhydrinate), various piperazine derivatives, and promethazine.

ANTICHOLINERGIC EFFECTS

Many of the first-generation H_1 antagonists tend to inhibit responses to acetylcholine that are mediated by muscarinic receptors. These atropine-like actions are sufficiently prominent in some of the drugs to be manifest during clinical usage (see below). Promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is among the most effective of the H_1 antagonists in combating motion sickness. The second-generation H_1 antagonists have no effect on muscarinic receptors.

ABSORPTION, FATE, AND EXCRETION The H_1 antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 2–3 hours, and effects usually last 4–6 hours; however, some of the drugs are much longer acting (Table 24–2).

Extensive studies of the metabolic fate of the older H_1 antagonists are limited. Diphenhydramine, given orally, reaches a maximal concentration in the blood in about 2 hours, remains at about this level for another 2 hours, and then falls exponentially with a plasma elimination $t_{1/2}$ of ~4–8 hours. The drug is distributed widely throughout the body, including the CNS. Little, if any, is excreted unchanged in the urine; most appears there as metabolites.

Peak concentrations of these drugs are achieved rapidly in the skin and persist after plasma levels have declined. This is consistent with inhibition of “wheal and flare” responses to the intradermal injection of histamine or allergen, which last for 36 hours or more after treatment, even when concentrations in plasma are very low. Such results emphasize the need for flexibility in the interpretation of the recommended dosage schedules (Table 24–2); less frequent dosage may suffice. *Doxepin*, a tricyclic antidepressant (see Chapter 17), is one of the most potent antihistamines available; it is ~800 times more potent than diphenhydramine. This may account for the observation that topical doxepin can be effective in the treatment of chronic urticaria when other antihistamines have failed.

H_1 antagonists are eliminated more rapidly by children than by adults (the activity of CYP1A2 and CYP3A4 appears to be greater in infants and children than in adults) and more slowly in those with severe liver disease. H_1 -receptor antagonists also induce hepatic CYPs and thus may facilitate their own metabolism.

Many H_1 antihistamines are metabolized by CYPs. Thus, inhibitors of CYP activity such as macrolide antibiotics (e.g., *erythromycin*) or imidazole antifungals (e.g., *ketocoazole*) can increase H_1 antihistamine levels, leading to toxicity. Some newer antihistamines, such as cetirizine, fexofenadine, levocabastine, and acrivastine, are not subject to these drug interactions.

The second-generation H_1 antagonist loratadine is absorbed rapidly from the GI tract and metabolized in the liver to an active metabolite by hepatic CYPs (see Chapter 3). Consequently, metabolism of loratadine can be affected by other drugs that compete for metabolism by these enzymes.

SIDE EFFECTS

Common Adverse Effects The most frequent side effect in the first-generation H_1 antagonists is sedation. Although sedation may be a desirable adjunct in the treatment of some patients, it may interfere with the patient’s daytime activities. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors.

The next most frequent side effects involve the digestive tract and include loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea. Taking the drug with meals may reduce their incidence. H_1 antagonists appear to increase appetite and cause weight gain in rare patients. Other side effects apparently owing to the antimuscarinic actions of some of the first-generation H_1 -receptor antagonists include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation H_1 antagonists.

Other Adverse Effects Drug allergy may develop when H_1 antagonists are given orally but results more commonly from topical application. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications such as leukopenia, agranulocytosis, and hemolytic anemia are very rare. Because H_1 antihistamines cross the placenta, caution must be used when they are taken by women who are or may become pregnant. Several antihistamines (e.g., *azelastine*, *hydroxyzine*, and fexofenadine) showed teratogenic effects in animal studies, whereas others (e.g., chlorpheniramine, diphenhydramine, cetirizine, and loratadine) did not. Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms in the nursing infant such as irritability, drowsiness, or respiratory depression. Since H_1 antagonists interfere with skin tests for allergy, they must be withdrawn well before such tests are performed.

AVAILABLE H_1 ANTAGONISTS Summarized below are the therapeutic and side effects of a number of H_1 antagonists based on their chemical structures. Representative preparations are listed in Table 24–2.

Dibenzoxepin Tricyclics (Doxepin) Doxepin, the only drug in this class, is marketed as a tricyclic antidepressant (see Chapter 17). It also is a remarkably potent H_1 antagonist. Doxepin is much better tolerated by patients who have depression than by those who do not. In nondepressed patients, sometimes even very small doses, e.g., 20 mg may be poorly tolerated because of disorientation and confusion.

Ethanolamines (Prototype: Diphenhydramine) These drugs possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated with conventional doses experience somnolence. The incidence of GI side effects is low.

Ethylenediamines (Prototype: Pyrilamine) These include some of the most specific H_1 antagonists. Although their central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are quite common.

Alkylamines (Prototype: Chlorpheniramine) These are among the most potent H_1 antagonists. The drugs are less prone than some H_1 antagonists to produce drowsiness and are more suitable agents for daytime use, but again, a significant proportion of patients do experience sedation. Side effects involving CNS stimulation are more common than with other groups.

First-Generation Piperazines The oldest member of this group, *chlorcyclizine*, has a more prolonged action and produces a comparatively low incidence of drowsiness. Hydroxyzine is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent antipruritic action. *Cyclizine* and *meclizine* have been used primarily to counter motion sickness, although promethazine and diphenhydramine (dimenhydrinate) are more effective (as is scopolamine; see below).

Second-Generation Piperazines (Cetirizine) Cetirizine is the only drug in this class. It has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than the other second-generation H_1 antagonists.

Phenothiazines (Prototype: Promethazine) Most drugs of this class are H_1 antagonists and also possess considerable anticholinergic activity. Promethazine, which has prominent sedative effects, and its many congeners are used primarily for their antiemetic effects (see Chapter 37).

First-Generation Piperidines (Cyproheptadine, Phenindamine) *Cyproheptadine* uniquely has both antihistamine and antiserotonin activity. *Cyproheptadine* and *phenindamine* cause drowsiness and also have significant anticholinergic effects.

Second-Generation Piperidines (Prototype: Loratadine) Current drugs in this class include loratadine, desloratadine, and fexofenadine. These agents are highly selective for H_1 receptors, lack significant anticholinergic actions, and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines.

Therapeutic Uses

H_1 antagonists have an established and valued place in the symptomatic treatment of various immediate hypersensitivity reactions. In addition, the central properties of some of the series are of therapeutic value for suppressing motion sickness or for sedation.

Allergic Diseases

H_1 antagonists are most useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis. Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, systemic anaphylaxis and angioedema, histamine antagonists have limited efficacy and are not used as sole therapy.

Other allergies are more amenable to therapy with H_1 antagonists. The best results are obtained in seasonal rhinitis and conjunctivitis (hay fever, pollinosis), in which these drugs relieve the sneezing, rhinorrhea, and itching of eyes, nose, and throat. A gratifying response is obtained in most patients, especially at the beginning of the season when pollen counts are low; however, the drugs are less effective when the allergens are most abundant, when exposure to them is prolonged, and when nasal congestion is prominent. Topical preparations, nasal sprays, or topical ophthalmic preparations of antihistamines have been shown to be effective in allergic conjunctivitis and rhinitis.

Certain allergic dermatoses respond favorably to H_1 antagonists. Benefit is most striking in acute urticaria, although the itching in this condition is perhaps better controlled than are the

edema and the erythema. Chronic urticaria is less responsive, but some benefit may occur in a fair proportion of patients. Furthermore, the combined use of H_1 and H_2 antagonists sometimes is effective when therapy with an H_1 antagonist alone has failed. Doxepin may be effective in the treatment of chronic urticaria that is refractory to other antihistamines.

H_1 antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients suffering atopic dermatitis and contact dermatitis (although topical glucocorticoids are more effective) and in such diverse conditions as insect bites and poison ivy. Again, doxepin may be more effective in suppressing pruritus than are other antihistamines. Many drug reactions attributable to allergic phenomena respond to therapy with H_1 antagonists, particularly those characterized by itch, urticaria, and angioedema; serum-sickness reactions also respond to intensive treatment.

Common Cold

Despite persistent popular belief, H_1 antagonists are without value in combating the common cold.

Motion Sickness, Vertigo, and Sedation

Scopolamine, given orally, parenterally, or transdermally, is the most effective of all drugs for the prophylaxis and treatment of motion sickness. Whenever possible, scopolamine should be administered an hour or so before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial.

Some H_1 antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Meniere's disease and in other types of true vertigo. Only promethazine has usefulness in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other effective antiemetic drugs are available (see Chapter 37).

H_2 -RECEPTOR ANTAGONISTS The pharmacology and clinical utility of H_2 antagonists to inhibit gastric acid secretion are described in Chapter 36.

H_3 Receptor and Ligands

The H_3 receptors are localized on terminals as well as on cell bodies/dendrites in the hypothalamic tuberomammillary nucleus on histaminergic neurons. By inhibiting Ca^{2+} conductance, the activated H_3 receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H_3 -receptor ligands are unique agents to modify histaminergic neurotransmission in brain; the agonists decrease it, and the antagonists increase it. H_3 -receptor ligands currently are research tools to delineate the functional role of cerebral histamine and are drug candidates in neuropsychiatry.

H_4 Receptor and Ligands

The H_4 receptor has considerable sequence similarity with the H_3 receptor and binds many H_3 agonists, although with lower affinity. The H_3 antagonist thioperamide also has significant H_4 antagonistic activity, whereas H_3 antagonists clobenpropit and burimamide are partial agonists of the H_4 receptor. Because the H_4 receptor is expressed primarily on cells of hematopoietic origin (notably mast cells, basophils, and eosinophils) and to a lesser extent in the intestine, there is great interest in the possible role of H_4 receptors in inflammatory processes. H_4 antagonists are promising drug candidates to treat inflammatory conditions involving mast cells and eosinophils, such as allergic rhinitis, asthma, and rheumatoid arthritis.

BRADYKININ, KALLIDIN, AND THEIR ANTAGONISTS

A number of factors, including tissue damage, allergic reactions, viral infections, and other inflammatory events, activate a series of proteolytic reactions that generate bradykinin and kallidin in tissues. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability. Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or endothelium-derived hyperpolarizing factor (EDHF).

The Endogenous Kallikrein–Kininogen–Kinin System

SYNTHESIS AND METABOLISM OF KININS

Bradykinin is a nonapeptide (Table 24–3). Kallidin has an additional lysine residue at the N-terminal position and is sometimes referred to as lysyl-bradykinin. The two peptides are cleaved from α_2 globulins termed kininogens (Figure 24–2). There are two kininogens, high-molecular-weight (HMW) and low-molecular-weight (LMW) kininogen. A number of serine proteases will generate

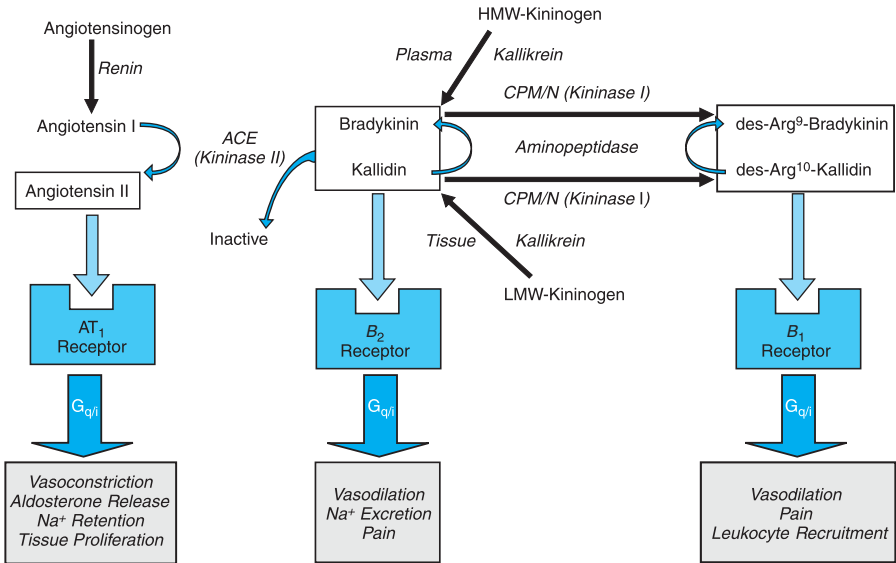

FIGURE 24-2 Synthesis and receptor interactions of active peptides generated by the kallikrein-kinin and renin-angiotensin systems. Bradykinin (BK) is generated by the action of *plasma* kallikrein on high-molecular-weight (HMW) kininogen, whereas kallidin (Lys-bradykinin) is synthesized by the hydrolysis of low-molecular-weight (LMW) kininogen by *tissue* kallikrein. Kallidin and BK are natural ligands of the B₂ receptor but can be converted to corresponding agonists of the B₁ receptor by removal of the C-terminal Arg by the action of kininase I-type enzymes: the plasma membrane-bound carboxypeptidase M (CPM) or soluble plasma carboxypeptidase N (CPN). Kallidin or [des-Arg¹⁰]kallidin can be converted to the active peptides BK or [des-Arg⁹]BK by aminopeptidase removal of the *N*-terminal Lys residue. In a parallel fashion, the inactive decapeptide angiotensin I (Ang I) is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His-Leu dipeptide, angiotensin-converting enzyme (ACE) generates the active peptide Ang II. These two systems have opposing effects. Whereas Ang II is a potent vasoconstrictor that also causes aldosterone release and Na⁺ retention via activation of the AT₁ receptor, BK is a vasodilator that stimulates Na⁺ excretion by activating the B₂ receptor. ACE generates active Ang II and at the same time inactivates BK and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B₂ receptor mediates most of BK's effects under normal circumstances, whereas synthesis of the B₁ receptor is induced by inflammatory mediators and plays a major role in chronic inflammatory conditions. Both the B₁ and B₂ receptors couple through G_{q/i} to activate PLC and increase intracellular Ca²⁺; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B₂ receptors results in Ca²⁺-calmodulin-dependent activation of eNOS and generation of NO, which causes cGMP accumulation and relaxation in neighboring smooth muscle cells. On smooth muscle cells, activation of kinin receptor coupling through the same pathway results in an increased [Ca²⁺]_i and contraction. B₁ and B₂ receptors also can couple through G_i to activate PLA₂, causing the release of arachidonic acid and the local generation of prostanoids and other metabolites.

kinins, but the highly specific proteases that release bradykinin and kallidin from the kininogens are termed kallikreins (see below).

KALLIKREINS

Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (Figure 24–2). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms. Plasma prekallikrein is an inactive protein that complexes in a 1:1 ratio with its substrate, HMW kininogen. The ensuing proteolytic cascade is restrained by the protease inhibitors present in plasma (e.g., inhibitor of the activated first component of complement [C1-INH] and α_2 -macroglobulin). Under experimental conditions, the kallikrein-kinin system is activated by the binding of factor XII, also known as Hageman factor, to negatively charged surfaces. Factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (see Chapter 54), undergoes autoactivation and, in turn, activates kallikrein. Importantly, kallikrein further activates factor XII, thereby exerting a positive feedback on the system.

Tissue kallikrein is synthesized as a preproprotein in the epithelial cells or secretory cells of a number of tissues, including salivary glands, pancreas, prostate, and distal nephron. Tissue kallikrein is also expressed in human neutrophils. It acts locally near its sites of origin. The synthesis of tissue prokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. The activation of tissue prokallikrein to kallikrein requires proteolytic cleavage to remove a 7-amino acid propeptide.

METABOLISM

The decapeptide kallidin is about as active as the nonapeptide bradykinin even without conversion to bradykinin, which occurs when the N-terminal Lys residue is removed by a plasma aminopeptidase (Figure 24–2). The minimal effective structure required to elicit the classical responses on the B_2 receptor is that of the nonapeptide.

The $t_{1/2}$ of kinins in plasma is ~15 seconds; 80–90% of the kinins may be destroyed in a single passage through the pulmonary vascular bed. Plasma concentrations of bradykinin are difficult to measure because inadequate inhibition of kininogenases or kininases in the blood can lead to artifactual formation or degradation of bradykinin during blood collection. Thus, the reported physiological concentrations of bradykinin range from picomolar to femtomolar.

The principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE (Figure 24–2) (see Chapter 30). Removal of the C-terminal dipeptide abolishes kinin-like activity. Neutral endopeptidase 24.11 or neprilysin also inactivates kinins by cleaving off the C-terminal dipeptide. A slower-acting enzyme, carboxypeptidase N (lysine carboxypeptidase, kininase I), releases the C-terminal EF residue, producing [des-Arg⁹] bradykinin and [des-Arg¹⁰] kallidin (Table 24–3 and Figure 24–2), which are themselves potent B_1 -kinin receptor agonists. Carboxypeptidase N is expressed constitutively in blood plasma, where its concentration is about 10^{-7} M. A familial carboxypeptidase N deficiency has been described in which affected individuals with low levels of this enzyme display angioedema or urticaria.

BRADYKININ RECEPTORS

There are at least two distinct receptors for kinins, which have been designated B_1 and B_2 . Both are GPCRs, sharing 36% amino acid sequence identity. Bradykinin receptor mechanisms are discussed in the legend to Figure 24–2. The classical bradykinin B_2 receptor is constitutively expressed in most normal tissues, where it selectively binds bradykinin and kallidin (Figure 24–2) and mediates the majority of their effects. The B_1 receptor selectively binds to the C-terminal des-Arg metabolites of bradykinin and kallidin released by carboxypeptidase N or M and is absent or expressed at low levels in most tissues. B_1 -receptor expression is up-regulated by inflammation and by cytokines, endotoxins, and growth factors. Under these conditions, B_1 -receptor effects may predominate.

Functions and Pharmacology of Kallikreins and Kinins

PAIN The kinins are powerful algescic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene-related peptide. Although there is overlap, B_2 receptors generally mediate acute bradykinin algesia, whereas the pain of chronic inflammation appears to involve increased numbers of B_1 receptors.

INFLAMMATION Kinins participate in a variety of inflammatory diseases. Plasma kinins increase permeability in the microcirculation. The effect, like that of histamine and serotonin in some species, is exerted on the small venules and involves separation of the junctions between

endothelial cells. This, together with an increased hydrostatic pressure gradient, causes edema. Such edema, coupled with stimulation of nerve endings (*see below*), results in a “wheal and flare” response to intradermal injections in human beings.

In hereditary angioedema, bradykinin is formed, and there is depletion of the components of the kinin cascade during episodes of swelling, laryngeal edema, and abdominal pain. B₁ receptors on inflammatory cells such as macrophages can elicit production of the inflammatory mediators interleukin 1 (IL-1) and tumor necrosis factor- α (TNF- α). Kinin levels are increased in a number of chronic inflammatory diseases, including rhinitis caused by inhalation of antigens and that associated with rhinoviral infection. Kinins may be significant in conditions such as gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, and asthma. Kinins also may contribute to the skeletal changes seen in chronic inflammatory states.

RESPIRATORY DISEASE The kinins have been implicated in the pathophysiology of allergic airway disorders such as asthma and rhinitis. Inhalation or intravenous injection of kinins causes bronchospasm in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and serious glandular secretions in patients with allergic rhinitis.

CARDIOVASCULAR SYSTEM Bradykinin causes vasodilation by activating its B₂ receptor on endothelial cells. The endothelium-dependent dilation is mediated by NO, prostacyclin, and a hyperpolarizing epoxyeicosatrienoic acid that is a CYP-derived metabolite of arachidonic acid. The endogenous kallikrein-kinin system plays a minor role in the regulation of blood pressure under normal circumstances, but it may be important in hypertensive states.

The kallikrein-kinin system appears to be cardioprotective. Bradykinin contributes to the beneficial effect of preconditioning the heart against ischemia and reperfusion injury. In the presence of endothelial cells, bradykinin prevents vascular smooth muscle cell growth and proliferation. Bradykinin stimulates tissue plasminogen activator (tPA) release from the vascular endothelium. In this way, bradykinin may contribute to the endogenous defense against cardiovascular events such as myocardial infarction and stroke.

KIDNEY Renal kinins act in a paracrine manner to regulate urine volume and composition. Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kininogen and kinin receptors are present in the cells of the collecting duct. Like other vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting sodium reabsorption at the cortical collecting duct. Renal kallikreins are increased by treatment with mineralocorticoids, ACE inhibitors, and neutral endopeptidase (neprilysin) inhibitors.

POTENTIAL THERAPEUTIC USES Bradykinin contributes to many of the effects of the ACE inhibitors (Figure 24–2). *Aprotinin*, a kallikrein inhibitor, is administered to patients undergoing coronary bypass to minimize bleeding and blood requirements (*see below*). Kinin agonists potentially may increase the delivery of chemotherapeutic agents past the blood-brain barrier. Based on some of the actions outlined earlier, kinin antagonists are being tested in inflammatory conditions.

KALLIKREIN INHIBITORS *Aprotinin* (TRASYLOL) is a natural proteinase inhibitor that inhibits mediators of the inflammatory response, fibrinolysis, and thrombin generation following cardiopulmonary bypass surgery, including kallikrein and plasmin. In several clinical studies, administration of aprotinin reduced requirements for blood products in patients undergoing coronary artery bypass grafting. Depending on patient risk factors, aprotinin is given as a loading dose of either 1 or 2 million kallikrein inhibitor units (KIU), followed by continuous infusion of 250,000 or 500,000 KIU/hr during surgery. Hypersensitivity reactions may occur with aprotinin, including anaphylactic or anaphylactoid reactions.

BRADYKININ AND THE EFFECTS OF ACE INHIBITORS ACE inhibitors are used widely in the treatment of hypertension, and they reduce mortality in patients with diabetic nephropathy, left ventricular dysfunction, previous myocardial infarction, or coronary artery disease. ACE inhibitors block the conversion of AngI to AngII, a potent vasoconstrictor and growth promoter (Figure 24–2) (*see Chapter 30*). Studies using the specific bradykinin B₂ antagonist HOE-140 demonstrate that bradykinin also contributes to many of the protective effects of ACE inhibitors. The contribution of bradykinin to the effects of ACE inhibitors may result not only from decreased degradation of bradykinin but also from induction of enhanced receptor sensitivity.

Occasional patients receiving ACE inhibitors have experienced angioedema, which occurs most often shortly after initiating therapy. This is a class effect of ACE inhibitors and is thought to be connected to the inhibition of kinin metabolism by ACE. ACE inhibitor-associated angioedema is more common in blacks than in Caucasians. A common side effect of ACE inhibitors (especially in women) is a chronic nonproductive cough that dissipates when the drug is stopped. The finding that angiotensin AT₁-receptor-subtype antagonists do not cause cough provides presumptive evidence for the role of bradykinin in this effect, but the mechanism and receptor subtype involved have not been clearly defined.

Preliminary data suggest that bradykinin also may contribute to the effects of the AT₁-receptor antagonists. During AT₁-receptor blockade, AngII concentrations increase. Renal bradykinin concentrations also increase through the effects of AngII on the unopposed AT₂-subtype receptor. Whether or not bradykinin contributes to the clinical effects of the AT₁-receptor antagonists remains to be determined.

LIPID-DERIVED AUTACOIDS: EICOSANOIDS AND PLATELET-ACTIVATING FACTOR

Membrane lipids supply the substrate for the synthesis of eicosanoids and platelet-activating factor (PAF). Eicosanoids—arachidonate metabolites, including prostaglandins, prostacyclin, thromboxane A_2 , leukotrienes, lipoxins, and hepxoylins—are not stored but are produced by most cells when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. Membrane glycerophosphocholine derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids contribute to inflammation, smooth muscle tone, hemostasis, thrombosis, parturition, and gastrointestinal (GI) secretion. Several classes of drugs, most notably *aspirin*, the *traditional nonsteroidal anti-inflammatory agents* (NSAIDs), and the specific inhibitors of cyclooxygenase-2 (COX-2), such as the *coxibs*, owe their principal therapeutic effects to blockade of eicosanoid formation.

EICOSANOIDS

Prostaglandins (PGs), leukotrienes (LTs), and related compounds are called eicosanoids, from the Greek eikosi (“twenty”). Precursor essential fatty acids contain 20 carbons and three, four, or five double bonds: 8,11,14-eicosatrienoic acid (dihomo- γ -linolenic acid), 5,8,11,14-eicosatetraenoic acid (arachidonic acid [AA]; Figure 25–1), and 5,8,11,14,17-eicosapentaenoic acid (EPA). AA, the most abundant precursor, is either derived from dietary linoleic acid (9,12-octadecadienoic acid) or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

BIOSYNTHESIS

Biosynthesis of eicosanoids is limited by the availability of substrate and depends primarily on the release of AA, esterified in the sn-2 domain of cell membrane phospholipids or other complex lipids, to the eicosanoid-synthesizing enzymes by acyl hydrolases, most notably phospholipase A_2 . Chemical and physical stimuli activate the Ca^{2+} -dependent translocation of group IV cytosolic PLA_2 (c PLA_2), which has high affinity for AA, to the membrane, where it hydrolyzes the sn-2 ester bond of membrane phospholipids (particularly phosphatidylcholine and phosphatidylethanolamine), releasing arachidonate. Multiple additional PLA_2 isoforms (group IIA secretory [s PLA_2], group V [s PLA_2], group VI Ca^{2+} -independent [i PLA_2], and group X [s PLA_2]) have been characterized. Under nonstimulated conditions, AA liberated by i PLA_2 is reincorporated into cell membranes, so there is negligible eicosanoid biosynthesis. While c PLA_2 dominates in the acute release of AA, the inducible s PLA_2 contributes under conditions of sustained or intense stimulation of AA production. Once liberated, a portion of the AA is metabolized rapidly to oxygenated products by several distinct enzyme systems, including cyclooxygenases, lipoxygenases, and CYPs.

Products of Prostaglandin G/H Synthases

The prostaglandins prostacyclin and thromboxane, collectively termed prostanoids, can be considered analogs of unnatural compounds with the trivial names prostanic acid and thrombanic acid, with the structures shown below:

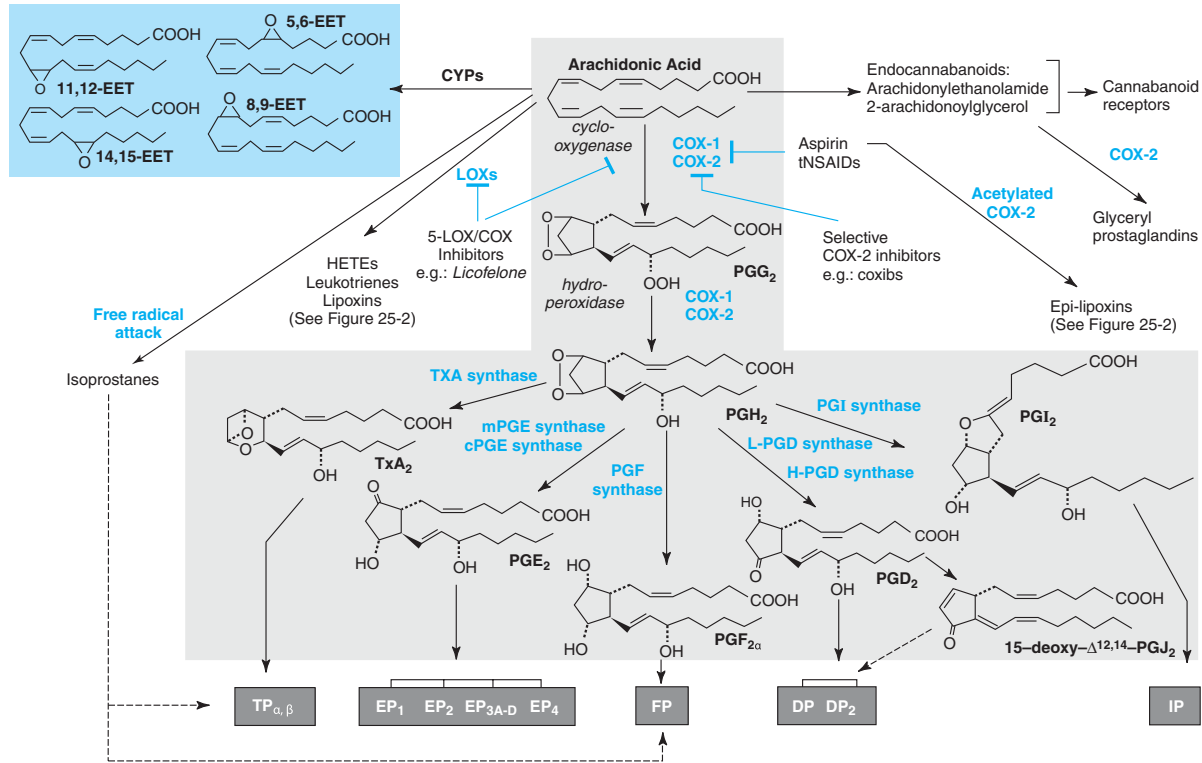

FIGURE 25-1 Metabolism of arachidonic acid. The cyclooxygenase (COX) pathway is highlighted in gray. The lipoxygenase (LOX) pathways are expanded in Figure 25-2. Cyclic endoperoxides (PGG₂ and PGH₂) arise from the sequential cyclooxygenase and hydroperoxidase actions of COX-1 or COX-2 on arachidonic acid released from membrane phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects via membrane-bound receptors (gray boxes). Dashed lines indicate putative ligand-receptor interactions. EETs (shaded in blue) and isoprostanes are generated via CYP activity and nonenzymatic free radical attack, respectively. COX-2 can use modified arachidonoylglycerol, an endocannabinoid, to generate the glyceryl prostaglandins. Aspirin and NSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. Epilipoxins are generated by COX-2 following its acetylation by aspirin (Figure 25-2). Dual 5-LOX-COX inhibitors interfere with both pathways. See text for other abbreviations.

AA is metabolized successively to the cyclic endoperoxide prostaglandins G (PGG) and H (PGH) (Figure 25–1) by the cyclooxygenase (COX) and hydroperoxidase (HOX) activities of the prostaglandin G/H synthases. Isomerases and synthases effect the transformation of PGH₂ into terminal prostanoids distinguished by substitutions on their cyclopentane rings.

Prostaglandins of the E and D series are hydroxyketones, whereas the F_α prostaglandins are 1,3-diols (Figure 25–1). A, B, and C prostaglandins are unsaturated ketones that arise nonenzymatically from PGE during extraction procedures; it is unlikely that they occur biologically. PGJ₂ and related compounds result from the dehydration of PGD₂. Prostacyclin (PGI₂) has a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes (Tx) contain a six-member oxirane ring instead of the cyclopentane ring of the prostaglandins. The main classes are further subdivided in accord with the number of double bonds in their side chains, as indicated by numerical subscripts. Dihomo-γ-linolenic acid is the precursor of the one series, AA for the two series, and EPA for the three series. Prostanoids derived from AA carry the subscript 2 and are the major series in mammals. There is little evidence that one- or three-series prostanoids are made in adequate amounts to be important under normal circumstances. However, the health benefits of dietary supplementation with ω-3 fatty acids remain a focus of investigation.

Synthesis of prostanoids is accomplished in a stepwise manner by a complex of microsomal enzymes. The first enzyme in this synthetic pathway is prostaglandin endoperoxide G/H synthase, which is colloquially called cyclooxygenase, or COX. There are two distinct COX isoforms, COX-1 and COX-2. COX-1 is expressed constitutively in most cells, whereas COX-2 is up-regulated by cytokines, shear stress, and growth factors. Thus, COX-1 is considered to subservise housekeeping functions such as cytoprotection of the gastric epithelium (see Chapter 36). COX-2 is the major source of prostanoids formed in inflammation and cancer. This distinction is overly simplistic: there are physiological and pathophysiological processes in which each enzyme is uniquely involved and others in which they function coordinately.

Products of Lipoxygenases

Lipoxygenases (LOXs) are a family of non-heme iron-containing enzymes that catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides. The enzymes require a fatty acid substrate with two *cis* double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to hydroperoxy eicosatetraenoic acids (HPETEs), which vary in the site of insertion of the hydroperoxy group. Analogous to PGG₂ and PGH₂, these unstable intermediates are further metabolized by a variety of enzymes. HPETEs are converted to their corresponding hydroxy fatty acid (HETE) either nonenzymatically or by a peroxidase.

The 5-LOX pathway leads to the synthesis of the leukotrienes (LTs), which play a major role in the development and persistence of the inflammatory response (Figure 25–2). A nomenclature (LTB₄, LTC₄, etc.) similar to that of prostanoids applies to the subclassification of the LTs. When eosinophils, mast cells, polymorphonuclear leukocytes, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with 5-LOX-activating protein (FLAP), an integral membrane protein essential for LT biosynthesis. FLAP may act as an AA transfer protein that presents the substrate to the 5-LOX. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA at C-5 to form 5-HPETE, followed by dehydration of 5-HPETE to an unstable 5,6-epoxide known as LTA₄. LTA₄ is transformed into bioactive eicosanoids by multiple pathways depending on the cellular context: transformation by LTA₄ hydrolase to a 5,12-dihydroxyeicosatetraenoic acid known as LTB₄; conjugation with reduced glutathione by LTC₄ synthase, in eosinophils, monocytes, and mast cells, to form LTC₄; and extracellular metabolism of the peptide moiety of LTC₄, leading to the removal of glutamic acid and subsequent cleavage of glycine, to generate LTD₄ and LTE₄, respectively. LTC₄, LTD₄, and LTE₄, the cysteinyl leukotrienes, were known originally as the slow-reacting substance of anaphylaxis (SRS-A; see Chapter 27). LTB₄ and LTC₄ are actively transported out of the cell.

Products of CYPs P450

Multiple CYPs metabolize arachidonic acid. For instance, epoxyeicosatrienoic acids (EETs) can be formed by CYP epoxygenases, primarily CYP2C and CYP2J. Their biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression (see Chapter 3).

EETs are important modulators of cardiovascular and renal function. They are synthesized in endothelial cells and cause vasodilation in a number of vascular beds by activating the large conductance Ca²⁺-activated K⁺ channels of smooth muscle cells. This results in hyperpolarization of smooth muscle and thus relaxation, leading to reduced blood pressure. Substantial evidence

FIGURE 25-2 Lipoxygenase pathways of arachidonic acid metabolism. FLAP presents arachidonic acid to 5-LOX, leading to the generation of the LTs. Cysteinyll Ts are shaded in gray. Lipoxins (shaded in blue) are products of cellular interaction via a 5-LOX-12-LOX pathway or via a 15-LOX-5-LOX pathway. Biological effects are transduced via membrane-bound receptors (dark gray boxes). Dashed line indicates putative ligand-receptor interactions. Zileuton inhibits 5-LOX but not the COX pathways (expanded in Figure 25-1). Dual 5-LOX-COX inhibitors interfere with both pathways. CysLT antagonists prevent activation of the CysLT₁ receptor. indicates that EETs may function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation.

Other Pathways

The *isoeicosanoids*, a family of eicosanoid isomers, are formed nonenzymatically by direct free radical-based attack on AA and related lipid substrates. Unlike eicosanoids, these compounds are generated initially on the esterified lipid in cell membranes, from which they are cleaved, presumably by phospholipases; the free isoeicosanoids circulate and are excreted in urine. Consequently, their production is not blocked *in vivo* by agents that suppress metabolism of free arachidonate, such as inhibitors of COX-1 or COX-2. Since several isoprostanes can activate prostanoid receptors, it has been speculated that they may contribute to the pathophysiology of inflammatory responses in a manner insensitive to COX inhibitors.

INHIBITORS OF EICOSANOID BIOSYNTHESIS A number of the biosynthetic steps just described can be inhibited by drugs. Inhibition of phospholipase A₂ decreases the release of the precursor fatty acid and thus the synthesis of all its metabolites. Since phospholipase A₂ is activated by Ca²⁺ and calmodulin, it may be inhibited by drugs that reduce the availability of Ca²⁺. *Glucocorticoids* also inhibit phospholipase A₂, but they appear to do so indirectly by inducing the synthesis of a group of proteins termed *annexins* (formerly *lipocortins*) that modulate phospholipase A₂ activity (see Chapter 59). Glucocorticoids also down-regulate induced expression of COX-2 but not of COX-1. Aspirin and tNSAIDs were found originally to prevent the synthesis of prostaglandins from AA in tissue homogenates. It now is known that these drugs inhibit the COX but not the HOX moieties of the prostaglandin G/H synthases and thus the formation of their downstream prostanoid products. *These drugs do not inhibit LOXs and may result in increased formation of LTs by shunting of substrate to the lipoxygenase pathway.*

COX-1 and COX-2 differ in their sensitivity to inhibition by certain anti-inflammatory drugs. This observation has led to the recent development of agents that selectively inhibit COX-2, including the *coxibs* (see Chapter 26). These drugs were predicted to offer advantages over NSAIDs because COX-2 is the predominant cyclooxygenase at sites of inflammation, whereas COX-1 is the major source of cytoprotective prostaglandins in the GI tract. The matter is not settled, but the anti-inflammatory actions of the *coxibs* were associated with improved GI safety compared with their nonselective counterparts in at least one trial of clinical outcomes. However, the withdrawal of rofecoxib (VIOXX) from the market because of an association in postmarketing studies with an increased risk of myocardial infarction, which may be present long after the drug is discontinued, leaves the therapeutic benefit of the COX-2-specific inhibitors in question (see Chapter 26).

Since leukotrienes mediate inflammation, efforts have focused on development of leukotriene-receptor antagonists and selective inhibitors of the LOXs. Zileuton, an inhibitor of 5-lipoxygenase, was marketed in the U.S. for the treatment of asthma but has been withdrawn. In addition, cysteinyl leukotriene-receptor antagonists, including zafirlukast, pranlukast, and montelukast, have established efficacy in the treatment of asthma (see Chapter 27). A common polymorphism in the gene for LTC₄ synthase that correlates with increased LTC₄ generation is associated with aspirin-intolerant asthma and with the efficacy of antileukotriene therapy. Interestingly, while polymorphisms in the genes encoding 5-LOX or FLAP do not appear to be linked to asthma, studies have demonstrated an association of these genes with myocardial infarction, stroke, and atherosclerosis; thus, inhibition of LT biosynthesis may be useful in the prevention of cardiovascular disease.

EICOSANOID CATABOLISM

Most eicosanoids are efficiently and rapidly inactivated. About 95% of infused PGE₂ (but not PGI₂) is inactivated during one passage through the pulmonary circulation. Broadly speaking, the enzymatic catabolic reactions are of two types: a relatively rapid initial step, catalyzed by widely distributed prostaglandin-specific enzymes, wherein prostaglandins lose most of their biological activity; and a second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β- and ω-oxidation of fatty acids.

The degradation of PGI₂ (t_{1/2} of 3 minutes) apparently begins with its spontaneous hydrolysis in blood to 6-keto-PGF_{1α}. The metabolism of this compound involves the same steps as those for PGE₂ and PGF_{2α}.

The degradation of LTC₄ occurs in the lungs, kidney, and liver. The initial steps involve its conversion to LTE₄. LTC₄ also may be inactivated by oxidation of its cysteinyl sulfur to a sulfoxide. In leukocytes, LTB₄ is inactivated principally by oxidation by members of the CYP4F subfamily.

Pharmacological Properties of Eicosanoids

CARDIOVASCULAR SYSTEM In most vascular beds, PGE₂ elicits vasodilation and a drop in blood pressure, although vasoconstrictor effects have been reported, depending on which PGE₂ receptor is activated (*see* below). Infusion of PGD₂ results in flushing, nasal stuffiness, and hypotension; subsequent formation of F-ring metabolites may result in hypertension. Responses to PGF_{2α} vary with vascular bed; it is a potent constrictor of both pulmonary arteries and veins but does not alter blood pressure.

PGI₂ relaxes vascular smooth muscle, causing prominent hypotension and reflex tachycardia on intravenous administration. It is about five times more potent than PGE₂ in producing this effect. TxA₂ is a potent vasoconstrictor.

LTC₄ and LTD₄ cause hypotension from a decrease in intravascular volume and also from decreased cardiac contractility secondary to a marked LT-induced reduction in coronary blood flow. Although LTC₄ and LTD₄ have little effect on most large arteries or veins, coronary arteries and distal segments of the pulmonary artery are contracted by nanomolar concentrations of these agents. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not.

The CysLTs have prominent effects on the microvasculature. LTC₄ and LTD₄ appear to act on the endothelial lining of postcapillary venules to cause exudation of plasma; they are more than a 1000-fold more potent than histamine in this regard. At higher concentrations, LTC₄ and LTD₄ constrict arterioles and reduce exudation of plasma.

Isoprostanes usually are vasoconstrictors, although there are examples of vasodilation in pre-constricted vessels.

PLATELETS Low concentrations of PGE₂ enhance and higher concentrations inhibit platelet aggregation. Both PGI₂ and PGD₂ inhibit the aggregation of platelets *in vitro*.

TxA₂, the major product of COX-1 in platelets, induces platelet aggregation. Perhaps more importantly, TxA₂ acts as an amplification signal for other, more potent platelet agonists such as thrombin and adenosine diphosphate (ADP). The actions of TxA₂ on platelets are restrained by PGI₂, which inhibits platelet aggregation by all recognized agonists.

INFLAMMATION AND IMMUNITY Eicosanoids play a major role in the inflammatory and immune responses, as reflected by the clinical usefulness of the NSAIDs. While LTs generally are proinflammatory and lipoxins anti-inflammatory, prostanoids can exert both kinds of activity.

LTB₄ is a potent chemotactic agent for polymorphonuclear leukocytes, eosinophils, and monocytes. In higher concentrations, LTB₄ stimulates the aggregation of polymorphonuclear leukocytes and promotes degranulation and the generation of superoxide. LTB₄ promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of proinflammatory cytokines from macrophages and lymphocytes. Prostaglandins generally inhibit lymphocyte function and proliferation, suppressing the immune response. PGE₂ depresses the humoral antibody response by inhibiting the differentiation of B-lymphocytes into antibody-secreting plasma cells. PGE₂ acts on T-lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE₂ and TxA₂ also may play a role in T-lymphocyte development by regulating apoptosis of immature thymocytes. PGD₂, a major product of mast cells, is a potent chemoattractant for eosinophils and induces chemotaxis and migration of Th2 lymphocytes.

Lipoxins have diverse effects on leukocytes, including activation of monocytes and macrophages and inhibition of the activation of neutrophils, eosinophils, and lymphocytes.

KIDNEY AND URINE FORMATION PGs influence renal salt and water excretion by alterations in renal blood flow and by direct effects on renal tubules. PGE₂ and PGI₂ infused directly into the renal arteries of dogs increase renal blood flow and provoke diuresis, natriuresis, and kaliuresis, with little change in glomerular filtration rate. TxA₂ decreases renal blood flow, decreases the rate of glomerular filtration, and participates in tubuloglomerular feedback. PGEs inhibit water reabsorption induced by vasopressin (antidiuretic hormone). PGE₂ also inhibits chloride reabsorption in the thick ascending limb of the loop of Henle in the rabbit. PGI₂, PGE₂, and PGD₂ stimulate renin secretion from the renal cortex, apparently through a direct effect on the granular juxtaglomerular cells.

EYE Although PGF_{2α} induces constriction of the iris sphincter muscle, its overall effect in the eye is to decrease intraocular pressure by increasing the aqueous humor outflow of the eye via the uveoscleral and trabecular meshwork pathway. A variety of F prostaglandin-receptor agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (*see* Chapter 63).

CENTRAL NERVOUS SYSTEM While effects have been reported following injection of several PGs into discrete brain areas, the best established biologically active mediators are PGE₂ and PGD₂. The induction of fever by a range of endogenous and exogenous pyrogens appears to be mediated by PGE₂. Exogenous PGF_{2α} and PGI₂ induce fever but do not contribute to the pyretic response. PGD₂ and TxA₂ do not induce fever. PGD₂ also appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep.

PGs contribute to pain both peripherally and centrally. PLA₂ and COX-2 synthesis are increased at sites of local inflammation that are, in turn, associated with increased central PGE₂ biosynthesis. PGE₂ and PGI₂ sensitize the peripheral nerve endings to painful stimuli by lowering the threshold of nociceptors. Centrally, PGE₂ can increase excitability in pain transmission neuronal pathways in the spinal cord. Hyperalgesia also is produced by LTB₄. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism (*see* below). The role of PGE₂ and PGI₂ in inflammation is discussed in Chapter 26. COX-2 has been implicated in several neurological diseases, and clinical trials of selective inhibitors of COX-2 are ongoing in the chemoprevention of Alzheimer's disease, Parkinson's disease, and epilepsy.

ENDOCRINE SYSTEM A number of endocrine tissues respond to PGs. In a number of species, the systemic administration of PGE₂ increases circulating concentrations of adrenocorticotropic hormone (ACTH), growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. The critical role of PGF_{2α} in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. PGE₂ works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation.

LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates part of the aldosterone release stimulated by angiotensin II, but not that occurring in response to ACTH.

BONE PGs are strong modulators of bone metabolism. PGE₂ stimulates bone formation and resorption through osteoblastic and osteoclastic activities affecting bone strength and composition.

MECHANISM OF ACTION OF EICOSANOIDS Many of the responses just described can be understood in light of the distribution of eicosanoid receptors and their coupling to second-messenger systems that modulate cellular activity.

Prostaglandin Receptors PGs act locally near their sites of formation. The diversity of their effects is explained to a large extent by their interaction with a diverse family of distinct receptors (Table 25-1). All eicosanoid receptors are G protein-coupled receptors that interact with G_s, G_i, or G_q to modulate the activities of adenylyl cyclase and phospholipase C (*see* Chapter 1). Single gene products have been identified for the receptors for prostacyclin (the IP receptor), PGF_{2α} (the FP receptor), and TxA₂ (the TP receptor). Four distinct PGE₂ receptors (EP 1-4) and two PGD₂ receptors (DP₁ and DP₂) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP₃ (A-D) receptors can arise through differential mRNA splicing.

Therapeutic Uses

INHIBITORS AND ANTAGONISTS As a consequence of the important and diverse physiological roles of eicosanoids, mimicking their effects with stable agonists, inhibiting eicosanoid formation, and antagonizing eicosanoid receptors produce noticeable and therapeutically useful responses. As outlined earlier and in Chapter 26, the tNSAIDs and their subclass of selective COX-2 inhibitors are used widely as anti-inflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection. LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glaucoma. EP agonists are used to induce labor and to ameliorate gastric irritation owing to tNSAIDs.

There are as yet no potent selective antagonists of prostanoid receptors in clinical use. TP antagonists are under evaluation in cardiovascular disease, whereas EP agonists and antagonists are under evaluation in the treatment of bone fracture and osteoporosis. Orally active antagonists of LTC₄ and D₄ have been approved for the treatment of asthma (*see* Chapter 27). These agents act by binding to the CysLT₁ receptor and include montelukast and zafirlukast. In patients with mild-to-moderately severe asthma, they cause bronchodilation, reduce the bronchoconstriction caused by

exercise and exposure to antigen, and decrease the patient's requirement for the use of β₂-adrenergic agonists. Their effectiveness in patients with aspirin-induced asthma also has been shown.

The use of eicosanoids or eicosanoid derivatives themselves as therapeutic agents is limited in part because systemic administration of prostanoids frequently is associated with significant adverse effects and because of their short half-lives in the circulation. Despite these limitations, several prostanoids are of clinical utility.

Therapeutic Abortion

There has been intense interest in the effects of the PGs on the female reproductive system. When given early in pregnancy, their action as abortifacients may be variable and often incomplete and accompanied by adverse effects. PGs appear, however, to be of value in missed abortion and molar gestation, and they have been used widely for the induction of midtrimester abortion. Systemic or intravaginal administration of the PGE₁ analog misoprostol in combination with mifepristone (RU486) or methotrexate is highly effective in the termination of early pregnancy.

PGE₂ or PGF_{2α} are used to facilitate labor by promoting ripening and dilation of the cervix.

Gastric Cytoprotection

The capacity of several PG analogs to suppress gastric ulceration is a property of therapeutic importance. Of these, misoprostol (CYTOTEC), a PGE₁ analog, is approved by the FDA. Misoprostol appears to heal gastric ulcers about as effectively as the H₂-receptor antagonists (see Chapter 36);

however, relief of ulcerogenic pain and healing of duodenal ulcers have not been achieved consistently with misoprostol. This drug currently is used primarily for the prevention of ulcers that often occur during long-term treatment with NSAIDs. In this setting, misoprostol appears to be as effective as the proton pump inhibitor omeprazole.

Impotence

PGE_1 (alprostadil) may be used in the treatment of impotence. Intracavernous injection of PGE_1 causes complete or partial erection in impotent patients who do not have disorders of the vascular system or cavernous body damage. The erection lasts for 1–3 hours and is sufficient for sexual intercourse. PGE_1 is more effective than papaverine. The agent is available as a sterile powder that is reconstituted with water for injections (CAVERJECT), although it has been superseded largely by the use of PDE5 inhibitors, such as sildenafil, tadalafil, and vardenafil (see Chapter 31).

Maintenance of Patent Ductus Arteriosus

The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE_1 . Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE_1 (alprostadil, PROSTIN VR PEDIATRIC) is highly effective for palliative, but not definitive, therapy to maintain temporary patency until surgery can be performed. Apnea is observed in ~10% of neonates so treated, particularly those who weigh <2 kg at birth.

Pulmonary Hypertension

Primary pulmonary hypertension is a rare idiopathic disease that mainly affects young adults. It leads to right-sided heart failure and frequently is fatal. Long-term therapy with PGI_2 (epoprostenol, FLOLAN) has either delayed or precluded the need for lung or heart–lung transplantation in a number of patients. In addition, many affected individuals have had a marked improvement in symptoms after receiving treatment with PGI_2 . Epoprostenol also has been used successfully to treat portopulmonary hypertension that arises secondary to liver disease, again with a goal of facilitating ultimate transplantation.

PLATELET-ACTIVATING FACTOR

Chemistry and Biosynthesis

PAF is 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine. Its structure is:

PLATELET-ACTIVATING FACTOR ($n = 11$ to 17)

PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2. PAF actually represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12 to 18 carbon atoms. In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated.

Like the eicosanoids, PAF is not stored in cells but is synthesized in response to stimulation. The major pathway by which PAF is generated involves the precursor 1-O-alkyl-2-acylglycerophosphocholine, a lipid found in high concentrations in the membranes of many types of cells. The 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 25–3). The first involves the action of phospholipase A_2 , the initiating enzyme for eicosanoid biosynthesis, with the formation of 1-O-alkyl-2-lyso-glycerophosphocholine (lyso-PAF) and a free fatty acid (usually AA). Eicosanoid and PAF biosynthesis thus is closely coupled. The second, rate-limiting step is performed by the acetylcoenzyme-A-lyso-PAF acetyltransferase. PAF synthesis also can occur de novo; a phosphocholine substituent is transferred to alkyl acetyl glycerol by a distinct lysoglycerophosphate acetylcoenzyme-A transferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. The synthesis of PAF may be stimulated during antigen–antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both

FIGURE 25-3 Synthesis and degradation of platelet-activating factor. RCOO^- is a mixture of fatty acids but is enriched in arachidonic acid that may be metabolized to eicosanoids. CoA, coenzyme A.

the phospholipase and acetyltransferase are Ca^{2+} -dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca^{2+} .

The inactivation of PAF also occurs in two steps (Figure 25-3). Initially, the acetyl group of PAF is removed by PAF acetylhydrolase to form lyso-PAF; this enzyme, a group VI phospholipase A_2 , exists as secreted and intracellular isoforms and has marked specificity for phospholipids with short acyl chains at the sn-2 position. Lyso-PAF is then converted to a 1-O-alkyl-2-acyl-glycerophosphocholine by an acyltransferase.

PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells, it is displayed on the surface for juxtacrine signaling.

In addition to these enzymatic routes, PAF-like molecules can be formed from the oxidative fragmentation of membrane phospholipids (oxPLs). These compounds are increased in settings of oxidant stress such as cigarette smoking and differ structurally from PAF in that they contain a fatty acid at the sn-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the sn-2 position. OxPLs mimic the structure of PAF closely enough to bind to its receptor (see below) and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated; degradation by PAF acetylhydrolase, therefore, is necessary to suppress the toxicity of oxPLs. Levels of PAF acetylhydrolase (also known as lipoprotein-associated phospholipase A_2) are increased in colon cancer, cardiovascular disease, and stroke; polymorphisms have been associated with altered risk of cardiovascular events. A common missense mutation in Japanese people is associated disproportionately with more severe asthma.

PHARMACOLOGICAL PROPERTIES

Cardiovascular System

PAF is a potent dilator in most vascular beds; when administered intravenously, it causes hypotension. PAF-induced vasodilation is independent of effects on sympathetic innervation, the

renin-angiotensin system, or arachidonate metabolism and likely results from a combination of direct and indirect actions. PAF induces vasoconstriction or vasodilation depending on the concentration, vascular bed, and involvement of platelets or leukocytes. The pulmonary vasculature also is constricted by PAF.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

Platelets

PAF potently stimulates platelet aggregation *in vitro*. While this is accompanied by the release of TxA_2 and the granular contents of the platelet, PAF does not require the presence of TxA_2 or other aggregating agents to produce this effect. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia.

Leukocytes

PAF stimulates polymorphonuclear leukocytes to aggregate, to release LTs and lysosomal enzymes, and to generate superoxide. PAF also promotes aggregation of monocytes and degranulation of eosinophils. It is chemotactic for eosinophils, neutrophils, and monocytes and promotes endothelial adherence and diapedesis of neutrophils. When given systemically, PAF causes leukocytopenia, with neutrophils showing the greatest decline.

Stomach

In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

Kidney

When infused intrarenally in animals, PAF decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na^+ without changes in systemic hemodynamics. These effects are the result of a direct action on the renal circulation. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

MECHANISM OF ACTION OF PAF

Extracellular PAF exerts its actions by stimulating a specific GPCR that is expressed in numerous cell types. The PAF receptor's strict recognition requirements, including a specific head group and specific atypical sn-2 residue, also are met by oxPLs. The PAF receptor couples with G_{O} to activate the PLC- IP_3 - Ca^{2+} pathway and phospholipases A_2 and D such that AA is mobilized from diacylglycerol, resulting in the synthesis of PGs, TxA_2 , or LTs, which may function as extracellular mediators of the effects of PAF. PAF also may exert actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, polymorphonuclear leukocytes, and monocytes, and acts cooperatively with P-selectin to promote adhesion. Endothelial cells under oxidant stress release oxPLs, which activate leukocytes and platelets and can spread tissue damage.

RECEPTOR ANTAGONISTS

Many compounds have been described that are PAF-receptor antagonists that selectively inhibit the actions of PAF *in vivo* and *in vitro*. One would expect a PAF receptor antagonist to be a potent anti-inflammatory agent that might be useful in the therapy of disorders such as asthma, sepsis, and other diseases in which PAF is postulated to play a role. However, trials in humans have been disappointing, and the clinical efficacy of PAF antagonists has yet to be realized.

INFLAMMATORY AND ALLERGIC RESPONSES

The proinflammatory actions of PAF and its elaboration by endothelial cells, leukocytes, and mast cells under inflammatory conditions are well characterized. PAF and PAF-like molecules are thought to contribute to the pathophysiology of inflammatory disorders, including anaphylaxis, bronchial asthma, endotoxic shock, and skin diseases. The plasma concentration of PAF is increased in experimental anaphylactic shock, and the administration of PAF reproduces many of its signs and symptoms, suggesting a role for the autacoid in anaphylactic shock. In addition, mice over expressing the PAF receptor exhibit bronchial hyperreactivity and increased lethality when

treated with endotoxin. PAF receptor knockout mice display milder anaphylactic responses to exogenous antigen challenge, including less cardiac instability, airway constriction, and alveolar edema; they are, however, still susceptible to endotoxic shock. Deletion of the PAF receptor augments the lethality of infection with gram-negative bacteria while improving host defense against gram-positive pneumococcal pneumonia.

Despite the broad implications of these observations, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. Although PAF antagonists reverse the bronchoconstriction of anaphylactic shock and improve survival in animal models, the impact of these agents on animal models of asthma and inflammation is marginal. Similarly, in patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

ANALGESIC-ANTIPYRETIC AND ANTI-INFLAMMATORY AGENTS; PHARMACOTHERAPY OF GOUT

INFLAMMATION The inflammatory process is the response to an injurious stimulus evoked by a wide variety of noxious agents (*e.g.*, infections, antibodies, or physical injuries). The ability to mount an inflammatory response is essential for survival in the face of environmental pathogens and injury; in some situations and diseases, the inflammatory response may be exaggerated and sustained without apparent benefit and even with severe adverse consequences.

Inflammatory responses occur in three distinct temporal phases, each apparently mediated by different mechanisms: (1) an acute phase characterized by transient local vasodilation and increased capillary permeability; (2) a delayed, subacute phase characterized by infiltration of leukocytes and phagocytic cells; and (3) a chronic proliferative phase, in which tissue degeneration and fibrosis occur.

Many mechanisms are involved in the promotion and resolution of the inflammatory process. Recent work has focused on adhesive interactions, including the E-, P-, and L-selectins, intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and leukocyte integrins, in the adhesion of leukocytes and platelets to endothelium at sites of inflammation.

Activated endothelial cells play a key role in “targeting” circulating cells to inflammatory sites. Cell adhesion occurs by recognition of cell-surface glycoproteins and carbohydrates on circulating cells due to the augmented expression of adhesion molecules on resident cells. Thus, endothelial activation results in leukocyte adhesion as the leukocytes recognize newly expressed L-selectin and P-selectin. Some, but not all, traditional non-steroidal anti-inflammatory drugs (tNSAIDs) may interfere with adhesion by inhibiting expression or activity of certain of these cell-adhesion molecules.

Recruitment of inflammatory cells to sites of injury involves the concerted interactions of several types of soluble mediators. These include the complement factor C5a, platelet-activating factor, and the eicosanoid LTB₄ (*see* Chapter 25). All can act as chemotactic agonists. Several cytokines also play essential roles in orchestrating the inflammatory process, especially interleukin-1 (IL-1) and tumor necrosis factor- α (TNF- α). IL-1 and TNF are considered principal mediators of the biological responses to bacterial lipopolysaccharide (LPS, also called endotoxin). They are secreted by monocytes and macrophages, adipocytes, and other cells. Working in concert with each other and various cytokines and growth factors (including IL-8 and granulocyte-macrophage colony-stimulating factor; *see* Chapter 53), they induce gene expression and protein synthesis in a variety of cells to mediate and promote inflammation.

Intradermal, intravenous, or intra-arterial injections of small amounts of prostaglandins mimic many components of inflammation. Administration of prostaglandin E₂ (PGE₂) or prostacyclin (PGI₂) causes erythema and an increase in local blood flow. Such effects may persist for up to 10 hours with PGE₂, and include the capacity to counteract the vasoconstrictor effects of substances such as norepinephrine and angiotensin II, properties not generally shared by other inflammatory mediators. In contrast to their long-lasting effects on cutaneous vessels and superficial veins, prostaglandin-induced vasodilation in other vascular beds vanishes within a few minutes.

Although PGE₁ and PGE₂ (but not PGF_{2 α}) cause edema, it is not clear if they can increase vascular permeability in the postcapillary and collecting venules without the participation of other inflammatory mediators (*e.g.*, bradykinin, histamine, and leukotriene C₄ [LTC₄]). Furthermore, PGE₁ is not produced in significant quantities except under rare circumstances such as essential fatty acid deficiency. Unlike LTs, prostaglandins are unlikely to be involved in chemotactic responses, even though they may promote the migration of leukocytes into an inflamed area by increasing blood flow.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

All NSAIDs, including the traditional nonselective drugs and the subclass of selective cyclooxygenase-2 (COX-2) inhibitors, are anti-inflammatory, analgesic, and antipyretic. NSAIDs are a chemically heterogeneous group of organic acids that share certain therapeutic actions and adverse effects. Aspirin also inhibits the COX enzymes but in a manner molecularly distinct from the competitive, reversible, active site inhibitors and is often distinguished from the NSAIDs. Similarly, acetaminophen, which is antipyretic and analgesic but largely devoid of anti-inflammatory activity, also is conventionally segregated from the group despite its sharing NSAID activity with other actions relevant to its clinical action *in vivo*.

Mechanism of Action and Therapeutic Effects of NSAIDs

Prostaglandins are released whenever cells are damaged, and aspirin and tNSAIDs inhibit their biosynthesis in all cell types. However, aspirin and tNSAIDs generally do not inhibit the formation of other inflammatory mediators, including other eicosanoids such as the LTs (see Chapter 25). While the clinical effects of these drugs are explicable in terms of inhibition of prostaglandin synthesis, substantial inter- and intraindividual differences in clinical response are known. At higher concentrations, NSAIDs also are known to reduce production of superoxide radicals, induce apoptosis, inhibit the expression of adhesion molecules, decrease nitric oxide synthase, decrease proinflammatory cytokines (e.g., TNF- α , IL-1), modify lymphocyte activity, and alter cellular membrane functions. However, there are differing opinions as to whether these actions might contribute to the anti-inflammatory activity of NSAIDs at the concentrations attained during treatment.

INHIBITION OF PROSTAGLANDIN BIOSYNTHESIS BY NSAIDs The first enzyme in the prostaglandin synthetic pathway is prostaglandin G/H synthase, also known as COX. This enzyme converts arachidonic acid (AA) to the unstable intermediates PGG₂ and PGH₂ and leads to the production of thromboxane A₂ (TXA₂) and a variety of prostaglandins (see Chapter 25).

Therapeutic doses of aspirin and other NSAIDs reduce prostaglandin biosynthesis by blocking COX, and there is a reasonably good correlation between potency as COX inhibitors and anti-inflammatory activity.

There are two forms of COX, COX-1 and COX-2. COX-1 is a primarily constitutive isoform found in most normal cells and tissues, while cytokines and inflammatory mediators that accompany inflammation induce COX-2 production. However, COX-2 also is constitutively expressed in certain areas of kidney and brain, and is induced in endothelial cells by laminar shear forces. Importantly, COX-1, but not COX-2, is expressed as the dominant, constitutive isoform in gastric epithelial cells and is the major source of cytoprotective prostaglandin formation. Inhibition of COX-1 at this site is thought to account largely for the gastric adverse events that complicate therapy with tNSAIDs, thus providing the rationale for the development of NSAIDs specific for inhibition of COX-2.

Aspirin and NSAIDs inhibit the COX enzymes and prostaglandin production; they do not inhibit the lipoxygenase pathways of AA metabolism and hence do not suppress LT formation (see Chapter 25). Table 26-1 provides a classification of NSAIDs and other analgesic and antipyretic agents based on their chemical structures.

Aspirin covalently modifies COX-1 and COX-2, irreversibly inhibiting COX activity. This is an important distinction from all the NSAIDs because the duration of aspirin's effects is related to the turnover rate of COX in different target tissues. The duration of effect of nonaspirin NSAIDs, which competitively inhibit the active sites of the COX enzymes, relates more directly to the time course of drug disposition. The importance of enzyme turnover in relief from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX (COX-1) last for the lifetime of the platelet. Inhibition of platelet COX-1-dependent TXA₂ formation, therefore, is cumulative with repeated doses of aspirin (at least as low as 30 mg/day) and takes roughly 8–12 days (the platelet turnover time) to recover once therapy has been stopped.

PAIN NSAIDs usually are classified as mild analgesics. However, consideration of the type of pain, as well as its intensity, is important in the assessment of analgesic efficacy. NSAIDs are particularly effective when inflammation has caused sensitization of pain receptors to normally painless mechanical or chemical stimuli. Pain that accompanies inflammation and tissue injury probably results from local stimulation of pain fibers and enhanced pain sensitivity (hyperalgesia), in part a consequence of increased excitability of central neurons in the spinal cord.

Bradykinin, released from plasma kininogen, and cytokines, such as TNF- α , IL-1, and IL-8, appear to be particularly important in eliciting the pain of inflammation. These agents liberate prostaglandins and probably other mediators that promote hyperalgesia. Neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP), also may be involved in eliciting pain.

The capacity of prostaglandins to sensitize pain receptors to mechanical and chemical stimulation apparently results from a lowering of the threshold of the polymodal nociceptors of C fibers. In general, NSAIDs do not affect either hyperalgesia or pain caused by the direct action of prostaglandins, consistent with the notion that the analgesic effects of these agents are due to inhibition of prostaglandin synthesis.

FEVER Regulation of body temperature requires a delicate balance between the production and loss of heat; the hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever (from infection, tissue damage, inflammation, graft rejection, or malignancy), as a result of formation of cytokines such as IL-1 β , IL-6, interferons, and TNF- α . The cytokines increase synthesis of PGE₂ in circumventricular organs in and adjacent to the preoptic hypothalamic area; PGE₂, in turn, increases cyclic AMP and triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. Aspirin and NSAIDs suppress this response by inhibiting PGE₂ synthesis but do not influence body temperature when it is elevated by factors such as exercise or in response to ambient temperature.

THERAPEUTIC EFFECTS All NSAIDs, including selective COX-2 inhibitors, are antipyretic, analgesic, and anti-inflammatory; the exception is acetaminophen, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity.

When employed as analgesics, these drugs usually are effective only against pain of low-to-moderate intensity, such as dental pain. Although their maximal efficacy is generally much less than the opioids, NSAIDs lack the respiratory depression and the development of physical dependence seen with opiates. NSAIDs do not change the perception of sensory modalities other than pain. Chronic postoperative pain or pain arising from inflammation is controlled particularly well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain.

It seems logical to select an NSAID with rapid onset for the management of fever associated with minor illness in adults. Due to the association with Reye's syndrome, aspirin and other salicylates are contraindicated in children and young adults <20 years old with fever associated with viral illness. Reye's syndrome is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera. The etiology and pathophysiology are not clear. However, the epidemiologic evidence for an association between aspirin use in children and Reye's syndrome was sufficiently compelling that labeling of aspirin and aspirin-containing medications to indicate Reye's syndrome as a risk in children was mandated in 1986. Since then, the use of aspirin in children has declined dramatically, and Reye's syndrome has almost disappeared. Acetaminophen has not been implicated in Reye's syndrome and is the drug of choice for antipyresis in children and teens.

NSAIDs find their chief clinical application as anti-inflammatory agents in the treatment of musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. In general, NSAIDs provide only symptomatic relief from pain and inflammation associated with the disease, do not arrest the progression of pathological injury to tissue, and are not considered to be "disease-modifying" (see below). A number of NSAIDs are FDA approved for the treatment of ankylosing spondylitis and gout. The use of NSAIDs for mild arthropathies, together with rest and physical therapy, generally is effective. When the symptoms are limited either to trouble sleeping because of pain or significant morning stiffness, a single NSAID dose given at night may suffice. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents. The choice of drugs for children with juvenile rheumatoid arthritis commonly is restricted to those that have been specifically tested in children, such as aspirin (see discussion of Reye's syndrome, above, under "Fever"), naproxen, or *tolmetin*.

Prostaglandins also have been implicated in the maintenance of patency of the ductus arteriosus, and indomethacin and other tNSAIDs have been used in neonates to close the inappropriately patent ductus.

OTHER CLINICAL USES

Systemic Mastocytosis Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin. In patients with systemic mastocytosis, prostaglandin D₂, released from mast cells in large amounts, has been found to be the major mediator of severe episodes of vasodilation and hypotension; this PGD₂ effect is resistant to antihistamines. The addition of aspirin or *ketoprofen* has provided relief. However, aspirin and tNSAIDs can trigger degranulation of mast cells, so blockade with H₁ and H₂ histamine receptor antagonists should be established before NSAIDs are initiated.

Cancer Chemoprevention Epidemiological studies suggested that frequent use of aspirin is associated with as much as a 50% decrease in the risk of colon cancer and similar observations have been made with other cancers. NSAIDs have been used in patients with familial adenomatous

polyposis (FAP), an inherited disorder characterized by multiple adenomatous colon polyps developing during adolescence and the inevitable occurrence of colon cancer by the sixth decade.

Niacin Tolerability Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce LDL, and raise HDL (*see* Chapter 35). However, niacin is tolerated poorly because it induces intense flushing. This flushing is mediated by a release of prostaglandin D₂ from the skin, which can be inhibited by treatment with aspirin.

ADVERSE EFFECTS OF NSAID THERAPY Common adverse events that complicate therapy with aspirin and NSAIDs are outlined in Table 26–2. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients.

Gastrointestinal

The most common symptoms associated with these drugs are GI, including anorexia, nausea, dyspepsia, abdominal pain, and diarrhea. These symptoms may be related to the induction of gastric or intestinal ulcers, which is estimated to occur in 15–30% of regular users. Ulceration may range from small superficial erosions to full-thickness perforation of the muscularis mucosa. There may be single or multiple ulcers, and ulceration can be accompanied by gradual blood loss leading to

anemia or by life-threatening hemorrhage. The risk is further increased in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids.

All of the selective COX-2 inhibitors have been shown to be less prone than equally efficacious doses of tNSAIDs to induce endoscopically visualized gastric ulcers, and this has provided the basis of FDA approval.

Cardiovascular

Given their relatively short half-lives, tNSAIDs, unlike aspirin, are not thought to afford cardio-protection, and most epidemiological overviews are consistent with this likelihood.

Selective inhibitors of COX-2 are thought to be problematic in this regard. They depress PGI₂ formation by endothelial cells without concomitant inhibition of platelet thromboxane. PGI₂ restrains the cardiovascular effects of TXA₂, affording a mechanism by which selective inhibitors might increase the risk of thrombosis; consistent with results from postmarketing trials of rofecoxib.

This mechanism should pertain to individuals otherwise at risk of thrombosis, such as those with rheumatoid arthritis, as the relative risk of myocardial infarction is increased in these patients compared to patients with osteoarthritis or no arthritis. The incidence of myocardial infarction and stroke has diverged in such at-risk patients when COX-2 inhibitors are compared with tNSAIDs. Placebo-controlled trials have now revealed an increased incidence of myocardial infarction and stroke in patients treated with rofecoxib, valdecoxib, and celecoxib, consistent with a mechanism-based cardiovascular hazard for the class. Regulatory agencies in the U.S., Europe, and Australia have concluded that all three drugs increase the risk of heart attack and stroke and will be labeled accordingly and restricted with respect to marketing directly to consumers. Only celecoxib remains on the market in the U.S.

Blood Pressure, Renal, and Renovascular Adverse Events

tNSAIDs and COX-2 inhibitors have been associated with renal and renovascular adverse events. NSAIDs have little effect on renal function or blood pressure in normal subjects. However, in patients with congestive heart failure, hepatic cirrhosis, chronic kidney disease, hypovolemia, and other states of activation of the sympathoadrenal or renin-angiotensin systems, prostaglandin formation becomes crucial. NSAIDs are associated with loss of the prostaglandin-induced inhibition of both the reabsorption of Cl⁻ and the action of vasopressin, leading to the retention of salt and water. Epidemiological studies suggest hypertensive complications occur more commonly in patients treated with coxibs than with tNSAIDs.

Analgesic Nephropathy

Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections. If recognized early, discontinuation of NSAIDs permits recovery of renal function.

Pregnancy and Lactation

Despite evidence that myometrial COX-2 expression and levels of prostaglandin E₂ and F_{2α} increase in the myometrium during labor, prolongation of gestation by NSAIDs is not useful for the treatment of preterm labor. The use of indomethacin as a tocolytic (preventing uterine contractions) is associated with closure of the ductus arteriosus and impaired fetal circulation in utero, particularly in fetuses older than 32 weeks' gestation. COX-2-selective inhibitors have been associated with stenosis of the ductus arteriosus and oligohydramnios. Finally, the use of NSAIDs and aspirin late in pregnancy may increase the risk of postpartum hemorrhage. Therefore pregnancy, especially close to term, is a relative contraindication to the use of all NSAIDs.

Hypersensitivity

Certain individuals display hypersensitivity to aspirin and NSAIDs, as manifested by symptoms that range from vasomotor rhinitis with profuse watery secretions, angioedema, generalized urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance is a contraindication to therapy with any other NSAID because cross-sensitivity can provoke a life-threatening reaction.

Although less common in children, this syndrome may occur in 10–25% of patients with asthma, nasal polyps, or chronic urticaria, and in 1% of apparently healthy individuals. It is provoked by even low doses (<80 mg) of aspirin and apparently involves COX inhibition. Aspirin hypersensitivity is associated with an increase in biosynthesis of LTs, perhaps reflecting diversion of AA to lipoxigenase metabolism.

Drug Interactions

CONCOMITANT NSAIDS AND LOW-DOSE ASPIRIN Many patients combine either tNSAIDs or COX-2 inhibitors with “cardioprotective” low-dose aspirin. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone.

OTHER DRUG INTERACTIONS Angiotensin-converting enzyme (ACE) inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate prostaglandin production. Thus, it is logical that NSAIDs might attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic prostaglandins. Due to hyperkalemia, the combination of NSAIDs and ACE inhibitors also can produce marked bradycardia leading to syncope, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. NSAIDs may increase the frequency or severity of GI ulceration when combined with glucocorticoids and augment the risk of bleeding in patients receiving *warfarin*. Many NSAIDs are highly bound to plasma proteins and thus may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with *warfarin*, sulfonyleurea hypoglycemic agents, or *methotrexate*; the dosage of such agents may require adjustment to prevent toxicity. The problem with *warfarin* is accentuated, both because almost all NSAIDs suppress normal platelet function and because some NSAIDs also increase *warfarin* levels by interfering with its metabolism; thus, concurrent administration should be avoided.

PHARMACOKINETICS AND PHARMACODYNAMICS Most NSAIDs are rapidly and completely absorbed from the GI tract, with peak concentrations occurring within 1–4 hours. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation. The presence of food tends to delay absorption without affecting peak concentration. Most NSAIDs are extensively protein bound (95–99%) and undergo hepatic metabolism and renal excretion. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects (*see below*).

OTHER CLINICAL CONSIDERATIONS IN THE RATIONAL SELECTION OF THERAPY

The choice of an agent for use as an antipyretic or analgesic is seldom a problem. Drugs with more rapid onset of action and shorter duration of action probably are preferable for simple fevers accompanying minor viral illnesses or pain after minor musculoskeletal injuries, whereas a longer duration of action may be preferable for postoperative pain management. Sometimes a loading dose of such NSAIDs may be required.

The choice among tNSAIDs for the treatment of chronic arthritic conditions such as rheumatoid arthritis largely is empirical. Substantial differences in response have been noted among individuals treated with the same tNSAID and within an individual treated with different tNSAIDs. It is reasonable to give a drug for two weeks as a therapeutic trial and to continue it if the response is satisfactory. Initially, all patients should be asked about previous hypersensitivity to aspirin or any member of the NSAID class. Thereafter, low doses of the chosen agent should be prescribed to determine initial patient tolerance. Doses then may be adjusted to maximize efficacy or minimize adverse effects.

Adverse effects usually become manifest in the first weeks of therapy, although gastric ulceration and bleeding may present much later. If the patient does not achieve therapeutic benefit from one NSAID, another should be tried. It is best to avoid combination therapy with more than one NSAID. There is little evidence of extra benefit for the patient, and the risk of side effects is at least additive.

Clinical trials have established that at least three selective inhibitors of COX-2—rofecoxib, valdecoxib, and celecoxib—confer an increased risk of heart attack and stroke (*see above*). Of immediate concern are some tNSAIDs, such as meloxicam and diclofenac, which resemble celecoxibs in terms of their selectivity. Evidence for hazard with both drugs has been suggested from observational studies, but controlled trials to address this hypothesis have not been performed. The cardiovascular hazard from both celecoxib and rofecoxib—the two inhibitors for which data are available from placebo-controlled trials lasting more than 1 year—increased with chronicity of dosing. This is consistent with a mechanism-based acceleration of atherogenesis directly *via* inhibition of PGI₂ and indirectly due to the rise in blood pressure consequent to inhibition of COX-2 derived PGE₂ and PGI₂.

If a COX-2 inhibitor is selected, it should be used at the lowest possible dose for the shortest period of time. Patients at risk of cardiovascular disease or prone to thrombosis should not be

treated with these drugs. Small absolute risks of thrombosis attributable to these drugs may interact synergistically with absolute risks from genetic variants like factor V Leiden or concomitant therapies, such as oral contraceptives.

The choice of drugs for children is considerably restricted, and only drugs that have been extensively tested in children should be used. This commonly points toward naproxen and ibuprofen.

THE SALICYLATES

Aspirin is the most widely consumed analgesic, antipyretic, and anti-inflammatory agent and is the standard for the comparison and evaluation of the others. Because aspirin is so available, the possibility of misuse and serious toxicity probably is underappreciated.

CHEMISTRY

Salicylic acid is only used externally; therefore various derivatives of this acid have been synthesized for systemic use. These comprise two large classes, namely esters of salicylic acid obtained from substitutions within the carboxyl group and salicylate esters of organic acids, in which the carboxyl group is retained and substitution is made in the hydroxyl group. For example, aspirin is an ester of acetic acid. In addition, there are salts of salicylic acid (Figure 26–1).

Pharmacological Properties of Therapeutic Doses

ANALGESIA

The salicylates are used more widely for pain relief than are any other classes of drugs. The types of pain usually relieved by salicylates are those of low intensity that arise from integumental structures rather than from viscera, especially headache, myalgia, and arthralgia.

ANTIPYRESIS

Salicylates usually lower elevated body temperatures rapidly and effectively. However, moderate doses that produce this effect also increase oxygen consumption and metabolic rate. These compounds have a pyretic effect at toxic doses, and sweating exacerbates the dehydration that occurs in salicylate intoxication (see below).

FIGURE 26–1 Structural formulas of the salicylates.

RESPIRATION

Salicylates increase oxygen consumption and CO_2 production (especially in skeletal muscle) at full therapeutic doses; these effects are a result of uncoupling oxidative phosphorylation. The increased production of CO_2 stimulates respiration (mainly by an increase in depth of respiration with only a slight increase in rate). The increased alveolar ventilation balances the increased CO_2 production, and thus plasma CO_2 tension (Pco_2) does not change or may decrease slightly.

ACID-BASE AND ELECTROLYTE BALANCE AND RENAL EFFECTS

Therapeutic doses of salicylate produce definite changes in the acid-base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis, is achieved by increased renal excretion of bicarbonate, which is accompanied by increased Na^+ and K^+ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This is the stage of compensatory renal acidosis seen most often in adults given intensive salicylate therapy and seldom proceeds further unless toxicity ensues (see below). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other compounds can produce papillary necrosis and interstitial nephritis.

CARDIOVASCULAR EFFECTS

Low doses of aspirin (<100 mg daily) are used widely for their cardioprotective effects (see above). At high therapeutic doses (>3 g daily), as might be given for acute rheumatic fever, salt and water retention can lead to an increase (up to 20%) in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive heart failure and pulmonary edema can occur. High doses of salicylates can produce noncardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

GASTROINTESTINAL EFFECTS

The ingestion of salicylates may result in epigastric distress, nausea, and vomiting. Salicylates also may cause gastric ulceration, exacerbation of peptic ulcer symptoms (heartburn, dyspepsia), GI hemorrhage, and erosive gastritis. These effects occur primarily with aspirin. Because nonacetylated salicylates lack the ability to acetylate COX and thereby irreversibly inhibit its activity, they are weaker inhibitors than aspirin.

Aspirin-induced gastric bleeding sometimes is painless, and if unrecognized may lead to iron-deficiency anemia (see Chapter 53). The daily ingestion of anti-inflammatory doses of aspirin (4 or 5 g) results in an average fecal blood loss of 3–8 mL/day, as compared with ~0.6 mL/day in untreated subjects. Gastroscopic examination of aspirin-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa; in many cases, multiple hemorrhagic lesions with sharply demarcated areas of focal necrosis are observed.

HEPATIC EFFECTS

High doses of salicylates can cause hepatic injury. The onset of injury characteristically occurs after several months of treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible upon discontinuation of salicylates. The use of salicylates is contraindicated in patients with chronic liver disease. Salicylates are associated with the severe hepatic injury and encephalopathy observed in Reye's syndrome.

URICOSURIC EFFECTS

Low doses (1 or 2 g/day) can decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/day) may not alter urate excretion; large doses (more than 5 g/day) induce uricosuria and lower plasma urate levels. However, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of probenecid and other uricosuric agents that decrease tubular reabsorption of uric acid.

BLEEDING TIME

A single 325-mg dose of aspirin (standard tablet dose) approximately doubles the mean bleeding time of normal persons for a period of 4–7 days. This effect is due to irreversible acetylation of

platelet COX and the consequent reduced formation of TXA₂ until sufficient numbers of new, unmodified platelets are produced and is the mechanistic basis of prophylaxis of thrombotic myocardial infarction.

Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because of the risk of hemorrhage. If possible, aspirin therapy should be stopped one week before surgery; care should be exercised with aspirin in combination with oral anticoagulant agents because of the combined danger of prolongation of bleeding time coupled with blood loss from the gastric mucosa; this is used to advantage coupling patients with bioprosthetic or mechanical heart valves (see Chapter 54).

METABOLIC EFFECTS

The uncoupling of oxidative phosphorylation by salicylates may occur with doses of salicylate used in the treatment of rheumatoid arthritis. Salicylates increase O₂ uptake and CO₂ production and in toxic doses may decrease aerobic metabolism and increase the production of strong organic acids.

Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen.

Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine but increases O₂ consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from binding proteins in plasma (see Chapter 56).

LOCAL IRRITANT EFFECTS

Salicylic acid is irritating to skin and mucosa and destroys epithelial cells. The keratolytic action of the free acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. Methyl salicylate (oil of wintergreen) is used topically as a counter-irritant for the relief of mild musculoskeletal pain.

PHARMACOKINETICS

Orally ingested salicylates are absorbed rapidly, predominantly from the upper small intestine. Appreciable concentrations are found in plasma in less than 30 minutes; after a single dose, a peak value is reached in ~1 hour and then declines gradually. After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent passive processes. Salicylates are transported actively by a low-capacity, saturable system out of the cerebrospinal fluid (CSF) across the choroid plexus. The drugs readily cross the placental barrier.

The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin.

The volume of distribution of usual doses of aspirin averages ~170 mL/kg of body weight; at high therapeutic doses, this volume increases to ~500 mL/kg because of saturation of binding sites on plasma proteins. Aspirin can be detected in the plasma only for a short time as a result of hydrolysis in plasma, liver, and erythrocytes.

Roughly 80–90% of the salicylate in plasma is bound to proteins, especially albumin, at concentrations encountered clinically; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein binding sites; these include thyroxine, triiodothyronine, penicillin, phenytoin, sulfapyrazone, bilirubin, uric acid, and other NSAIDs such as naproxen.

The biotransformation of salicylates takes place in many tissues, but particularly in the liver. The three chief metabolic products are salicylic acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide.

The plasma $t_{1/2}$ for aspirin is ~20 minutes, and for salicylate 2–3 hours at antiplatelet doses, rising to 12 hours at usual anti-inflammatory doses. The $t_{1/2}$ of salicylate may be as long as 15–30 hours at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicylic acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses.

Tinnitus may be a reliable index of exceeding the acceptable plasma concentration in patients with normal hearing, but is not a reliable indicator in patients with preexisting hearing loss; thus, surveillance for this symptom is no substitute for periodic monitoring of serum salicylate levels during chronic aspirin treatment.

The plasma concentration of salicylate is increased by conditions that decrease glomerular filtration rate or reduce proximal tubule secretion of salicylates, such as renal disease or the presence

of inhibitors that compete for the transport system (e.g., probenecid). Changes in urinary pH also have significant effects on salicylate excretion. For example, the clearance of salicylate is about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria.

Therapeutic Uses

SYSTEMIC USES

The two most commonly used preparations of salicylate for systemic effects are aspirin (acetylsalicylic acid) and sodium salicylate. The dose of salicylate depends on the condition being treated.

Other salicylates available for systemic use include salsalate (salicylsalicylic acid; *DISALCID*, others), which is hydrolyzed to salicylic acid during and after absorption, sodium thiosalicylate (injection; *REXOLATE*), choline salicylate (oral liquid; *ARTHROPAN*), and magnesium salicylate (tablets; *MAGAN*, *MOEMENTUM*, others). A combination of choline and magnesium salicylates (choline magnesium, trisalicylate, *TRILISATE*, others) also is available.

Antipyresis

Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. The course of the patient's illness may be obscured by the relief of symptoms and the reduction of fever by the use of antipyretic drugs. The antipyretic dose of salicylate for adults is 325–650 mg orally every 4 hours. Salicylates are contraindicated for fever associated with viral infection in children; for nonviral etiologies, 50–75 mg/kg/day has been given in 4–6 divided doses, not to exceed a total daily dose of 3.6 g. The rectal administration of aspirin suppositories may be necessary in infants or when the oral route is unavailable.

Analgesia

Salicylates are valuable for the nonspecific relief of minor aches and pain (e.g., headache, arthritis, dysmenorrhea, neuralgia, and myalgia). For this purpose, they are prescribed in the same doses and manner as for antipyresis.

Rheumatoid Arthritis

Although aspirin is regarded as the standard against which other drugs should be compared for the treatment of rheumatoid arthritis, many clinicians favor the use of other NSAIDs perceived to have better GI tolerability, even though this perception remains unproven. Moreover, some patients perceive that aspirin is too commonly available to be effective. Therapy with salicylates produces analgesia adequate to allow more effective movement and physical therapy in osteoarthritis and rheumatoid arthritis. In addition, aspirin therapy is associated with improvement in appetite, a feeling of well-being, and a reduction in the inflammation in joint tissues and surrounding structures.

Inflammatory Bowel Disease

Mesalamine (5-aminosalicylic acid; *ASACOL*, others) is a salicylate that is used for its local effects in the treatment of inflammatory bowel disease (see Chapter 38). It currently is available as a suppository and rectal suspension enema (*ROWASA*) for treatment of mild-to-moderate proctosigmoiditis; a rectal suppository (*CANASA*, others) for the treatment of distal ulcerative colitis, proctosigmoiditis, or proctitis. Oral formulations and controlled-release capsule that deliver drug to the lower intestine are efficacious in treatment of inflammatory bowel disease, in particular ulcerative colitis. Sulfasalazine (salicylazosulfapyridine; *AZULFIDINE*) contains mesalamine linked covalently to sulfapyridine (see Chapter 38); it is absorbed poorly after oral administration, but it is cleaved to its active components by bacteria in the colon. The drug is of benefit in the treatment of inflammatory bowel disease, principally because of the local actions of mesalamine.

Salicylate Intoxication

Salicylate poisoning or serious intoxication often occurs in children and sometimes is fatal. Salicylate intoxication should be seriously considered in any young child with coma, convulsions, or cardiovascular collapse. The fatal dose varies with the preparation. Death has followed use of 10–30 g of sodium salicylate or aspirin in adults, but larger amounts have been ingested without a fatal outcome. The lethal dose of methyl salicylate (oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as 4 mL (4.7 g) of methyl salicylate may be fatal in children.

Mild chronic salicylate intoxication is called salicylism. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

NEUROLOGICAL EFFECTS

In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. The tinnitus and hearing loss of salicylate poisoning are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. Tinnitus typically is observed at plasma salicylate concentrations of 200–450 $\mu\text{g/mL}$, and there is a close relationship between the extent of hearing loss and plasma salicylate concentration. Tinnitus generally resolves within 2 or 3 days after withdrawal of the drug.

RESPIRATION

The respiratory effects of salicylates contribute to the serious acid–base balance disturbances that characterize poisoning. Salicylates stimulate respiration directly and indirectly. Uncoupling of oxidative phosphorylation leads to increased peripheral CO_2 production and a compensatory increase in minute ventilation, usually with no overall change in PCO_2 . Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children.

Salicylates directly stimulate the respiratory center in the medulla. This is characterized by an increase in depth and a pronounced increase in respiration rate. This can be seen with plasma salicylate concentrations of 350 $\mu\text{g/mL}$ and marked hyperventilation occurs when the level approaches 500 $\mu\text{g/mL}$. When a barbiturate or opioid (e.g., FIORINAL or DARVON COMPOUND 32) is present, then central respiratory depression will prevent hyperventilation, and the salicylate-induced uncoupling of oxidative phosphorylation will be associated with a marked increase in plasma PCO_2 and respiratory acidosis.

Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO_2 production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning.

ACID–BASE BALANCE AND ELECTROLYTES

As described above, high therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory renal acidosis. Subsequent changes in acid–base status generally occur only when toxic doses of salicylates are ingested by infants and children or occasionally after large doses in adults.

The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and renal acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma PCO_2 . Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO_2 . Consequently, plasma PCO_2 increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid–base status at this stage essentially is an uncompensated respiratory acidosis. Superimposed, however, is a true metabolic acidosis caused by accumulation of acids as a result of three processes. First, toxic concentrations of salicylates displace $\sim 2\text{--}3$ mEq/L of plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The low plasma PCO_2 leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na^+ , K^+ , and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation; dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia. Prolonged exposure to high doses of salicylate also causes depletion of K^+ due to both renal and extrarenal factors.

TREATMENT

Salicylate poisoning is a medical emergency, and death may result; there is no specific antidote. Management begins with a rapid assessment (see Chapter 64) followed by the “A (airway), B (breathing), C (circulation), D (decontamination)” approach to medical emergencies. Because of the need for respiratory alkalosis to compensate for the metabolic acidosis of salicylate toxicity, intubation should be avoided unless the patient demonstrates hypoventilation or obtundation. High concentrations of inspired oxygen may be required.

Aspirin poisoning leads to inappropriate vasodilation compounded by volume depletion and acidosis, which worsens vasodilation. Aggressive volume repletion with intravenous fluids should be instituted. The aim is to achieve large-volume diuresis to optimize salicylate elimination. If necessary, vasopressors (e.g., norepinephrine, phenylephrine) are added.

Activated charcoal is used to prevent further absorption of aspirin from the GI tract. This is particularly important when enteric-coated aspirin, which has delayed absorption, has been ingested. Sodium bicarbonate should be administered to maintain the pH between 7.5 and 7.55, and if possible, the pH of the urine greater than 8. Forced alkaline diuresis maximizes salicylate elimination. Hemodialysis may be required if the above measures are inadequate, there is clinical deterioration despite therapy, or if plasma salicylate levels are greater than 1000 $\mu\text{g/mL}$. Plasma salicylate, glucose, pH, and potassium should be monitored frequently and therapy modified accordingly. Decreased CNS glucose levels may occur despite normal plasma glucose levels, and supplemental glucose should be given in cases of altered mental status, regardless of the plasma glucose levels.

Diflunisal

Diflunisal (DOLOBID) is a difluorophenyl derivative of salicylic acid (Figure 26–1). It is almost completely absorbed after oral administration, and peak plasma concentrations occur within 2–3 hours. It is extensively bound to plasma albumin (99%). About 90% of the drug is excreted as glucuronide conjugates, and its rate of elimination is dose-dependent. At the usual analgesic dose (500–750 mg/day), the plasma $t_{1/2}$ averages 8–12 hours. Diflunisal appears in the milk of lactating women.

The drug has been used primarily as an analgesic in the treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances it is about three to four times more potent than aspirin. The usual initial dose is 500–1000 mg, followed by 250–500 mg every 8–12 hours. For rheumatoid arthritis or osteoarthritis, 250–500 mg is administered twice daily; maintenance dosage should not exceed 1.5 g/day. Diflunisal does not produce auditory side effects and appears to cause fewer and less intense GI and antiplatelet effects than aspirin.

PARA-AMINOPHENOL DERIVATIVES: ACETAMINOPHEN

Acetaminophen (paracetamol; *N*-acetyl-*p*-aminophenol; TYLENOL, others) is an effective alternative to aspirin as an analgesic–antipyretic agent; however, its anti-inflammatory effects are much weaker. While it is indicated for pain relief in patients with noninflammatory osteoarthritis, it is not a suitable substitute for aspirin or other NSAIDs in chronic inflammatory conditions such as rheumatoid arthritis. Acetaminophen is well tolerated and has a low incidence of GI side effects. It is available without a prescription. Acute overdosage can cause severe hepatic damage, and the number of accidental or deliberate poisonings with acetaminophen continues to grow. Chronic use of less than 2 g/day is not typically associated with hepatic dysfunction.

PHARMACOLOGICAL PROPERTIES

Acetaminophen has only weak anti-inflammatory effects and has been thought to have a generally poor ability to inhibit COX in the presence of high concentrations of peroxides, as are found at sites of inflammation.

Single or repeated therapeutic doses of acetaminophen have no effect on the cardiovascular and respiratory systems, on platelets, or on coagulation. Acid–base changes and uricosuric effects do not occur, nor does the drug produce the gastric irritation, erosion, or bleeding that may occur after salicylate administration.

PHARMACOKINETICS AND METABOLISM

*Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30–60 minutes and the $t_{1/2}$ in plasma is ~2 hours. Binding of the drug to plasma proteins is less than with other NSAIDs. Some 90–100% of the drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (~60%), sulfuric acid (~35%), or cysteine (~3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (Table 26–1). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of acetaminophen undergoes CYP-mediated *N*-hydroxylation to form *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a highly reactive intermediate (see below).*

THERAPEUTIC USES

Acetaminophen is a suitable substitute for aspirin for analgesic or antipyretic uses; it is particularly valuable for patients in whom aspirin is contraindicated (e.g., those with peptic ulcer, aspirin hypersensitivity, children with a febrile illness). The conventional oral dose of acetaminophen is 325–1000 mg (650 mg rectally); total daily doses should not exceed 4000 mg (2000 mg/day for

chronic alcoholics). The most common daily dose is 1000 mg, the dose at which epidemiological studies suggest that GI adverse effects are less common than with therapeutic doses of tNSAIDs. Higher doses, which may accomplish complete inhibition of COXs, may approach the adverse effect profile of tNSAIDs. Single doses for children range from 40–480 mg, depending upon age and weight; no more than five doses should be administered in 24 hours. A dose of 10 mg/kg also may be used.

COMMON ADVERSE EFFECTS AND TOXICITY

Acetaminophen usually is well tolerated. Erythematous or urticarial rash may occur and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to acetaminophen.

The most serious acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic necrosis. Renal tubular necrosis and hypoglycemic coma also may occur. The mechanism by which overdosage with acetaminophen leads to hepatocellular injury and death involves its conversion to the toxic NAPQI metabolite (see Chapter 64). The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated N-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of acetaminophen overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis.

Management of Acetaminophen Overdose

Acetaminophen overdose constitutes a medical emergency. Severe liver damage occurs in 90% of patients with plasma concentrations of acetaminophen >300 $\mu\text{g/mL}$ at 4 hours or 45 $\mu\text{g/mL}$ at 15 hours after the ingestion of the drug. Early diagnosis and treatment of acetaminophen overdose is essential to optimize outcome. Perhaps 10% of poisoned patients who do not receive specific treatment develop severe liver damage; 10–20% of these eventually die of hepatic failure despite intensive supportive care. Activated charcoal, if given within 4 hours of ingestion, decreases acetaminophen absorption by 50–90% and is the preferred method of gastric decontamination. Gastric lavage is not recommended.

N-acetylcysteine (NAC) (MUCOMYST, MUCOSIL, PARVOLEX) is indicated for those at risk of hepatic injury. NAC therapy should be instituted in suspected cases of acetaminophen poisoning before blood levels become available, with treatment terminated if assay results subsequently indicate that the risk of hepatotoxicity is low.

NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. Even in the presence of activated charcoal, there is ample absorption of NAC, and neither should activated charcoal be avoided nor NAC administration be delayed because of concerns of a charcoal-NAC interaction. Adverse reactions to NAC include rash (including urticaria, which does not require drug discontinuation), nausea, vomiting, diarrhea, and rare anaphylactoid reactions.

An oral loading dose of 140 mg/kg is given, followed by the administration of 70 mg/kg every 4 hours for 17 doses. Where available, the intravenous loading dose is 150 mg/kg by intravenous infusion in 100 mL of 5% dextrose over 15 minutes (for those weighing less than 20 kg), followed by 50 mg/kg by intravenous infusion in 250 mL of 5% dextrose over 4 hours, then 100 mg/kg by intravenous infusion in 500 mL of 5% dextrose over 16 hours.

ACETIC ACID DERIVATIVES: INDOMETHACIN, SULINDAC, AND ETODOLAC

Indomethacin

CHEMISTRY

The structural formula of indomethacin, a methylated indole derivative, is:

PHARMACOLOGICAL PROPERTIES

Indomethacin has prominent anti-inflammatory and analgesic–antipyretic properties similar to those of the salicylates. Indomethacin is a more potent inhibitor of COX than is aspirin, but patient intolerance generally limits its use to short-term dosing. Indomethacin has analgesic properties distinct from its anti-inflammatory effects, and there is evidence for central and peripheral actions.

PHARMACOKINETICS AND METABOLISM

Oral indomethacin has excellent bioavailability. Peak concentrations occur 1–2 hours after dosing (Table 26–1). Indomethacin is 90% bound to plasma proteins and tissues. The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 hours of administration.

Between 10% and 20% of indomethacin is excreted unchanged in the urine, partly by tubular secretion. The majority is converted to inactive metabolites, including those formed by O-demethylation (~50%), conjugation with glucuronic acid (~10%), and N-deacylation. Free and conjugated metabolites are eliminated in the urine, bile, and feces. There is enterohepatic cycling of the conjugates and probably of indomethacin itself. The $t_{1/2}$ in plasma is variable, perhaps because of enterohepatic cycling, but averages 2.5 hours.

DRUG INTERACTIONS

Indomethacin does not directly modify the effect of warfarin, but platelet inhibition and gastric irritation increase the risk of bleeding; concurrent administration is not recommended. Indomethacin antagonizes the natriuretic and antihypertensive effects of furosemide and thiazide diuretics and blunts the antihypertensive effect of β receptor antagonists, AT_1 receptor antagonists, and ACE inhibitors.

THERAPEUTIC USES

Indomethacin (INDOCIN) is effective for relieving joint pain, swelling, and tenderness, increasing grip strength, and decreasing the duration of morning stiffness. It is estimated to be ~20 times more potent than aspirin. Overall, about two-thirds of patients benefit from treatment with indomethacin, which typically is initiated at 25 mg two or three times daily. In some patients, 100 mg taken at night provides better relief from morning stiffness. Failure to obtain adequate symptom relief with 100 mg within 7–10 days is an indication to try an alternative therapy.

When tolerated, indomethacin often is more effective than aspirin in the treatment of ankylosing spondylitis and osteoarthritis. It also is very effective in the treatment of acute gout pain, although it is not uricosuric.

Indomethacin is FDA approved for closure of persistent patent ductus arteriosus. Successful closure is obtained in >70% of neonates treated with the drug. Such therapy is indicated primarily in premature infants who weigh between 500 and 1750 g, who have a hemodynamically significant patent ductus arteriosus, and in whom other supportive maneuvers have been attempted. Unexpectedly, treatment with indomethacin also may decrease the incidence and severity of intraventricular hemorrhage in low-birth-weight neonates. The principal limitation of treating neonates is renal toxicity, and therapy is stopped if urine output falls to <0.6 mL/kg/h. Renal failure, enterocolitis, thrombocytopenia, or hyperbilirubinemia are contraindications to the use of indomethacin.

COMMON ADVERSE EFFECTS

A high percentage (35–50%) of patients receiving usual therapeutic doses of indomethacin experience untoward symptoms, and ~20% must discontinue its use because of the side effects. Most adverse effects are dose-related.

Gastrointestinal complaints are common and can be serious. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Underlying peptic ulcer disease is a contraindication to indomethacin use. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect (indeed, the most common side effect) is severe frontal headache, occurring in 25–50% of patients who take the drug for long periods. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson's disease, because they are at greater risk for the development of serious CNS adverse effects.

Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia. As is common with other tNSAIDs, platelet function is impaired transiently during the dosing interval.

Sulindac

CHEMISTRY

Sulindac is related closely to indomethacin; its structure is:

PHARMACOLOGICAL PROPERTIES

Sulindac, which is less than half as potent as indomethacin, is a prodrug whose anti-inflammatory activity resides in its sulfide metabolite. The same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity or renal impairment also apply to sulindac.

PHARMACOKINETICS AND METABOLISM

About 90% of the drug is absorbed after oral administration (Table 26–1). Peak concentrations of sulindac in plasma are attained within 1–2 hours, while those of the sulfide metabolite occur ~8 hours after the oral administration of sulindac.

Sulindac is oxidized to the sulfone and then reversibly reduced to the active sulfide by the action of bowel microflora on sulindac excreted in the bile.

The $t_{1/2}$ of sulindac is ~7 hours, but the active sulfide has a $t_{1/2}$ as long as 18 hours. Sulindac and its metabolites undergo extensive enterohepatic circulation, and all are bound extensively to plasma protein.

Little of the sulfide (or of its conjugates) is found in urine. The principal components excreted in the urine are the sulfone and its conjugates, which account for nearly 30% of an administered dose; sulindac and its conjugates account for ~20%. Up to 25% of an oral dose may appear as metabolites in the feces.

THERAPEUTIC USES

Sulindac (CLINORIL) has been used mainly for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and acute gout. Its analgesic and anti-inflammatory effects are comparable to those of aspirin. The most common dosage for adults is 150–200 mg twice a day. The drug usually is given with food to reduce gastric discomfort, although this may delay absorption and reduce its concentration in plasma.

COMMON ADVERSE EFFECTS

Although the incidence of toxicity is lower than with indomethacin, GI side effects (less severe than indomethacin) are seen in nearly 20% of patients. CNS side effects as described above for indomethacin are seen in up to 10% of patients. Rash and pruritus occur in 5% of patients. Transient elevations of hepatic transaminases in plasma are less common.

Etodolac

Etodolac is another acetic acid derivative with some degree of COX-2 selectivity. Thus, at anti-inflammatory doses, the frequency of gastric irritation may be less than with other tNSAIDs.

PHARMACOKINETICS AND METABOLISM

Etodolac is rapidly and well absorbed orally. It is highly bound to plasma protein and undergoes hepatic metabolism and renal excretion (Table 26–1). The drug may undergo enterohepatic circulation in humans; its $t_{1/2}$ in plasma is ~7 hours.

THERAPEUTIC USES

A single oral dose (200–400 mg) of etodolac (LODINE) provides postoperative analgesia that typically lasts for 6–8 hours. Etodolac also is effective in the treatment of osteoarthritis and rheumatoid

arthritis and the drug appears to be uricosuric. A sustained-release preparation (LODINE XL) is available, allowing once-a-day administration.

COMMON ADVERSE EFFECTS

Etdolac appears to be relatively well tolerated. About 5% of patients who have taken the drug for up to 1 year discontinue treatment because of side effects, which include GI intolerance, rashes, and CNS effects.

THE FENAMATES

The fenamates include *mefenamic*, *meclofenamic*, and *flufenamic* acids.

Therapeutically, they have no clear advantages over several other tNSAIDs and frequently cause GI side effects.

Mefenamic acid (PONSTEL, others) and *meclofenamate sodium* (MECLOMEN) have been used mostly in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and in rheumatoid and osteoarthritis. These drugs are not recommended for use in children or pregnant women.

Mefenamic acid and *meclofenamate*, but not *flufenamic acid*, are available in the U.S. All three are available in Europe. They are used rarely for chronic therapy of the arthritides.

CHEMISTRY

Mefenamic acid and *meclofenamate* are N-substituted phenylanthranilic acids.

PHARMACOLOGICAL PROPERTIES

Mefenamic acid has central and peripheral actions, and *meclofenamic acid* may antagonize directly certain effects of prostaglandins, although it is not clear that receptor blockade is attained at therapeutic concentrations.

PHARMACOKINETIC PROPERTIES

These drugs are absorbed rapidly and have short durations of action. In humans, ~50% of a dose of *mefenamic acid* is excreted in the urine, primarily as the 3-hydroxymethyl and 3-carboxyl metabolites and their conjugates. About 20% of the drug is recovered in the feces, mainly as the unconjugated 3-carboxyl metabolite.

COMMON ADVERSE EFFECTS AND PRECAUTIONS

Approximately 25% of users develop GI side effects at therapeutic doses. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

The fenamates are contraindicated in patients with a history of GI disease. If diarrhea or rash occur, these drugs should be stopped at once. Vigilance is required for signs or symptoms of hemolytic anemia.

TOLMETIN, KETOROLAC, AND DICLOFENAC

Tolmetin and *ketorolac* are structurally related heteroaryl acetic acid derivatives with different pharmacological features. *Diclofenac* is a phenylacetic acid derivative that was developed specifically as an anti-inflammatory agent.

Tolmetin

Tolmetin is an anti-inflammatory, analgesic, and antipyretic agent that, in recommended doses (200–600 mg three times a day), appears to be approximately equivalent in efficacy to moderate doses of aspirin. *Tolmetin* possesses typical tNSAID properties and side effects.

PHARMACOKINETICS AND METABOLISM

Tolmetin demonstrates rapid and complete absorption, extensive plasma protein binding, and a short $t_{1/2}$ (Table 26–1). It undergoes extensive hepatic metabolism, mostly by oxidation of the *para*-methyl group to a carboxylic acid. Metabolites are excreted in the urine. Accumulation of the drug in synovial fluid begins within 2 hours and persists for up to 8 hours after a single oral dose.

THERAPEUTIC USES

Tolmetin (*tolmetin sodium*; TOLECTIN) is approved in the U.S. for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis; it also has been used in the treatment of ankylosing spondylitis. In general, *tolmetin* is thought to have similar therapeutic efficacy to aspirin. The maximum recommended dose is 2 g/day, typically given in divided doses with meals,

milk, or antacids to lessen abdominal discomfort. Peak plasma concentrations and bioavailability are reduced when the drug is taken with food.

COMMON ADVERSE EFFECTS

Side effects occur in 25–40% of patients who take tolmetin, and 5–10% discontinue use of the drug. Gastrointestinal side effects are the most common (15%) and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

Ketorolac

Ketorolac is a potent analgesic but only a moderately effective anti-inflammatory drug. It is one of the few NSAIDs approved for parenteral administration.

PHARMACOLOGICAL PROPERTIES

Ketorolac has greater systemic analgesic than anti-inflammatory activity. Like other tNSAIDs, it inhibits platelet aggregation and promotes gastric ulceration. Ketorolac also has anti-inflammatory activity when topically administered in the eye.

PHARMACOKINETICS AND METABOLISM

Ketorolac has a rapid onset of action, extensive protein binding, and a short duration of action (Table 26–1). Oral bioavailability is ~80%. Urinary excretion accounts for ~90% of eliminated drug, with ~10% excreted unchanged and the remainder as a glucuronidated conjugate. The rate of elimination is reduced in the elderly and in patients with renal failure.

THERAPEUTIC USES

Ketorolac (TORADOL, ULTRAM) has been used as a short-term alternative (<5 days) to opioids for the treatment of moderate-to-severe pain and is administered intramuscularly, intravenously, or orally. Unlike the case with opioids, tolerance, withdrawal, and respiratory depression do not occur. Like other NSAIDs, aspirin sensitivity is a contraindication to the use of ketorolac. Typical doses are 30–60 mg (intramuscular); 15–30 mg (intravenous); and 5–30 mg (oral). Ketorolac is used widely in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac is FDA-approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation after cataract extraction.

COMMON ADVERSE EFFECTS

Side effects at usual doses include somnolence, dizziness, headache, GI pain, dyspepsia, nausea, and pain at the site of injection.

Diclofenac

Diclofenac is the most commonly used tNSAID in Europe. The selective inhibitor of COX-2 lumiracoxib is an analog of diclofenac.

PHARMACOLOGICAL PROPERTIES

Diclofenac has analgesic, antipyretic, and anti-inflammatory activities. Diclofenac appears to reduce intracellular concentrations of free AA in leukocytes, perhaps by altering its release or

uptake. The selectivity of diclofenac for COX-2 resembles that of celecoxib. Observational studies have raised the possibility of a cardiovascular hazard from chronic therapy with diclofenac.

PHARMACOKINETICS

Diclofenac has rapid absorption, extensive protein binding, and a short $t_{1/2}$ (Table 26–2). There is a substantial first-pass effect, such that only ~50% of diclofenac is available systemically. Diclofenac accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than the plasma $t_{1/2}$. Diclofenac is metabolized in the liver by a member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation the metabolites are excreted in the urine (65%) and bile (35%).

THERAPEUTIC USES

Diclofenac is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis (100–200 mg in divided doses). Three formulations are available: an intermediate-release potassium salt (CATAFLAM), a delayed-release form (VOLTARIN, VOLTAROL [UK]), and an extended-release form (VOLTARIN-XR). Diclofenac also is useful for short-term treatment of acute musculoskeletal pain, postoperative pain, and dysmenorrhea. Diclofenac is also available in combination with misoprostol, a PGE₁ analog (ARTHROTEC). An ophthalmic solution of diclofenac is available for treatment of postoperative inflammation following cataract extraction.

COMMON ADVERSE EFFECTS

Diclofenac produces side effects (particularly GI) in ~20% of patients, and ~2% of patients discontinue therapy as a result. Modest reversible elevation of hepatic transaminases in plasma occurs in 5–15% of patients. Transaminases should be measured during the first 8 weeks of therapy with diclofenac, and the drug should be discontinued if abnormal values persist or if other signs or symptoms develop. Other untoward responses to diclofenac include CNS effects, rashes, allergic reactions, fluid retention, and edema, and rarely impairment of renal function. The drug is not recommended for children, nursing mothers, or pregnant women. Consistent with its preference for COX-2, and unlike ibuprofen, diclofenac does not interfere with the antiplatelet effect of aspirin. Given these observations, diclofenac is not a suitable alternative to a selective COX-2 inhibitor in individuals at risk of cardiovascular or cerebrovascular disease.

PROPIONIC ACID DERIVATIVES

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and acute gouty arthritis; they also are used as analgesics, for acute tendinitis and bursitis, and for primary dysmenorrhea.

Ibuprofen, the most commonly used tNSAID in the U.S., was the first member of the propionic acid class of NSAIDs to come into general use, and it is available without a prescription in the U.S. Naproxen, also available without prescription, has a longer but variable $t_{1/2}$, making twice-daily administration feasible (and perhaps once daily in some individuals). Oxaprozin also has a long $t_{1/2}$ and may possibly be given once daily.

Small clinical studies suggest that the propionic acid derivatives are comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis, perhaps with improved tolerability.

Ibuprofen and naproxen are representative of the class and are described individually below.

PHARMACOLOGICAL PROPERTIES The pharmacodynamic properties of the propionic acid derivatives do not differ significantly. All are nonselective COX inhibitors with the effects and side effects common to other tNSAIDs. Some of the propionic acid derivatives, particularly naproxen, have prominent inhibitory effects on leukocyte function, and some data suggest that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness. Epidemiological studies suggest that while the relative risk of myocardial infarction is unaltered by ibuprofen, it is reduced by around 10% by naproxen, compared to a reduction of 20–25% by aspirin. This suggestion of benefit accords with the clinical pharmacology of naproxen that suggests that some but not all individuals dosed with 500 mg twice daily sustain platelet inhibition throughout the dosing interval.

DRUG INTERACTIONS As do other NSAIDs, the propionic acid derivatives may interfere with the action of antihypertensive and diuretic agents, increase the risk of bleeding with warfarin, and increase the risk of bone marrow suppression with methotrexate. Ibuprofen also has been

shown to interfere with the antiplatelet effects of aspirin (*see above*). There is also evidence for a similar interaction between aspirin and naproxen.

Ibuprofen

Ibuprofen is supplied as tablets containing 200–800 mg; only the 200-mg tablets (ADVIL, MOTRIN, NUPRIN, others) are available without a prescription.

Doses of up to 800 mg four times daily can be used in the treatment of rheumatoid arthritis and osteoarthritis, but lower doses often are adequate. The usual dose for mild-to-moderate pain, such as that of primary dysmenorrhea, is 400 mg every 4–6 hours as needed.

PHARMACOKINETICS

Ibuprofen is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The $t_{1/2}$ is ~2 hours. Slow equilibration with the synovial space means that its antiarthritic effects may persist after plasma levels decline. In experimental animals, ibuprofen and its metabolites readily cross the placenta.

COMMON ADVERSE EFFECTS

Ibuprofen is thought to be better tolerated than aspirin and indomethacin and has been used in patients with a history of gastrointestinal intolerance to other NSAIDs. Nevertheless, 5–15% of patients experience GI side effects. Less frequent adverse effects include thrombocytopenia, rashes, headache, dizziness, blurred vision, and in a few cases toxic amblyopia, fluid retention, and edema. Patients who develop ocular disturbances should discontinue the use of ibuprofen. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.

Naproxen

PHARMACOKINETICS

Naproxen, (ALEVE, NAPROSYN, others), is absorbed fully when administered orally. Food delays the rate but not the extent of absorption. Peak concentrations in plasma occur within 2–4 hours and are somewhat more rapid after the administration of naproxen sodium. Absorption is accelerated by the concurrent administration of sodium bicarbonate but delayed by magnesium oxide or aluminum hydroxide. Naproxen also is absorbed rectally, but more slowly than after oral administration. The $t_{1/2}$ of naproxen is ~14 hours in the young; it may increase about twofold in the elderly because of age-related decline in renal function (Table 26–1).

Metabolites of naproxen are excreted almost entirely in the urine. About 30% of the drug undergoes 6-demethylation, and most of this metabolite, as well as naproxen itself, is excreted as the glucuronide or other conjugates.

Naproxen is almost completely (99%) bound to plasma proteins after normal therapeutic doses. Naproxen crosses the placenta and appears in the milk of lactating women at ~1% of the maternal plasma concentration.

COMMON ADVERSE EFFECTS

Typical GI adverse effects with naproxen occur at approximately the same frequency as with indomethacin, but perhaps with less severity. CNS side effects range from drowsiness, headache,

dizziness, and sweating, to fatigue, depression, and ototoxicity. Less common reactions include pruritus and a variety of dermatological problems. A few instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

ENOLIC ACIDS (OXICAMS)

The oxicam derivatives are enolic acids that inhibit COX-1 and COX-2 and have anti-inflammatory, analgesic, and antipyretic activity. In general, they are nonselective COX inhibitors, although one member (meloxicam) shows modest COX-2 selectivity comparable to celecoxib and was approved as a selective COX-2 inhibitor in some countries (*see below*). They are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid arthritis or osteoarthritis. The main advantage suggested for these compounds is their long $t_{1/2}$, which permits once-a-day dosing.

Piroxicam

PHARMACOLOGICAL PROPERTIES

Piroxicam is effective as an anti-inflammatory agent. It can inhibit activation of neutrophils, apparently independently of its ability to inhibit COX. Approximately 20% of patients experience side effects with piroxicam, and ~5% of patients discontinue use because of these effects.

PHARMACOKINETICS AND METABOLISM

Piroxicam is absorbed completely after oral administration and undergoes enterohepatic recirculation; peak concentrations in plasma occur within 2–4 hours (Table 26–1). Food may delay absorption. Estimates of the $t_{1/2}$ in plasma have been variable; the average is ~50 hours.

After absorption, piroxicam is extensively (99%) bound to plasma proteins. Concentrations in plasma and synovial fluid are similar at steady state (e.g., after 7–12 days). Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation is CYP-mediated hydroxylation to an inactive metabolite and its glucuronide conjugate.

THERAPEUTIC USES

Piroxicam (FELDENE) is approved in the U.S. for the treatment of rheumatoid arthritis and osteoarthritis. Due to delayed attainment of steady state (7–12 days), it has slow onset of action and is less suited for acute analgesia, but has been used in acute gout. Piroxicam can reduce the renal excretion of lithium to a clinically significant extent. The usual daily dose is 20 mg.

Meloxicam

Meloxicam (MOBIC) is approved by the FDA for use in osteoarthritis. The recommended dose is 7.5–15 mg once daily for osteoarthritis and 15 mg once daily for rheumatoid arthritis.

Meloxicam demonstrates some COX-2 selectivity, but a clinical advantage or hazard has yet to be established. There is significantly less gastric injury compared to piroxicam (20 mg/day) in subjects treated with 7.5 mg/day of meloxicam, but the advantage is lost with 15 mg/day. Like diclofenac, meloxicam does not offer a desirable alternative to prescribing celecoxib to patients at increased risk of myocardial infarction or stroke.

Nabumetone

Nabumetone is an anti-inflammatory agent with the following structure:

Clinical trials with nabumetone (RELAFEN) have indicated substantial efficacy in the treatment of rheumatoid arthritis and osteoarthritis, with a relatively low incidence of side effects. The dose typically is 1000 mg given once daily. The drug also has off-label use in the short-term treatment of soft-tissue injuries.

PHARMACOKINETICS AND METABOLISM

Nabumetone is absorbed rapidly and is converted in the liver to one or more active metabolites, principally 6-methoxy-2-naphthylacetic acid, a potent nonselective inhibitor of COX. This

metabolite, inactivated by O-demethylation in the liver, is then conjugated before excretion, and eliminated with a $t_{1/2}$ of ~24 hours.

SIDE EFFECTS

Nabumetone is associated with crampy lower abdominal pain and diarrhea, but the incidence of GI ulceration appears to be lower than with other tNSAIDs, although randomized, controlled studies directly comparing tolerability and clinical outcomes have not been performed. Other side effects include rash, headache, dizziness, heartburn, tinnitus, and pruritus.

CYCLCOOXYGENASE-2 SELECTIVE NSAIDS

The therapeutic use of the tNSAIDs has been limited by poor tolerability. Chronic users are prone to experience GI irritation in up to 20% of cases. However, the incidence of these adverse events had been falling sharply in the population prior to the introduction of the coxibs, perhaps reflecting a move away from use of high-dose aspirin as an anti-inflammatory drug strategy. Studies of the immediate early genes induced by inflammation led to the discovery of a gene with significant homology to the original COX enzyme, now designated COX-2. Because expression of this second COX enzyme was regulated by cytokines and mitogens, it was proposed to be the dominant source of prostaglandin formation in inflammation and cancer. It further was proposed that the original, constitutively expressed COX was the predominant source of cytoprotective prostaglandins formed by the gastrointestinal epithelium. Thus, selective inhibition of COX-2 was postulated to afford efficacy similar to tNSAIDs but with better tolerability. Subsequent crystallization of COX-1 and COX-2 revealed remarkable conservation of tertiary structure. However, one difference was in the hydrophobic channel by which the AA substrate gains access to the COX active site, buried deep within the molecule. This channel is more accommodating in the COX-2 structure and consequently exhibits wider substrate specificity than in COX-1. It also contains a side pocket that in retrospect affords a structural explanation for the identification in screens of the two enzymes *in vitro* of small molecule inhibitors that are differentially specific for COX-2. Although there were differences, most tNSAIDs expressed similar selectivity for inhibition of the two enzymes.

Drugs that were developed specifically to favor inhibition of COX-2 are called coxibs. As discussed above, several older drugs (*e.g.*, diclofenac and meloxicam) exhibit relative selectivity for COX-2 inhibition that resembles that of the first-approved specific inhibitor of COX-2, celecoxib.

Three members of the initial class of COX-2 inhibitors, the coxibs, were approved for use in the U.S. and Europe. Both rofecoxib and valdecoxib have now been withdrawn from the market in view of their adverse event profile.

Celecoxib

PHARMACOKINETICS

The bioavailability of oral celecoxib (CELEBREX) is not known, but peak plasma levels occur at 2–4 hours postdose. Celecoxib is bound extensively to plasma proteins. Little drug is excreted unchanged; most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination $t_{1/2}$ is ~11 hours. The drug commonly is given once or twice per day during chronic treatment. Renal insufficiency is associated with a modest, clinically insignificant decrease in plasma concentration. Celecoxib has not been studied in patients with severe renal insufficiency. Plasma concentrations are increased by ~40% and 180% in patients with mild and moderate hepatic impairment, respectively, and dosages should be reduced by at least 50% in patients with moderate hepatic impairment. Significant interactions occur with fluconazole and lithium but not with ketoconazole or methotrexate. Celecoxib is metabolized predominantly by

CYP2C9. Although not a substrate, celecoxib also is an inhibitor of CYP2D6. Clinical vigilance is necessary during coadministration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6.

PHARMACOLOGICAL PROPERTIES, ADVERSE EFFECTS, AND THERAPEUTIC USES

Effects attributed to inhibition of prostaglandin production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Studies in mice and some epidemiological evidence suggest that the likelihood of hypertension on NSAIDs reflects the degree of inhibition of COX-2 and the selectivity with which it is attained. Thus, the risk of thrombosis, hypertension, and accelerated atherogenesis are mechanistically integrated. The coxibs should be avoided in patients prone to cardiovascular or cerebrovascular disease. None of the coxibs has established clinical efficacy over tNSAIDs, while celecoxib has failed to establish superiority over tNSAIDs in reducing GI adverse events. While selective COX-2 inhibitors do not interact to prevent the antiplatelet effect of aspirin, it now is thought that they lose their GI advantage over a tNSAID alone when used in conjunction with aspirin. Experience with selective COX-2 inhibitors in patients who exhibit aspirin hypersensitivity is limited, and caution should be observed.

Celecoxib is approved in the U.S. for the treatment of osteoarthritis and rheumatoid arthritis. The recommended dose for treating osteoarthritis is 200 mg/day as a single dose or as two 100-mg doses. In the treatment of rheumatoid arthritis, the recommended dose is 100–200 mg twice per day. In the light of recent information on a potential cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible time. Current evidence does not support use of a coxib as a first choice among the NSAIDs.

OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Apazone (Azapropazone)

Apazone is a tNSAID that has anti-inflammatory, analgesic, and antipyretic activity and is a potent uricosuric agent. It is available in Europe but not the U.S. Some of its function may arise from its ability to inhibit neutrophil migration, degranulation, and superoxide production.

Apazone has been used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and gout but usually is restricted to cases where other tNSAIDs have failed. Typical doses are 600 mg three times per day for acute gout. Once symptoms have abated, or for nongout indications, typical dosage is 300 mg three–four times per day. Clinical experience to date suggests that apazone is well tolerated. Mild GI side effects (nausea, epigastric pain, dyspepsia) and rashes occur in ~3% of patients, while CNS effects (headache, vertigo) are reported less frequently. Precautions appropriate to other nonselective COX inhibitors also apply to apazone.

Nimesulide

Nimesulide is a sulfonanilide compound available in Europe that demonstrates COX-2 selectivity similar to celecoxib in whole blood assays. Additional effects include inhibition of neutrophil activation, decrease in cytokine production, decrease in degradative enzyme production, and possibly activation of glucocorticoid receptors. Its structure is:

Nimesulide is anti-inflammatory, analgesic, and antipyretic and reportedly is associated with a low incidence of gastrointestinal adverse effects. Given its selectivity profile, it is not a logical alternative for patients switching from the coxibs because of the risk of cardiovascular and cerebrovascular events.

PHARMACOTHERAPY OF GOUT

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes an exquisitely painful distal monoarthritis, but it also can cause

joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects ~0.5–1% of the population of Western countries.

The pathophysiology of gout is understood poorly. While a prerequisite, hyperuricemia does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Urate tends to crystallize in colder or more acidic conditions. Neutrophils ingesting urate crystals secrete inflammatory mediators that lower the local pH and lead to further urate precipitation.

The aims of treatment are to decrease the symptoms of an acute attack, decrease the risk of recurrent attacks, and lower serum urate levels. Therapy of gout focuses on *colchicine*, *allopurinol*, and the uricosuric agents—*probenecid*, *sulfinpyrazone*, and *benzbromarone*.

Treatment of Acute Gout

Several tNSAIDs reportedly are effective in the treatment of acute gout. The specific COX-2 inhibitor *etoricoxib* has been shown to be effective in gout. When effective, NSAIDs should be given at relatively high doses for 3–4 days and then tapered for a total of 7–10 days. *Indomethacin*, *naproxen*, *sulindac*, and *celecoxib* all have been found to be effective, although the first three are the only NSAIDs that are FDA-approved for the treatment of gout. *Aspirin* is not used because it can inhibit urate excretion at low doses, and through its uricosuric actions increase the risk of renal calculi at higher doses. In addition, *aspirin* can inhibit the actions of uricosuric agents. Likewise, *apazone* should not be used in acute gout because of the concern that its uricosuric effects may promote nephrolithiasis.

Prevention of Recurrent Attacks

Recurrent attacks of gout can be prevented with the use of *colchicine* (e.g., 0.6 mg daily or on alternate days). *Indomethacin* (25 mg/day) also has been used. These agents are used early in the course of uricosuric therapy when mobilization of urate is associated with a temporary increase in the risk of acute gouty arthritis.

ANTIHYPERURICEMIC THERAPY

Isolated hyperuricemia is not necessarily an indication for therapy, as not all of these patients develop gout. Persistently elevated uric acid levels, complicated by recurrent gouty arthritis, nephropathy, or subcutaneous tophi, can be lowered by *allopurinol*, which inhibits the formation of urate, or by uricosuric agents. Some physicians recommend measuring 24-hour urinary urate levels in patients who are on a low-purine diet to distinguish underexcretors from overproducers. However, tailored and empirical therapies have similar outcomes.

Certain drugs, particularly thiazide diuretics (see Chapter 28) and immunosuppressant agents (especially *cyclosporine*) may impair urate excretion and thereby increase the risk of gout.

Colchicine

Colchicine is one of the oldest available therapies for acute gout and is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses.

CHEMISTRY

The structure of *colchicine* is:

MECHANISM OF ACTION

Colchicine exerts a variety of pharmacological effects, but how these occur or how they relate to its activity in gout is not well understood. It has antimitotic effects, arresting cell division in G1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This

effect is greatest on cells with rapid turnover (e.g., neutrophils and GI epithelium). Colchicine renders cell membranes more rigid and decreases the secretion of chemotactic factors by activated neutrophils.

Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores; whether this occurs at clinically relevant concentrations is questionable.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation but depresses it by a direct effect, and alters neuromuscular function.

PHARMACOKINETICS AND METABOLISM

Colchicine absorption is rapid but variable. Peak plasma concentrations occur 0.5–2 hours after dosing. In plasma, 50% of colchicine is protein-bound. There is significant enterohepatic circulation. The exact metabolism of colchicine is unknown but seems to involve deacetylation by the liver. Only 10–20% is excreted in the urine, although this increases in patients with liver disease. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. The plasma $t_{1/2}$ of colchicine is ~9 hours, but it can be detected in leukocytes and in the urine for at least 9 days after a single intravenous dose.

TOXIC EFFECTS

Exposure of the GI tract to large amounts of colchicine and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects of colchicine and the earliest signs of impending toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose or route of administration, of several hours or more between the administration of the drug and the onset of symptoms. For this reason, adverse effects are common during initial dosing for acute gout. However, since patients often remain relatively consistent in their response to a given dose of the drug, toxicity can be reduced or avoided during subsequent courses of therapy by reducing the dose. Acute intoxication causes hemorrhagic gastropathy. Intravenous colchicine sometimes is used to treat acute gouty arthritis when other medications are not effective, when the patient is unable to take oral medications, or when rapid therapeutic intervention is necessary. The narrow margin of safety for colchicine is even further diminished by intravenous administration because this route obviates early GI side effects that can be a harbinger of serious systemic toxicity. Indiscriminate use of intravenous colchicine has been associated with preventable fatalities. Due to the high rate of serious bone marrow and renal complications (including death from sepsis), this route is not generally recommended.

Colchicine toxicity is associated with bone marrow suppression, particularly from the third to eighth days. There is a tendency toward leukocytosis with appearance of less mature forms. Chronic colchicine use may lead to agranulocytosis. Thrombocytopenia also can occur, and disseminated intravascular coagulation has been reported in cases of severe poisoning.

Chronic use is associated with a proximal myopathy. The associated weakness may go unrecognized, and creatine kinase levels should be monitored in those receiving chronic therapy. Ascending paralysis of the CNS has been reported with acute poisoning.

Proteinuria, hematuria, and acute tubular necrosis have been reported in severely intoxicated patients. Gouty nephropathy may occur in chronically treated patients. Azoospermia has been reported with chronic use.

There is no specific therapy for acute colchicine poisoning. Supportive measures should be used, particularly fluid repletion. Activated charcoal may decrease total colchicine exposure. Hemodialysis does not remove colchicine but may be required as part of supportive care.

THERAPEUTIC USES

Acute Gout

Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 hours of the onset of the attack. Pain, swelling, and redness abate within 12 hours and are completely gone within 48–72 hours. The typical oral dose is 0.6 mg each hour for a total of three doses. This dose should not be exceeded. Treatment with colchicine should not be repeated within 7 days to avoid cumulative toxicity.

Great care should be exercised in prescribing colchicine for elderly patients. For those with cardiac, renal, hepatic, or GI disease, NSAIDs or glucocorticoids may be preferred.

Prevention of Acute Gout

The main indication for colchicine is in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose is 0.6 mg twice a day, which should be decreased for patients with impaired renal function. One suggestion is 0.6 mg/day for a creatinine clearance of 35–50 mL/min, or in patients younger than 70 years of age, 0.6 mg every 2–3 days for creatinine clearances of 10–35 mL/min, and avoidance in those with creatinine clearance of less than 10 mL/min or with combined hepatic and renal disease.

Allopurinol

Allopurinol inhibits xanthine oxidase and prevents the synthesis of urate from hypoxanthine and xanthine. It is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

CHEMISTRY AND PHARMACOLOGICAL PROPERTIES

Allopurinol, an analog of hypoxanthine, has the following structure:

ALLOPURINOL

Both allopurinol and its primary metabolite oxypurinol inhibit xanthine oxidase. Allopurinol competitively inhibits xanthine oxidase at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for xanthine oxidase; the product of this reaction, oxypurinol, is also a noncompetitive inhibitor of the enzyme. The formation of oxypurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Since each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy; this can be minimized by liberal fluid intake and urine alkalinization.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal function but may delay disease progression. The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid.

Coadministration of colchicine helps suppress such acute attacks. After reduction of excess tissue stores of uric acid, the incidence of acute attacks decreases and colchicine can be discontinued.

In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of reutilization of oxypurines and feedback inhibition of de novo purine biosynthesis.

PHARMACOKINETICS

Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60–90 minutes. About 20% is excreted in the feces in 48–72 hours, presumably as unabsorbed drug, and 10–30% is excreted unchanged in the urine. The remainder undergoes

metabolism, mostly to oxypurinol. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma $t_{1/2}$ of allopurinol is ~1–2 hours and of oxypurinol ~18–30 hours (longer in those with renal impairment). This allows for once-daily dosing and makes allopurinol the most commonly used antihyperuricemic agent.

Allopurinol and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the two compounds do not correlate well with therapeutic or toxic effects.

DRUG INTERACTIONS

Allopurinol increases the $t_{1/2}$ of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol.

Allopurinol inhibits the enzymatic inactivation of mercaptopurine and its derivative azathioprine by xanthine oxidase. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced by 25–33% (see Chapters 38 and 51). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with cytotoxic agents that are not metabolized by xanthine oxidase, particularly cyclophosphamide.

Allopurinol may interfere with the hepatic inactivation of warfarin and increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 27).

THERAPEUTIC USES

Allopurinol (ZYLOPRIM, ALOPRIM, others) is available for oral use and provides effective therapy for the primary hyperuricemia of gout and the hyperuricemia secondary to polycythemia vera, myeloid metaplasia, other blood dyscrasias, or acute tumor lysis syndrome.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication, and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in complicated hyperuricemia (see above), to prevent acute tumor lysis syndrome, or in patients with hyperuricemia post-transplantation. If necessary, it can be used in conjunction with uricosuric agents.

The goal of therapy is to reduce the plasma uric acid concentration to <6 mg/dL (360 μ mol). In the management of gout, it is customary to antecede allopurinol therapy with colchicine and to avoid starting allopurinol during an acute attack of gouty arthritis. Fluid intake should be sufficient to maintain daily urinary volume of more than 2 L; slightly alkaline urine is preferred. An initial daily dose of 100 mg is increased by 100-mg increments at weekly intervals. Most patients can be maintained on 300 mg/day. Those with more severe gout may require 400–600 mg/day, and those with hematological malignancies may need up to 800 mg/day beginning 2–3 days before the start of chemotherapy. Daily doses in excess of 300 mg should be divided. Dosage must be reduced in patients in proportion to the reduction in glomerular filtration (e.g., 300 mg/day if creatinine clearance is >90 mL/min, 200 mg/day if creatinine clearance is between 60 and 90 mL/min, 100 mg/day if creatinine clearance is 30–60 mL/min, and 50–100 mg/day if creatinine clearance is <30 mL/min).

The usual daily dose in children with secondary hyperuricemia associated with malignancies is 150–300 mg, depending on age.

Allopurinol also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome and thereby prevents the complications resulting from hyperuricemia; there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease.

COMMON ADVERSE EFFECTS

Allopurinol is tolerated well by most patients. The most common adverse effects are hypersensitivity reactions that may occur after months or years of medication. The effects usually subside within a few days after medication is discontinued. Serious reactions preclude further use of the drug.

The cutaneous reaction caused by allopurinol is predominantly a pruritic, erythematous, or maculopapular eruption, but occasionally the lesion is urticarial or purpuric. Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment. Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue allopurinol. If indicated, desensitization to allopurinol can be carried out starting at 10–25 $\mu\text{g}/\text{day}$, with the drug diluted in oral suspension and doubled every 3–14 days until the desired dose is reached. This is successful in approximately half of patients. Oxypurinol is available for compassionate use in the U.S. for patients intolerant of allopurinol. The safety of oxypurinol in patients with severe allopurinol hypersensitivity is unknown; it is not recommended in this setting.

Fever, malaise, and myalgias also may occur. Such effects are noted in ~3% of patients with normal renal function and more frequently in those with renal impairment.

Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Rasburicase

Rasburicase (ELITEK) is a recombinant urate-oxidase that catalyzes the enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It lowers urate levels more effectively than allopurinol and is indicated for the initial management of elevated plasma uric acid levels in pediatric patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia.

Produced by a genetically modified *Saccharomyces cerevisiae* strain, the therapeutic efficacy may be hampered by the production of antibodies against the drug. Hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis all have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug. The recommended dose of rasburicase is 0.15 mg/kg or 0.2 mg/kg as a single daily dose for 5 days, with chemotherapy initiated 4–24 hours after infusion of the first rasburicase dose.

URICOSURIC AGENTS

Uricosuric agents increase the rate of excretion of uric acid. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption predominates, and the amount excreted usually is ~10% of that filtered. This process is mediated by a specific transporter, which can be inhibited (see Chapter 2).

The first step in urate reabsorption is its uptake from tubular fluid by a transporter that exchanges urate for either an organic or an inorganic anion. Uricosuric drugs compete with urate for the brush-border transporter, thereby inhibiting its reabsorption *via* the urate–anion exchanger system. However, transport is bidirectional, and depending on dosage, a drug may either decrease or increase the excretion of uric acid. Decreased excretion usually occurs at a low dosage, while increased excretion is observed at a higher dosage. Not all agents show this phenomenon, and one uricosuric drug may either add to or inhibit the action of another. The biphasic effect may be seen within the normal dosage range with some drugs such as salicylates.

There are two mechanisms by which one drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

Probenecid

CHEMISTRY

Probenecid is a highly lipid-soluble benzoic acid derivative (pK_a 3.4) with the following structure:

PHARMACOLOGICAL ACTIONS**Inhibition of Inorganic Acid Transport**

The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. When tubular secretion of a substance is inhibited, its final concentration in the urine is determined by the degree of filtration—which in turn is a function of binding to plasma protein—and by the degree of reabsorption. The significance of each of these factors varies widely with different compounds. Usually, the end result is decreased tubular secretion of the compound, leading to decreased urinary and increased plasma concentration.

Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. This results from inhibition of its reabsorption (see above). The uricosuric action of probenecid is blunted by the coadministration of salicylates.

ABSORPTION, FATE, AND EXCRETION

Probenecid is absorbed completely after oral administration. Peak concentrations in plasma are reached in 2–4 hours. The $t_{1/2}$ of the drug in plasma is dose-dependent and varies from <5 hours to >8 hours over the therapeutic range. Between 85% and 95% of the drug is bound to plasma albumin; unbound drug is cleared by glomerular filtration. The majority of the drug is secreted actively by the proximal tubule. The high lipid solubility of the undissociated form results in virtually complete absorption by backdiffusion unless the urine is markedly alkaline. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

COMMON ADVERSE EFFECTS

Probenecid is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses, and caution should be used in those with a history of peptic ulcer. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of <50 mL/min. Mild hypersensitivity reactions may occur in 2–4% of patients; serious hypersensitivity is extremely rare. The appearance of a rash during the concurrent administration of probenecid and penicillin G presents the physician with an awkward diagnostic dilemma. Substantial overdose with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

THERAPEUTIC USE**Gout**

Probenecid (BENEEMID, others) is marketed for oral administration. The starting dose is 250 mg twice daily, increasing over 1–2 weeks to 500–1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in up to 20% of gouty patients treated with probenecid alone.

Combination with Penicillin

Probenecid was developed for the purpose of delaying the excretion of penicillin, and it still is used as an adjunct to prolong penicillin concentrations in patients being treated for specific infections (e.g., syphilis) or in cases where penicillin resistance may be an issue (see Chapter 44).

Benzbromarone

This potent uricosuric agent is used in Europe. It is a potent and reversible inhibitor of the urate–anion exchanger in the proximal tubule. As the micronized powder, it is effective in a single daily dose of 40–80 mg. It is effective in patients with renal insufficiency and may be useful clinically in patients who are either allergic or refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone lower serum uric acid levels more effectively than either drug alone, despite the fact that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol.

PHARMACOTHERAPY OF ASTHMA

In the U.S., asthma accounts for 1–3% of all office visits, 500,000 hospital admissions per year, more pediatric hospital admissions than any other single illness, and >5000 deaths annually.

The pharmacotherapy of asthma employs drugs aimed at reducing airway inflammation (*i.e.*, antiinflammatory agents) and drugs aimed more directly at decreasing bronchospasm (*i.e.*, bronchodilators). To these ends, six classes of therapeutic agents are presently indicated for asthma treatment: β adrenergic receptor agonists, glucocorticoids, leukotriene inhibitors, chromones, methylxanthines, and inhibitors of immunoglobulin E (IgE).

ASTHMA AS AN INFLAMMATORY ILLNESS

Asthma is associated with inflammation of the airway wall. Increased numbers of various types of inflammatory cells, most notably eosinophils but also basophils, mast cells, macrophages, and certain types of lymphocytes, can be found in airway wall biopsies and in bronchoalveolar lavage fluid from asthmatic patients. Inflammatory mediators and various cytokines also are increased in the airways of asthmatic subjects compared with healthy control subjects. How bronchial inflammation contributes to the asthmatic condition remains poorly understood. Even asthmatics with normal baseline lung function and no recent exacerbations of their asthma have increased numbers of inflammatory cells in their airways. Conversely, many individuals allergic to inhaled allergens have evidence of lower airway inflammation but suffer only from the symptoms of allergic rhinitis. Many individuals with asthma are atopic and have clearly defined allergen exposures that are partially or substantially responsible for their asthmatic inflammation. Epidemiological studies show a strong correlation between increasing IgE levels and the prevalence of asthma regardless of atopic status. Nonallergic individuals also can suffer from asthma, as is often seen in subjects in whom the onset of disease is later in life.

Although there are subtypes of asthma (allergic *vs.* nonallergic), certain features of airway inflammation are common to all asthmatic airways (Figure 27–1). Airway inflammation presumably is triggered by innate and/or adaptive immune responses. Although there may be multiple “triggers” for an inflammatory response (such as mast cell secretion), there is consensus that a lymphocyte-directed eosinophilic bronchitis is a hallmark of asthma. The lymphocytes that participate in asthma are of the T-helper type 2 (Th2) phenotype, leading to increases in production of interleukin 4 (IL-4), IL-5, and IL-13. IL-4 promotes IgE synthesis in B cells, while IL-5 supports eosinophil survival. The innate or adapted immune response triggers the production of additional cytokines and chemokines, resulting in trafficking of blood-borne cells (*i.e.*, eosinophils, basophils, neutrophils, and lymphocytes) into airway tissues; these cells further generate a variety of autacoids and cytokines. The inflammatory cascade also leads to activation of resident cells within the airways that, in turn, produce a panoply of cytokines, growth factors, chemokines, and autacoids. Over time, the chronic inflammatory response leads to epithelial shedding and reorganization, mucous hypersecretion, and airway wall remodeling most often exemplified by subepithelial fibrosis and smooth muscle hyperplasia. How these processes lead to attacks of asthma, which most often are induced or exacerbated by respiratory viral infections, remains unclear.

In addition to airway inflammation, asthmatics commonly exhibit bronchial hyperreactivity. The concentration of a bronchial spasmogen (*e.g.*, methacholine or histamine) needed to produce a 20% increase in airway resistance in asthmatics is often only 1–2% of the equally effective concentration in healthy control subjects. This bronchial hyperreactivity most often is nonspecific such that the airways are also inordinately reactive to stimuli such as strong odors, cold air, and pollutants.

The pharmacotherapy of asthma centers on controlling the disease with drugs that inhibit airway inflammation. Other drugs that relax bronchial smooth muscle are used for faster, more direct relief of the symptoms of asthma.

TREATMENT OF ASTHMA Aerosol Delivery of Drugs

Topical delivery of drugs to the lungs can be accomplished by use of aerosols. In theory, this approach should produce a high local concentration in the lungs with a low systemic delivery, thereby significantly minimizing systemic side effects. The drugs used most commonly in the treatment of asthma, β_2 adrenergic receptor agonists and glucocorticoids, have potentially serious side effects when delivered systemically. Since the pathophysiology of asthma appears to involve the

FIGURE 27-1 Simplified view of allergic inflammation in the airways. Asthma is an episodic narrowing of the bronchi thought to be caused by an underlying chronic inflammatory disorder. In allergic asthma, inhaled allergen initiates the inflammatory response by interacting with IgE bound to mast cells and basophils. This leads to a cascade of events involving other immune cells and resulting in the release of numerous inflammatory mediators into the interstitial space, where they influence the growth and function of cell types within the airway wall. The drugs available for the treatment of asthma are targeted at inhibiting the inflammatory responses and/or relaxing the bronchial smooth muscle. respiratory tract alone, the advantages of aerosol treatments with limited systemic effects are substantial. Indeed, in clinical practice, probably >90% of asthmatic patients who are capable of manipulating inhaler devices can be managed by aerosol treatments alone.

Because of the specialized nature of aerosol delivery and the substantial effects that these systems have on the therapeutic index, the principles of this delivery method are important to review (see Figure 27-2). Even under ideal circumstances, only a small fraction of the aerosolized drug is deposited in the lungs, typically 2–10%. Most of the remainder is swallowed. To minimize systemic effects, an aerosolized drug should be either poorly absorbed from the gastrointestinal (GI) system or rapidly inactivated *via* first-pass hepatic metabolism. Furthermore, any maneuvers that increase deposition in the lungs or decrease the percentage of drug reaching the GI system should enhance the desired effects and reduce undesired systematic effects. Because >50% of patients using inhalers do not use proper technique and thus deposit too small a fraction of inhaled drug into the lungs, patients should be counseled in the proper use of an inhaler.

β_2 Adrenergic Receptor Agonists

The chemistry, pharmacological properties, and mechanisms of action of the β adrenergic agonists are discussed in Chapter 10. Their discussion here is restricted to their uses in asthma.

MECHANISM OF ACTION AND USE IN ASTHMA The β adrenergic receptor agonists available for the treatment of asthma are selective for the β_2 receptor subtype. With few exceptions, they are delivered directly to the airways *via* inhalation. The agonists can be classified as short- or long-acting. Short-acting agonists are used only for symptomatic relief of asthma, whereas long-acting agonists are used prophylactically in the treatment of the disease.

The mechanism of the antiasthmatic action of β adrenergic receptor agonists is undoubtedly linked to the direct relaxation of airway smooth muscle and consequent bronchodilation. Although

FIGURE 27-2 Schematic representations of the disposition of inhaled drugs. Inhalation therapy deposits asthma medications directly, but not exclusively, in the lungs. Distribution of inhaled drug between lungs and esophagus depends on particle size and efficiency of delivery to lungs. Most material, ~90%, will be swallowed and absorbed, entering the systemic circulation. Some drug also will be absorbed from the lungs. Optimal particle size for deposition in small airways is 1–5 μm .

human bronchial smooth muscle receives little or no sympathetic innervation, it nevertheless contains large numbers of β_2 adrenergic receptors. Stimulation of these receptors activates the G_s -adenylyl cyclase–cyclic AMP pathway with a consequent reduction of in smooth muscle tone. β_2 Adrenergic receptor agonists also increase the conductance of Ca^{2+} -sensitive K^+ channels in airway smooth muscle, leading to membrane hyperpolarization and relaxation.

There are β_2 adrenergic receptors on cell types in the airways other than bronchial smooth muscle. Of particular interest, stimulation of β_2 adrenergic receptors inhibits the function of numerous inflammatory cells, including mast cells, basophils, eosinophils, neutrophils, and lymphocytes. In general, stimulating β_2 adrenergic receptors in these cells increase intracellular cyclic AMP, ultimately inhibiting the release of inflammatory mediators and cytokines.

Long-term exposure to β_2 agonists may desensitize some of these receptor-response pathways; thus, there is little evidence that these drugs, used chronically, reduce airway inflammation.

Short-Acting β_2 Adrenergic Receptor Agonists Drugs in this class include *albuterol* (PROVENTIL, VENTOLIN), *levalbuterol*, the (R)-enantiomer of albuterol (XOPENEX), *metaproterenol* (ALUPENT), *terbutaline* (BRETHAIRE), and *pirbuterol* (MAXAIR). These drugs are used for acute inhalation treatment of bronchospasm. Terbutaline (BRETHINE, BRICANYL), albuterol, and metaproterenol also are available in oral dosage form. Each of the inhaled drugs has an onset of action within 1–5 minutes and produces bronchodilation that lasts for ~2–6 hours. Oral dosage forms have a somewhat longer duration of action (e.g., 4–8 hours for oral terbutaline). Although there are slight differences in the relative β_2/β_1 receptor potency ratios among the drugs, all of them are selective for the β_2 subtype.

The most effective drugs in relaxing airway smooth muscle and reversing bronchoconstriction are short-acting β_2 adrenergic receptor agonists. They are the preferred treatment for rapid symptomatic relief of dyspnea associated with asthmatic bronchoconstriction. Although these drugs are prescribed on an as-needed basis, it is imperative that guidelines be given to the patient so that reliance on relief of symptoms during times of deteriorating asthma does not occur. When the asthma symptoms become persistent, the patient should be reevaluated so that drugs aimed at controlling, in addition to reversing, the disease can be prescribed.

Long-Acting β Adrenergic Receptor Agonists *Salmeterol xinafoate* (SEREVENT) and *formoterol* (FORADIL) are long-lasting adrenergic agents with very high selectivity for the β_2 receptor subtype; bronchodilation lasts over 12 hours. The mechanism underlying the extended duration of action of salmeterol appears related to its high lipophilicity. After binding the receptor, the less lipophilic, short-acting agonists are removed rapidly from the receptor environment by diffusion in the aqueous phase, while salmeterol persists in the membrane and only slowly dissociates from the environment of the receptor.

Chronic treatment with a receptor agonist often leads to receptor desensitization and diminished effect (see Chapter 1). The β_2 receptors on human bronchial smooth muscle are relatively resistant to desensitization, whereas receptors on mast cells and lymphocytes are desensitized rapidly following agonist exposure. This may help to explain why there is little evidence that these drugs are effective in inhibiting airway inflammation associated with asthma.

ADVERSE DRUG EFFECTS

Owing to their β_2 -receptor selectivity and topical delivery, inhaled β adrenergic receptor agonists at recommended doses have relatively few adverse effects. A portion of inhaled drug inevitably is absorbed into the systemic circulation. At higher doses, these drugs may lead to increased heart rate, cardiac arrhythmias, and central nervous system (CNS) effects associated with β adrenergic receptor activation (see Chapter 10). This is of particular concern in patients with poorly controlled asthma, in whom there may be excessive and inappropriate reliance on symptomatic treatment with short-acting β receptor agonists.

Oral Therapy with β Adrenergic Receptor Agonists The use of orally administered β adrenergic agonists for bronchodilation has not gained wide acceptance largely because of the risk of adverse effects, especially tremulousness, muscle cramps, cardiac tachyarrhythmias, and metabolic disturbances (see Chapter 10). Brief courses of oral therapy (albuterol or metaproterenol syrups) are well tolerated and effective in young children (<5 years old) who cannot manipulate metered-dose inhalers yet have occasional wheezing with viral upper respiratory infections. In some patients with severe asthma exacerbations, any aerosol, whether delivered *via* a metered-dose inhaler or a nebulizer, can worsen cough and bronchospasm owing to local irritation. In this setting, oral therapy with β_2 adrenergic agonists (*e.g.*, albuterol, metaproterenol, or terbutaline tablets) can be effective. However, the frequency of adverse systemic effects with orally administered agents is higher in adults than in children.

Glucocorticoids

Systemic glucocorticoids long have been used to treat severe chronic asthma or severe acute exacerbations of asthma. The development of aerosol formulations significantly improved the safety of glucocorticoid treatment, allowing it to be used for moderate asthma. Asthmatic subjects who require inhaled β_2 adrenergic agonists four or more times weekly are viewed as candidates for inhaled glucocorticoids.

MECHANISM OF GLUCOCORTICOID ACTION IN ASTHMA

Glucocorticoids do not directly relax airway smooth muscle and thus have little effect on acute bronchoconstriction. Their anti-inflammatory effects in asthma include modulation of cytokine and chemokine production; inhibition of eicosanoid synthesis; marked inhibition of accumulation of basophils, eosinophils, and other leukocytes in lung tissue; and decreased vascular permeability. Because of their profound and generalized anti-inflammatory actions, glucocorticoids are the most effective drugs used in the treatment of asthma.

INHALED GLUCOCORTICOID A major advance in asthma therapy was the development of inhaled glucocorticoids that targeted the drug directly to the relevant site of inflammation. These formulations greatly enhance the therapeutic index of the drugs, substantially diminishing the number and degree of side effects without sacrificing clinical utility. There are five glucocorticoids available in the U.S. for inhalation therapy: *beclomethasone dipropionate* (BECLOVENT, VANCERIL), *triamcinolone acetonide* (AZMACORT), *flunisolide* (AEROBID), *budesonide* (PULMOCORT), and *fluticasone propionate* (FLOVENT); all are effective in controlling asthma at the appropriate doses.

Inhaled glucocorticoids are used prophylactically to control asthma rather than acutely to reverse asthma symptoms. As with all prophylactic therapies, compliance is a significant concern. Issues relating to drug compliance, therefore, become relevant when choosing among the various

steroid formulations. The newer, highly potent drugs (*e.g.*, fluticasone, flunisolide, and budesonide) can be effective with as little as 1–2 puffs administered twice or even once daily. Many patients prefer this more convenient dosage regimen, providing improved compliance and better asthma control. The appropriate dose of steroid must be determined empirically. Important variables that influence the effective dose include the severity of disease, the particular steroid used, and the device used for drug delivery, which determines the actual quantity of drug delivered to the lungs. Maximal improvement in lung function may require several weeks of treatment.

SYSTEMIC GLUCOCORTICOIDS

Systemic glucocorticoids are used for acute asthma exacerbations and chronic severe asthma. Substantial doses of glucocorticoids (e.g., 40–60 mg prednisone or equivalent daily for 5 days; 1–2 mg/kg/day for children) often are used to treat acute exacerbations of asthma. Although an additional week at somewhat reduced dosage may be required, the steroids can be withdrawn once control of the symptoms by other medications has been restored; any suppression of adrenal function dissipates within 1–2 weeks. More protracted bouts of severe asthma may require longer treatment and slower tapering of the dose to avoid exacerbating asthma symptoms and suppressing pituitary/adrenal function. Previously, alternate-day therapy with oral prednisone was employed commonly in persistent asthma. Now, most patients with asthma are better treated with inhaled glucocorticoids.

TOXICITY

Inhaled Glucocorticoids

While inhaled glucocorticoids in asthma are effective, local and systemic adverse effects remain a concern (Table 27–1). Inhaled glucocorticoids have extremely low oral bioavailability owing to extensive first-pass metabolism by the liver and reach the circulation almost exclusively by absorption from the lung. In contrast to the beneficial effects on asthma, which plateau at ~1600 µg/day, the risk of adverse effects continues to increase at higher doses. Oropharyngeal candidiasis and, more frequently, dysphonia can be encountered. The incidence of candidiasis can be reduced substantially by rinsing the mouth and throat with water after each use and by employing spacer or reservoir devices attached to the dispenser to decrease drug deposition in the oral cavity. Appreciable suppression of the hypothalamic-pituitary-adrenal axis is rarely of physiologic importance even at doses up to 1600 µg/day. Modest but statistically significant decreases in bone mineral density do occur in female asthmatics receiving inhaled steroids. While the clinical relevance of these bone metabolism findings remains to be determined, it is argued that inhaled glucocorticoid treatment should be reserved for moderate or severe asthma because such treatment is likely to last for many years. Nonetheless, it has been suggested that the small risk of adverse effects at high doses of inhaled glucocorticoids is outweighed by the risks of inadequately controlling severe asthma.

Table 27–1

Potential Adverse Effects Associated with Inhaled Glucocorticoids

Adverse Effect	Risk
Hypothalamic–pituitary–adrenal axis suppression	No significant risk until dosages of budesonide or beclomethasone increased to >1500 µg/day in adults or >400 µg/day in children
Bone resorption	Modest but significant effects at doses possibly as low as 500 µg/day
Carbohydrate and lipid metabolism	Minor, clinically insignificant changes occur with dosages of beclomethasone >1000 µg/day
Cataracts	Anecdotal reports, risk unproven
Skin thinning	Dosage-related effect with beclomethasone dipropionate over a range of 400 to 2000 µg/day
Purpura	Dosage-related increase in occurrence with beclomethasone over a range of 400 to 2000 µg/day
Dysphonia	Usually of little consequence
Candidiasis	Incidence <5%, reduced by use of spacer device
Growth retardation	Difficult to separate effect of disease from effect of treatment, but no discernible effects on growth when all studies are considered

Systemic Glucocorticoids

The adverse effects of systemic administration of glucocorticoids are well known (see Chapter 59), but treatment for brief periods (5–10 days) causes relatively little dose-related toxicity. The most common adverse effects during a brief course are mood disturbances, increased appetite, impaired glucose control in diabetics, and candidiasis.

Leukotriene Receptor Antagonists and Leukotriene Synthesis Inhibitors

Zafirlukast (ACCOLATE) and montelukast (SINGULAIR) are leukotriene receptor antagonists. Zileuton (ZYFLO) is an inhibitor of 5-lipoxygenase, which catalyzes the formation of leukotrienes from arachidonic acid.

ZAFIRLUKAST

MONTELUKAST

ZILEUTON

PHARMACOKINETICS AND METABOLISM

The leukotriene-modifying drugs are administered orally. Zafirlukast is absorbed rapidly, with >90% bioavailability. At therapeutic plasma concentrations, it is >99% protein-bound. Zafirlukast is metabolized extensively by hepatic CYP2C9. The parent drug is responsible for its therapeutic activity, with metabolites being <10% as effective. The $t_{1/2}$ of zafirlukast is ~10 hours.

Montelukast is absorbed rapidly, with ~60–70% bioavailability. At therapeutic concentrations, it is highly protein-bound (99%). It is metabolized extensively by CYP3A4 and CYP2C9. The $t_{1/2}$ of montelukast is 3–6 hours.

Zileuton is absorbed rapidly on oral administration and is metabolized extensively by CYPs and by UDP-glucuronosyltransferases. The parent molecule is responsible for its therapeutic action. Zileuton is a short-acting drug with a $t_{1/2}$ of ~2.5 hours and also is highly protein-bound (93%).

MECHANISM OF ACTION IN ASTHMA Leukotriene-modifying drugs act either as competitive antagonists of leukotriene receptors or by inhibiting the synthesis of leukotrienes. The pharmacological properties of leukotrienes are discussed in detail in Chapter 25.

Leukotriene-Receptor Antagonists Cysteinyl leukotrienes (CysLTs) include leukotriene C₄ (LTC₄), leukotriene D₄ (LTD₄), and leukotriene E₄ (LTE₄). All the CysLTs are potent constrictors of bronchial smooth muscle. On a molar basis, LTD₄ is ~1000 times more potent than is histamine as a bronchoconstrictor. The receptor responsible for the bronchoconstrictor effect of leukotrienes is the CysLT₁ receptor. Although each of the CysLTs is an agonist at the CysLT₁ receptor, LTE₄ is less potent than either LTC₄ or LTD₄. Zafirlukast and montelukast are selective high-affinity competitive antagonists for the CysLT₁ receptor. *Pranlukast* is another CysLT₁-receptor antagonist used in some countries in the treatment of asthma, but it is not approved for use in the U.S.

Inhibition of CysLT-induced bronchial smooth muscle contraction likely is involved in the therapeutic effects of these agents to relieve the symptoms of asthma.

Leukotriene-Synthesis Inhibitors The formation of leukotrienes depends on lipoxygenation of arachidonic acid by 5-lipoxygenase. Zileuton is a potent and selective inhibitor of 5-lipoxygenase activity and thus blocks the formation of all 5-lipoxygenase products. Thus, in addition to inhibiting the formation of the cys-LTs, zileuton also inhibits the formation of leukotriene B₄ (LTB₄), a potent chemotactic autacoid, and other eicosanoids that depend on leukotriene A₄ (LTA₄) synthesis. Logically, the therapeutic effects of a 5-lipoxygenase inhibitor would include all those observed with the CysLT-receptor antagonists, as well as other effects that may result from inhibiting the formation of LTB₄ and other 5-lipoxygenase products.

TOXICITY

There are few adverse effects directly associated with inhibition of leukotriene synthesis or function. This likely is due to the fact that leukotriene production is limited predominantly to sites of inflammation.

Zafirlukast and Montelukast

In large clinical studies the adverse-effect profiles of these drugs were similar to that observed with placebo treatment. Very rarely, patients taking these drugs develop systemic eosinophilia and a vasculitis with features similar to Churg-Strauss syndrome. This problem, often associated with a reduction in glucocorticoid therapy, may represent the unmasking of a preexisting disease. Zafirlukast, but not montelukast, may interact with warfarin and increase prothrombin times, which should be monitored in patients subject to this interaction.

Zileuton

In ~4–5% of patients taking zileuton, there is an elevation in hepatic transaminases, generally within the first 2 months of therapy. Zileuton decreases the steady-state clearance of theophylline, substantially increasing its plasma concentrations. Zileuton also decreases warfarin clearance.

USE IN ASTHMA Most clinical trials with these drugs have studied patients with mild asthma who were not taking glucocorticoids. In general, the studies show a modest but significant improvement in pulmonary function and a decrease in symptoms and asthma exacerbations. For those who respond to antileukotriene therapy, the National Heart, Lung, and Blood Institute recognizes these drugs as alternatives to low-dose inhaled steroids for control of mild chronic asthma.

This class of drugs is not indicated for rapid bronchodilator therapy; thus, patients are instructed to have short-acting β adrenergic receptor agonists available as rescue medication. Montelukast and zafirlukast are effective with once- or twice-daily treatment, respectively. In contrast, zileuton is taken 4 times a day. Hepatic transaminases should be monitored in patients beginning zileuton therapy to guard against the potential of liver toxicity.

Anti-IgE Therapy

Omalizumab (XOLAIR) is the first biological agent approved for the treatment of asthma. Omalizumab is a recombinant humanized monoclonal antibody of the IgG1 κ subclass, targeted against IgE. IgE bound to omalizumab cannot bind to IgE receptors on mast cells and basophils, thereby preventing the allergic reaction at a very early step in the process (Figure 27–3).

PHARMACOKINETICS AND METABOLISM Omalizumab is delivered as a single subcutaneous injection every 2–4 weeks. It has a bioavailability of ~60%, reaching peak serum levels after 7–8 days. The serum elimination $t_{1/2}$ is 26 days, with a clearance rate of ~2.5 mL/kg/day. The elimination of omalizumab–IgE complexes occurs in the liver reticuloendothelial system at a rate somewhat faster than that of free IgG. Some intact omalizumab is also excreted in the bile. There is little evidence of specific uptake of omalizumab by any tissue.

TOXICITY

Omalizumab generally was well tolerated in several clinical trials. The most frequent adverse effect was injection-site reactions (e.g., redness, stinging, bruising, and induration), but these reactions also were seen at comparable frequencies with placebo. Low titers of antibodies against omalizumab developed in 1 of 1723 treated patients, whereas anaphylaxis was seen in 0.1% of treated patients. Malignancies of various types were observed in 20 of 4127 patients taking omalizumab, a higher frequency than the 5 malignancies in 2236 patients taking other asthma and allergy drugs; additional study is needed to clarify this risk.

FIGURE 27–3 Mechanism of Action of Omalizumab. *Omalizumab is a monospecific anti-IgE antibody.* Specific B lymphocytes produce IgE antibodies. The Fc region of IgE heavy chains binds with high affinity to receptors (FcεRI) in the plasma membranes of mast cells and basophils (and other cells). Allergen interacts with the antigen-binding site of cell-bound IgE, causing FcεRI cross-linking and cell activation. Omalizumab neutralizes the free IgE in the serum by binding to the Fc regions of the heavy chains to form high-affinity IgE–anti-IgE complexes. This prevents the IgE from binding to FcεRI, thereby blocking allergen-induced cell activation.

USE IN ASTHMA Omalizumab is indicated for adults and adolescents >12 years of age with allergies and moderate-to-severe persistent asthma. In this population, omalizumab has proven to be effective in reducing the dependency on inhaled and oral corticosteroids and in decreasing the frequency of asthma exacerbations. Omalizumab is not an acute bronchodilator and should not be used as a rescue medication or as a treatment of status asthmaticus.

Based on its mechanism of action, omalizumab has been used in the treatment of other allergic disorders, such as nasal allergy and food allergy, but large-scale clinical trials are limited to asthma.

Cromolyn Sodium (disodium cromoglycate) and Nedocromil Sodium

MECHANISM OF ACTION

Cromolyn and nedocromil inhibit mediator release from bronchial mast cells; reverse the increased functional activation in leukocytes obtained from the blood of asthmatic patients; suppress the activating effects of chemotactic peptides on human neutrophils, eosinophils, and monocytes; inhibit parasympathetic and cough reflexes; and inhibit leukocyte trafficking in asthmatic airways.

PHARMACOKINETICS For asthma, cromolyn is given by inhalation using either solutions (delivered by aerosol spray or nebulizer) or, in some countries but not in the U.S., powdered drug (mixed with lactose and delivered by a special turboinhaler). The pharmacological effects result from the topical deposition of the drug in the lung, since only ~1% of an oral dose of cromolyn is absorbed. Once absorbed, the drug is excreted unchanged in the urine and bile in about equal proportions. Peak concentrations in plasma occur within 15 minutes of inhalation, and excretion begins after some delay such that the biological $t_{1/2}$ ranges from 45–100 minutes. The terminal $t_{1/2}$ of elimination following intravenous administration is ~20 minutes.

TOXICITY

Cromolyn and nedocromil generally are well tolerated by patients. Adverse reactions are infrequent and minor and include bronchospasm, cough or wheezing, laryngeal edema, joint swelling and pain, angioedema, headache, rash, and nausea. Such reactions have been reported at a frequency of <1 in 10,000 patients. Very rare instances of anaphylaxis also have been documented.

USE IN ASTHMA The main use of cromolyn (INTAL) and nedocromil (TILADE) is to prevent asthmatic attacks in individuals with mild- to-moderate bronchial asthma. These agents are ineffective in treating ongoing bronchoconstriction. When inhaled several times daily, cromolyn inhibits both the immediate and the late asthmatic responses to antigenic challenge or to exercise. With regular use for >2–3 months, bronchial hyperreactivity is reduced, as measured by response to challenge with histamine or methacholine. Nedocromil is approved for use in asthmatic patients 12 years of age and older; cromolyn is approved for all ages.

Theophylline

Theophylline, a methylxanthine, still is commonly used for asthma pharmacotherapy in many countries. In developed countries, the advent of inhaled glucocorticoids, β adrenergic receptor agonists, and leukotriene-modifying drugs has diminished theophylline use significantly, and it has been relegated to a third- or fourth-line treatment in patients whose asthma is otherwise difficult to control.

THEOPHYLLINE

MECHANISM OF ACTION Theophylline inhibits cyclic nucleotide phosphodiesterases (PDEs), thereby preventing hydrolysis of cyclic AMP and cyclic GMP to 5'-AMP and 5'-GMP. Inhibition of PDEs leads to an accumulation of cyclic AMP and cyclic GMP, thereby increasing signal transduction through these pathways. Theophylline and related methylxanthines are relatively nonselective in PDE inhibition. Cyclic nucleotide production is regulated by endogenous receptor–ligand interactions leading to activation of adenylyl cyclase and guanylyl cyclase. Inhibitors of PDEs therefore can be thought of as drugs that enhance the activity of endogenous autacoids, hormones, and neurotransmitters that signal *via* cyclic nucleotides.

Theophylline is also a competitive antagonist at adenosine receptors (*see* Chapter 12). Adenosine can act as an autacoid and transmitter with myriad biological actions. Of particular relevance to asthma are the observations that adenosine can cause bronchoconstriction in asthmatics and potentiate immunologically induced mediator release from lung mast cells. Inhibition of the actions of adenosine therefore also must be considered when attempting to explain the mechanism of action of theophylline.

Theophylline also may owe part of its anti-inflammatory action to its ability to activate histone deacetylases in the nucleus. In theory, the deacetylation of histones could decrease the transcription of several proinflammatory genes and potentiate the effect of corticosteroids.

Pulmonary System

Theophylline effectively relaxes airway smooth muscle; this bronchodilation likely contributes to its acute therapeutic efficacy in asthma. Both adenosine receptor antagonism and PDE inhibition are likely involved in the bronchodilating effect of theophylline. Inhibition of PDE4 and PDE5 effectively relaxes human isolated bronchial smooth muscle, and inhibition of these PDEs likely contributes to the bronchodilating effect of theophylline. Studies with the related methylxanthine enprofylline (3-propylxanthine), which has been investigated extensively for treatment of asthma in Europe, also support a mechanistic role for PDE inhibition in the bronchodilator actions of theophylline.

Theophylline also inhibits synthesis and secretion of inflammatory mediators from numerous cell types, including mast cells and basophils. This effect of theophylline likely is due to PDE inhibition and can be mimicked in large part with drugs that selectively inhibit PDE4.

Absorption, Fate, and Excretion

Theophylline administered in liquids or uncoated tablets is absorbed rapidly and completely. In the absence of food, solutions or uncoated tablets of theophylline produce maximal concentrations in plasma within 2 hours and maximal plasma concentrations are achieved within 1 hour. Numerous sustained-release preparations of theophylline are available, designed for dosing intervals of 8, 12, or 24 hours. There is marked interpatient variability in the rate and extent of absorption, and especially in the effect of food and time of administration on these parameters. Thus, it is necessary to avoid substituting one apparently similar product for another.

Food ordinarily slows the rate of theophylline absorption but does not limit its extent. With sustained-release preparations, food may decrease the bioavailability of theophylline with some products but may increase it with others. Recumbency or sleep also may significantly reduce the rate or extent of absorption. These factors make it difficult to maintain relatively constant concentrations of theophylline in plasma throughout the day. Concentrations required to alleviate asthmatic symptoms do not remain constant, and the emphasis has shifted toward designing dosing regimens that ensure peak concentrations in the early morning hours, when symptoms frequently worsen.

Theophylline is distributed into all body compartments; crossing the placenta and passing into breast milk. Theophylline is eliminated primarily by metabolism in the liver. Less than 15% of administered theophylline is recovered in the urine unchanged. In premature infants, the rate of elimination of theophylline is quite slow; the average $t_{1/2}$ for theophylline ranges between 20 and 36 hours.

There is marked individual variation in the rate of elimination of theophylline owing to both genetic and environmental factors; fourfold differences are not uncommon. The $t_{1/2}$ averages ~3.5 hours in young children, whereas values of 8–9 hours are more typical in adults. In most patients the drug obeys first-order elimination kinetics within the therapeutic range. At higher concentrations, zero-order kinetics become evident because of saturation of metabolic enzymes, prolonging the decline of theophylline concentrations to nontoxic levels.

Hepatic cirrhosis, congestive heart failure, and acute pulmonary edema all increase the $t_{1/2}$ of theophylline, as does concurrent therapy with cimetidine or erythromycin. In contrast, clearance is increased twofold by phenytoin or barbiturates, whereas cigarette smoking, rifampin, and oral contraceptives induce smaller changes.

Although scarcely detectable in adults, the conversion of theophylline to caffeine is significant in preterm infants. In this setting, caffeine accumulates in plasma to a concentration ~25% that of theophylline. About 50% of the theophylline administered to such infants appears in the urine unchanged; the excretion of 1,3-dimethyluric acid, 1-methyluric acid, and caffeine derived from theophylline accounts for nearly all the remainder.

USE IN ASTHMA Theophylline now is relegated to a far less prominent role primarily because of the modest benefits it affords, its narrow therapeutic window, and the required monitoring of drug levels. Nocturnal asthma can be improved with slow-release theophylline preparations, but other interventions such as inhaled glucocorticoids or salmeterol probably are more effective.

Therapy is initiated by the administration of 12–16 mg/kg/day of theophylline (calculated as the free base) up to a maximum of 400 mg/day for at least 3 days. Children <1 year of age require considerably less; the dose in milligrams per kilogram per day may be calculated as $0.2 \times (\text{age in weeks}) + 5$. Starting with these low doses minimizes early side effects of nausea, vomiting, nervousness, and insomnia that often subside with continued therapy and virtually eliminates the possibility of exceeding plasma concentrations of 20 $\mu\text{g/mL}$ in patients older than age 1 year who do not have compromised hepatic or cardiac function. Thereafter, the dosage is increased in two successive

stages to between 16 and 20 and, subsequently, 18 and 22 mg/kg/day (up to a maximum of 800 mg/day) depending on the age and clinical response of the patient and allowing at least 3 days between adjustments. The plasma concentration of theophylline is determined before a further adjustment in dosage is made. Although extended-release preparations of theophylline usually allow twice-daily dosing, variations in the rate and extent of absorption of such preparations require individualized calibration of regimens for each patient and preparation.

ADVERSE EFFECTS Adverse CNS effects include headache, anxiety, restlessness, agitation, insomnia, dizziness, and seizures. These reactions are more likely to occur in children than in adults and are also more likely following rapid intravenous administration or in patients with excessive theophylline serum concentrations. Serious reactions can occur without antecedent minor symptoms. A reduction in dosage may eliminate CNS side effects, but if they continue or become severe, theophylline may have to be discontinued.

Urticaria can develop from a hypersensitivity to the ethylenediamine salt in aminophylline. Allergic reactions may not become evident for 12–24 hours after initiation of treatment.

Theophylline decreases peripheral resistance, increases cardiac output, and causes a central vagal effect. Palpitations, sinus bradycardia, extrasystoles, hypotension, ventricular tachycardia, premature ventricular contractions (PVCs), and cardiac arrest have been reported. Although cardiovascular effects are generally mild and transient, serious reactions, such as ventricular arrhythmias, can develop without warning. Patients should be carefully monitored.

In theophylline acute overdose patients are more likely to exhibit hypotension, hypokalemia, and/or metabolic acidosis than are patients receiving chronic overmedication. Patients suffering chronic overmedication can develop seizures and serious arrhythmias with serum concentrations of 28–70 $\mu\text{g}/\text{mL}$. Cardiac arrhythmias include atrial fibrillation or atrial flutter, multifocal atrial tachycardia, sinus tachycardia, supraventricular tachycardia and premature ventricular contractions with hemodynamic instability.

APNEA OF PRETERM INFANTS

In premature infants, episodes of prolonged apnea lasting >15 seconds and accompanied by bradycardia pose the threat of recurrent hypoxemia and neurologic damage. Although they often are associated with serious systemic illness, in many instances no specific cause is found. Methylxanthines have undergone numerous clinical trials for the treatment of apnea of undetermined origin. The oral or intravenous administration of methylxanthines can eliminate episodes of apnea that last >20 seconds and markedly reduces the number of episodes of shorter duration. Satisfactory responses may occur with plasma concentrations of theophylline of 4–8 $\mu\text{g}/\text{mL}$, but concentrations of nearly 13 $\mu\text{g}/\text{mL}$ are required more frequently. Still higher concentrations may produce a more regular pattern of respiration without further reduction in the frequency of episodes of apnea and bradycardia, and these usually are associated with a definite tachycardia. Therapeutic concentrations are achieved with loading doses of ~5 mg/kg of theophylline (calculated as the free base) and can be maintained with 2 mg/kg given every 12 or 24 hours.

Anticholinergic Agents

The use of anticholinergic agents in the treatment of asthma is discussed in detail in Chapter 7. With the advent of inhaled β adrenergic agonists, use of anticholinergic agents declined. Renewed interest in anticholinergic agents paralleled the realization that parasympathetic pathways are important in bronchospasm in some asthmatics and the availability of *ipratropium bromide* (ATROVENT), a quaternary muscarinic receptor antagonist that has better pharmacological properties than prior drugs. A particularly good response to ipratropium may be seen in the subgroup of asthmatic patients who experience psychogenic exacerbations.

The cholinergic receptor subtype responsible for bronchial smooth muscle contraction is the muscarinic M_3 receptor. The bronchodilation produced by ipratropium in asthmatic subjects develops more slowly and usually is less intense than that produced by adrenergic agonists. Some asthmatic patients may experience a useful response lasting up to 6 hours. The variability in the response of asthmatic subjects to ipratropium presumably reflects differences in the strength of parasympathetic tone and in the degree to which reflex activation of cholinergic pathways participates in generating symptoms in individual patients. Hence, the utility of ipratropium must be assessed on an individual basis by a therapeutic trial.

Combined treatment with ipratropium and β_2 adrenergic agonists results in slightly greater and more prolonged bronchodilation than with either agent alone in baseline asthma. In acute

bronchoconstriction, the combination of a β_2 adrenergic agonist and ipratropium is more effective than either agent alone and more effective than simply giving more β_2 adrenergic agonist. Thus, the combination of a selective β_2 adrenergic agonist and ipratropium should be considered in acute treatment of severe asthma exacerbations. Ipratropium is available in metered-dose inhalers and as a nebulizer solution. A metered-dose inhaler containing a mixture of ipratropium and albuterol (COMBIVENT) also is available in the U.S. In Europe, metered-dose inhalers containing a mixture of ipratropium and fenoterol are available (DUOVENT, BERODUAL).

Recently, tiotropium (SPIRIVA), a structural analogue of ipratropium, has been approved for the treatment of chronic obstructive pulmonary disease (COPD) and emphysema. Like ipratropium, tiotropium has high affinity for all muscarinic receptor subtypes, but it dissociates from the receptors much more slowly than ipratropium. In particular, binding and functional studies indicate that tiotropium dissociates from muscarinic M_3 receptors more slowly than from muscarinic M_2 receptors. The high affinity of tiotropium for muscarinic receptors, combined with its very slow dissociation rate, permits once-daily dosing. The slow dissociation rate also provides a theoretical advantage in that it limits the capacity of large concentrations of the endogenous agonist acetylcholine to surmount the receptor blockade. Tiotropium is provided as a capsule containing a dry-powder formulation that is intended only for oral inhalation using the HandiHaler inhalation device.

PHARMACOGENETICS AND VARIABILITY OF RESPONSE TO ASTHMA MEDICATIONS There is significant interindividual variability in the response of asthmatic subjects to pharmacotherapy. For example, some individuals benefit dramatically from treatment with leukotriene modifiers, whereas many others are essentially resistant to these treatments. Although more rare, the “steroid resistant” asthmatic receives relatively little benefit from treatment with inhaled corticosteroids. At present, it is impossible to predict who will benefit the most from a given treatment. This unpredictability of response largely reflects our limited understanding of the underlying pathophysiology of asthma. In addition, some component of this variability likely is explained by specific pharmacogenetic factors.

Use of Asthma Drugs in Rhinitis

Seasonal allergic rhinitis (hay fever) is caused by deposition of allergens on the nasal mucosa, resulting in an immediate hypersensitivity reaction. This reaction usually is not accompanied by asthma because the allergenic particles are too large to be inhaled into the lower airways (*e.g.*, pollens). Treatment for allergic rhinitis is similar to that for asthma. Topical glucocorticoids, including *beclomethasone* (BECONASE), *mometasone* (NASONEX), *budesonide* (RHINOCORT), *flunisolide* (NASAREL), *fluticasone* (FLONASE), and *triamcinolone* (NASACORT), can be highly effective with minimal side effects, particularly if treatment is instituted immediately prior to the allergy season. Topical glucocorticoids can be administered twice daily (beclomethasone and flunisolide) or even once daily (budesonide, mometasone, fluticasone, and triamcinolone). Cromolyn usually requires dosing three to six times daily for full effects. Rare instances of local candidiasis have been reported with glucocorticoids and probably can be avoided by rinsing the mouth after use. Unlike in asthma, antihistamines (*see* Chapter 24) afford considerable, though incomplete, symptom relief in allergic rhinitis. Nasal decongestants rely on β adrenergic agonists (*e.g.*, pseudoephedrine and phenylephrine) as vasoconstrictors and are discussed in Chapter 10. Anticholinergic agents such as ipratropium bromide (ATROVENT) are effective in inhibiting parasympathetic reflex-evoked secretions from serous glands lining the nasal mucosa.

Use of Asthma Drugs in COPD

Emphysema can be prevented or its progression slowed if the patient stops smoking. Pharmacological interventions can help patients to stop smoking. *Nicotine gum* (NICORETTE), *nicotine transdermal patches* (NICODERM), and the antidepressant agent *bupropion* (ZYBAN) are moderately useful when combined with other interventions such as support groups and healthcare provider encouragement. Clonidine may be helpful in reducing the craving for cigarettes. Treatment of nicotine addiction is discussed in Chapter 23.

The pharmacological treatment of established emphysema resembles that of asthma largely because the inflammatory/bronchospastic component of a patient's disease is the aspect amenable to therapy. For patients with emphysema who have a significant degree of active inflammation with bronchospasm and excessive mucus production, symptomatic use of inhaled ipratropium or a β_2 adrenergic agonist may be helpful. Ipratropium or tiotropium usually produces about the same

modest degree of bronchodilation in patients with COPD as do maximal doses of β_2 adrenergic agonists. As in asthmatic patients, continuous use of bronchodilators is controversial, with some studies suggesting that it is associated with an unfavorable course of COPD. A subgroup of patients may respond favorably to short courses of oral glucocorticoids. Without a treatment trial, it is not possible to predict whether a particular patient will respond to glucocorticoids. Response to oral glucocorticoids may predict those patients who will respond to inhaled glucocorticoids. Except for the treatment of acute bronchospastic episodes, glucocorticoids have given mixed results in the treatment of COPD. In some patients, theophylline may be effective; in others who have a salutary response to β_2 adrenergic agonists, theophylline may provide no additional bronchodilation beyond that already achieved.

In a minority of patients, emphysema results from a genetic deficiency of the plasma proteinase inhibitor α_1 -antiproteinase (also called α_1 -antitrypsin). Lung tissue destruction is caused by the unopposed action of neutrophil elastase and other proteinases. Purified α_1 -antiproteinase (PROLASTIN) from human plasma is available for intravenous replacement.

CLINICAL SUMMARY

Bronchodilating drugs, exemplified by the *short-acting β_2 adrenergic receptor agonists*, are used acutely to reverse the bronchospasm of an asthma attack. Anti-inflammatory drugs such as inhaled *glucocorticoids* are used to quell bronchial inflammation in an effort to reduce the severity and frequency of asthma attacks. In hospitalized patients, a short course of systemic steroids often is given, followed by a rapid taper. In patients who remain symptomatic despite inhaled glucocorticoid therapy, *long-acting β_2 adrenergic receptor agonists* may be added to the steroid regimen with good success. Newer agents, directed at specific mechanisms underlying the initiation or progression of asthma, include the *leukotriene receptor antagonists* and the anti-IgE therapy *omalizumab*. The anticholinergic agent *tiotropium* is approved for the treatment of COPD in the U.S.

DRUGS AFFECTING RENAL AND CARDIOVASCULAR FUNCTION

DIURETICS

RENAL ANATOMY AND PHYSIOLOGY

The kidney filters large quantities of plasma, reabsorbs substances that the body must conserve, and leaves behind and/or secretes substances that must be eliminated. The two kidneys in humans produce together ~120 mL/min of ultrafiltrate, yet only 1 mL/min of urine is produced. The basic urine-forming unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to a long tubular portion that reabsorbs and conditions the glomerular ultrafiltrate. Each human kidney has $\sim 1 \times 10^6$ nephrons. The structure of the nephron and the site of action of different classes of diuretics are shown in Figure 28–1.

The proximal tubule of the nephron is contiguous with Bowman's capsule and takes a tortuous path until finally forming a straight portion that dives into the renal medulla. Normally, ~65% of filtered Na^+ is reabsorbed in the proximal tubule; since this part of the tubule is highly permeable to water, reabsorption is essentially isotonic. Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the descending thin limb (DTL), which penetrates the inner medulla, makes a hairpin turn, and then forms the ascending thin limb (ATL). At the juncture between the inner and outer medulla, the tubule becomes the thick ascending limb (TAL), which consists of three segments: a medullary portion (MTAL), a cortical portion (CTAL), and a postmacular segment. Together the proximal straight tubule, DTL, ATL, MTAL, CTAL, and postmacular segment are known as the loop of Henle. The DTL is highly permeable to water but relatively impermeable to NaCl and urea. In contrast, the ATL is permeable to NaCl and urea but impermeable to water. The TAL actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na^+ is reabsorbed in the loop of Henle, mostly in the TAL, which has a large reabsorptive capacity.

The TAL passes between the afferent and efferent arterioles and makes contact with the afferent arteriole via a cluster of specialized columnar epithelial cells known as the macula densa. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict. This, in turn, causes a reduction in glomerular filtration rate (GFR). This homeostatic mechanism, known as tubuloglomerular feedback (TGF), serves to protect the organism from salt and volume wasting. The macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule becomes the distal convoluted tubule (DCT). The postmacular segment of the TAL and the DCT often are referred to as the early distal tubule. Like the TAL, the DCT actively transports NaCl and is impermeable to water. Since these characteristics impart the ability to produce a dilute urine, the TAL and the DCT are collectively called the diluting segment of the nephron, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the TAL, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (see below).

The collecting duct system (connecting tubule, initial collecting tubule, cortical collecting duct, and outer and inner medullary collecting ducts) is an area of fine control of ultrafiltrate composition and volume and is where final adjustments in electrolyte composition are made. In addition, vasopressin (also called antidiuretic hormone; see Chapter 29) modulates water permeability of this part of the nephron.

The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of vasopressin, the collecting duct system is impermeable to water, and a dilute urine is excreted. In the presence of vasopressin, the collecting duct system is permeable to water, which is reabsorbed down a steep concentration gradient that exists between the tubular fluid and the medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the ability to concentrate urine, which is accomplished via a combination of the unique topography of the loop of Henle and the specialized permeability features of the loop's subsegments. The "passive countercurrent

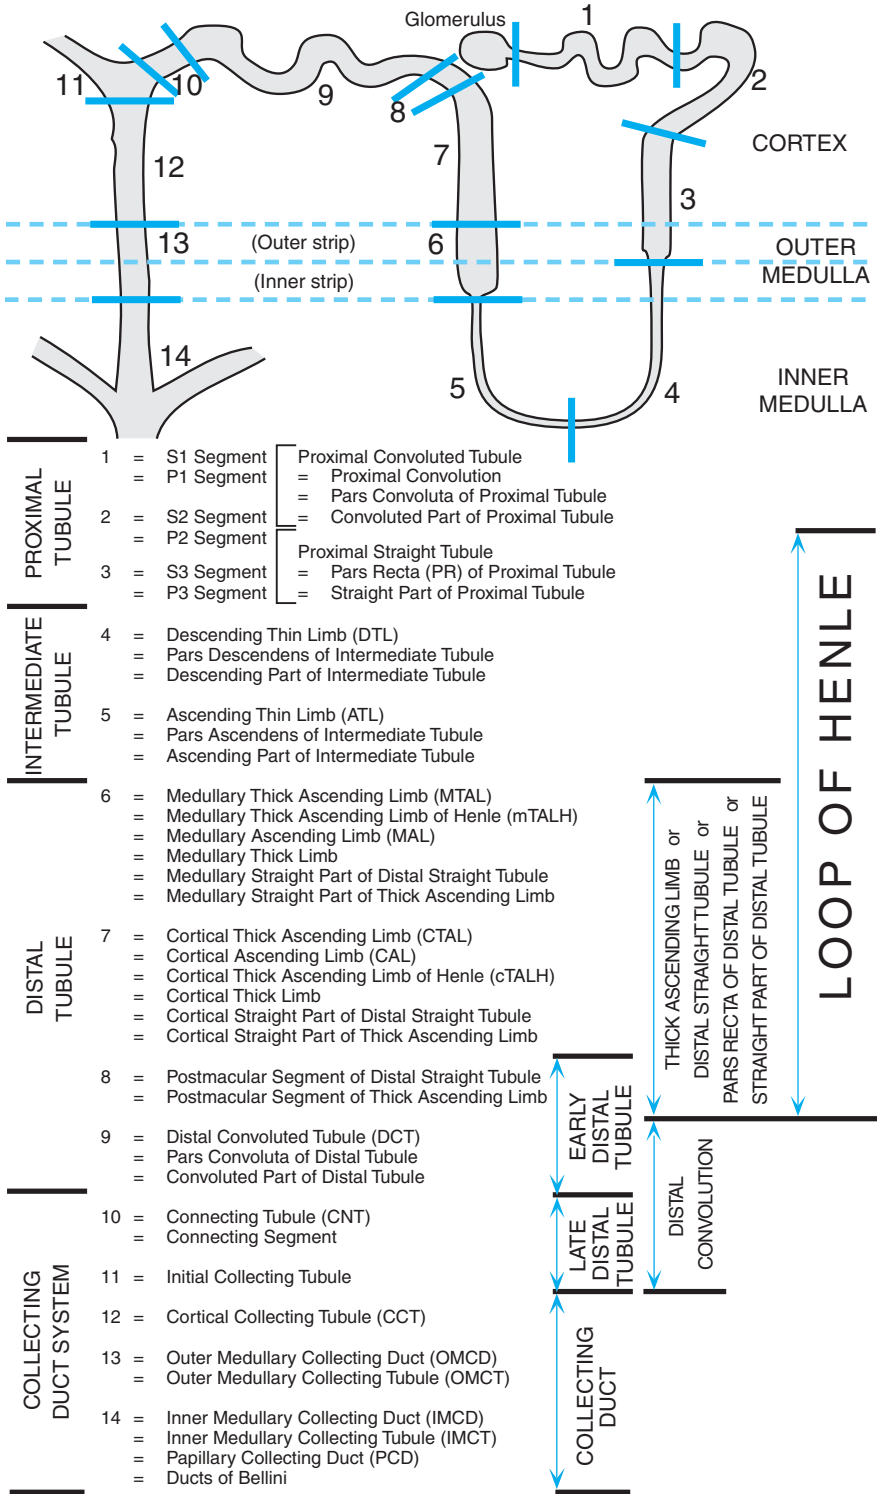

FIGURE 28-1 Anatomy and nomenclatures of the nephron.

multiplier hypothesis” proposes that active transport in the TAL concentrates NaCl in the interstitium of the outer medulla, thus generating its hypertonicity. Since this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting-duct system, water is extracted if, and only if, vasopressin is present. Since the cortical and outer medullary collecting ducts have a low permeability to urea, urea is concentrated in the tubular fluid. The inner medullary collecting duct, however, is permeable to urea, so urea diffuses into the inner medulla, where it is trapped by countercurrent exchange in the vasa recta. Since the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, contributing to the hypertonicity of the medullary interstitium.

In the glomerular capillaries, a portion of the plasma water is forced through a filter that has three basic components: fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by the epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into the urinary (Bowman’s) space, whereas formed elements and macromolecules are retained by the filtration barrier.

PRINCIPLES OF DIURETIC ACTION

Diuretics are drugs that increase the rate of urine flow; clinically useful diuretics also increase the rate of excretion of Na^+ (natriuresis) and an accompanying anion, usually Cl^- . Most clinical applications of diuretics aim to reduce extracellular fluid volume by decreasing total-body NaCl content. Although continued administration of a diuretic causes a sustained net deficit in total-body Na^+ , the time course of natriuresis is finite because renal compensatory mechanisms bring Na^+ excretion in line with Na^+ intake, a phenomenon known as *diuretic braking*. Compensatory mechanisms include activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), hypertrophy of renal epithelial cells, increased expression of renal epithelial transporters, and perhaps alterations in natriuretic hormones such as atrial natriuretic peptide.

Diuretics alter the excretion of Na^+ and also may modify renal handling of other cations (e.g., K^+ , H^+ , Ca^{2+} , and Mg^{2+}), anions (e.g., Cl^- , HCO_3^- , and H_2PO_4^-), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 28–1 compares the general effects of diuretics classified according to mechanism of action.

INHIBITORS OF CARBONIC ANHYDRASE

The three carbonic anhydrase inhibitors available in the U.S. are *acetazolamide* (DIAMOX), *dichlorophenamide* (DARANIDE), and *methazolamide* (GLAUC TABS). Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase), as well as in the cytoplasm (type II carbonic anhydrase). Carbonic anhydrase plays a key role in NaHCO_3 reabsorption and acid secretion. In the proximal tubule, the free energy in the Na^+ gradient established by the basolateral Na^+ pump is used by a Na^+/H^+ antiporter (also referred to as an Na^+/H^+ exchanger) in the luminal membrane to transport H^+ into the tubular lumen in exchange for Na^+ (Figure 28–1). In the lumen, H^+ reacts with filtered HCO_3^- to form H_2CO_3 . Normally, the breakdown of H_2CO_3 to form CO_2 and water occurs slowly, but carbonic anhydrase reversibly accelerates this reaction several thousand times. CO_2 rapidly diffuses across the luminal membrane into the epithelial cell, where it reacts with water to form H_2CO_3 , a reaction catalyzed by cytoplasmic carbonic anhydrase. Continued operation of the Na^+/H^+ antiporter maintains a low proton concentration in the cell, so H_2CO_3 ionizes spontaneously to form H^+ and HCO_3^- , creating an electrochemical gradient for HCO_3^- across the basolateral membrane. The electrochemical gradient for HCO_3^- is used by a $\text{Na}^+/\text{HCO}_3^-$ symporter (also referred to as the $\text{Na}^+/\text{HCO}_3^-$ cotransporter) in the basolateral membrane to transport NaHCO_3 into the interstitial space. The net effect is transport of NaHCO_3 from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl^- in the tubular lumen, and consequently Cl^- diffuses down its concentration gradient into the interstitium *via* the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit both the membrane-bound and cytoplasmic forms of carbonic anhydrase, resulting in nearly complete abolition of NaHCO_3 reabsorption in the proximal tubule (Figure 28–2). Because of the large excess of carbonic anhydrase in proximal tubules, a high percentage of enzyme activity must be inhibited before an effect on electrolyte

[‡]In general, these effects are restricted to those individual agents that inhibit carbonic anhydrase. However, there are notable exceptions in which symport inhibitors increase bicarbonate and phosphate (*e.g.*, metolazone, bumetanide).

excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system, which is a secondary site of action for these drugs.

EFFECTS ON URINARY EXCRETION Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO_3^- excretion to ~35% of filtered load. This, along with inhibition of titratable acid and NH_4^+ secretion in the collecting-duct system, results in an increase in urinary pH to ~8 and development of a metabolic acidosis. However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO_3^- is rescued from excretion by poorly understood mechanisms. Inhibition of the transport mechanism described above results in increased delivery of Na^+ and Cl^- to the loop of Henle, which has a large reabsorptive capacity and captures most of the Cl^- and a portion of the Na^+ . Thus, only a small increase in Cl^- excretion occurs, HCO_3^- being the major anion excreted along with the cations Na^+ and K^+ . The fractional excretion of Na^+ may be as much as 5%, and the fractional excretion of K^+ can be as much as 70%. The increased excretion of K^+ in part reflects increased delivery of Na^+ to the distal nephron, as described in the section on inhibitors of Na^+ channels. Other mechanisms contributing to enhanced K^+ secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin–angiotensin–aldosterone axis. Carbonic anhydrase inhibitors increase phosphate excretion but have little or no effect on the excretion of Ca^{2+} or Mg^{2+} . The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of HCO_3^- to the point that the uncatalyzed reaction between CO_2 and water is sufficient to achieve HCO_3^- reabsorption.

EFFECTS ON RENAL HEMODYNAMICS By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase solute delivery to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces renal blood flow (RBF) and GFR.

OTHER ACTIONS Carbonic anhydrase is present in a number of extrarenal tissues. Carbonic anhydrase in the ciliary processes of the eye mediates the formation of large amounts of HCO_3^- in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous

humor and consequently reduces intraocular pressure (IOP). Acetazolamide frequently causes paresthesias and somnolence, suggesting a central nervous system (CNS) action of carbonic anhydrase inhibitors. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO_2 levels in peripheral tissues and decrease CO_2 levels in expired gas. Large doses of carbonic anhydrase inhibitors reduce gastric acid secretion, but this has no therapeutic applications. Acetazolamide causes vasodilation by opening vascular Ca^{2+} -activated K^+ channels; however, the clinical significance of this effect is unclear.

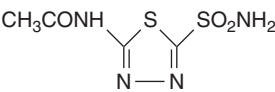

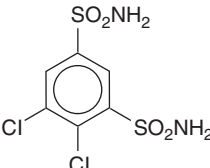

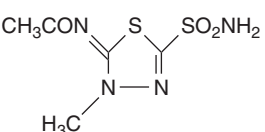

ABSORPTION AND ELIMINATION The oral bioavailability, plasma $t_{1/2}$, and route of elimination of the three available carbonic anhydrase inhibitors are listed in Table 28–2. Carbonic anhydrase inhibitors bind avidly to the enzyme; thus, tissues rich in this enzyme will have higher concentrations of drug following systemic administration.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions (*see* Chapter 43). With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalization or metabolic acidosis, including (1) diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis); (2) calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in an alkaline urine; (3) worsened metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease); and (4) reduced urinary excretion of weak organic bases.

THERAPEUTIC USES The efficacy of carbonic anhydrase inhibitors as single agents for the treatment of edema is low. However, the combination of acetazolamide with diuretics that block Na^+ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na^+ (<0.2%), who are resistant to diuretic monotherapy. Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis.

The major indication for carbonic anhydrase inhibitors is open-angle glaucoma. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute angle-closure glaucoma to lower IOP before surgery (*see* Chapter 63). Acetazolamide also is used for the treatment of epilepsy, but the rapid development of tolerance may limit its usefulness. Acetazolamide may provide symptomatic relief in patients with altitude sickness; however, it is more effective when given prophylactically. Acetazolamide also is useful in patients with familial periodic paralysis. The mechanism for the beneficial effects of acetazolamide in altitude sickness and familial periodic paralysis may be related to the induction of a metabolic acidosis. Finally, carbonic anhydrase inhibitors can be useful for correcting metabolic alkalosis, especially that caused by diuretic-induced increases in H^+ excretion.

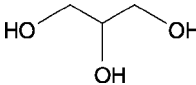

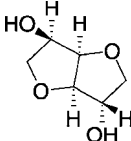

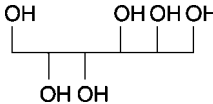

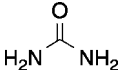

OSMOTIC DIURETICS

Osmotic diuretics are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in sufficient doses to increase significantly the osmolality of plasma and tubular fluid. Table 28–3 gives pharmacokinetic properties of four osmotic diuretics—*glycerin* (OSMOGLYN), *isosorbide* (ISMOTIC), *mannitol* (OSMITROL), and *urea* (UREAPHIL). The major site of action of osmotic diuretics is the loop of Henle.

By extracting water from intracellular compartments, osmotic diuretics expand the extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary tonicity. Under some circumstances, prostaglandins may contribute to the renal vasodilation and medullary washout induced by osmotic diuretics. A reduction in medullary tonicity causes a decrease in the extraction of water from the DTL, which limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition, osmotic diuretics may also interfere with transport processes in the TAL.

EFFECTS ON URINARY EXCRETION Osmotic diuretics increase the urinary excretion of nearly all electrolytes, including Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , and phosphate.

EFFECTS ON RENAL HEMODYNAMICS Osmotic diuretics increase RBF by a variety of mechanisms, but total GFR usually is little changed.

ABSORPTION AND ELIMINATION The oral bioavailability, plasma $t_{1/2}$, and route of elimination of the available osmotic diuretics are listed in Table 28–3. Glycerin and isosorbide can be given orally; mannitol and urea must be administered intravenously.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS Osmotic diuretics are distributed in the extracellular fluid and contribute to extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. On the other hand, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics generally are contraindicated in patients who are anuric owing to renal disease or who are unresponsive to test doses of the drugs. Urea may cause thrombosis or pain if extravasation occurs and should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active intracranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

THERAPEUTIC USES Acute renal failure (ARF) occurs in 5% of hospitalized patients and is associated with a significant mortality rate. Acute tubular necrosis (ATN), *i.e.*, damage to tubular epithelial cells, accounts for most cases of intrinsic ARF. The clinical efficacy of mannitol in attenuating the reduction in GFR due to ischemic or nephrotoxic insults is debated and controlled studies have not shown a benefit over hydration *per se*. In patients with mild-to-moderate renal insufficiency, hydration with 0.45% NaCl is as good as or better than either mannitol or furosemide in protection against decreases in GFR induced by radiocontrast agents. Prophylactic mannitol apparently is effective in jaundiced patients undergoing surgery. However, in vascular and open-heart surgery, prophylactic mannitol maintains urine flow but not GFR. In established ATN, mannitol will increase urine volume in some patients, and patients converted from oliguric to nonoliguric ATN appear to recover more rapidly and require less dialysis compared with patients who do not respond to mannitol. Whether these benefits are due to the diuretic or whether “responders” have lesser degrees of renal damage from the outset compared with “nonresponders” is not clear. Repeated administration of mannitol to nonresponders is not recommended, and loop diuretics are used more frequently to convert oliguric to nonoliguric ATN.

Another use for mannitol and urea is in the treatment of dialysis disequilibrium syndrome. Too rapid removal of solutes from the extracellular fluid by hemo- or peritoneal dialysis reduces the osmolality of the extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (*i.e.*, headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment.

By increasing plasma osmotic pressure, osmotic diuretics extract water from the eye and brain. All four osmotic diuretics are used to control IOP during acute attacks of glaucoma and for short-term reductions in IOP in patients who require ocular surgery. Mannitol and urea also are used to reduce cerebral edema before and after neurosurgery.

INHIBITORS OF $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

These diuretics inhibit the activity of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter in the TAL of the loop of Henle, hence, their designation as *loop diuretics*. Although the proximal tubule reabsorbs ~65% of the filtered Na^+ , diuretics acting only in the proximal tubule have limited efficacy because the TAL has the capacity to reabsorb most of the rejectate from the proximal tubule. In contrast, inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport in the TAL, sometimes called *high-ceiling diuretics*, are highly efficacious due to a combination of two factors: (1) Approximately 25% of the filtered Na^+ load normally is reabsorbed by the TAL, and (2) nephron segments past the TAL do not possess the reabsorptive capacity to rescue the flood of rejectate exiting the TAL.

Inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport are chemically diverse. Furosemide (LASIX), bumetanide (BUMEX), ethacrynic acid (EDECRIN), and torsemide (DEMADEX) are available in the U.S. Furosemide and bumetanide contain a sulfonamide moiety, ethacrynic acid is a phenoxyacetic acid derivative, and torsemide is a sulfonylurea.

The flux of Na^+ , K^+ , and Cl^- from the lumen into the epithelial cells in the TAL is mediated by the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter (Figure 28–1). This symporter captures the free energy in the Na^+ electrochemical gradient established by the basolateral Na^+ pump and provides for “uphill” transport of K^+ and Cl^- into the cell. Hyperpolarization of the luminal membrane due to K^+ conductance through apical K^+ channels (called *ROMK*) and depolarization of the basolateral membrane due to Cl^- conductance through basolateral Cl^- channels (called *CLC-Kb*) result in a transepithelial potential difference, with the lumen positive with respect to the interstitial space. This lumen-positive potential difference repels cations (Na^+ , Ca^{2+} , and Mg^{2+}) and thereby provides an important driving force for the paracellular flux of these cations into the interstitial space.

Inhibitors of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter block its function, virtually abolishing salt transport in this segment of the nephron (Figure 28–3). Evidence suggests that these drugs attach to the Cl^- -binding site located in the symporter’s transmembrane domain. Inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport also inhibit Ca^{2+} and Mg^{2+} reabsorption in the TAL by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

$\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporters are found in many secretory and absorbing epithelia and are of two varieties. The “absorptive” symporter (called ENCC2, NKCC2, or BSC1) is expressed only in the kidney, where it is localized to the apical membrane and subapical intracellular vesicles of the TAL and regulated by cyclic AMP-PKA. The “secretory” symporter (called ENCC3, NKCC1, or BSC2) is a widely expressed “housekeeping” protein. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., fourfold difference for bumetanide). Mutations in the genes coding for the absorptive $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter; the apical K^+ channel, or the basolateral Cl^- channel are causes of Bartter’s syndrome (inherited hypokalemic alkalosis with salt wasting and hypotension).

FIGURE 28–3 *NaCl reabsorption in thick ascending limb and mechanism of diuretic action of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport inhibitors. S, symporter; CH, ion channel. Numbers in parentheses indicate stoichiometry. Designated voltages are the potential differences across the indicated membrane or cell. The mechanisms illustrated here apply to the medullary, cortical, and postmacular segments of the thick ascending limb. BL and LM indicate basolateral and luminal membranes, respectively.*

EFFECTS ON URINARY EXCRETION Loop diuretics profoundly increase the urinary excretion of Na^+ and Cl^- (*i.e.*, up to 25% of the filtered load of Na^+) and markedly increase the excretion of Ca^{2+} and Mg^{2+} . Furosemide but not bumetanide also has weak carbonic anhydrase-inhibiting activity that increases the urinary excretion of HCO_3^- and phosphate. All inhibitors of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter increase the urinary excretion of K^+ and titratable acid, due in part to increased delivery of Na^+ to the distal tubule. The mechanism by which increased distal delivery of Na^+ enhances excretion of K^+ and H^+ is discussed in the section on inhibitors of Na^+ channels. Other mechanisms contributing to enhanced K^+ and H^+ excretion include flow-dependent enhancement of ion secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin-angiotensin-aldosterone axis. Loop diuretics acutely increase the excretion of uric acid, whereas their chronic administration reduces uric acid excretion, possibly due to enhanced transport in the proximal tubule secondary to volume depletion or to competition between the diuretic and uric acid for the organic acid secretory mechanism in the proximal tubule.

By blocking active NaCl reabsorption in the TAL, inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney's ability to concentrate urine. Also, since the TAL is part of the diluting segment, inhibitors of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter markedly impair the kidney's ability to excrete a dilute urine during water diuresis.

EFFECTS ON RENAL HEMODYNAMICS If volume depletion is prevented by replacing fluid losses, inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport generally increase total RBF and redistribute it to the midcortex. However, these effects are variable. The mechanism of the increase in RBF is not known, but nonsteroidal anti-inflammatory drugs (NSAIDs) attenuate the diuretic response to loop diuretics in part by preventing prostaglandin-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer can detect NaCl concentrations in the tubular fluid. Unlike carbonic anhydrase inhibitors, loop diuretics do not decrease GFR by activating TGF. Loop diuretics stimulate renin release by interfering with NaCl transport by the macula densa and, if volume depletion occurs, by reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism. Prostaglandins (*e.g.*, PGI_2) may play a key role in mediating the renin-release response to loop diuretics.

OTHER ACTIONS Loop diuretics may cause direct vascular effects. Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by prostaglandins and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. High doses of inhibitors of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter can inhibit electrolyte transport in many tissues, but this effect is clinically important only in the inner ear.

ABSORPTION AND ELIMINATION The oral bioavailabilities, plasma $t_{1/2}$, and routes of elimination of inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport are listed in Table 28-4. Because these drugs are bound extensively to plasma proteins, their delivery to the tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to their binding sites on the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter in the luminal membrane of the TAL.

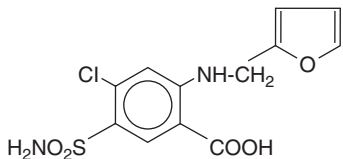

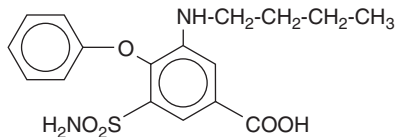

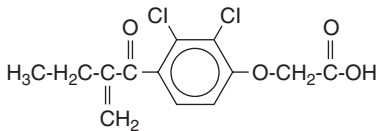

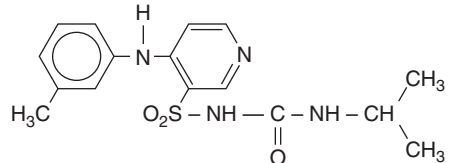

Approximately 65% of furosemide is excreted unchanged in the urine, and the rest is conjugated to glucuronic acid in the kidney; thus, the elimination $t_{1/2}$ of furosemide is prolonged in patients with renal disease. Bumetanide and torsemide have significant hepatic metabolism, and their elimination half-lives are prolonged by liver disease.

Although the average oral availability of furosemide is ~60%, this varies from 10–100%; oral availabilities of bumetanide and torsemide are reliably high. Heart failure patients treated with torsemide have fewer hospitalizations and better quality of life than those treated with furosemide, perhaps because of its reliable absorption.

As a class, loop diuretics have short elimination half-lives, and prolonged-release preparations are not available. Consequently, the dosing interval often is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer $t_{1/2}$ than other agents available in the U.S. (Table 28-4). As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na^+ , which often nullifies the overall effect of the loop diuretic on total-body Na^+ . This phenomenon of “postdiuretic Na^+ retention” can be overcome by restricting dietary Na^+ intake or by more frequent administration of the loop diuretic.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS

Adverse effects unrelated to diuretic efficacy are rare, and most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can seriously deplete total-body Na^+ , which may be manifest as hyponatremia and/or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic events, and in patients with liver disease, hepatic encephalopathy. Increased delivery of Na^+ to the distal tubule, particularly when combined with activation of the renin-angiotensin system, leads to increased urinary excretion of K^+ and H^+ , causing a hypochloremic alkalosis. If dietary K^+ intake is not sufficient, hypokalemia may develop, and this may induce cardiac arrhythmias, particularly in patients taking cardiac glycosides or antiarrhythmic drugs that prolong repolarization (*see* Chapter 34). Increased Mg^{2+} and Ca^{2+} excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Recent evidence suggests that loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca^{2+} excretion may have deleterious effects on bone metabolism.

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be used only in patients who cannot tolerate the other drugs. Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia (infrequently precipitating diabetes mellitus) and can increase plasma levels of low-density lipoprotein (LDL) cholesterol and triglycerides while decreasing plasma levels of high-density lipoprotein (HDL) cholesterol. Other adverse effects include rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances.

Contraindications to the use of loop diuretics include severe Na^+ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are coadministered with (1) aminoglycosides (synergism of ototoxicity caused by both drugs), (2) anticoagulants (increased anticoagulant activity), (3) cardiac glycosides and antiarrhythmic drugs that prolong repolarization (increased arrhythmias), (4) lithium (increased plasma levels of Li^+), (5) propranolol (increased plasma levels of propranolol), (6) sulfonylureas (hyperglycemia), (7) cisplatin (increased risk of diuretic-induced ototoxicity), (8) NSAIDs (blunted diuretic response and salicylate toxicity when given with high doses of salicylates), (9) probenecid (blunted diuretic response), (10) thiazide diuretics (synergism of diuretic activity of both drugs leading to profound diuresis), and (11) amphotericin B (increased potential for nephrotoxicity and toxicity and intensification of electrolyte imbalance).

THERAPEUTIC USES A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with a brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for the treatment of chronic congestive heart failure when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (*see* Chapter 33). In this regard, a meta-analysis of randomized clinical trials demonstrates that diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity.

Diuretics are used widely for the treatment of hypertension (*see* Chapter 32), and loop diuretics appear to lower blood pressure as effectively as $\text{Na}^+\text{-Cl}^-$ symporter inhibitors (*e.g.*, thiazides and thiazide-like diuretics) while causing smaller perturbations in the lipid profile. However, the short elimination half-lives of loop diuretics render them less useful for hypertension than thiazide-type diuretics. The edema of nephrotic syndrome often is refractory to other classes of diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this disease. Loop diuretics also are employed in the treatment of edema and ascites of hepatic cirrhosis; however, care must be taken not to induce encephalopathy or hepatorenal syndrome. In patients with a drug overdose, loop diuretics can be used to induce a forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney's capacity to produce a concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hyponatremia. Loop diuretics also are used to treat edema associated with chronic renal insufficiency. Most patients with ARF receive

a trial dose of a loop diuretic in an attempt to convert oliguric ARF to nonoliguric ARF. However, there is no evidence that loop diuretics prevent ATN or improve outcome in patients with ARF.

INHIBITORS OF $\text{Na}^+\text{-Cl}^-$ SYMPORT (THIAZIDE AND THIAZIDE-LIKE DIURETICS)

The original inhibitors of $\text{Na}^+\text{-Cl}^-$ symport were benzothiadiazine derivatives, hence this class of diuretics became known as thiazide diuretics. Subsequently, drugs that are pharmacologically similar to thiazide diuretics but are not thiazides were developed and are called thiazide-like diuretics. The term thiazide diuretics is used here to refer to all members of the class of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport.

Thiazide diuretics inhibit NaCl transport in the DCT; the proximal tubule may be a secondary site of action. Figure 28-4 illustrates the current model of electrolyte transport in the DCT. Transport is powered by a Na^+ pump in the basolateral membrane. The free energy in the electrochemical gradient for Na^+ is harnessed by a $\text{Na}^+\text{-Cl}^-$ symporter in the luminal membrane that moves Cl^- into the epithelial cell against its electrochemical gradient. Cl^- then exits the basolateral membrane passively via a Cl^- channel. Thiazide diuretics inhibit the $\text{Na}^+\text{-Cl}^-$ symporter (Figure 28-4). Na^+ or Cl^- binding to the $\text{Na}^+\text{-Cl}^-$ symporter modifies thiazide-induced inhibition of the symporter, suggesting that the thiazide-binding site is shared or altered by both Na^+ and Cl^- . The $\text{Na}^+\text{-Cl}^-$ symporter (called ENCC1) is expressed predominantly in the kidney and is localized to the apical membrane of DCT epithelial cells; its expression is regulated by aldosterone. Mutations in the $\text{Na}^+\text{-Cl}^-$ symporter cause a familial hypokalemic alkalosis called Gitelman's syndrome.

EFFECTS ON URINARY EXCRETION Inhibitors of the $\text{Na}^+\text{-Cl}^-$ symporter increase Na^+ and Cl^- excretion, but are only moderately efficacious (*i.e.*, maximum excretion of filtered load of Na^+ is only 5%) because ~90% of the filtered Na^+ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO_3^- and phosphate excretion and probably accounts for their weak proximal tubular effects. Inhibitors of the $\text{Na}^+\text{-Cl}^-$ symporter increase the excretion of K^+ and titratable acid by the same mechanisms discussed for loop diuretics. Acute administration of thiazides increases the excretion of uric acid, but uric acid excretion is reduced following chronic administration by the same mechanisms as for loop diuretics. Acute effects of inhibitors of the $\text{Na}^+\text{-Cl}^-$ symporter on Ca^{2+} excretion are variable; when administered chronically, thiazide diuretics decrease Ca^{2+} excretion. The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca^{2+} reabsorption in the DCT. Thiazide diuretics may cause a mild magnesuria by a poorly understood mechanism. Since inhibitors of $\text{Na}^+\text{-Cl}^-$ symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the ability of the kidney to excrete a

FIGURE 28-4 NaCl reabsorption in distal convoluted tubule and mechanism of diuretic action of $\text{Na}^+\text{-Cl}^-$ symport inhibitors. S, symporter; CH, ion channel. Numbers in parentheses indicate stoichiometry. BL and LM indicate basolateral and luminal membranes, respectively.

diluted urine during water diuresis. However, since the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney's ability to concentrate urine during hydropenia.

In general, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport do not affect RBF and only variably reduce GFR owing to increases in intratubular pressure. Since thiazides act at a point past the macula densa, they have little or no influence on TGF.

ABSORPTION AND ELIMINATION The relative potency, oral bioavailability, plasma $t_{1/2}$, and route of elimination of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport are listed in Table 28–5. Of special note is the wide range of half-lives for this class of drugs. Sulfonamides are organic acids and therefore are secreted into the proximal tubule by the organic acid secretory pathway. Since thiazides must gain access to the tubular lumen to inhibit the $\text{Na}^+\text{-Cl}^-$ symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into the proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS

Thiazide diuretics rarely cause CNS (*e.g.*, vertigo, headache, paresthesias, and weakness), GI (*e.g.*, anorexia, nausea, vomiting, cramping, diarrhea, constipation, cholecystitis, and pancreatitis), hematological (*e.g.*, blood dyscrasias), and dermatological (*e.g.*, photosensitivity and rashes) disorders. The incidence of erectile dysfunction is greater with the $\text{Na}^+\text{-Cl}^-$ symporter inhibitors than with several other antihypertensive agents (*e.g.*, β receptor antagonists, Ca^{2+} channel blockers, angiotensin-converting enzyme inhibitors, and α_1 antagonists) but usually is tolerable. Serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance, including extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia. Thiazide diuretics have caused fatal or near-fatal hyponatremia, and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance, sometimes unmasking latent diabetes mellitus. The mechanism of the impaired glucose tolerance appears to involve reduced insulin secretion and alterations in glucose metabolism; hyperglycemia is reduced when K^+ is given along with the diuretic. In addition to contributing to hyperglycemia, thiazide-induced hypokalemia compromises the antihypertensive effect and cardiovascular protection afforded by thiazides in patients with hypertension. Thiazide diuretics may increase plasma levels of LDL cholesterol and triglycerides. The drugs are contraindicated in individuals who are hypersensitive to sulfonamides.

Thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonyleureas, and insulin and increase the effects of anesthetics, diazoxide, cardiac glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

A potentially lethal drug interaction is that with antiarrhythmic drugs that prolong QT interval (ventricular repolarization) such as quinidine. Prolongation of the QT interval can lead to the development of polymorphic ventricular tachycardia (*torsades de pointes*) owing to triggered activity originating from early after-depolarizations (*see* Chapter 34). Although usually self-limiting, *torsades de pointes* may deteriorate into fatal ventricular fibrillation. Hypokalemia increases the risk of quinidine-induced *torsades de pointes*, and thiazide-induced K^+ depletion may contribute to many cases of quinidine-induced *torsades de pointes*.

THERAPEUTIC USES Thiazide diuretics are used to treat edema associated with heart (congestive heart failure), liver (cirrhosis), and renal (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis) disease. With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is $<30\text{--}40$ mL/min.

Thiazide diuretics decrease blood pressure in hypertensive patients and are used widely for the treatment of hypertension, either alone or in combination with other antihypertensive drugs (*see* Chapter 32). In this regard, thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications; moreover, they have additive or synergistic effects when combined with antihypertensive agents. Although thiazides may marginally increase the risk of sudden death and renal cell carcinoma, they generally are safe and reduce cardiovascular morbidity and mortality in hypertensive patients. Because adverse effects of thiazides

increase progressively in severity at doses higher than maximally effective antihypertensive doses, only low doses should be prescribed for hypertension. A common dose for hypertension is 25 mg/day of hydrochlorothiazide or the equivalent of another thiazide. Many experts view thiazide diuretics as the best initial therapy for uncomplicated hypertension. Concern regarding the risk of diabetes should not cause clinicians to avoid thiazides in nondiabetic hypertensives.

Thiazide diuretics, which reduce urinary excretion of Ca^{2+} , sometimes are employed to treat calcium nephrolithiasis and may be useful for the treatment of osteoporosis (see Chapter 61). Thiazide diuretics also are a mainstay for treatment of nephrogenic diabetes insipidus, reducing urine volume by up to 50%. The mechanism of this paradoxical effect remains unknown. Since other halides are excreted by renal processes similar to those for Cl^- , thiazide diuretics may be useful for the management of Br^- intoxication.

INHIBITORS OF RENAL EPITHELIAL Na^+ CHANNELS (K^+ -SPARING DIURETICS)

Triamterene (DYRENIUM) and *amiloride* (MID-AMOR) are the two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antidiuretic actions to offset the effects of other diuretics that increase K^+ excretion. Consequently, triamterene and amiloride, along with spironolactone (see next section), often are classified as *potassium (K^+)-sparing diuretics*. Both drugs are organic bases, are transported by the organic base secretory mechanism in the proximal tubule, and act by similar mechanisms. As illustrated in Figure 28–5, principal cells in the late distal tubule and collecting duct have epithelial Na^+ channels in their luminal membranes that provide a conductive pathway for the entry of Na^+ into the cell down the electrochemical gradient created by the basolateral Na^+ pump. The higher permeability of the luminal membrane for Na^+ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K^+ into the lumen *via* K^+ channels (ROMK) in the luminal membrane.

FIGURE 28–5 *NaCl* reabsorption in distal convoluted tubule and mechanism of diuretic action of Na^+ - Cl^- symport inhibitors. CA, carbonic anhydrase; S, symporter; CH, ion channel. Numbers in parentheses indicate stoichiometry. BL and LM indicate basolateral and luminal membranes, respectively.

Amiloride and triamterene block epithelial Na^+ channels in the luminal membrane of principal cells in the late distal tubule and collecting duct, perhaps by competing with Na^+ for negatively charged areas within the pore of the Na^+ channel. The amiloride-sensitive Na^+ channel (called *ENaC*) consists of three subunits (α , β , and γ). Although the α subunit is sufficient for channel activity, maximal Na^+ permeability is induced when all three subunits are coexpressed in the same cell. Liddle's syndrome (pseudohyperaldosteronism) is an autosomal dominant form of low-renin, volume-expanded hypertension that is due to mutations in the β or γ subunits, leading to increased basal activity of ENaC. Amiloride is very effective in treating hypertension in patients carrying these mutations.

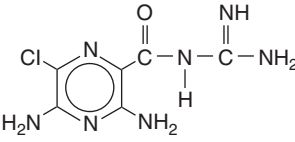

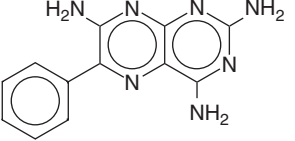

EFFECTS ON URINARY EXCRETION Since the late distal tubule and collecting duct have limited capacity to reabsorb solutes, blockade of Na^+ channels in this part of the nephron only mildly increases the excretion rates of Na^+ and Cl^- (~2% of filtered load). Blockade of Na^+ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Since the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases the excretion rates of K^+ , H^+ , Ca^{2+} , and Mg^{2+} . Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence chronic administration of amiloride and triamterene may decrease uric acid excretion. Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

ABSORPTION AND ELIMINATION The relative potency, oral bioavailability, plasma $t_{1/2}$, and route of elimination for amiloride and triamterene are listed in Table 28–6. Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized extensively to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in the urine. Therefore, the toxicity of triamterene may be enhanced in both hepatic disease (decreased metabolism of triamterene) and renal failure (decreased urinary excretion of active metabolite).

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS The most dangerous adverse effect of Na^+ -channel inhibitors is hyperkalemia, which can be life-threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (*e.g.*, patients with renal failure, patients receiving other K^+ -sparing diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K^+ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na^+ -channel inhibitors. Pentamidine and high-dose trimethoprim are used often to treat *Pneumocystis carinii* pneumonia in patients with acquired immune deficiency syndrome (AIDS). Because these compounds weakly inhibit ENaC, they too may cause

hyperkalemia, which may explain the frequent occurrence of hyperkalemia in AIDS patients. Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

THERAPEUTIC USES Because of the mild natriuresis induced by Na⁺-channel inhibitors, these drugs seldom are used as sole agents in the treatment of edema or hypertension. Rather, their major utility is in *combination* with other diuretics. Coadministration of a Na⁺-channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na⁺-channel inhibitors to reduce K⁺ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics; consequently, the combination of a Na⁺-channel inhibitor with a thiazide or loop diuretic tends to result in normal values of plasma K⁺. Liddle's syndrome can be treated effectively with Na⁺-channel inhibitors. Approximately 5% of people of African origin carry a *T594M* polymorphism in the β subunit of ENaC, and amiloride is particularly effective in lowering blood pressure in hypertensive patients who carry this polymorphism. Aerosolized amiloride improves mucociliary clearance in patients with cystic fibrosis. By inhibiting Na⁺ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic diabetes insipidus because it blocks Li⁺ transport into the cells of the collecting tubules.

ANTAGONISTS OF MINERALOCORTICOID RECEPTORS (ALDOSTERONE ANTAGONISTS, K⁺-SPARING DIURETICS)

Mineralocorticoids cause salt and water retention and increase the excretion of K⁺ and H⁺ by binding to specific mineralocorticoid receptors (MRs). Currently, two MR antagonists are available in the U.S., *spironolactone* and *eplerenone*; two others are available elsewhere (Table 28–7). Epithelial cells in the late distal tubule and collecting duct contain cytosolic MRs that have a high affinity for aldosterone. Aldosterone enters the epithelial cell from the basolateral membrane and binds to MRs; the MR–aldosterone complex translocates to the nucleus, where it regulates the expression of multiple gene products called *aldosterone-induced proteins* (AIPs). Figure 28–6 illustrates some of the proposed effects of AIPs. The net effect of AIPs is to increase Na⁺ conductance of the luminal membrane and sodium pump activity of the basolateral membrane. Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for secretion of K⁺ and H⁺ into the tubular lumen.

Spironolactone and eplerenone competitively inhibit the binding of aldosterone to the MR. Unlike the MR–aldosterone complex, the MR–spironolactone complex is unable to induce the synthesis of AIPs. Since spironolactone and eplerenone block the biological effects of aldosterone, these agents also are referred to as *aldosterone antagonists*. MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

EFFECTS ON URINARY EXCRETION The effects of MR antagonists on urinary excretion are very similar to those induced by renal epithelial Na⁺-channel inhibitors. However, unlike that of the Na⁺-channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous levels of aldosterone. The higher the levels of endogenous aldosterone, the greater are the effects of MR antagonists on urinary excretion. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

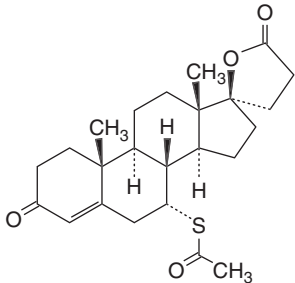

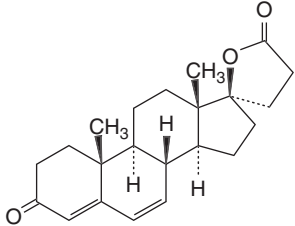

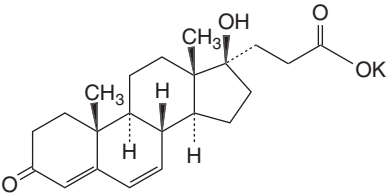

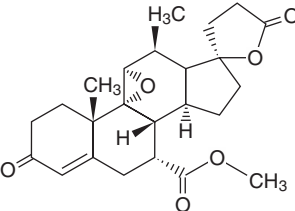

OTHER ACTIONS Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to the 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. Therapeutic concentrations of spironolactone block human *ether-a-go-go*-related gene (HERG) K⁺ channels, and this may account for the antiarrhythmic effects of spironolactone in heart failure. High concentrations of spironolactone can interfere with steroid biosynthesis by inhibiting CYPs (*see* Chapter 59).

ABSORPTION AND ELIMINATION Spironolactone is absorbed partially (~65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic

recirculation, is highly protein-bound, and has a short $t_{1/2}$ (~1.6 hours). However, an active metabolite of spironolactone, canrenone, has a $t_{1/2}$ of ~16.5 hours, which prolongs the biological effects of spironolactone. Although not available in the U.S., canrenone and canrenoate also are in clinical use. Canrenoate is not active *per se* but is converted to canrenone in the body. Eplerenone has good oral availability and is eliminated with a $t_{1/2}$ of ~5 hours, primarily by conversion to inactive metabolites by hepatic CYP3A4.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS

As with other K^+ -sparing diuretics, MR antagonists may cause life-threatening hyperkalemia. Indeed, hyperkalemia is the principal risk of MR antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia either because of disease or because of administration of other medications. MR antagonists also can induce metabolic acidosis in cirrhotic patients.

Salicylates may reduce the tubular secretion and decrease the diuretic efficacy of spironolactone, and spironolactone may alter the clearance of cardiac glycosides. Owing to its effects on other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause rashes and, rarely, blood dyscrasias. Whether therapeutic doses of spironolactone can induce malignancies remains an open question. Strong inhibitors of CYP3A4 (*see* Chapter 3) may increase plasma levels of eplerenone; such drugs should not be administered to patients taking eplerenone, and *vice versa*. Other than hyperkalemia and GI disorders, the rate of adverse events for eplerenone is similar to that of placebo.

THERAPEUTIC USES Spironolactone often is coadministered with thiazide or loop diuretics in the treatment of edema and hypertension. Such combinations result in increased mobilization of edema fluid with lesser perturbations of K^+ homeostasis. Spironolactone is particularly useful in the treatment of primary hyperaldosteronism (due either to adrenal adenomas or bilateral adrenal

hyperplasia) and refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). Spironolactone is considered the diuretic of choice in patients with hepatic cirrhosis. Spironolactone, added to standard therapy, substantially reduces morbidity and mortality and ventricular arrhythmias in patients with heart failure (see Chapter 34).

Clinical experience with eplerenone is limited; it appears to be a safe and effective antihypertensive drug. In patients with acute myocardial infarction complicated by left ventricular systolic dysfunction, addition of eplerenone to optimal medical therapy significantly reduces morbidity and mortality.

OVERVIEW OF DIURETIC USE

Diuretics are used clinically to treat hypertension (see Chapter 32) and to reduce edema associated with cardiac, renal, and hepatic disorders. Three fundamental strategies exist for mobilizing edema fluid: correct the underlying disease, restrict Na^+ intake, or administer diuretics. The most desirable course of action would be to correct the primary disease; however, this often is impossible. Restriction of Na^+ intake is the favored nonpharmacologic approach to the treatment of edema and hypertension and should be attempted; however, compliance is a major obstacle. Diuretics therefore remain the cornerstone for the treatment of edema or volume overload, particularly that owing to congestive heart failure, ascites, chronic renal failure, or nephrotic syndrome.

The clinical situation dictates whether a patient should receive diuretics and what therapeutic regimen should be used (*i.e.*, type of diuretic, dose, route of administration, and speed of fluid mobilization). Acute pulmonary edema in patients with left-sided heart failure is a medical emergency requiring rapid, aggressive therapy including intravenous administration of a loop diuretic. In this setting, use of oral or less potent diuretics is inappropriate. On the other hand, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. Loop and thiazide diuretics decrease morbidity and mortality in heart failure; MR antagonists also reduce morbidity and mortality in heart failure patients receiving optimal therapy with other drugs. Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during the paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of the more powerful loop diuretics usually are required. In the nephrotic syndrome, the response to diuretics often is disappointing. In chronic renal failure and cirrhosis, edema does not pose an immediate health risk. Even so, uncomfortable, oppressive, and/or disfiguring edema can greatly reduce quality of life, and the decision to treat will be based in part on quality-of-life issues. In such cases, only partial removal of edema fluid should be attempted, and the fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology. Figure 28–7 provides an algorithm for diuretic therapy in patients with edema caused by renal, hepatic, or cardiac disorders.

Diuretic resistance refers to edema that is refractory to a given diuretic. If diuretic resistance develops against a less efficacious diuretic, a more potent diuretic can be substituted (*e.g.*, a loop diuretic for a thiazide). However, resistance to loop diuretics can result from several causes. NSAIDs block prostaglandin-mediated increases in RBF and increase expression of the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter in the TAL, resulting in resistance to loop diuretics. In chronic renal failure, reduced RBF decreases diuretic delivery to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, the concentration of diuretic at the active site in the tubular lumen is diminished. In nephrotic syndrome, protein binding of diuretics may limit drug response. In hepatic cirrhosis, nephrotic syndrome, or heart failure, nephrons may have diminished responsiveness to diuretics because of increased proximal tubular Na^+ reabsorption, leading to diminished delivery of Na^+ to the distal nephron.

Faced with resistance to loop diuretics, the clinician has several options. Bed rest may restore drug responsiveness by improving renal circulation. An increase in the dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (*i.e.*, the ceiling dose) of the diuretic. Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic will increase the length of time that an effective concentration of the diuretic is present at the site of action. Combination therapy to sequentially block more than one site in the nephron may result in a synergistic interaction between two diuretics. For instance, combining a loop diuretic with a K^+ -sparing or a thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of two

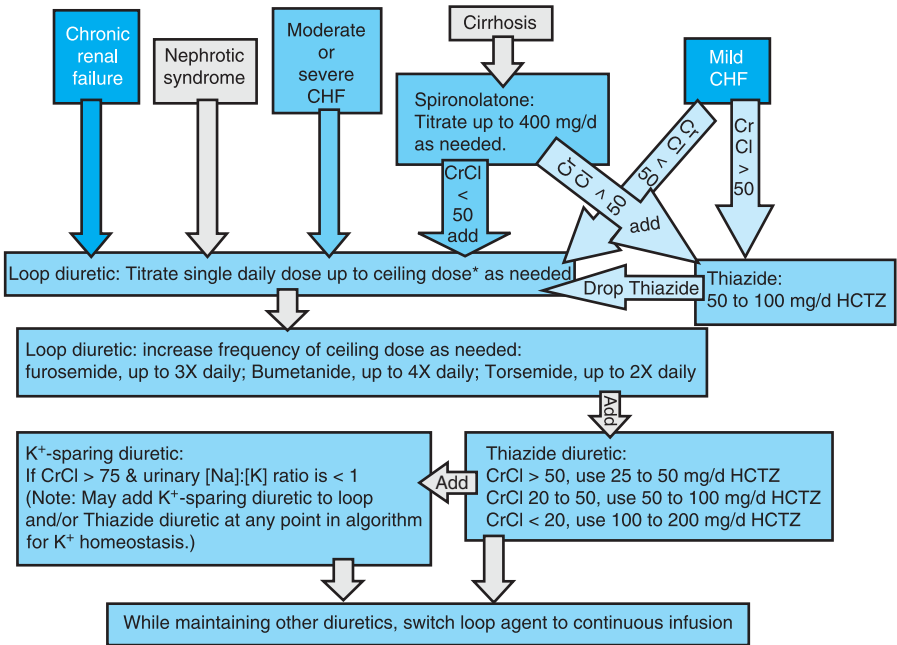

FIGURE 28-7 “Brater’s algorithm” for diuretic therapy of chronic renal failure, nephrotic syndrome, congestive heart failure, and cirrhosis. Follow algorithm until adequate response is achieved. If adequate response is not obtained, advance to the next step. For illustrative purposes, the thiazide diuretic used in Brater’s algorithm is hydrochlorothiazide (HCTZ). An alternative thiazide-type diuretic may be substituted with appropriate dosage adjustment so as to be pharmacologically equivalent to the recommended dose of HCTZ. Do not combine two K⁺-sparing diuretics because of the risk of hyperkalemia. CrCl indicates creatinine clearance in mL/min, and ceiling dose refers to the smallest dose of diuretic that produces a near-maximal effect. Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state-specific; see Brater (1998) for recommended dosages. Doses are for adults only.

drugs of the same type. Thiazide diuretics with significant proximal tubular effects (*e.g.*, metolazone) are particularly well suited for sequential blockade when coadministered with a loop diuretic. Reducing salt intake will diminish postdiuretic Na⁺ retention that can nullify previous increases in Na⁺ excretion. Diuretic dosing shortly before eating will provide effective drug concentrations in the tubular lumen when the salt load is highest.

VASOPRESSIN AND OTHER AGENTS AFFECTING THE RENAL CONSERVATION OF WATER

Body fluid osmolality is controlled by a homeostatic mechanism that adjusts both the rate of water intake and the rate of solute-free water excretion by the kidneys—*i.e.*, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs, and may cause serious and potentially life-threatening deviations in plasma osmolality. Arginine vasopressin is the main hormone that regulates body fluid osmolality.

INTRODUCTION TO VASOPRESSIN

Vasopressin is the mediator of a remarkable regulatory system for the conservation of water. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia and/or hypotension. In humans, vasopressin acts primarily in the renal collecting duct, increasing the permeability of the cell membrane to water and permitting water to move passively down an osmotic gradient across the collecting duct into the extracellular compartment.

Vasopressin also is a potent vasopressor whose name was chosen in recognition of its vasoconstrictor action. Vasopressin is a neurotransmitter; among its actions in the CNS are apparent roles in the secretion of ACTH and in the regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also may play a role in hemostasis by promoting the release of coagulation factors by the vascular endothelium and increasing platelet aggregation.

PHYSIOLOGY OF VASOPRESSIN

The antidiuretic mechanism in mammals involves two anatomical components: a CNS component for the synthesis, transport, storage, and release of vasopressin, and a renal collecting-duct system composed of epithelial cells that respond to vasopressin by increasing their permeability to water. The CNS component of this mechanism, called the hypothalamic-neurohypophysial system, consists of neurosecretory neurons with perikarya located predominantly in two specific hypothalamic nuclei, the supraoptic nucleus (SON) and the paraventricular nucleus (PVN). The long axons of magnocellular neurons in the SON and PVN terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin. The relevant anatomy of the renal collecting-duct system is described in Chapter 28.

Vasopressin is synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN; parvocellular neurons in the PVN also synthesize vasopressin. Vasopressin synthesis is regulated solely at the transcriptional level. In humans, a 168–amino acid preprohormone (Figure 29–1) is synthesized and packaged into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1–9), vasopressin (VP)–neurophysin (residues 13–105), and VP–glycopeptide (residues 107–145). The vasopressin domain is linked to the VP–neurophysin domain through a Gly–Lys–Arg-processing signal, and the VP–neurophysin is linked to the VP–glycopeptide domain by an Arg-processing signal. In the secretory granules, an endopeptidase, exopeptidase, monooxygenase, and lyase act sequentially on the prohormone to produce vasopressin, VP–neurophysin (sometimes referred to as neurophysin II), and VP–glycopeptide. The synthesis and transport of vasopressin depend on the conformation of the preprohormone. In particular, VP–neurophysin binds vasopressin and is critical to the correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or VP–neurophysin give rise to central diabetes insipidus.

REGULATION OF VASOPRESSIN SECRETION An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary. Severe hypovolemia/hypotension also is a powerful stimulus for vasopressin release. In addition, pain, nausea, and hypoxia can stimulate vasopressin secretion, and several endogenous hormones and pharmacological agents can modify vasopressin release.

Hyperosmolality The osmolality threshold for secretion of vasopressin is ~280 mOsm/kg. Below this threshold, vasopressin is barely detectable in plasma; above this osmolality, vasopressin levels are a steep and relatively linear function of plasma osmolality. Indeed, a 2% elevation in plasma osmolality causes a 2–3 fold increase in plasma vasopressin levels, which, in turn, causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality >290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system

AVP PREPROHORMONE (HUMAN)

affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. Above a plasma osmolality of ~290 mOsm/kg, plasma levels of vasopressin exceed 5 pM. Since urinary concentration is maximal (~1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss.

Hepatic Portal Osmoreceptors An oral salt load activates hepatic portal osmoreceptors, leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

Hypovolemia and Hypotension

Vasopressin secretion also is regulated hemodynamically by changes in effective blood volume and/or arterial blood pressure. Regardless of the cause (e.g., hemorrhage, salt depletion, diuretics, heart failure, cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume and/or arterial blood pressure are associated with high circulating concentrations of vasopressin. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; i.e., small decreases (5–10%) in blood volume and/or pressure have little effect on vasopressin secretion, whereas larger decreases (20–30%) can increase vasopressin levels to 20–30 times normal (exceeding the concentration of vasopressin required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss and/or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality–plasma vasopressin relationship.

The neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in the left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in the carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals ultimately are relayed to the SON and PVN.

Hormones and Neurotransmitters

Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron. Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei that project, either directly or indirectly, to the SON and PVN. Because of these complexities, the physiological relevance of modulation of vasopressin secretion by most hormones and neurotransmitters is unclear.

Several agents are known to stimulate vasopressin secretion, including acetylcholine (via nicotinic receptors), histamine (via H_1 receptors), dopamine (via both D_1 and D_2 receptors), glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, prostaglandins, and angiotensin II (AngII). Inhibitors of vasopressin secretion include atrial natriuretic peptide, GABA, and opioids (particularly dynorphin via κ receptors). The effects of AngII have received the most attention because AngII synthesized in the brain and circulating angiotensin may stimulate vasopressin release. Inhibition of the conversion of AngII to AngIII blocks AngII-induced vasopressin release, suggesting that AngIII is the main effector peptide of the brain renin-angiotensin system controlling vasopressin release.

Pharmacological Agents

A number of drugs alter urine osmolality by stimulating or inhibiting the secretion of vasopressin. In most cases the mechanism is not known. Stimulators of vasopressin secretion include vincristine, cyclophosphamide, tricyclic antidepressants, nicotine, epinephrine, and high doses of morphine. Lithium, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin secretion include ethanol, phenytoin, low doses of morphine, glucocorticoids, fluphenazine, haloperidol, promethazine, oxilorphan, and butorphanol. Carbamazepine has a renal action to produce antidiuresis in patients with central diabetes insipidus but actually inhibits vasopressin secretion via a central action.

BASIC PHARMACOLOGY OF VASOPRESSIN

VASOPRESSIN RECEPTORS The cellular effects of vasopressin are mediated mainly by its interactions with the 3 types of receptors, V_{1a} , V_{1b} , and V_2 . The V_{1a} receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, the adrenal gland, myometrium, the bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the renal cortical collecting-duct, spleen, testis, and many CNS structures. V_{1b} receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, the pancreas, and the adrenal medulla. V_2 receptors are located predominantly in principal cells of the renal collecting-duct system but also are present on epithelial cells in the thick ascending limb and on vascular endothelial cells. Vasopressin receptors are GPCRs.

V_1 RECEPTOR-EFFECTOR COUPLING

Figure 29-2 summarizes the current model of V_1 receptor-effector coupling. Vasopressin binding to V_1 receptors activates the G_q -PLC pathway, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth of smooth muscle cells.

V_2 RECEPTOR-EFFECTOR COUPLING

Principal cells in the renal collecting duct have V_2 receptors on their basolateral membranes that couple to G_s to stimulate adenylyl cyclase activity (Figure 29-3). The resulting increase in cellular cyclic AMP and PKA activity triggers increased insertion of water channel-containing vesicles (WCVs) into the apical membrane and decreased endocytosis of WCVs from the apical membrane. The distribution of WCVs between the cytosolic compartment and the apical membrane compartment thus is shifted in favor of the apical membrane compartment. Because WCVs contain preformed aquaporin 2 water channels, their net shift into apical membranes in response to V_2 -receptor stimulation greatly increases water permeability of the apical membrane.

Aquaporins are a family of water channel proteins that allow water molecules to cross biological membranes. Of the 10 cloned mammalian aquaporins, at least 7 are found in the kidney. Aquaporin 1 is present in the apical and basolateral membrane of the proximal tubule and in the thin descending limb. Aquaporin 2 resides in the apical membrane and WCVs of the collecting-duct principal cells, whereas aquaporins 3 and 4 are present in the basolateral membrane of principal cells. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6 and 8 are

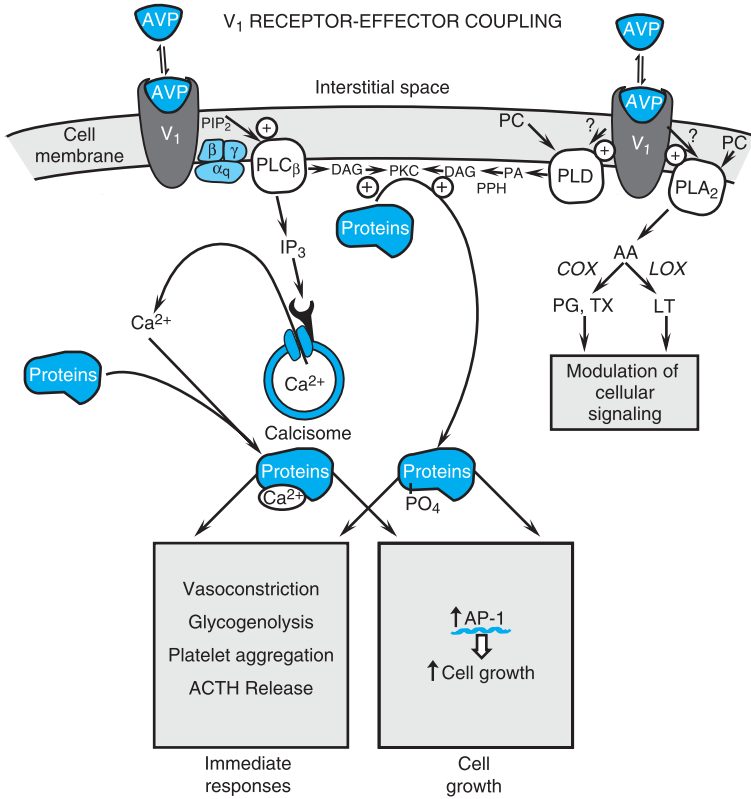

FIGURE 29–2 Mechanism of V₁ receptor–effector coupling. Binding of 8-arginine vasopressin (AVP) to V₁ vasopressin receptors (V₁) stimulates several membrane-bound phospholipases. Stimulation of the G_q-PLC_β pathway results in IP₃ formation, mobilization of intracellular Ca²⁺, and activation of PKC. Activation of V₁ receptors also causes influx of extracellular Ca²⁺ by an unknown mechanism. PKC and Ca²⁺/calmodulin-activated protein kinases phosphorylate cell-type-specific proteins leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA₂; the resulting mobilization of arachidonic acid (AA) provides substrate for eicosanoid synthesis via the cyclooxygenase (COX) and lipoxygenase (LOX) pathways, leading to local production of prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT), which may activate a variety of signaling pathways, including those linked to G_s and G_i. Biological effects mediated by the V₁ receptor include vasoconstriction, glycogenolysis, platelet aggregation, ACTH release, and growth of vascular smooth muscle cells. The effects of vasopressin on cell growth involve transcriptional regulation via the FOS/JUN AP-1 transcription complex.

located intracellularly in the collecting-duct principal cells. In addition to increasing the insertion of aquaporin 2 into apical membranes in collecting-duct principal cells, vasopressin also increases the expression of aquaporin 2 mRNA and protein. Chronic dehydration leads to long-term up-regulation of aquaporin 2 and water transport in the collecting duct.

For maximum concentration of urine, large amounts of urea must be deposited in the interstitium of the inner medullary collecting duct. It is not surprising, therefore, that V₂-receptor activation also increases urea permeability by 400% in the terminal portions of the inner medullary collecting duct by activating a vasopressin-regulated urea transporter (termed VRUT, UT1, or UT-A1), most likely by PKA-induced phosphorylation. The kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regulation of VRUT does not entail vesicular trafficking to the plasma membrane.

In addition to increasing the water permeability of the collecting duct and the urea permeability of the inner medullary collecting duct, V₂-receptor activation also increases Na⁺ transport in the thick ascending limb and collecting duct. Increased Na⁺ transport in the thick ascending limb is mediated by three mechanisms that affect the Na⁺-K⁺-2Cl⁻ symporter: rapid phosphorylation of the symporter, translocation of the symporter into the luminal membrane, and increased

V₂ RECEPTOR-EFFECTOR COUPLING

FIGURE 29-3 Mechanism of V₂ receptor-effector coupling. Binding of vasopressin (AVP) to the V₂ receptor activates the G_s-adenylyl cyclase-cAMP-PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of serine 256 of aquaporin 2 is involved in V₂ receptor signaling, other proteins located both in the water channel-containing vesicles and the apical membrane of the cytoplasm also may be involved.

expression of symporter protein. Enhanced Na⁺ transport in the collecting duct is mediated by increased expression of subunits of the epithelial sodium channel. The multiple mechanisms by which vasopressin increases water reabsorption are summarized in Figure 29-4.

RENAL ACTIONS OF VASOPRESSIN Several actions of vasopressin in the kidney involve both V₁ and V₂ receptors. V₁ receptors mediate contraction of mesangial cells in the glomerulus and vascular smooth muscle cells in the vasa recta and efferent arteriole. Indeed, V₁-receptor-mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney (Figure 29-4). V₁ receptors also stimulate prostaglandin synthesis by

medullary interstitial cells. Since PGE₂ inhibits adenylyl cyclase in the collecting duct, stimulation of prostaglandin synthesis by V₁ receptors may counterbalance V₂-receptor-mediated antidiuresis. V₁ receptors on principal cells in the cortical collecting duct may also inhibit V₂-receptor-mediated water flux *via* activation of PKC. V₂ receptors mediate the most prominent response to vasopressin, increased water permeability of the collecting duct. Indeed, vasopressin can increase water permeability in the collecting duct at concentrations as low as 50 fM. Thus, V₂-receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage V₁-receptor-mediated actions.

Other renal actions mediated by V₂ receptors include increased urea transport in the inner medullary collecting duct and increased Na⁺ transport in the thick ascending limb; both effects contribute to the urine-concentrating ability of the kidney (Figure 29-4). V₂ receptors also increase Na⁺ transport in the cortical collecting duct, which may synergize with aldosterone to enhance Na⁺ reabsorption during hypovolemia.

PHARMACOLOGICAL MODIFICATION OF THE ANTIDIURETIC RESPONSE TO VASOPRESSIN NSAIDs (*see* Chapter 26), particularly *indomethacin*, enhance the antidiuretic response to vasopressin. Since prostaglandins attenuate antidiuretic responses to vasopressin and NSAIDs inhibit prostaglandin synthesis, reduced prostaglandin production probably accounts for the potentiation of vasopressin's antidiuretic response. *Carbamazepine* and *chlorpropamide* also

enhance the antidiuretic effects of vasopressin by unknown mechanisms. Chlorpropamide rarely can induce water intoxication.

A number of drugs inhibit the antidiuretic actions of vasopressin. *Lithium* is of particular importance because of its use in the treatment of manic–depressive disorders. Lithium-induced polyuria is usually reversible. Acutely, lithium appears to reduce V_2 -receptor-mediated stimulation of adenylyl cyclase. Also, lithium increases plasma levels of parathyroid hormone, a partial antagonist to vasopressin. In most patients, the antibiotic *demeclocycline* attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP.

NONRENAL ACTIONS OF VASOPRESSIN

Cardiovascular System

The cardiovascular effects of vasopressin are complex. Vasopressin is a potent vasoconstrictor (V_1 -receptor-mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appear most sensitive, with significant vasoconstriction also occurring in the GI tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses in vivo are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V_1 receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V_2 receptors cause vasodilation in some blood vessels.

Vasopressin appears to help maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. There is no convincing evidence for a role of vasopressin in essential hypertension. The effects of vasopressin on the heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control diabetes insipidus, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

Central Nervous System

Vasopressin likely functions as a CNS neurotransmitter and/or neuromodulator, but the physiological relevance of vasopressin's CNS effects is unclear. Although vasopressin is not the principal corticotropin-releasing factor, it may assist in sustained activation of the hypothalamic–pituitary–adrenal axis during chronic stress (see Chapter 59). CNS effects of vasopressin are mediated predominantly by V_1 receptors.

Blood Coagulation

Activation of V_2 receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and von Willebrand factor. These effects are mediated by extrarenal V_2 receptors. Presumably, vasopressin stimulates the secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. Since release of von Willebrand factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

OTHER NONRENAL EFFECTS OF VASOPRESSIN

At high concentrations, vasopressin stimulates contraction of smooth muscle in the uterus (via oxytocin receptors) and GI tract (via V_1 receptors). Vasopressin is stored in platelets, and activation of V_1 receptors stimulates platelet aggregation. Also, activation of V_1 receptors on hepatocytes stimulates glycogenolysis. The physiological significance of these effects of vasopressin is not known.

VASOPRESSIN RECEPTOR AGONISTS AND ANTAGONISTS

The neurohypophyseal vasopressin peptide is 8-arginine vasopressin, and the terms *vasopressin*, *arginine vasopressin* (AVP), and *antidiuretic hormone* (ADH) are used interchangeably. Arginine vasopressin is a nonapeptide (Cys¹-Tyr²-Phe³-Gln⁴-Asn⁵-Cys⁶-Pro⁷-Arg⁸-Gly⁹-NH₂), containing Cys residues in positions 1 and 6 that form an intramolecular disulfide bridge (essential for agonist activity), and an amidated carboxyl terminus. The chemical structure of *oxytocin* is closely related to that of vasopressin: Oxytocin is [Ile³, Leu⁸]AVP. Oxytocin binds to specific oxytocin receptors on myoepithelial cells in the mammary gland (causing milk ejection) and on smooth muscle cells in the uterus (causing contraction). Inasmuch as vasopressin and oxytocin are structurally similar, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other's

receptors. Indeed, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

Vasopressin analogs with longer duration of action and selectivity for vasopressin receptor subtypes (V_1 vs. V_2 vasopressin receptors, which mediate pressor responses and antidiuretic responses, respectively) have been synthesized. The V_2 -selective agonist, 1-deamino-8-D-arginine vasopressin, also called *desmopressin* (DDAVP), has ~3000 times greater antidiuretic-to-vasopressor ratio than vasopressin and is the preferred drug for the treatment of central diabetes insipidus. Substitution of Val for Gln in position 4 further increases the antidiuretic selectivity, and the antidiuretic-to-vasopressor ratio for deamino[Val⁴, D-Arg⁸]AVP is ~11,000 times greater than vasopressin.

Increasing V_1 selectivity has been more difficult than increasing V_2 selectivity. Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V_1 nor V_2 receptors. Since the vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V_1 receptors, and since many vasopressin analogs with vasoconstrictor activity release ACTH, V_1 receptors have been subclassified into V_{1a} (vascular/hepatic) and V_{1b} (pituitary) receptors. V_{1b} receptors also are called V_3 receptors. Vasopressin analogs that are selective agonists for V_{1a} and V_{1b} receptors have been synthesized but are not available clinically.

DISEASES AFFECTING THE VASOPRESSIN SYSTEM

DIABETES INSIPIDUS (DI) DI is a disease of impaired renal conservation of water owing either to an inadequate secretion of vasopressin from the neurohypophysis (central DI) or to an insufficient renal response to vasopressin (nephrogenic DI). Very rarely, DI can be caused by an abnormally high rate of degradation of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central and/or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing the renal sensitivity to vasopressin. Patients with DI excrete large volumes (>30 mL/kg/day) of dilute (<200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are polydipsic. The diagnosis of DI rests on demonstrating that the patient is unable to reduce urine volume and increase urine osmolality during a period of carefully observed fluid deprivation. Central DI can be distinguished from nephrogenic DI by administration of desmopressin, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients with DI.

Central DI Head injury, either surgical or traumatic, in the region of the pituitary and/or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections. Finally, central DI may be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20); vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI results from mutations in the vasopressin gene that cause the prohormone to misfold and oligomerize improperly, resulting in accumulation of the mutant vasopressin precursor in the affected neuron and neuronal death. Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin peptide.

Antidiuretic peptides are the primary treatment for central DI, with desmopressin being the preferred peptide. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available. *Chlorpropamide*, an oral sulfonyleurea, potentiates the action of small or residual amounts of circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. A dose of 125–500 mg daily is particularly effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic (see Chapter 28) to the regimen usually results in an adequate reduction in the volume of urine. *Carbamazepine* (800–1000 mg daily in divided doses) and *clofibrate* (1–2 g daily in divided doses) also reduce urine volume in patients with central DI. Long-term use of these agents may induce serious adverse effects; therefore, carbamazepine and clofibrate are used rarely to treat central DI. The antidiuretic mechanisms of chlorpropamide, carbamazepine, and clofibrate are not clear. These agents are not effective in nephrogenic DI, which indicates that functional V_2 receptors are required for the antidiuretic effect. Since carbamazepine inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V_2 receptor-mediated antidiuresis.

Nephrogenic DI Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, lithium, foscarnet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many as 1 in 3 patients treated with lithium may develop nephrogenic DI. X-linked nephrogenic DI is caused by mutations in the gene encoding the V_2 receptor, which maps to Xq28. A number of missense, nonsense, and frame-shift mutations in this gene have been identified in patients with this disorder, causing impaired routing of the V_2 receptor to the cell surface, defective coupling to G proteins, or decreased affinity of the receptor for vasopressin. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings establish that aquaporin 2 is essential for the antidiuretic effect of vasopressin.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate intake of water, drugs also can be used to reduce polyuria. *Amiloride* blocks the uptake of lithium by the Na^+ channel in the collecting-duct system and is used off-label for lithium-induced nephrogenic DI. Paradoxically, *thiazide diuretics* reduce the polyuria of patients with DI and often are used to treat non-lithium-induced nephrogenic DI. In infants with nephrogenic DI, thiazides may be crucially important because uncontrolled polyuria may exceed the child's capacity to imbibe and absorb fluids. The natriuretic action of thiazides and resulting depletion of extracellular fluid volume may play an important role in the thiazide-induced antidiuresis since these effects appear to parallel the ability of thiazides to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of sodium intake can enhance the antidiuretic effectiveness of thiazides.

While case reports describe the effectiveness of indomethacin in the treatment of nephrogenic DI, other cyclooxygenase inhibitors (*e.g.*, *ibuprofen*) appear to be less effective. The mechanism of the effect may involve a decrease in glomerular filtration rate, an increase in medullary solute concentration, and/or enhanced proximal reabsorption of fluid. Also, since prostaglandins attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V_2 -receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the prostaglandin effect and enhancement of the effects of vasopressin on principal cells of the collecting duct.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE (SIADH) SIADH is a disease of impaired water excretion with accompanying hyponatremia and hypo-osmolality caused by the *inappropriate* secretion of vasopressin. The clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH, including malignancies, pulmonary diseases, CNS injuries/diseases (*e.g.*, head trauma, infections, and tumors), and general surgery. The three drug classes most commonly implicated in drug-induced SIADH include psychotropic medications (*e.g.*, *fluoxetine*, haloperidol, and *tricyclic antidepressants*), sulfonyleureas (*e.g.*, chlorpropamide), and vinca alkaloids (*e.g.*, *vincristine* and *vinblastine*). Other drugs strongly associated with SIADH include thiazide diuretics, clonidine, *enalapril*, *ifosphamide*, and *methyl dopa*. In a normal individual, an elevation in plasma vasopressin *per se* does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin. Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with the concentrating ability of the kidneys), and drugs that inhibit the effect of vasopressin to increase water permeability in the collecting ducts. To inhibit vasopressin's action in the collecting ducts, *demeclocycline*, a tetracycline, is the preferred drug.

Although lithium can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index. Therefore, lithium should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated, *e.g.*, patients with liver disease. It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na^+ stabilizes in the range of 125–132 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na^+ levels drop below 120 mM, should therapy with demeclocycline be initiated. Since hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal.

OTHER WATER-RETAINING STATES In patients with congestive heart failure, cirrhosis, or nephrotic syndrome, *effective* blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Since hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V_2 receptor antagonists and specific inhibitors of water channels in the collecting duct would provide an effective therapeutic strategy not only in patients with SIADH but also in the much more common setting of hyponatremia in patients with heart failure, cirrhosis, or nephrotic syndrome.

CLINICAL USE OF VASOPRESSIN PEPTIDES

THERAPEUTIC USES Only two antidiuretic peptides are available for clinical use in the U.S. Vasopressin (synthetic 8-L-arginine vasopressin; PITRESSIN) is available as a sterile aqueous solution; it may be administered subcutaneously, intramuscularly, or intranasally. *Desmopressin acetate* (synthetic 1-deamino-8-D-arginine vasopressin; DDAVP, others) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a nasal solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration. Based on the type of vasopressin receptor involved, the therapeutic uses of vasopressin and its congeners can be divided into two main categories.

V_1 receptor-mediated therapeutic applications are based on the rationale that V_1 receptors cause contraction of GI and vascular smooth muscle. V_1 receptor-mediated contraction of GI smooth muscle has been used to treat postoperative ileus and abdominal distension and to dispel intestinal gas before abdominal roentgenography to avoid interfering gas shadows. V_1 receptor-mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow to the portal system and thereby attenuates pressure and bleeding in esophageal varices. Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V_1 receptor agonists have been used emergently until endoscopy can be performed. Simultaneous administration of nitroglycerin with V_1 receptor agonists may attenuate the cardiotoxic effects of V_1 agonists while enhancing their beneficial splanchnic effects. Also, V_1 receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. Finally, V_1 receptor-mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, caesarean section, and uterine myoma resection. The applications of V_1 receptor agonists can be accomplished with vasopressin; however, the use of vasopressin for all these indications is no longer recommended because of significant adverse reactions. Although not yet available in the U.S., *terlipressin* (GLYPRESSIN) is preferred for bleeding esophageal varices because of increased safety compared with vasopressin. Terlipressin also is effective in patients with hepatorenal syndrome, particularly when combined with albumin.

Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of vasopressin. The combination of vasopressin and *norepinephrine* is superior to NE alone in the management of catecholamine-resistant vasodilatory shock. Although the efficacy of vasopressin in the resuscitation of patients with ventricular fibrillation or pulseless electrical activity is similar to that of epinephrine, vasopressin followed by Epi appears to be more effective than Epi alone in the treatment of patients with asystole.

V_2 receptor-mediated therapeutic applications are based on the rationale that V_2 receptors cause water conservation and release of blood coagulation factors. Central DI can be treated with V_2 receptor agonists, and polyuria and polydipsia usually are well controlled. While some patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary), therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients and is efficacious and well-tolerated in both adults and children. A single intranasal dose lasts from 6 to 20 hours; twice-daily administration is effective in most patients. There is considerable variability in the intranasal dose of desmopressin required to maintain normal urine volume, and the dosage must be tailored individually. The usual intranasal dosage in adults is 10–40 $\mu\text{g}/\text{day}$, either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. An initial dose of 2.5 μg can be used, with therapy directed toward the control of nocturia. An equivalent or higher morning dose controls daytime polyuria in most patients, although a third dose occasionally may be needed in the afternoon. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable absorption of the peptide

following nasal administration. Oral administration of desmopressin in doses 10–20 times the intranasal dose provides adequate blood levels of desmopressin to control polyuria. Daily subcutaneous administration of 1–2 μg of desmopressin also is effective.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V_1 receptor-mediated side effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

V_2 receptor agonists (*e.g.*, desmopressin) are also used in bleeding disorders. In most patients with type I von Willebrand's disease (vWD) and in some with type II vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types IIa, IIb, and III vWD. Desmopressin may transiently cause a marked thrombocytopenia in individuals with type IIb vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild-to-moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. The response of any given patient with type I vWD or hemophilia A to desmopressin should be determined with a test dose of nasal spray at the time of diagnosis or 1–2 weeks before elective surgery to assess the extent of increase in factor VIII or von Willebrand factor. In patients with renal insufficiency or uremia, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII-related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with cirrhosis- or drug-induced (*e.g.*, *heparin*, *hirudin*, and *antiplatelet agents*) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 $\mu\text{g}/\text{kg}$, increases factor VIII and von Willebrand factor for >6 hours. Desmopressin can be given at intervals of 12–24 hours depending on the clinical response and the severity of bleeding. Tachyphylaxis to desmopressin, which usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites), limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V_2 receptor-mediated application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin intranasal spray or tablets provides a high response rate that is sustained with long-term use, that is safe, and that accelerates the cure rate. Desmopressin also relieves post-lumbar puncture headache, probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

PHARMACOKINETICS When vasopressin and desmopressin are given orally, they are rapidly inactivated by trypsin, which cleaves the peptide bond between amino acids 8 and 9. Inactivation by peptidases in various tissues (particularly the liver and kidneys) results in a plasma $t_{1/2}$ of vasopressin of 17–35 minutes. Following intramuscular or subcutaneous injection, the antidiuretic effects of vasopressin last 2–8 hours. The plasma $t_{1/2}$ of desmopressin has a fast component of 6.5–9 minutes and a slow component of 30–117 minutes. Only 3% and 0.15%, respectively, of intranasally and orally administered desmopressin is absorbed.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS

Most adverse effects are mediated through the V_1 receptor acting on vascular and GI smooth muscle; such adverse effects are much less common and less severe with desmopressin than with vasopressin. After the injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Most serious, however, is the effect on the coronary circulation. Vasopressin should be administered only at low doses and with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene also have been encountered in patients receiving large doses of vasopressin.

The major V_2 receptor-mediated adverse effect is water intoxication, which can occur with desmopressin or vasopressin. Many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants and NSAIDs, can potentiate the antidiuretic effects of these peptides, while lithium, demeclocycline and ethanol can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin should be used cautiously when a rapid increase in extracellular water may impose risks (*e.g.*, in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be

advised to reduce fluid intake. It is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue.

Mild facial flushing and headache are the most common adverse effects associated with desmopressin. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

Future Directions in Vasopressin Analogs

Nonpeptide vasopressin receptor antagonists and agonists are being developed for a wide range of clinical indications. The V_2 receptor antagonist *conivaptin* (VAPRISOL) is now FDA-approved for the treatment of euvolemic hyponatremia in hospitalized patients who do not have congestive heart failure (e.g., patients with SIADH, or with hypothyroidism or adrenal insufficiency). Conivaptin is contraindicated in patients with volume depletion or those receiving other drugs that inhibit CYP3A4 (e.g., ketoconazole, itraconazole, clarithromycin, indinavir, and ritonavir). Other vasopressin receptor antagonists now in clinical trials, such as *tolvaptan* and *satavaptan*, can be administered orally.

RENIN AND ANGIOTENSIN

OVERVIEW Angiotensin II (AngII), the most active angiotensin peptide, is derived from angiotensinogen via two proteolytic steps. First, renin, an enzyme released from the kidneys, cleaves the decapeptide angiotensin I (AngI) from the amino terminus of angiotensinogen (renin substrate). Angiotensin-converting enzyme (ACE) then removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. AngII is degraded subsequently by further proteolysis (see summary, Figure 30–1). AngII acts by binding to two GPCRs (see below).

RENIN

The major determinant of the rate of AngII production is the amount of renin released by the kidney. Renin is an aspartyl protease whose principal natural substrate is the circulating α_2 -globulin, angiotensinogen, secreted by hepatocytes. Renin is synthesized as a proenzyme of 406 amino acid residues and processed to prorenin, a mature but inactive form. Prorenin then is activated by proteolytic cleavage to yield the active 340-amino acid renin. Both renin and prorenin are stored in the juxtaglomerular (j-g) cells and, after release, circulate in the blood. The concentration of prorenin in the circulation is approximately tenfold greater than that of the active enzyme. The $t_{1/2}$ of circulating renin is ~15 minutes.

Control of Renin Secretion

Renin secretion from j-g cells is controlled predominantly by three pathways: two acting locally within the kidney, the third acting through the CNS and mediated by norepinephrine (NE) release from renal nerves (Figure 30–2). One intrarenal mechanism controlling renin release is the macula densa pathway (top of Figure 30–2A). Increased NaCl reabsorption and flux across the macula densa inhibits, while decreased NaCl flux stimulates, renin release. Both adenosine and prostaglandins mediate the macula densa pathway; the former is released when Na^+ transport increases, and the latter is released when NaCl transport decreases. Adenosine, acting via the A_1 adenosine receptor, inhibits renin release, while prostaglandins stimulate renin release. Inducible cyclooxygenase (COX-2) and neuronal nitric oxide synthase (nNOS) also play a role in macula densa–stimulated renin release. Figure 30–2B summarizes possible mechanisms regulating renin release.

Although a change in NaCl transport is a key modulator, regulation of the macula densa pathway depends more on the luminal concentration of Cl^- than Na^+ . Physiological changes in Cl^- concentrations (e.g., from 20 to 60 mEq/L) at the macula densa profoundly affect macula densa–mediated renin release.

The second intrarenal mechanism controlling renin release is the intrarenal baroreceptor pathway (middle of Figure 30–2A). Increases and decreases in blood pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. Changes in renal prostaglandins may partly mediate the intrarenal baroreceptor pathway, as may biomechanical coupling via stretch-activated ion channels.

The third mechanism, the β adrenergic receptor pathway (bottom of Figure 30–2A), is mediated by the release of NE from postganglionic sympathetic nerves; activation of β_1 receptors on juxtaglomerular cells enhances renin secretion.

Increased renin secretion enhances the formation of AngII, which stimulates angiotensin subtype 1 (AT_1) receptors on j-g cells to inhibit renin release, an effect termed short-loop negative feedback. AngII also increases arterial blood pressure via AT_1 receptors. Increases in blood pressure inhibit renin release by (1) activating high-pressure baroreceptors and reducing renal sympathetic tone, (2) increasing pressure in the preglomerular vessels, and (3) reducing NaCl reabsorption in the proximal tubule, which increases tubular delivery of NaCl to the macula densa. The inhibition of renin release by AngII–induced increases in blood pressure has been termed long-loop negative feedback.

The physiological pathways regulating renin release can be influenced by blood pressure, salt intake, and a number of drugs. In all these cases, renin release is affected by the interplay of mechanisms summarized in Figure 30–2A. Loop diuretics (see Chapter 28) stimulate renin release in part by blocking NaCl reabsorption at the macula densa. Nonsteroidal anti-inflammatory drugs (NSAIDs) (see Chapter 26) inhibit prostaglandin synthesis and thereby decrease renin release. ACE inhibitors, angiotensin receptor blockers (ARBs), and renin inhibitors interrupt both the short- and long-loop negative feedback mechanisms and therefore increase renin release. Chronic administration of ACE inhibitors up-regulates renal COX-2 and nNOS expression. In general, diuretics and vasodilators increase renin release by decreasing arterial blood pressure. Centrally acting sympatholytic drugs and β adrenergic receptor antagonists decrease renin secretion by

B. Possible mechanisms by which the macula densa regulates renin release. Both acute changes in tubular delivery of NaCl to the macula densa and chronic changes in dietary sodium intake cause appropriate signals to be conveyed from macula densa to the juxtaglomerular cells. Chronic sodium depletion up-regulates neuronal nitric oxide synthase (nNOS) and inducible cyclooxygenase (COX-2) in the macula densa. nNOS increases nitric oxide (NO) production, and NO reacts with superoxide anion (O₂⁻) to form peroxynitrite, an activator of COX-2. In addition, COX-2 may be rapidly, although indirectly, inhibited and stimulated by increases and decreases in NaCl transport, respectively, across the macula densa. Arachidonic acid (AA) is converted to prostaglandins (PGs), which diffuse to nearby juxtaglomerular cells to stimulate adenyl cyclase (AC) via prostaglandin receptors, such as EP₄ and IP, that couple to G_s. Circulating and locally released catecholamines also stimulate adenyl cyclase via β₁ receptors. Cyclic AMP (cAMP) augments renin release. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels in the macula densa. ADO diffuses to the juxtaglomerular cells and activates the AT₁-G_i pathway, inhibiting AC and reducing cellular cAMP. Increased NaCl transport in the macula densa augments the efflux of ATP through basolateral maxi-anion channels, and ATP is converted to adenosine in the extracellular compartment and inhibits adenyl cyclase via A₁ receptors. In addition, ATP released from the macula densa may inhibit renin release directly by binding to P2Y receptors coupled to G_i on juxtaglomerular cells. Activation of G_i increases intracellular Ca²⁺, which inhibits renin release. Circulating AngII binds to AT₁ receptors on juxtaglomerular cells and inhibits renin release via G_i-induced increases in intracellular Ca²⁺.

reducing activation of β adrenergic receptors on j-g cells. Phosphodiesterase inhibitors stimulate renin release by increasing cyclic AMP in j-g cells.

ANGIOTENSINOGEN

Angiotensinogen is circulating glycoprotein containing 452 amino acids that is synthesized primarily in the liver as preangiotensinogen, (MW = 55,000–60,000). Angiotensinogen synthesis is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII.

During pregnancy, plasma levels of angiotensinogen increase severalfold owing to increased estrogen.

AngI is cleaved by renin from the amino terminus of angiotensinogen. Circulating levels of angiotensinogen are approximately equal to its K_m for renin cleavage ($\sim 1 \mu\text{M}$), and the rate of AngII synthesis therefore can be significantly influenced by changes in angiotensinogen levels. For example, estrogen therapy increases circulating levels of angiotensinogen, possibly inducing hypertension, and a missense mutation in the angiotensinogen gene (M235T) that increases circulating angiotensinogen is associated with essential and pregnancy-induced hypertension.

ACE, KININASE II, DIPEPTIDYL CARBOXYPEPTIDASE

The rapid conversion of AngI to AngII in plasma is due to the activity of membrane-bound ACE on the luminal surface of endothelial cells throughout the vasculature. ACE has a large amino-terminal extracellular domain, a short carboxyl-terminal intracellular domain, and a 17-amino acid hydrophobic region that anchors the ectoenzyme to the cell membrane. Circulating ACE represents membrane ACE that has undergone proteolysis. ACE cleaves dipeptides from substrates. Preferred substrates have only one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, ACE does not degrade AngII. ACE also inactivates bradykinin and other potent vasodilator peptides.

ANGIOTENSIN PEPTIDES

AngI is <1% as potent as AngII on smooth muscle, heart, and the adrenal cortex. Angiotensin III (AngIII), also called [des-Asp¹]AngII or angiotensin (2–8), can be formed either by the action of aminopeptidase on AngII or by the action of ACE on [des-Asp¹]AngI (Figure 30–1). AngIII and AngII have qualitatively similar effects; both stimulate aldosterone secretion with equal potency, but AngIII is only 25% and 10% as potent as AngII in elevating blood pressure and stimulating the adrenal medulla, respectively.

Angiotensin(1–7) is formed by multiple pathways (Figure 30–1). ACE inhibitors increase tissue and plasma levels of angiotensin(1–7), both because AngI levels are increased and diverted away from AngII formation (Figure 30–1) and because ACE contributes importantly to the plasma clearance of angiotensin(1–7). The pharmacological profile of angiotensin(1–7) is distinct from that of AngII: angiotensin(1–7) does not cause vasoconstriction, aldosterone release, or facilitation of noradrenergic neurotransmission. Angiotensin(1–7) releases vasopressin, stimulates prostaglandin biosynthesis, elicits depressor responses when microinjected into certain brainstem nuclei, dilates some blood vessels, and exerts a natriuretic action on the kidneys. Angiotensin(1–7) also inhibits proliferation of vascular smooth muscle cells. The effects of angiotensin(1–7) may be mediated by a specific angiotensin(1–7) receptor; it has been proposed that angiotensin(1–7) serves to counterbalance the actions of AngII. Angiotensin(3–8), also called AngIV, is another biologically active angiotensin peptide that also appears to counteract the effects of AngII.

Various peptidases degrade and inactivate angiotensin peptides, including aminopeptidases, endopeptidases, and carboxypeptidases; none is specific.

LOCAL (TISSUE) RENIN–ANGIOTENSIN SYSTEMS

Circulating renin from the kidney acts on circulating angiotensinogen of hepatic origin to produce AngI in the plasma, circulating AngI is converted by ACE to AngII, and AngII then is delivered to its target organs via the bloodstream to induce a physiological response. This traditional view must be expanded to include local (tissue) renin–angiotensin systems, which consist of extrinsic and intrinsic local renin–angiotensin systems.

Extrinsic Local Renin–Angiotensin Systems

ACE is present on the luminal face of vascular endothelial cells throughout the circulation, and circulating renin of renal origin can be sequestered by the arterial wall and other tissues, permitting the local conversion of precursors to AngII. Indeed, many vascular beds locally produce AngI and II.

Intrinsic Local Renin–Angiotensin Systems

Many tissues (e.g., brain, pituitary, blood vessels, heart, kidney, and adrenal gland) express mRNAs for renin, angiotensinogen, and/or ACE, and can produce renin, angiotensinogen, ACE, and AngI, II, and III. These local renin–angiotensin systems may influence vascular, cardiac, and renal function and structure.

ALTERNATIVE PATHWAYS FOR ANGIOTENSIN BIOSYNTHESIS

Some tissues contain non-renin enzymes that convert angiotensinogen to AngI or directly to AngII (e.g., cathepsin G, tonin) and non-ACE AngI–processing enzymes that convert AngI to AngII

(e.g., cathepsin G, chymostatin-sensitive AngII-generating enzyme, heart chymase). Chymase, possibly derived from mast cells, contributes to the local tissue conversion of AngI to AngII, particularly in the heart and kidneys.

ANGIOTENSIN RECEPTORS

Angiotensins act through two specific GPCRs, designated AT_1 and AT_2 . The AT_1 receptor has a high affinity for losartan, a low affinity for PD 123177, and a low affinity for CGP 42112A (a peptide analog). In contrast, the AT_2 receptor has a high affinity for PD 123177 and CGP 42112A but a low affinity for losartan.

The AT_1 and AT_2 receptors have little sequence homology. Most of the known biological effects of AngII are mediated by the AT_1 receptor. Consistent with its functional preeminence, the AT_1 -receptor gene contains a polymorphism (A1166C) that is associated with hypertension, hypertrophic cardiomyopathy, coronary artery vasoconstriction, and aortic stiffness, while preeclampsia is associated with the development of activating autoantibodies against the AT_1 receptor. Potential roles for the AT_2 receptor include antiproliferative, proapoptotic, vasodilatory, and antihypertensive effects.

ANGIOTENSIN RECEPTOR-EFFECTOR COUPLING

AT_1 receptors activate a large array of signal-transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses (Figure 30–3). The relative importance of these myriad signal-transduction pathways in mediating biological responses to AngII is tissue-specific. Other receptors may alter the response to AT_1 -receptor activation (e.g., AT_1 receptors heterodimerize with bradykinin B_2 receptors, which enhances AngII sensitivity in preeclampsia).

Signaling from AT_2 receptors is mediated largely by G_i . Consequences of AT_2 -receptor activation include activation of phosphatases, K^+ channels, and bradykinin and NO production and inhibition of Ca^{2+} channel function.

Functions and Effects of the Renin–Angiotensin System

The renin–angiotensin system plays a major role in the regulation of arterial blood pressure. Modest increases in plasma concentrations of AngII. When a single moderate dose of AngII is injected intravenously, systemic blood pressure begins to rise within seconds, peaks rapidly, and returns to

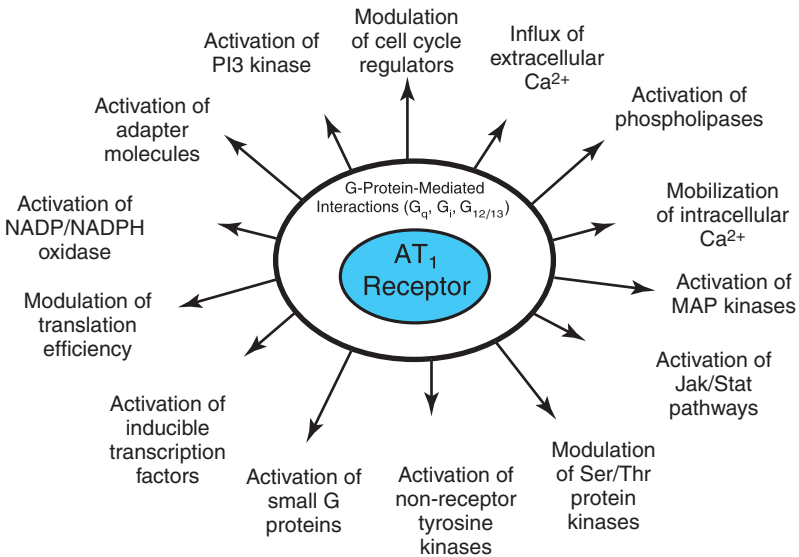

FIGURE 30–3 Multiple mechanisms of AT_1 receptor–effector coupling. AT_1 receptors couple to G_q , G_i , and $G_{12/13}$. Through effectors, second messengers, and signaling cascades, a large array of response pathways is subsequently engaged to produce immediate and long-term effects of AngII.

normal within minutes. This *rapid pressor response* to AngII is due to a swift increase in total peripheral resistance—a response that helps to maintain arterial blood pressure in the face of blood loss or vasodilation. Although AngII increases cardiac contractility directly *via* voltage-gated Ca^{2+} channels and increases heart rate indirectly (*via* facilitation of sympathetic tone, enhanced adrenergic neurotransmission, and adrenal catecholamine release), the rapid increase in arterial blood pressure activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological state, AngII may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by AngII.

AngII also causes a *slow pressor response* that chronically helps to maintain blood pressure. Continuous infusion of initially suppressor doses of AngII gradually increases blood pressure over a period of days. This slow pressor response probably is mediated by decreases in renal excretion that shift the renal pressure–natriuresis curve to the right (*see below*). AngII stimulates the synthesis of endothelin-1 and superoxide anion, which may contribute to the slow pressor response. In addition to its effects on arterial blood pressure, AngII causes hypertrophy of vascular and cardiac cells and increased collagen deposition by cardiac fibroblasts. The effects of AngII on total peripheral resistance, renal function, and cardiovascular structure are mediated by direct and indirect mechanisms (*see Figure 30–4*).

MECHANISMS BY WHICH ANGIOII INCREASES TOTAL PERIPHERAL RESISTANCE

AngII increases total peripheral resistance (TPR) by direct and indirect effects on blood vessels.

Direct Vasoconstriction AngII constricts precapillary arterioles and, to a lesser extent, post-capillary venules by activating AT_1 receptors on vascular smooth muscle cells. AngII has differential effects on vascular beds. The kidneys and splanchnic bed constrict markedly, thereby decreasing blood flow. Blood flow to the brain, lung, and skeletal muscle may actually increase in response to AngII because the elevated systemic blood pressure overcomes the relatively weak vasoconstriction. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow.

Enhancement of Peripheral Noradrenergic Neurotransmission AngII augments NE release from sympathetic nerve terminals, inhibits the reuptake of NE into nerve terminals, and enhances the vascular response to NE. Intracoronary AngII potentiates sympathetic nervous system–induced coronary vasoconstriction.

Effects on the CNS Small amounts of AngII infused into the vertebral arteries increases blood pressure. This response—mediated by increased sympathetic outflow—reflects effects of the hormone on circumventricular nuclei that are not protected by the blood–brain barrier. Circulating AngII also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial pressure. The CNS is affected both by blood-borne AngII and by AngII formed locally. The brain contains all components of a renin–angiotensin system, suggesting that AngII serves as a neurotransmitter or modulator. In addition to increasing sympathetic tone, AngII also causes a centrally mediated dipsogenic effect and enhances the release of vasopressin.

Release of Catecholamines from the Adrenal Medulla AngII stimulates catecholamine release from the adrenal medulla by depolarizing chromaffin cells. Although this response usually is of minimal physiological importance, dangerous reactions have followed AngII administration to individuals with pheochromocytoma.

MECHANISMS BY WHICH ANGIOII ALTERS RENAL FUNCTION

AngII has pronounced effects on renal function, reducing urinary excretion of Na^+ and water while increasing K^+ excretion. The overall effect of AngII on the kidneys is to shift the renal pressure–natriuresis curve to the right (*see below*).

Direct Effects of AngII on Sodium Reabsorption in the Renal Tubules Very low concentrations of AngII stimulate Na^+/H^+ exchange in the proximal tubule—an effect that increases Na^+ , Cl^- , and bicarbonate reabsorption. Approximately 25% of the bicarbonate handled by the nephron may be affected by this mechanism. AngII also increases the expression of the Na^+ –glucose symporter in the proximal tubule. Paradoxically, at high concentrations, AngII may inhibit Na^+ transport in the proximal tubule. AngII also directly stimulates the Na^+ – K^+ – 2Cl^- symporter in the thick ascending limb. The proximal tubule secretes angiotensinogen, and the connecting tubule releases renin, so a paracrine tubular renin–angiotensin system may modulate Na^+ reabsorption.

ANGIOTENSIN II

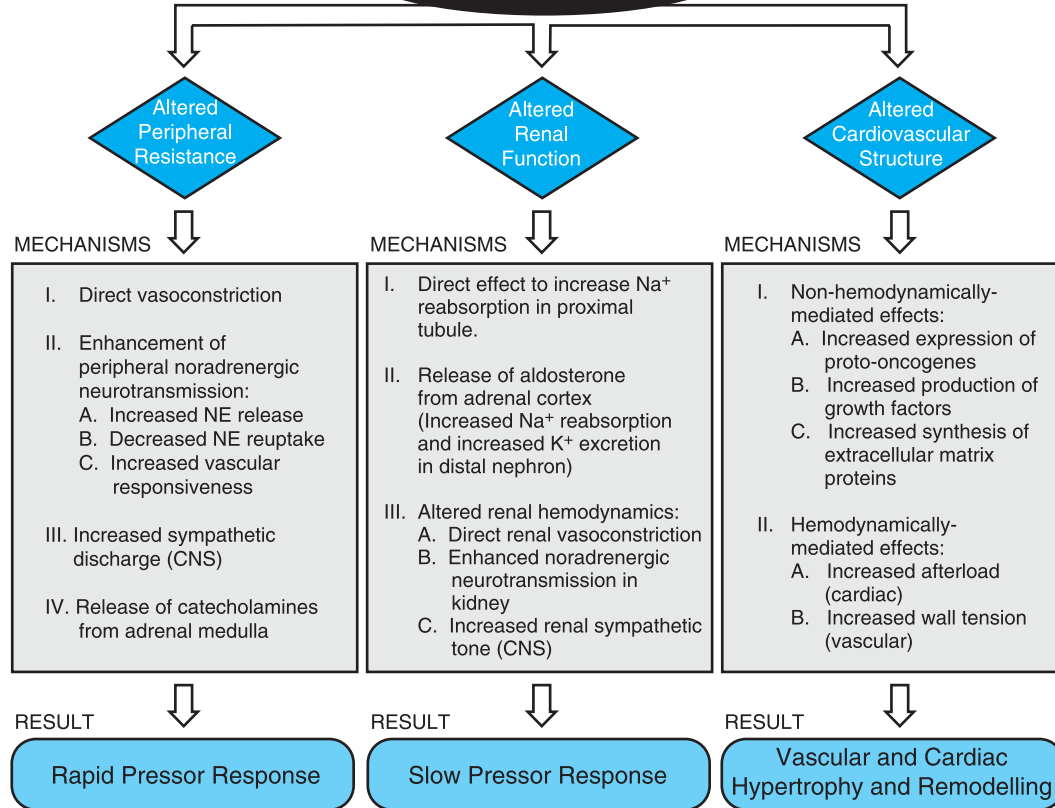

FIGURE 30-4 Summary of the three major effects of angiotensin II and the mechanisms that mediate them. NE, norepinephrine.

Release of Aldosterone from the Adrenal Cortex AngII stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone and also exerts permissive effects that augment responses to ACTH and K^+ . Increased output of aldosterone is elicited by concentrations of AngII that have little or no acute effect on blood pressure. Aldosterone acts on the distal and collecting tubules to cause retention of Na^+ and excretion of K^+ and H^+ . AngII-induced stimulation of aldosterone synthesis is enhanced by hyponatremia or hyperkalemia.

Altered Renal Hemodynamics Reduced renal blood flow markedly attenuates renal excretory function, and AngII reduces renal blood flow by directly constricting the renal vascular smooth muscle, enhancing renal sympathetic tone (a CNS effect), and facilitating renal adrenergic transmission. AngII-induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine. AT_1 receptors are highly expressed in the vasa recta of the renal medulla, and AngII may reduce Na^+ excretion in part by diminishing medullary blood flow. AngII variably influences glomerular filtration rate (GFR) via several mechanisms: (1) constriction of the afferent arterioles, which reduces intraglomerular pressure and tends to reduce GFR, (2) contraction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and also tends to reduce GFR, and (3) constriction of efferent arterioles, which increases intraglomerular pressure and tends to increase GFR. The outcome of these opposing effects depends on the physiological state. Normally, GFR is slightly reduced by AngII; however, during renal artery hypotension, the effects of AngII on the efferent arteriole predominate and AngII increases GFR. Thus, blockade of the renin-angiotensin system may cause acute renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

MECHANISMS BY WHICH AngII ALTERS CARDIOVASCULAR STRUCTURE

Several cardiovascular diseases are accompanied by changes in the morphology of the heart and/or blood vessels that increase morbidity and mortality, including: (1) increased wall-to-lumen ratio in blood vessels (associated with hypertension), (2) concentric cardiac hypertrophy (also associated with hypertension), (3) eccentric cardiac hypertrophy and fibrosis (associated with congestive heart failure and myocardial infarction), and (4) thickening of the intimal surface of the blood vessel wall (associated with atherosclerosis and angioplasty). The renin-angiotensin system, particularly AngII, may contribute importantly to these deleterious structural changes.

AngII stimulates migration, proliferation, hypertrophy, and/or synthetic capacity of vascular smooth muscle cells, cardiac myocytes, and fibroblasts.

In addition to these direct cellular effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na^+ retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Hypertension also contributes to hypertrophy and remodeling of blood vessels.

ROLE OF THE RENIN-ANGIOTENSIN SYSTEM IN LONG-TERM MAINTENANCE OF ARTERIAL BLOOD PRESSURE DESPITE EXTREMES IN DIETARY Na^+ INTAKE

Blood pressure is a major determinant of Na^+ excretion, as illustrated graphically by plotting urinary Na^+ excretion versus mean arterial blood pressure (Figure 30-5), a plot known as the *renal pressure-natriuresis curve*. Chronically, Na^+ excretion must equal Na^+ intake; therefore, the set point for long-term levels of blood pressure will be the intersection of a horizontal line representing Na^+ intake with the renal pressure-natriuresis curve. If the renal pressure-natriuresis curve were fixed, then over the long-term, arterial blood pressure would be greatly affected by dietary Na^+ intake. However, the renin-angiotensin system plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na^+ intake (Figure 30-5). When dietary Na^+ intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure-natriuresis curve to the right; when dietary Na^+ is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure-natriuresis curve to the left. Consequently, despite large swings in dietary Na^+ intake, the intersection of salt intake with the renal pressure-natriuresis curve remains near the same set point. When modulation of the renin-angiotensin system is blocked by drugs, changes in salt intake markedly affect blood pressure.

INHIBITORS OF THE RENIN-ANGIOTENSIN SYSTEM

AngII has limited therapeutic utility and is not available for therapeutic use in the U.S. Instead, clinical interest focuses on inhibitors of the renin-angiotensin system.

FIGURE 30-5 Interactions among salt intake, the renal pressure-natriuresis mechanism, and the rennin-angiotensin system to stabilize long-term levels of arterial blood pressure despite large variations in dietary sodium intake.

Renin Inhibitors

The orally active renin inhibitor *aliskiren* (TEKTURN) is now available for the treatment of hypertension. In studies to date, it has produced a dose-dependent decrease in blood pressure with few adverse effects. Renin inhibitors will likely provide an attractive alternative to current drugs used to inhibit the renin-angiotensin system.

ACE Inhibitors

The essential effect of these agents on the renin-angiotensin system is to inhibit the conversion of AngI to the active AngII (or the conversion of [des-Asp¹]AngI to AngIII). Thus, ACE inhibitors attenuate or abolish responses to AngII but not to AngIII (Figure 30-1). They do not interact directly with other components of the renin-angiotensin system, and their principal pharmacological and clinical effects all apparently arise from suppression of AngII synthesis. Nevertheless, ACE is an enzyme with many substrates, and inhibition of ACE may induce effects unrelated to reducing the levels of AngII. Since ACE inhibitors increase bradykinin levels and bradykinin stimulates prostaglandin biosynthesis, bradykinin and/or prostaglandins may contribute to the pharmacological effects of ACE inhibitors. In addition, ACE inhibitors interfere with both short- and long-loop negative feedbacks on renin release (Figure 30-2A). Consequently, ACE inhibitors increase renin release and the rate of formation of AngI. Since the metabolism of AngI to AngII is blocked by ACE inhibitors, AngI is directed down alternative metabolic routes, resulting in increased production of peptides such as Ang(1-7). Whether biologically active peptides such as angiotensin(1-7) contribute to pharmacological effects of ACE inhibitors is unknown.

In a healthy, Na⁺-replete person, a single oral dose of an ACE inhibitor has little effect on blood pressure, but repeated doses over several days cause a small reduction in blood pressure. By contrast, even a single dose of these inhibitors lowers blood pressure substantially in normal subjects when they have been depleted of Na⁺.

CLINICAL PHARMACOLOGY ACE inhibitors can be classified into three groups based on structure: (1) sulfhydryl-containing ACE inhibitors related to captopril; (2) dicarboxyl-containing ACE inhibitors related to enalapril (*e.g.*, lisinopril, benazepril, quinapril, moexipril, ramipril,trandolapril, and perindopril); and (3) phosphorus-containing ACE inhibitors related to fosinopril. Many ACE inhibitors are ester-containing prodrugs that are 100–1000 times less potent but have a much better oral bioavailability than the active molecules.

Currently, 11 ACE inhibitors are available for clinical use in the U.S. In general, ACE inhibitors differ with regard to three properties: (1) potency, (2) whether ACE inhibition is primarily

a direct effect of the drug itself or the effect of an active metabolite, and (3) pharmacokinetics (*i.e.*, extent of absorption, effect of food on absorption, plasma $t_{1/2}$, tissue distribution, and mechanisms of elimination).

All ACE inhibitors effectively block the conversion of AngI to AngII, and all have similar therapeutic indications, adverse-effect profiles, and contraindications. ACE inhibitors differ markedly in tissue distribution, and this difference might be exploited to inhibit some local renin-angiotensin systems while leaving others relatively intact; possible therapeutic advantages remain to be established.

With the notable exceptions of fosinopril and spirapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Therefore, impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and drug dosages should be reduced in patients with renal impairment. *Elevated plasma renin activity (PRA) renders patients hyperresponsive to ACE inhibitor-induced hypotension, and initial dosages of all ACE inhibitors should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and salt-depleted patients).*

Captopril (CAPOTEN) Captopril is a potent ACE inhibitor ($K_i \sim 1.7$ nM). Given orally, captopril is absorbed rapidly and has a bioavailability of $\sim 75\%$. Peak concentrations in plasma occur within an hour, and the drug is cleared with a $t_{1/2}$ of ~ 2 hours. Most of the drug is eliminated in urine, 40–50% as captopril and the rest as captopril disulfide dimers and captopril-cysteine disulfide. The oral dose of captopril ranges from 6.25 to 150 mg two to three times daily, with 6.25 mg three times daily or 25 mg twice daily being appropriate for the initiation of therapy for heart failure or hypertension, respectively. Most patients should not receive daily doses in excess of 150 mg. Since food reduces the oral bioavailability of captopril by 25–30%, the drug should be given 1 hour before meals.

Enalapril (VASOTEC) Enalapril maleate is a prodrug that is hydrolyzed by esterases in the liver to produce the active dicarboxylic acid, enalaprilat. *Enalaprilat* is a highly potent inhibitor of ACE with a $K_i \sim 0.2$ nM. Although it also contains a “proline surrogate,” enalaprilat differs from captopril in that it is an analog of a tripeptide rather than a dipeptide. Enalapril is absorbed rapidly when given orally and has an oral bioavailability of about 60% (not reduced by food). Although peak concentrations of enalapril in plasma occur within an hour, enalaprilat concentrations peak only after 3–4 hours. Enalapril has a $t_{1/2}$ of 1.3 hours; enalaprilat, because of tight binding to ACE, has a plasma $t_{1/2}$ of ~ 11 hours. Nearly all the drug is eliminated by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5–40 mg daily (single or divided dosage), with 2.5 and 5 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. The initial dose for hypertensive patients who are taking diuretics, are water- or Na^+ -depleted, or have heart failure is 2.5 mg daily.

Enalaprilat (VASOTEC INJECTION) Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate. For hypertensive patients, the dosage is 0.625–1.25 mg given intravenously over 5 minutes. This dosage may be repeated every 6 hours.

Lisinopril (PRINIVIL, ZESTRIL) Lisinopril is the Lys analog of enalaprilat; unlike enalapril, lisinopril itself is active. Lisinopril is slightly more potent than enalaprilat. Lisinopril is absorbed slowly, variably, and incompletely (about 30%) after oral administration (bioavailability is not reduced by food); peak concentrations in plasma are achieved in ~ 7 hours. It is cleared intact by the kidney, and its $t_{1/2}$ in plasma is about 12 hours. The oral dosage of lisinopril ranges from 5 to 40 mg daily (single or divided dosage), with 5 and 10 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg is recommended for patients with heart failure who are Na^+ -depleted or have renal impairment.

Benazepril (LOTENSIN) Cleavage of the ester moiety by hepatic esterases transforms benazepril, a prodrug, into benazeprilat, an ACE inhibitor that is more potent than captopril, enalaprilat, or lisinopril. Benazepril is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is nearly completely metabolized to benazeprilat and to glucuronide conjugates of benazepril and benazeprilat, which are excreted into both the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in about 0.5–1 hour and 1–2 hours, respectively. Benazeprilat has an effective $t_{1/2}$ in plasma of ~ 10 –11 hours. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5–80 mg daily (single or divided dosage).

Fosinopril (MONOPRIL) Fosinopril contains a phosphinate group that binds to the active site of ACE. Cleavage of the ester moiety by hepatic esterases transforms fosinopril, a prodrug, into fosinoprilat, an ACE inhibitor that is more potent than captopril yet less potent than enalaprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugate of fosinoprilat. These are excreted in urine and bile; peak concentrations of fosinoprilat in plasma are achieved in about 3 hours. Fosinoprilat has an effective $t_{1/2}$ in plasma of about 12 hours, and its clearance is not significantly altered by renal impairment. The oral dosage of fosinopril ranges from 10 to 80 mg daily (single or divided dosage). The dose is reduced to 5 mg daily in patients with Na^+ or water depletion or renal failure.

Trandolapril (MAVIK) Approximately 10% and 70% of an oral dose of trandolapril is bioavailable (absorption rate but not extent is reduced by food) as trandolapril and trandolaprilat, respectively. Trandolaprilat is about eight times more potent than trandolapril as an ACE inhibitor. Trandolapril is metabolized to trandolaprilat and to inactive metabolites (mostly glucuronides of trandolapril and deesterification products), and these are recovered in the urine (33%, mostly trandolaprilat) and feces (66%). Peak concentrations of trandolaprilat in plasma are achieved in 4–10 hours. Trandolaprilat displays biphasic elimination kinetics with an initial $t_{1/2}$ of ~10 hours (the major component of elimination), followed by a more prolonged $t_{1/2}$ owing to slow dissociation of trandolaprilat from tissue ACE. Plasma clearance of trandolaprilat is reduced by both renal and hepatic insufficiency. The oral dosage ranges from 1 to 8 mg daily (single or divided dosage). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment.

Quinapril (ACCUPRIL) Cleavage of the ester moiety by hepatic esterases transforms quinapril, a prodrug, into quinaprilat, an ACE inhibitor that is about as potent as benazeprilat. Quinapril is absorbed rapidly (peak concentrations are achieved in 1 hour, but the peak may be delayed after food), and the rate but not extent of oral absorption (60%) may be reduced by food. Quinapril is metabolized to quinaprilat and to other minor metabolites, and quinaprilat is excreted in the urine (61%) and feces (37%). Peak concentrations of quinaprilat in plasma are achieved in about 2 hours. Conversion of quinapril to quinaprilat is reduced in patients with diminished liver function. The initial $t_{1/2}$ of quinaprilat is about 2 hours; a prolonged terminal $t_{1/2}$ of ~25 hours may be due to high-affinity binding of the drug to tissue ACE. The oral dosage of quinapril is 5–80 mg daily (single or divided dosage).

Ramipril (ALTACE) Cleavage of the ester moiety by hepatic esterases transforms ramipril into ramiprilat, an ACE inhibitor that is about as potent as benazeprilat and quinaprilat. Ramipril is absorbed rapidly (peak concentrations of ramipril achieved in 1 hour), and the rate but not extent of its oral absorption (50–60%) is reduced by food. Ramipril is metabolized to ramiprilat and to inactive metabolites (glucuronides of ramipril and ramiprilat and the diketopiperazine ester and acid) that predominantly are excreted by the kidneys. Peak concentrations of ramiprilat in plasma are achieved in about 3 hours. Ramiprilat displays triphasic elimination kinetics with $t_{1/2}$ of 2–4 hours, 9–18 hours, and >50 hours. This triphasic elimination is due to extensive distribution to all tissues (initial $t_{1/2}$), clearance of free ramiprilat from plasma (intermediate $t_{1/2}$), and dissociation of ramiprilat from tissue ACE (terminal $t_{1/2}$). The oral dosage of ramipril is 1.25–20 mg daily (single or divided dosage).

Moexipril (UNIVASC) Moexipril is another prodrug whose antihypertensive activity is almost entirely due to its de-esterified metabolite, moexiprilat. Moexipril is absorbed incompletely, with bioavailability as moexiprilat of ~13%. Bioavailability is markedly decreased by food; therefore, the drug should be taken 1 hour before meals. The time to peak plasma concentration of moexiprilat is almost 1.5 hours, and the elimination $t_{1/2}$ is variable (2–12 hours). The recommended dosage range is 7.5–30 mg daily in one or two divided doses. The dosage range is halved in patients who are taking diuretics or who have renal impairment.

Perindopril (ACEON) Perindopril erbumine is a prodrug, and 30–50% of systemically available perindopril is transformed to perindoprilat by hepatic esterases. The oral bioavailability of perindopril (75%) is not affected by food. Perindopril is metabolized to perindoprilat and to inactive metabolites (glucuronides of perindopril and perindoprilat, dehydrated perindopril, and diastereomers of dehydrated perindoprilat) that are excreted predominantly by the kidneys. Peak concentrations of perindoprilat in plasma are achieved in 3–7 hours. Perindoprilat displays biphasic

elimination kinetics with half-lives of 3–10 hours (the major component of elimination) and 30–120 hours (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage ranges from 2 to 16 mg daily (single or divided dosage).

THERAPEUTIC USES OF ACE INHIBITORS AND CLINICAL SUMMARY

ACE Inhibitors in Hypertension ACE inhibition lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states (*see* Chapter 32). ACE inhibitors commonly lower blood pressure in hypertensive subjects, except in those with primary aldosteronism. The initial change in blood pressure is most marked in subjects with high PRA and AngII plasma levels prior to treatment. Several weeks into treatment, additional patients show sizeable reductions in blood pressure that correlate poorly or not at all with pretreatment PRA values. It is possible that increased local (tissue) production of AngII and/or increased responsiveness of tissues to normal levels of AngII in some hypertensive patients makes them sensitive to ACE inhibitors despite normal PRA. Regardless of the mechanisms, ACE inhibitors have broad clinical utility as antihypertensive agents.

The long-term fall in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure–natriuresis curve (Figure 30–5) and a reduction in total peripheral resistance that varies in different vascular beds. Vasodilation in the kidney is a relatively constant finding that is explained by the exquisite sensitivity of renal vessels to the vasoconstrictor actions of AngII. Increased renal blood flow occurs without an increase in GFR; thus, the filtration fraction is reduced. Both the afferent and efferent arterioles are dilated. Blood flows in the cerebral and coronary beds, where autoregulatory mechanisms are powerful, generally are well maintained.

Besides causing systemic arteriolar dilatation, ACE inhibitors increase the compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Even when a substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion in most hypertensive individuals is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K^+ . The activity of these secretagogues on the zona glomerulosa of the adrenal cortex requires only very small trophic or permissive amounts of AngII, which always are present because ACE inhibition never is complete. Excessive K^+ retention is encountered only in patients taking supplemental K^+ , patients with renal impairment, or patients taking other medications that reduce K^+ excretion.

ACE inhibitors alone normalize blood pressure in ~50% of patients with mild-to-moderate hypertension. Ninety percent of patients with mild-to-moderate hypertension will be controlled by the combination of an ACE inhibitor and either a Ca^{2+} channel blocker, a β adrenergic receptor blocker, or a diuretic. Diuretics in particular augment the antihypertensive response to ACE inhibitors by rendering the blood pressure renin-dependent.

There is increasing evidence that ACE inhibitors are superior to many other antihypertensive drugs in hypertensive patients with diabetes, in whom they improve endothelial function and reduce cardiovascular events more so than do Ca^{2+} channel blockers or diuretics and β adrenergic receptor antagonists.

ACE Inhibitors in Left Ventricular Systolic Dysfunction Left ventricular systolic dysfunction ranges from a modest, asymptomatic reduction in systolic performance to a severe impairment of left ventricular systolic function with florid congestive heart failure (*see* Chapter 33). Unless contraindicated, ACE inhibitors should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure.

Inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. The more severe the ventricular dysfunction, the greater is the benefit from ACE inhibition.

Although the mechanisms by which ACE inhibitors improve outcome in patients with systolic dysfunction are not completely understood, the induction of a more favorable hemodynamic state most likely plays an important role. Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and cardiac index increase, as do indices of stroke work and stroke volume. In systolic dysfunction, AngII decreases arterial compliance, which is reversed by ACE inhibition. Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by AngII, and the diminished direct effects of AngII on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an increased capacity of the venous bed, which is somewhat unexpected because AngII has little acute vasoconstrictor activity. The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced.

The beneficial effects of ACE inhibitors in systolic dysfunction also involve improvements in ventricular geometry. In heart failure, ACE inhibitors reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling *via* changes in preload/afterload, by preventing the growth effects of AngII on myocytes, and by attenuating cardiac fibrosis induced by AngII and aldosterone.

ACE Inhibitors in Acute Myocardial Infarction ACE inhibitors reduce overall mortality when treatment is begun during the peri-infarction period. The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive and diabetic patients. Unless contraindicated (*e.g.*, cardiogenic shock or severe hypotension), ACE inhibitors should be started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists. After several weeks, ACE-inhibitor therapy should be reevaluated. In high-risk patients (*e.g.*, large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term.

ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events Patients at high risk of cardiovascular events (no left ventricular dysfunction but evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease) benefit considerably from ACE inhibitors, with significant decreases in the rates of myocardial infarction, stroke, and death. The benefits of ACE inhibition in patients at high risk of cardiovascular events persist even after coronary revascularization.

ACE Inhibitors in Chronic Renal Failure Diabetes mellitus is the leading cause of renal disease. In patients with type 1 diabetes mellitus and diabetic nephropathy, ACE inhibitors clearly prevent or delay the progression of renal disease. The renoprotective effects of ACE inhibitors in type 1 diabetes are largely independent of blood pressure reduction. Specific renoprotection by ACE inhibitors is more difficult to demonstrate in type 2 diabetics, with some studies providing positive results, but others failing to demonstrate blood pressure-independent renoprotection. In addition to attenuating diabetic nephropathy, ACE inhibitors also may decrease retinopathy progression in type 1 diabetics. ACE inhibitors also attenuate the progression of renal insufficiency in patients with a variety of nondiabetic nephropathies and may arrest the decline in GFR even in patients with severe renal disease.

Several mechanisms participate in the renal protection afforded by ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter both by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, two processes that contribute to expansion of the mesangium in diabetic nephropathy. Since AngII is a growth factor, reductions in the intrarenal levels of AngII may further attenuate mesangial cell growth and matrix production.

ADVERSE EFFECTS OF ACE INHIBITORS Serious untoward reactions to ACE inhibitors are rare, and they generally are well tolerated. Metabolic side effects are not encountered during long-term therapy with ACE inhibitors. The drugs do not alter plasma concentrations of uric acid or Ca^{2+} and actually may improve insulin sensitivity in patients with insulin resistance and decrease cholesterol and lipoprotein(a) levels in proteinuric renal disease.

Hypotension A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. Special care should be exercised in patients who are salt-depleted, in patients being treated with multiple antihypertensive drugs, and in patients who have congestive heart failure. Such patients should be started on very small doses of ACE inhibitors, or salt intake should be increased and diuretics stopped before beginning therapy.

Cough In 5–20% of patients, ACE inhibitors induce a dry cough; it usually is not dose-related, occurs more frequently in women than men, usually develops between 1 week and 6 months after initiation of therapy, and sometimes requires cessation of therapy. This adverse effect may be mediated by bradykinin, substance P, and/or prostaglandins. Thromboxane antagonism, aspirin, and iron supplementation reduce cough induced by ACE inhibitors. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days.

Hyperkalemia Despite some reduction in the concentration of aldosterone, significant K^+ retention is rarely encountered in patients with normal renal function who are not taking other drugs that cause K^+ retention. However, ACE inhibitors may cause hyperkalemia in patients with renal insufficiency or in patients taking K^+ -sparing diuretics, K^+ supplements, β adrenergic receptor antagonists, or NSAIDs.

Acute Renal Failure By constricting the efferent arteriole, AngII helps to maintain adequate glomerular filtration when renal perfusion pressure is low. Consequently, ACE inhibition can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics. Older patients with congestive heart failure are particularly susceptible to ACE inhibitor–induced acute renal failure. However, nearly all patients who receive appropriate treatment recover renal function without sequelae.

Fetopathic Potential Administration of ACE inhibitors during the second and third trimesters can cause oligohydramnios, fetal calvarial hypoplasia, fetal pulmonary hypoplasia, fetal growth retardation, fetal death, neonatal anuria, and neonatal death. These fetopathic effects may be due in part to fetal hypotension. While ACE inhibitors are not contraindicated in women of reproductive age, *once pregnancy is diagnosed, it is imperative that ACE inhibitors be discontinued as soon as possible*. If necessary, an alternative antihypertensive regimen should be instituted. The fetus is not at risk of ACE inhibitor–induced pathology if ACE inhibitors are discontinued during the first trimester of pregnancy.

Skin Rash ACE inhibitors occasionally cause a maculopapular rash that may be pruritic. The rash may resolve spontaneously or may respond to a reduced dosage or a brief course of antihistamines. Although initially attributed to the presence of the sulfhydryl group in captopril, a rash also may occur with other ACE inhibitors, albeit less frequently.

Proteinuria ACE inhibitors have been associated with proteinuria (more than 1 g/day); however, a causal relationship has been difficult to establish. In general, proteinuria is not a contraindication for ACE inhibitors because ACE inhibitors are renoprotective in diseases associated with proteinuria, such as diabetic nephropathy.

Angioedema In 0.1–0.5% of patients, ACE inhibitors induce a rapid swelling in the nose, throat, mouth, glottis, larynx, lips, and/or tongue. This untoward effect, called *angioedema*, apparently is not dose-related, and if it occurs, it does so within the first week of therapy, usually within the first few hours after the initial dose. Airway obstruction and respiratory distress may lead to death. Although the mechanism is unknown, angioedema may involve accumulation of bradykinin or inhibition of complement 1–esterase inhibitor. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient's airway should be protected, and if necessary, epinephrine, an antihistamine, and/or a glucocorticoid should be administered. African Americans have a 4.5 times greater risk of ACE inhibitor–induced angioedema than do Caucasians. Although rare, angioedema of the intestine, characterized by emesis, watery diarrhea, and abdominal pain, also has been associated with ACE inhibitors.

Other Adverse Effects Dysgeusia, an alteration in or loss of taste, can occur. It may be more frequent with captopril and is reversible. Neutropenia is a rare but serious side effect of ACE inhibitors; it occurs predominantly in hypertensive patients with collagen-vascular or renal parenchymal disease. If the serum creatinine concentration is 2 mg/dL or greater, the dose of ACE inhibitor should be kept low, and the patient should be counseled to seek medical evaluation if symptoms (e.g., sore throat, fever) develop. Glycosuria in the absence of hyperglycemia is an exceedingly rare and reversible side effect whose mechanism is unknown. Hepatotoxicity, usually of the cholestatic variety, also is exceedingly rare and reversible. The mechanism again is unknown.

Drug Interactions Antacids may reduce the oral bioavailability of ACE inhibitors; capsaicin may worsen ACE inhibitor–induced cough; NSAIDs, including aspirin, may reduce the antihypertensive response to ACE inhibitors; and K^+ -sparing diuretics and K^+ supplements may exacerbate ACE inhibitor–induced hyperkalemia. ACE inhibitors may increase plasma levels of digoxin and lithium and may increase hypersensitivity reactions to allopurinol.

NONPEPTIDE AngII RECEPTOR ANTAGONISTS

The AngII receptor blockers (ARBs) bind to the AT_1 receptor with high affinity and generally are at least 10,000-fold more selective for the AT_1 receptor *versus* the AT_2 receptor. The rank-order affinity of the AT_1 receptor for ARBs is candesartan = omesartan > irbesartan = eprosartan > telmisartan = valsartan = EXP 3174 (the active metabolite of losartan) > losartan. Although binding of ARBs to the AT_1 receptor is competitive, the inhibition often is insurmountable; *i.e.*, the maximal response to AngII cannot be restored in the presence of the ARB.

ARBs potently and selectively inhibit most of the biological effects of AngII, including AngII–induced (1) contraction of vascular smooth muscle, (2) rapid pressor responses, (3) slow pressor responses, (4) thirst, (5) vasopressin release, (6) aldosterone secretion, (7) release of adrenal catecholamines, (8) enhancement of noradrenergic neurotransmission, (9) increases in sympathetic tone, (10) changes in renal function, and (11) cellular hypertrophy and hyperplasia.

A critical issue is whether or not ARBs are equivalent to ACE inhibitors with regard to therapeutic efficacy. Both classes of drugs block the renin–angiotensin system, but ARBs and ACE inhibitors differ in several important aspects: (1) *ARBs reduce activation of AT_1 receptors more effectively than do ACE inhibitors.* ACE inhibitors reduce AngII produced by ACE but do not inhibit alternative non-ACE AngII–generating pathways. Because ARBs block the AT_1 receptor, the actions of AngII via the AT_1 receptor are inhibited regardless of how AngII is formed. (2) In contrast to ACE inhibitors, *ARBs permit activation of AT_2 receptors.* ACE inhibitors increase renin release; however, ACE inhibitors block the conversion of AngI to AngII, resulting in decreased levels of AngII. Blockade of AT_1 receptors by ARBs enhances renin release, which does result in increased circulating levels of AngII. This increased level of AngII is available to activate AT_2 receptors. (3) *ACE inhibitors may increase Ang(1–7) levels more than do ARBs,* since ACE is involved in the clearance of Ang(1–7). (4) *ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin.* ACE processes an array of substrates; inhibiting ACE therefore increases the levels of ACE substrates and decreases the levels of their corresponding products. Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

CLINICAL PHARMACOLOGY Oral bioavailability of ARBs generally is low (<50%, except for irbesartan, with 70% available), and protein binding is high (>90%).

Candesartan Cilexetil (ATACAND) Candesartan cilexetil is an inactive ester prodrug that is completely hydrolyzed to the active form, candesartan, during absorption from the GI tract. Peak plasma levels are obtained 3–4 hours after oral administration, and the plasma $t_{1/2}$ is about 9 hours. Plasma clearance of candesartan is due to renal (33%) and biliary (67%) excretion and is affected by renal insufficiency but not by mild-to-moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dosage of 4–32 mg.

Eprosartan (TEVETEN) Peak plasma levels are obtained ~1–2 hours after oral administration, and the plasma $t_{1/2}$ varies (5–9 hours). Eprosartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal and biliary

elimination such that plasma clearance is affected by both renal and hepatic insufficiency. The recommended dosage of eprosartan is 400–800 mg/day in one or two doses.

Irbesartan (AVAPRO) Peak plasma levels are obtained approximately 1.5–2 hours after oral administration, and the plasma $t_{1/2}$ ranges (11–15 hours). Irbesartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild-to-moderate hepatic insufficiency. The oral dosage of irbesartan is 150–300 mg once daily.

Losartan (COZAAR) Approximately 14% of an oral dose of losartan is converted to the 5-carboxylic acid metabolite EXP 3174, which is more potent than losartan as an AT_1 -receptor antagonist. The metabolism of losartan to EXP 3174 and to inactive metabolites is mediated by CYP2C9 and CYP3A4. Peak plasma levels of losartan and EXP 3174 occur ~1–3 hours after oral administration, respectively, and the plasma half-lives are 2.5 and 6–9 hours, respectively. The plasma clearances of losartan and EXP 3174 (600 and 50 mL/min, respectively) are due to renal clearance (75 and 25 mL/min, respectively) and hepatic clearance (metabolism and biliary excretion). The plasma clearance of losartan and EXP 3174 is affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25–100 mg. In addition to being an ARB, losartan is a competitive antagonist of the thromboxane A_2 receptor and attenuates platelet aggregation. Also, EXP 3179 reduces COX-2 mRNA up-regulation and COX-dependent prostaglandin generation.

Olmesartan Medoxomil (BENICAR) Olmesartan medoxomil is an inactive ester prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the GI tract. Peak plasma levels are obtained 1.4–2.8 hours after oral administration, and the plasma $t_{1/2}$ varies (10–15 hours). Plasma clearance of olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20–40 mg once daily.

Telmisartan (MICARDIS) Peak plasma levels are obtained ~0.5–1 hour after oral administration, and the plasma $t_{1/2}$ is about 24 hours. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug and clearance is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40–80 mg once daily.

Valsartan (DIOVAN) Peak plasma levels occur 2–4 hours after oral administration, and the plasma $t_{1/2}$ is ~9 hours. Food markedly decreases absorption. Valsartan is cleared by the liver (~70%); plasma clearance is affected by hepatic but not renal insufficiency. The oral dosage of valsartan is 80–320 mg once daily.

THERAPEUTIC USES OF AngII RECEPTOR ANTAGONISTS All ARBs are approved for the treatment of hypertension. In addition, irbesartan and losartan are approved for diabetic nephropathy, losartan is approved for stroke prophylaxis, and valsartan is approved for heart failure patients who are intolerant of ACE inhibitors. The efficacy of ARBs in lowering blood pressure is comparable with that of other established antihypertensive drugs, with an adverse-effect profile similar to that of placebo. ARBs also are available as fixed-dose combinations with hydrochlorothiazide.

Losartan is well tolerated in patients with heart failure and is comparable to enalapril with regard to improving exercise tolerance. Both valsartan and candesartan reduce mortality and morbidity in heart failure patients. Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors. At present, there is conflicting evidence regarding the benefit of combining an ARB and an ACE inhibitor in heart failure patients.

In part *via* blood pressure-independent mechanisms, ARBs are renoprotective in type 2 diabetes mellitus and many experts now consider them the drugs of choice for renoprotection in diabetic patients. ARBs are superior to β_1 adrenergic receptor antagonists in reducing stroke in hypertensive patients with left ventricular hypertrophy. Irbesartan appears to maintain sinus rhythm in patients with persistent, long-standing atrial fibrillation. Losartan is reported to be safe and highly effective in the treatment of portal hypertension in patients with cirrhosis without compromising renal function.

ADVERSE EFFECTS The incidence of discontinuation of ARBs owing to adverse reactions is comparable with that of placebo. Unlike ACE inhibitors, ARBs do not cause cough, and the incidence of angioedema with ARBs is much less than with ACE inhibitors. As with ACE inhibitors, *ARBs have teratogenic potential and should be discontinued before the second trimester of pregnancy*. ARBs should be used cautiously in patients whose blood pressure or renal function is highly dependent on the renin–angiotensin system (*e.g.*, renal artery stenosis). In such patients, ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or taking K^+ supplements or K^+ -sparing diuretics. ARBs enhance the blood pressure–lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment.

TREATMENT OF MYOCARDIAL ISCHEMIA

PATHOPHYSIOLOGY OF ISCHEMIC HEART DISEASE

Angina pectoris is caused by transient episodes of myocardial ischemia due to an imbalance in myocardial oxygen supply and demand that may result from an increase in myocardial oxygen demand, a decrease in myocardial oxygen supply, or sometimes from both (Figure 31-1). Among the pharmacological agents used in the treatment of angina are nitrovasodilators, β adrenergic receptor antagonists, Ca^{2+} channel antagonists, and antiplatelet agents. All approved antianginal agents improve the balance of myocardial oxygen supply and demand, increasing supply by dilating the coronary vasculature or decreasing demand by reducing cardiac work (Figure 31-1). Drugs used in typical angina function principally by reducing myocardial oxygen demand by decreasing heart rate, myocardial contractility, and/or ventricular wall stress. By contrast, the principal therapeutic goal in unstable angina is to increase myocardial blood flow; strategies include the use of antiplatelet agents and *heparin* to reduce intracoronary thrombosis and coronary stents or coronary bypass surgery to restore flow by mechanical means. The therapeutic aim in variant or Prinzmetal's angina is to prevent coronary vasospasm.

ORGANIC NITRATES

Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid. Nitrate esters ($-\text{C}-\text{O}-\text{NO}_2$) and nitrite esters ($-\text{C}-\text{O}-\text{NO}$) are characterized by a sequence of carbon-oxygen-nitrogen, whereas nitro compounds possess carbon-nitrogen bonds ($\text{C}-\text{NO}_2$). Glyceryl trinitrate is not a nitro compound, but the name nitroglycerin is well entrenched. Organic nitrates of low molecular mass (e.g. nitroglycerin) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (e.g., erythryl tetranitrate, isosorbide dinitrate, and isosorbide mononitrate) are solids. The organic nitrates and nitrites, collectively termed nitrovasodilators, must be reduced to produce the reactive free radical NO, the active principle of this class of compounds.

Nitrites, organic nitrates, nitroso compounds, and a variety of other nitrogen oxide-containing substances (including *nitroprusside*) lead to NO formation. NO activates guanylyl cyclase, increases the cellular level of cyclic GMP, activates PKG, and modulates the activities of PDEs 2, 3, and 5 in a variety of cell types. In smooth muscle, NO-mediated increase in intracellular cyclic GMP activate PKG, which leads to reduced phosphorylation of myosin light chain, reduced Ca^{2+} concentration in the cytosol, and vasorelaxation. Although the soluble isoform of guanylyl cyclase remains the most extensively characterized target for NO, NO also forms specific adducts with thiol groups in proteins and with reduced glutathione to form nitrosothiol compounds with distinctive biological properties.

CARDIOVASCULAR EFFECTS

Hemodynamic Effects Low concentrations of nitroglycerin preferentially dilate the veins more than the arterioles. This venodilation decreases left and right ventricular chamber size and end-diastolic pressures but results in little change in systemic vascular resistance. Systemic arterial pressure may fall slightly, and heart rate is unchanged or may increase slightly in response to a decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of nitroglycerin that do not alter systemic arterial pressure often produce arteriolar dilation in the face and neck, resulting in a flush, or dilation of meningeal arterial vessels, causing headache.

Higher doses of organic nitrates cause further venous pooling and also may decrease arteriolar resistance, thereby decreasing systolic and diastolic blood pressure and cardiac output and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. The reflex tachycardia and peripheral arteriolar vasoconstriction tend to restore systemic vascular resistance; this is superimposed on sustained venous pooling. Coronary blood flow may increase transiently as a result of coronary vasodilation but may decrease subsequently if cardiac output and blood pressure decrease sufficiently.

In patients with autonomic dysfunction who cannot increase sympathetic outflow, the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated; thus, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina. The appropriate therapy in patients with orthostatic angina and normal coronary arteries is to correct the orthostatic hypotension by expanding volume (*fludrocortisone* and a high-sodium diet), to prevent venous pooling with

FIGURE 31–1 Pharmacological modification of the major determinants of myocardial O₂ supply. When myocardial O₂ requirements exceed O₂ supply, an ischemic episode results. This figure shows the primary hemodynamic sites of actions of pharmacological agents that can reduce O₂ demand (left side) or enhance O₂ supply (right side). Some classes of agents have multiple effects (see text). Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O₂ supply. Both pharmacotherapy and mechanotherapy attempt to restore a dynamic balance between O₂ demand and O₂ supply.

fitted support garments, and to carefully titrate use of oral vasopressors. Since patients with autonomic dysfunction occasionally may have coexisting coronary artery disease, the coronary anatomy should be defined before therapy is undertaken.

Effects on Total and Regional Coronary Blood Flow Ischemia is a powerful stimulus to coronary vasodilation, and regional blood flow is adjusted by autoregulatory mechanisms. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation; if the stenosis is severe, much of the dilatory capacity is needed to maintain resting blood flow and further dilation may not be possible when demand increases. Significant coronary stenoses disproportionately reduce blood flow to the subendocardial regions of the heart, which are subjected to the greatest extravascular compression during systole; organic nitrates tend to restore blood flow in these regions. The hemodynamic mechanisms responsible for the effects on coronary blood flow appear to be due to the ability of organic nitrates to cause dilation and prevent vasoconstriction of large epicardial vessels without impairing autoregulation in the small vessels. By dilating epicardial stenoses and reducing the resistance to flow through such areas, the resulting increase in blood flow would be distributed preferentially to ischemic myocardial regions as a consequence of vasodilation induced by autoregulation. An important indirect mechanism for a preferential increase in subendocardial blood flow is the nitroglycerin-induced reduction in intracavitary systolic and diastolic pressures that oppose blood flow to the subendocardium (see below).

Effects on Myocardial Oxygen Requirements By their effects on the systemic circulation, the organic nitrates also can reduce myocardial oxygen demand. The major determinants of myocardial oxygen consumption include left ventricular wall tension, heart rate, and myocardial contractility. Ventricular wall tension is affected by preload and afterload. *Preload* is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension. Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases oxygen consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. *Afterload* is the impedance against which the ventricle must eject, which—in the absence of aortic valvular disease—is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and oxygen consumption.

Organic nitrates decrease both preload and afterload as a result of dilation of venous capacitance and arteriolar resistance vessels. They do not directly alter the inotropic or chronotropic state of the heart. Since nitrates reduce the primary determinants of oxygen demand, their net effect usually is to decrease myocardial oxygen consumption. Nitrovasodilators also increase cyclic GMP in platelets, with consequent inhibition of platelet function. While this may contribute to their antianginal efficacy, the effect appears to be modest.

Mechanism of Relief of Symptoms of Angina Pectoris The nitrate-induced relief of anginal pain has been ascribed to a decrease in cardiac work secondary to the fall in systemic arterial pressure. The ability of nitrates to dilate epicardial coronary arteries is modest; the bulk of evidence favors a reduction in myocardial work and thus in myocardial oxygen demand as their primary effect in chronic stable angina. Paradoxically, high doses of organic nitrates may reduce blood pressure to such an extent that coronary flow is compromised; reflex tachycardia and adrenergic

enhancement of contractility also occur. These effects may override the beneficial action of the drugs on myocardial oxygen demand and can aggravate ischemia. Additionally, sublingual nitroglycerin administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

ABSORPTION, FATE, AND EXCRETION NITROGLYCERIN

In humans, peak concentrations of nitroglycerin are found in plasma within 4 minutes of sublingual administration; the drug has a $t_{1/2}$ of 1–3 minutes. The onset of action of nitroglycerin may be even more rapid if it is delivered as a sublingual spray. Anginal pain may be prevented when the drug is used prophylactically immediately prior to exercise or stress. The smallest effective dose should be prescribed. Patients should be instructed to seek medical attention immediately if three tablets taken over a 15-minute period do not relieve a sustained attack because this situation may be indicative of myocardial infarction or another cause of the pain. Patients also should be advised that there is no virtue in trying to avoid taking sublingual nitroglycerin for anginal pain. Application of nitroglycerin ointment (2%) applied to the skin can relieve angina, prolong exercise capacity, and reduce ischemic ST-segment depression with exercise for 4 hours or more. Effects are apparent within 30–60 minutes (although absorption is variable) and last for 4–6 hours. The ointment is particularly useful for controlling nocturnal angina, which commonly develops within 3 hours after the patient goes to sleep. Transdermal nitroglycerin disks use a nitroglycerin-impregnated polymer that permits gradual absorption and a continuous plasma nitrate concentration over 24 hours. The onset of action is slow, with peak effects occurring at 1–2 hours. To avoid tolerance, therapy should be interrupted for at least 8 hours each day. With this regimen, long-term prophylaxis of ischemic episodes often can be attained. Transmucosal or buccal nitroglycerin is inserted under the upper lip above the incisors, where it adheres to the gingiva and dissolves gradually in a uniform manner. Hemodynamic effects are seen within 2–5 minutes, and it is therefore useful for short-term prophylaxis of angina. Nitroglycerin continues to be released into the circulation for a prolonged period, and exercise tolerance may be enhanced for up to 5 hours.

Isosorbide Dinitrate (ISORDIL, SORBITRATE)

Sublingual administration produces maximal plasma concentrations of the drug by 6 minutes, and the fall in concentration is rapid ($t_{1/2}$ of ~45 minutes). The major route of metabolism of isosorbide dinitrate in humans appears to be by enzymatic denitration followed by glucuronide conjugation. The primary initial metabolites, isosorbide-2-mononitrate and isosorbide-5-mononitrate, have longer half-lives (3–6 hours) and presumably contribute to therapeutic efficacy.

Isosorbide-5-Mononitrate (IMDUR)

This agent is available in tablet form. It does not undergo significant first-pass metabolism and so has excellent bioavailability after oral administration. The mononitrate has a significantly longer $t_{1/2}$ than does isosorbide dinitrate and has been formulated as a plain tablet and as a sustained-release preparation; both have longer durations of action than the corresponding dosage forms of isosorbide dinitrate.
